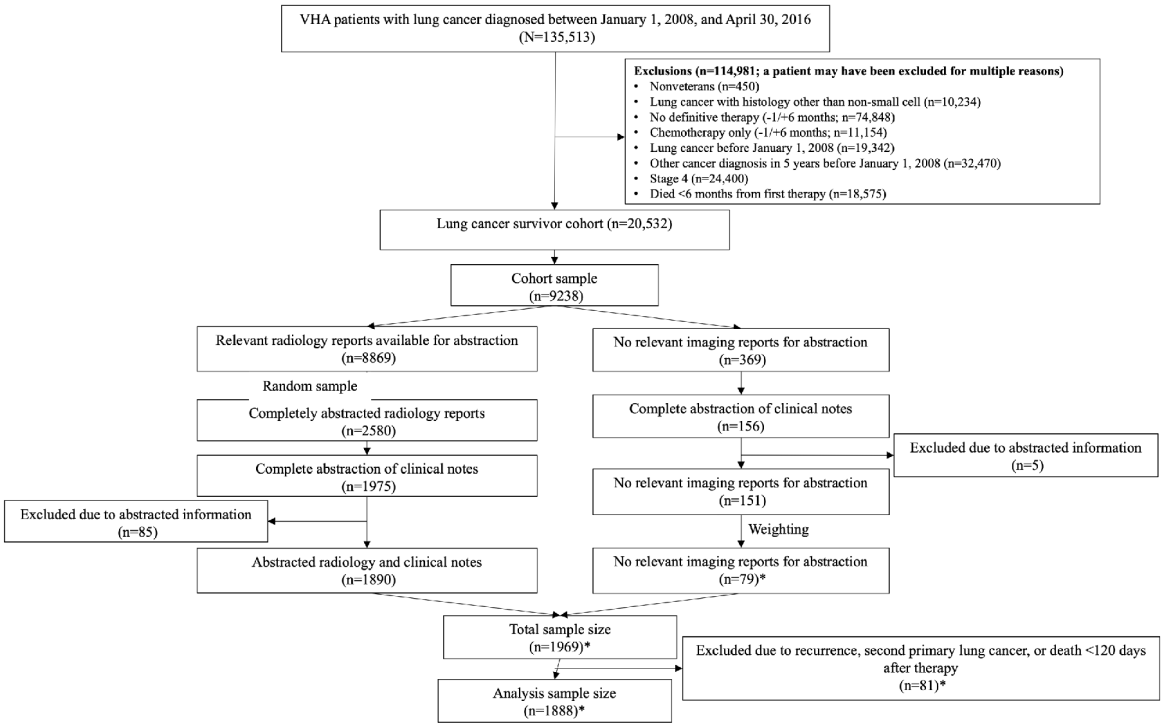
We used the Aalen-Johansen estimator and corresponding CIs to analyze the primary outcome, that is, the receipt of guideline-concordant surveillance imaging within the 120 to 270 days after curative-intent treatment. Death, recurrence, SPLC, and nonconcordant surveillance were treated as the competing events in this analysis.

To evaluate the factors associated with the primary outcome, we used multivariable cause-specific Cox regression to estimate hazard ratios (HRs) and CIs. We considered various demographic factors (eg, sex, age, race, marital status, and year of diagnosis) and clinical factors (eg, treatment, histology, and disease stage) in this model. To adjust for multiple testing, we applied the Bonferroni correction method for 11 independent variables in each model. We reported unadjusted *P* values and interpreted any value <.004 (<0.05/11) as significant. For consistency, we calculated 99.6% CIs for all point estimates. Missing data were treated as a separate category in models. To avoid very small groups, we combined stage 0 and stage 1 (due to the very small proportion of patients in stage 0). In addition, recurrences and SPLC malignancies were combined as a single competing event referred to as "recurrence" for brevity. A univariable model of the primary outcome is shown in Table S4 in Multimedia Appendix 1. Statistical analysis was performed using R (version 4.2.2) [20].



Results

Demographics of the Analytic Cohort

Of 135,513 patients diagnosed with primary NSCLC between January 1, 2008, and April 30, 2016, a total of 20,532 met the study eligibility requirements (Figure 1). The study cohort comprised a random sample of 1890 patients with abstracted clinical notes and radiology reports, while 369 of all eligible patients had no relevant radiology reports available; these 369 patients were weighted to prevent overestimation. The effective study sample size was 1888 patients after weighting (see *Cohort and Definitions* section; Table 1). The mean age of the analysis cohort was 66.4 (SD 7.9) years, of which 95.9% (1811/1888) were male, 71.1% (1342/1888) were White, and 43.1% (814/1888) were married. Of the 1888 patients, 57% (n=1076) presented with stage 1 disease, and the most common treatment modality was surgery alone (n=1068, 56.6%).

Distribution of Imaging Performed

Overall, the most common imaging performed during the initial 120- to 270-day window was chest CT (1460/3278, 44.5%; Table 2). CXR accounted for 36.3% (1190/3278) of all imaging performed, while the remaining 11.8% (386/3278) and 7.4% (242/3278) were PET scans or other imaging modalities, respectively. Chest CT was found to be the most common modality when evaluating imaging performed for surveillance. The proportion of CXR imaging performed for surveillance was 12.2% (176/1448), while the proportion of chest CT and PET imaging performed for surveillance was 70.9% (1026/1448) and 14.4% (209/1448), respectively. Chest CT remained the most common imaging procedure for surveillance across all types of primary treatment groups (Table 3). However, PET imaging comprised 24% (46/192) of surveillance imaging in patients receiving radiation therapy as a part of their primary treatment (38/129, 29.5% in radiation alone), compared to 14.4% (209/1448) across all other treatment groups combined.

Cumulative Probability of Receiving Posttreatment Imaging

To estimate the cumulative probability of patients receiving guideline-concordant surveillance imaging after curative-intent therapy, we used a competing risks framework to correctly estimate the cumulative probability by accounting for competing events (eg, death or recurrence). This analysis shows that the cumulative probability of receiving guideline-concordant imaging for surveillance was 43.8% (827/1888; 99.6% CI 41.6%-46.1%; Figure 2). The cumulative probability of receiving nonconcordant surveillance imaging within this window (120-270 days) was 15.2% (287/1888; 99.6% CI 13.0%-17.8%), whereas 33.4% (630/1888; 99.6% CI 30.4%-36.6%) of patients received no imaging at all. A total of 5% (95/1888; 99.6% CI 3.8%-6.7%) of patients experienced recurrence, while 2.6% (49/1888; 99.6% CI 1.8%-3.7%) of patients died during the posttreatment surveillance period, that is, roughly 7.6% (144/1888) of patients were ineligible for surveillance during this period.

RenderX

Figure 2. Cumulative probability estimated from an Aalen-Johansen competing events model for receipt of guideline-concordant imaging, defined as chest computed tomography imaging with a documented indication of surveillance, within 120 to 270 days after definitive therapy. The probability curves are stacked such that the sum at any time point is 100%. Patients were followed only until the first event, and cumulative probability is therefore the expected proportion of patients who had the event as their first event before a given time point. The overlaid table shows the cumulative probability (Pr) and 99.6% CI at 270 days after therapy.

Factors Associated With Receiving Guideline-Concordant Surveillance Imaging

We evaluated the association between the receipt of guideline-concordant surveillance imaging and various demographic and clinical variables using multivariable cause-specific Cox regression (Table 4). Compared to patients treated for NSCLC between 2008 and 2010, patients receiving treatment from 2014 to 2016 were significantly more likely to receive guideline-concordant surveillance imaging (HR 1.42, 99.6% CI 1.09-1.87, *P*<.001). There was a similar trend toward an increased likelihood of guideline-concordant surveillance in years 2011 to 2013 compared to 2008 to 2010, although this did not reach statistical significance. No other variables were significantly associated with receipt of guideline-concordant surveillance imaging. Although radiation alone was not significantly associated with a decreased likelihood of receiving guideline-concordant surveillance imaging (HR 0.68, 99.6% CI 0.45-1.03, *P*=.007), radiation alone was associated with an increased likelihood of nonconcordant surveillance imaging in the same model (HR 1.93, 99.6% CI 1.10-3.38, *P*<.001) consistent with the increased use of PET for surveillance in this group (Table S3 in Multimedia Appendix 1).

Factors Associated With Recurrent Cancer or SPLC and Death

There were no significant factors associated with developing recurrence or SPLC in the multivariable cause-specific Cox proportional hazards model for competing outcomes (Table S3 in Multimedia Appendix 1). Compared to surgery alone, treatment with surgery and radiation was associated with an increased likelihood of death in the same model (HR 12.3, 99.6% CI 2.52-60.19, $P<.001$).

Discussion

Principal Findings

Despite widespread recommendations for posttreatment surveillance, we found that roughly one-third of patients undergoing treatment for NSCLC before 2016 did not receive any form of surveillance. Moreover, the true fraction of patients receiving surveillance imaging consistent with recommended guidelines in this study was less than half (43.8%). This is an improvement over results from our previous study of patients' first imaging procedures within 4 to 8 months after resection (representing the first surveillance window) of early-stage NSCLC in the Medicare population, where 24.6% of patients received a chest CT scan and 59.6% received a CXR [7]. Similar to other studies, our work demonstrates evidence of the increasing use of posttreatment chest CT imaging for surveillance over time in line with routine surveillance guidelines [9,14]. Sustained improvement in posttreatment surveillance adherence necessitates dedicated efforts both at the individual level, through education and interventions, and at a systems level, through multidisciplinary collaboration and advocacy.

Comparison to Existing Literature

We observed that the rate of guideline-concordant surveillance CT imaging is substantially lower than that previously reported by Malhotra et al [10] and Erb et al [9]. In their 2018 study using SEER-Medicare data, Malhotra et al [10] defined adherent imaging as a patient receiving at least a CT scan or PET and CT scan during the 7- to 18-month, 19- to 30-month, 31- to 42-month, and 43- to 60-month intervals after treatment. The rate of adherent surveillance imaging at 18 months was 70.6%. The variation in reported rates across these and other studies is likely reflected in the fact that very few large studies concerning posttreatment surveillance contain information on the indication for posttreatment imaging. Therefore, many of these studies likely reflect imaging done for various indications, including the evaluation of symptoms (eg, cough and pneumonia), or are unknown and do not truly reflect imaging done for the explicit purpose of surveillance. In addition, the study by Malhotra et al [10] defines the receipt of adherent imaging as receiving CT or PET and CT despite guideline recommendations against the routine use of PET imaging for posttreatment surveillance of NSCLC, which was excluded in our definition. Our study, as well as other studies, has demonstrated that nonconcordant surveillance imaging makes up a significant fraction of radiology evaluations in patients treated for NSCLC. This may be due in part to clinical practice variations in using distinct treatment modalities to monitor treatment response or disease progression (ie, the use of PET or CT imaging in patients undergoing radiation or neoadjuvant therapy). Differences in patient population, comorbidities, and systems of care delivery also likely play some role in varying the reported rates of surveillance.

Strengths

An important strength of our study is the inclusion of detailed VHA data that provided insights into the indications for radiology procedures. Indeed, true rates of posttreatment surveillance were previously obscured by the fact that imaging reported from other studies may have been done for purposes other than surveillance, as it is nearly impossible to reliably categorize imaging indications using administrative and claims data alone. Another strength of our study was the ability of the competing risks model to evaluate true surveillance rates in the presence of competing events that alter estimates put forth in other studies. Indeed, we found 7.6% (144/1888) of patients

XSL•FO
RenderX

were not eligible to receive surveillance in our sample cohort because of death or recurrence. Accounting for competing events addresses the potential for overestimating the incidence of the event of interest, a potential weakness of using the Kaplan-Meier method or claims-based data in this setting. Each of these features present in this study likely describes our report of relatively lower rates of guideline-concordant surveillance compared with the literature. Thus, using the most liberal interpretation of our data, excluding those patients with competing events of early recurrence or death, 59% (1114/1888) of our cohort received imaging with the explicit intent of surveillance (44%, 827/1888 guideline concordant and 15%, 287 discordant). This is consistent with other reports lacking indication data, yet 33% (630/1888) received no imaging at all during this initial surveillance period. This allows us to highlight the latter group of patients with no surveillance imaging as the most important group to target when considering interventions in the future.

Limitations

There are limitations to be acknowledged in this study. First is the use of administrative *ICD-9/10* and CPT codes to identify patients with relevant treatment procedures. We did not have structured diagnosis dates and staging information from a cancer registry for cohort construction. Thus, we used a conservative approach to ensure patients included in the cohort were newly diagnosed with NSCLC. Our approach may have missed some patients with a previous NSCLC diagnosis and the 20,532-patient cohort such that the data may not reflect the total incidence of early-stage NSCLC in VHA data during this period. Second, we abstracted only radiology report information on patients receiving imaging studies at VHA facilities. Veterans who received relevant imaging studies at external facilities do not have reports that are easily viewable in the VHA database except through an archival process requiring a review request of any scanned reports that were provided by the community imaging clinic. In our sensitivity analyses, we examined the rates of non-VA care including imaging paid for by the VHA (fee-based care) and care that veterans received through Medicare or Medicaid. Data are not available for any community care services patients pay for out of pocket or those covered by other insurance providers such as a veteran's private insurance provider, although dual use of care from private insurance providers is rare among patients who otherwise rely on the VHA for the majority of their care and, in particular, cancer care [21]. This sensitivity analysis identified that among the entire cohort, fewer than 16% of veterans had any non-VA imaging scans performed in the available administrative data, with 8% of these scans corresponding to CT scans. Thus, the inclusion of these studies would still result in the underuse of surveillance overall. Third, our dataset reflects patterns from 2008 to 2016 as well as care within the VHA, which is a more homogenous population than the general population. Given the changing guidelines, practice patterns, and differences in the general population, our observations may differ from the reality of the non-VA population in the current state. Yet, cancer outcomes within the VHA and quality of care (including lung cancer in particular) have been reported in the literature as being noninferior and at times superior to lung cancer care provided in the non-VA population [22]. Thus, if anything, our main limitation might be in underestimating the true adherence rate in the non-VA setting.

Future Directions

In conclusion, the use of this detailed clinical database, along with the novel application of a competing risks model, has provided additional clarity on the current state of adherence to posttreatment surveillance. Our analysis shows that the rate of guideline-concordant surveillance in this national cohort was lower than that reported in many studies. There is a need to develop efficient strategies to monitor the rate of guideline-concordant surveillance as well as patient education and health care professional advocacy to ensure these patients do not fall through the cracks of the health system. In addition, future studies are needed to determine how guideline adherence and other aspects of current surveillance practices influence clinical outcomes, especially given the recent literature casting doubts on the survival benefits of routine surveillance imaging [22,23].

Acknowledgments

Abstract

Background: Complementary therapies are being increasingly used by cancer survivors. As a channel for customers to share their feelings, outcomes, and perceived knowledge about the products purchased from e-commerce platforms, Amazon consumer reviews are a valuable real-world data source for understanding cancer survivorship care needs.

Objective: In this study, we aimed to highlight the potential of using Amazon consumer reviews as a novel source for identifying cancer survivorship care needs, particularly related to symptom self-management. Specifically, we present a publicly available, manually annotated corpus derived from Amazon reviews of health-related products and develop baseline natural language processing models using deep learning and large language model (LLM) to demonstrate the usability of this dataset.

Methods: We preprocessed the Amazon review dataset to identify sentences with cancer mentions through a rule-based method and conducted content analysis including text feature analysis, sentiment analysis, topic modeling, cancer type, and symptom association analysis. We then designed an annotation guideline, targeting survivorship-relevant constructs. A total of 159 reviews were annotated, and baseline models were developed based on deep learning and large language model (LLM) for named entity recognition and text classification tasks.

Results: A total of 4703 sentences containing positive cancer mentions were identified, drawn from 3349 reviews associated with 2589 distinct products. The identified topics through topic modeling revealed meaningful insights into cancer symptom management and survivorship experiences. Examples included discussions of green tea use during chemotherapy, cancer prevention strategies, and product recommendations for breast cancer. Top 15 symptoms in reviews were also identified, with pain being the most frequent symptom, followed by inflammation, fatigue, etc. The annotation labels were designed to capture cancer types, indicated symptoms, and symptom management outcomes. The resulting annotation corpus contains 2067 labels from 159 Amazon reviews. It is publicly accessible, together with the annotation guideline through the Open Health Natural Language Processing (OHNLP) GitHub. Our baseline model, Bert-base-cased, achieved the highest weighted average F_1-score, that is, 66.92%, for named entity recognition, and LLM gpt4-1106-preview-chat achieved the highest F_1-score for text classification tasks, that is, 66.67% for “Harmful outcome,” 88.46% for “Favorable outcome” and 73.33% for “Ambiguous outcome.”

Conclusions: Our results demonstrate the potential of Amazon consumer reviews as a novel data source for identifying persistent symptoms, concerns, and self-management strategies among cancer survivors. This corpus, along with the baseline natural language processing models developed for named entity recognition and text classification, lays the groundwork for future methodological advancements in cancer survivorship research. Importantly, insights from this study could be evaluated against established clinical guidelines for symptom management in cancer survivorship care. By revealing the feasibility of using consumer-generated data for mining survivorship-related experiences, this study offers a promising foundation for future research and argumentation analysis aimed at improving long-term outcomes and support for cancer survivors.

real-world data; cancer research; cancer survivorship care; natural language processing; annotation; baseline models; deep learning; large language model

Introduction

The treatment of cancer results in unintended side effects and outcomes including pain, fatigue, weakness, anorexia, constipation, anxiety, dyspnea, nausea, and vomiting. These symptoms may emerge during active treatment and frequently persist into the posttreatment phase, necessitating continued monitoring and support. The National Cancer Institute defines cancer survivorship care as beginning at cancer diagnosis and continuing through the remainder of a patient's life, encompassing both medical and supportive care needs across the continuum of care [1]. Recognizing its importance, the Institute of Medicine, the National Cancer Institute, and the American Society of Clinical Oncologists have increasingly prioritized survivorship care as a critical component of efforts to improve long-term cancer outcomes and quality of life [2-4].

Cancer survivorship care extends well beyond surveillance for recurrence or secondary malignancies. According to the National Cancer Institute's National Standards for Cancer Survivorship Care, high-quality survivorship care should address several key focus areas: communication and coordination of care, prevention and surveillance of new or recurrent cancers, symptom management and supportive care, and provision of practical resources to help survivors navigate life after treatment [2]. These standards underscore the need for a comprehensive, patient-centered approach that supports cancer survivors during and after the transition out of active oncology care. Addressing ongoing needs—such as managing long-term and late effects of treatment, promoting healthy behaviors, and ensuring access to psychosocial support—is critical to optimizing survivors' quality of life, particularly during periods of reduced clinical oversight.

Digital platforms such as social media and forums have emerged as important spaces where cancer survivors seek support, share experiences, and access health information [5,6]. These platforms also offer a rich, untapped source of real-world data for researchers seeking to understand the survivorship experience from the patient's perspective. Advances in large learning models such as OpenAI, Gemini, and LLAMA have also made it increasingly feasible to process and extract insights from these large, unstructured text datasets.

One such promising resource is Amazon's consumer product review system. As a widely used e-commerce platform with national reach—including rural and underserved areas—Amazon provides consumers with the opportunity to share detailed reflections on their experiences with health and wellness products. These reviews often contain personal narratives about symptom self-management, perceived product effectiveness, and emotional responses, which may be particularly relevant for understanding the needs of cancer survivors. Theoretically, language content (eg, the percentage of words related to a topic)—such as the proportion of words associated with specific symptoms or outcomes—can reflect an individual's focus and meaning-making processes [7]. Analyzing large-scale consumer-review data can thus offer insights into consumer knowledge, attitudes, and behaviors from a population health perspective [8,9]. Furthermore, the structured format of Amazon reviews, coupled with the inclusion of product use experiences and verified purchase indicators, enhances their value as a real-world data source for health care studies.

To process the large volume of unstructured text generated by consumers, text mining and natural language processing (NLP) techniques are essential for extracting meaningful patterns and insights. For example, previous applications of NLP in health forums have successfully extracted clinically relevant information such as treatment types, medication names, and side effects from cancer-related user-generated content [10]. Health NLP—an interdisciplinary field that integrates computational linguistics with health care—has received growing attention in recent years [11], leading to the development of a range of NLP tools and systems. One such platform, Open Health NLP (OHNLP), provides open-source clinical NLP software that facilitates large-scale analysis of free-text health data [12-14].

Despite the growing application of NLP in health care, existing studies using Amazon reviews as data sources for health-related insights have largely focused on noncancer domains such as erectile dysfunction and testosterone supplements [15], eye health [16], and chronic pain [17]. These studies demonstrate the feasibility of extracting product-related health experiences from consumer reviews. They also underscore a critical gap: there has been limited exploration of how individuals affected by cancer—particularly survivors—use Amazon to share experiences with complementary therapies, long-term symptoms, and navigate posttreatment concerns. Understanding these patterns is crucial for addressing the informational and self-management needs of cancer survivors.

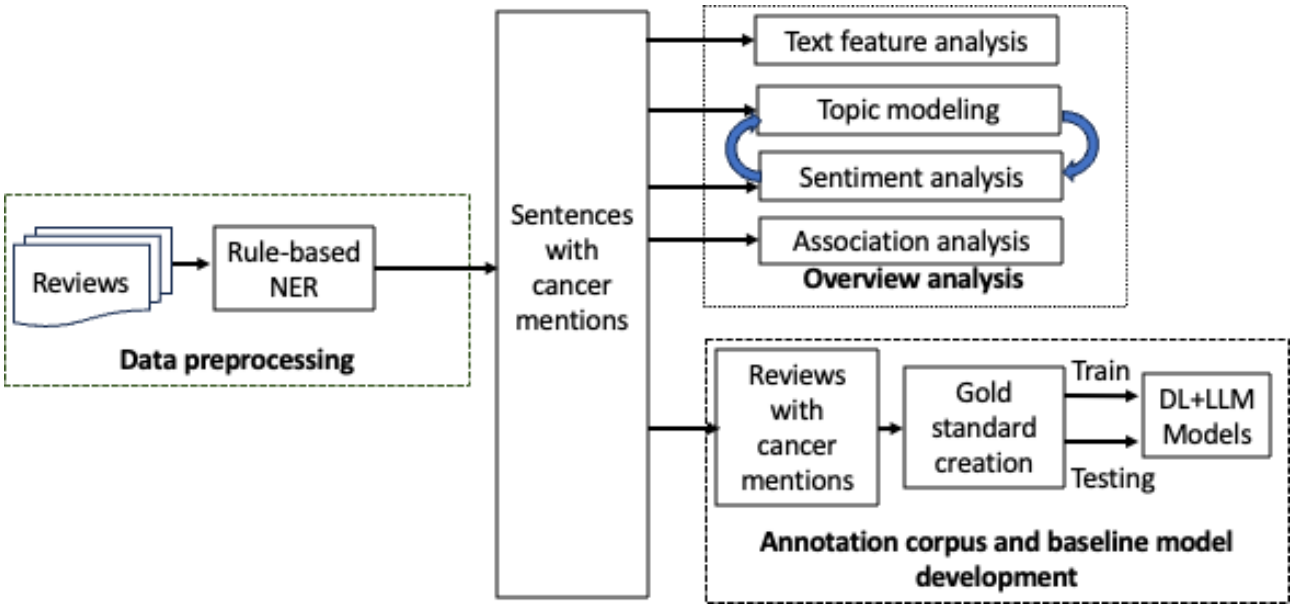
Amazon product reviews represent a novel and largely untapped data resource for exploring cancer symptom management from the survivor's perspective. These reviews may reveal implicit information about how survivors respond to persistent symptoms, evaluate over-the-counter and complementary therapies, and seek support outside of traditional health care settings. Annotated corpora are critical for training and evaluating NLP algorithms that can reliably identify these patterns. However, existing Amazon review datasets have been developed primarily for sentiment analysis [18-20], and there is a lack of manually annotated cancer-specific corpora that focus on survivorship-related constructs.

In this study, we aim to address this gap by evaluating the potential of Amazon consumer reviews to surface cancer

XSL•FO
RenderX

survivors' ongoing concerns, persistent symptoms, and unmet needs. Specifically, we (1) present a publicly available, manually annotated corpus derived from Amazon reviews of health-related products, and (2) develop baseline NLP models using deep learning and large language model (LLM) approaches to demonstrate the usability of this dataset. These tools provide the foundation for future research that leverages consumer-generated data to inform survivorship interventions and improve long-term outcomes for cancer survivors.

Methods



Data Source

We used the preprocessed dataset of Health & Personal Care category containing reviews and metadata from Amazon between May 1996-July 2014 [21]. This dataset has been deduplicated, consisting of 2,982,326 reviews and 263,032 metadata. Review data includes reviewer ID, the Amazon Standard Identification Number (ASIN) which Amazon uses to identify products, reviewer name, helpfulness of rating, review text, overall rating (1 - 5 stars), summary of review, and review time. Metadata of the reviews includes ASIN, title, price, image URL, what items the customer also bought, what items the customer also viewed, what items the customer bought together, sales rank, brand, and categories. ASIN is the primary key to link review text and metadata.

Study Design

Figure 1 shows the study design. Multiple methodologies have been developed to identify named entities in texts, that is, machine learning, deep learning, hybrid, and rule-based methods [22]. In the first step, we used a rule-based method to identify a set of review texts with cancer mentions for a high-level content analysis. We then created an annotated corpus from the set of review texts and developed baseline NLP models, including deep learning and LLM, for named entity recognition (NER) and text classification.

Figure 1. Study design. DL: deep learning; LLM: large language models; NER: named entity recognition.

Data Preprocessing With Rule-Based NLP Method

To identify the reviews with cancer mentions, we prepared a cancer dictionary based on the cancer branch of the Disease Ontology. It includes cell type cancer and organ system cancer integrated from different terminologies and vocabularies including the Catalog of Somatic Mutations in Cancer, The Cancer Genome Atlas, International Cancer Genome Consortium, Therapeutically Applicable Research to Generate Effective Treatments, Integrative Oncogenomics, and the Early Detection Research Network [23]. In total, there are 4343 cancer term variants corresponding to 1535 cancer concepts. The cancer terms were prepared into the symbolic lexicon format compatible with the Open Health Natural Language Processing (OHNLP) Toolkit's NLP engine MedTagger [24]. The open-source clinical NLP pipeline analyzed review texts and identified cancer-related medical concepts along with the assertion status of the cancer concept including certainty (ie, positive, negative, and hypothetical and possible). We kept only positive cancer concept mentions for further analysis.

Content Analysis

We summarized the features of texts containing sentences with cancer mentions, conducted sentiment analysis, topic modeling, and visualization of cancer types and symptoms association for the review sentences with cancer mentions to gain insights into the prevailing themes and mood surrounding discussions related to cancer within the dataset.

Text Feature Analysis

To understand the text features of review data, we performed text complexity analysis to summarize review texts containing the sentences with cancer mention, including number of review texts, number of sentences, and number of words. For comparison purposes, the above metrics were also calculated for the entire collection of reviews from the Health & Personal Care category.

XSL•FO
RenderX

Sentiment Analysis

Bert-base-multilingual-uncased-sentiment [25] is a fine-tuned model from a bertbase-multilingual-uncased model for sentiment analysis on product reviews in 6 languages including English. Based on 5000 held-out product reviews for English, the accuracy (exact), that is, exact match for the number of stars is 67%. Accuracy (off-by-1), that is, the percentage of reviews where the number of stars the model predicts differs by a maximum of 1 from the number given by the human reviewer is 95%. The fine-tuned model was used for sentiment analysis of review sentences with cancer term mentions. This model predicts the sentiment of input text as a number of stars (between 1 and 5). The higher the sentiment score, the more positive the review. The lack of context has been one major challenge in sentiment analysis that can affect the interpretation of sentiment [26]. We consider that identifying customer attitudes based on the sentence containing cancer mentions instead of the whole review text can be better constructive in understanding consumers' efficacy and safety perceptions. The sentiment of the review sentences with cancer mentions detected by Medtagger was further analyzed to identify positive or negative attitudes toward the product [27,28]. We analyzed the distribution of sentiment scores across the review sentences with cancer mentions, and the trend of average sentiment score between 1996 and 2014.

Topic Modeling

We used a sentence embedding model (ie, bge-small-en) [29] to transform the textual content of reviews into numerical embeddings. These embeddings capture the semantic essence of each document in a high-dimensional space. We then applied UMAP (Uniform Manifold Approximation and Projection) [30] to the embeddings for dimensionality reduction. This step is crucial for visualization, as it converts high-dimensional data into a 2-dimensional format suitable for plotting. The core of the analysis is performed by BERTopic [31], a model that identifies distinct topics within the text data. BERTopic relies on sub-models for embeddings (provided by SentenceTransformer of bge-small-en), dimensionality reduction (UMAP), and hierarchical clustering (HDBSCAN) [32]. In addition, a quantized LLM (ie, openhermes-2.5-mistral-7b) [33] is incorporated for topic label generation. After fitting the data to the BERTopic model, topics are extracted along with their probabilities. Each topic is then assigned a label generated by the LLM based on a predefined prompt. These labels are designed to be concise, with a maximum of 5 words, and describe the essence of the documents within each topic.

The chosen sentences were preprocessed by removing stop-words, special characters, and numbers and removing sentences with pets (dog, cat, etc). We detected topics based on all sentences with cancer mentions, as well as the sentences from 5 sentiment score groups. We then visualized the results.

Cancer Type and Symptom Association

To explore the relationship between reported cancer types and symptoms, we constructed bipartite graphs based on co-occurrence patterns in the chosen sentences. Symptom mentions were identified using a state-of-the-art LLM for NER, specifically, the UniversalNER-7b-all model, which was applied via a 0-shot strategy. We then calculated the frequency of cancer type-symptom co-occurrences to generate a set of unique pairs. Each bipartite graph consisted of 2 node sets—cancer and symptoms—with edges indicating their association frequency. Node placement was optimized to ensure even distribution and visual clarity within each group. Edge widths were normalized and scaled to reflect the relative frequency of each cancer type-symptom pair, allowing for a visual representation of the strength of association between nodes.

Development of Gold Standards and Baseline Models

Gold Standard Creation

We developed an annotation guideline (Multimedia Appendix 1) to support the systematic labeling of target data elements and their associated class and type designations from Amazon customer reviews. The guideline was designed to be concise in order to minimize annotators' cognitive load while ensuring consistency and enabling the annotated dataset's future use for information extraction tasks. The schema of annotated labels is presented in Table S1 in Multimedia Appendix 2. Target concepts included cancer type, indicated symptoms, favorable outcome, harmful outcome, and product, with each concept having class or type options.

The cancer type concept has the class of either human or pet. The indicated symptoms, favorable outcome, and harmful outcome concepts were further categorized as either cancer-related or other, while the product concept was labeled as itself or other. In addition to class and type assignments, we also annotated each cancer type, indicated symptom, favorable outcome, and harmful outcome instance with one of 4 levels of certainty: positive, negative, hypothetical, or possible. For example, in the sentence: "I've had salivary gland cancer," the phrase "salivary gland cancer" was annotated as the cancer type concept, with the human class and positive certainty. In contrast, the phrase "might prevent cancer" in the sentence: "Some people say it might prevent cancer," was annotated as a favorable outcome concept, with the cancer-related class and hypothetical certainty.

MedTator [13], a free and open-source annotation tool, was used to perform the annotation task. Two annotators with backgrounds in medicine and informatics were first trained to annotate following the annotation guideline. After initial training, inter-annotator agreement (IAA) was assessed during the process. Once the annotators achieved a high level of agreement (F_1-score ≥0.9), they proceeded to independently annotate the review texts. Discrepancies were resolved through an adjudication process involving discussion and consensus, resulting in a finalized gold standard corpus.

A total of 200 review texts containing cancer-related mentions, identified from the first step, were randomly selected for annotation. During the annotation process, we focused on reviews reflecting customer perspectives and excluded those summarizing books or other nonproduct-related content. This yielded a final sample of 159 consumer-generated reviews that were chosen for annotation.

XSL•FO
RenderX

Development of Baseline Models

The annotated dataset was used to develop baseline models for 2 NLP tasks: NER and text classification. The goal of the NER task was to identify and classify entities mentioned in consumer reviews, specifically focusing on cancer types, indicated symptoms, and product mentions. For model development, we restricted annotations to human cancer types and cancer-related symptoms. The cancer type entity category included specific diagnoses such as “breast cancer,” “leukemia,” “lymphoma,” and “melanoma,” and only entities annotated with a positive certainty value were included. The indicated symptoms category captured phrases that suggested the condition or symptom the product was used to address (eg, “affected her eye” in the sentence “She had cancer that affected her eye”). The product entity included both direct product mentions and anaphoric references (eg, “this”).

For the text classification task, review excerpts were categorized into one of 3 outcome classes based on product impact on cancer-related conditions: favorable, harmful, or ambiguous. Favorable outcomes are comments where the product is noted to positively affect a cancer-related condition. Harmful outcomes are comments indicating a negative impact on cancer-related conditions. Ambiguous outcomes include comments with possible and hypothetical certainties, reflecting the speculative nature of the feedback.

We developed 2 types of baseline models for the NER and text classification tasks. The first used supervised fine-tuning (SFT) of BERT-like models, with 2 different classification heads on top, that is, token classification and sequence classification, respectively. We evaluated the performance of 2 widely used BERT-like models: bert-base-cased and Bio_ClinicalBERT. The second type of baseline was based on an LLM approach using the gpt4-1106-preview-chat model. We prompted the model to perform both tasks under varying in-context learning conditions: zero-shot, few-shot (using 5 examples), and many-shot (using all available training examples) [34]. The prompts used for NER and text classification are included in Appendix File 3. For both NER and text classification tasks, we partitioned the annotated dataset using an 80-20 train-test split, with 80% of the data used for training and 20% reserved for evaluation.

Ethical Considerations

The data used in the study were publicly available [21]. As Amazon customer reviews typically do not contain personally identifiable information and we used the public dataset; therefore, personally identifiable information was not a concern in this study.

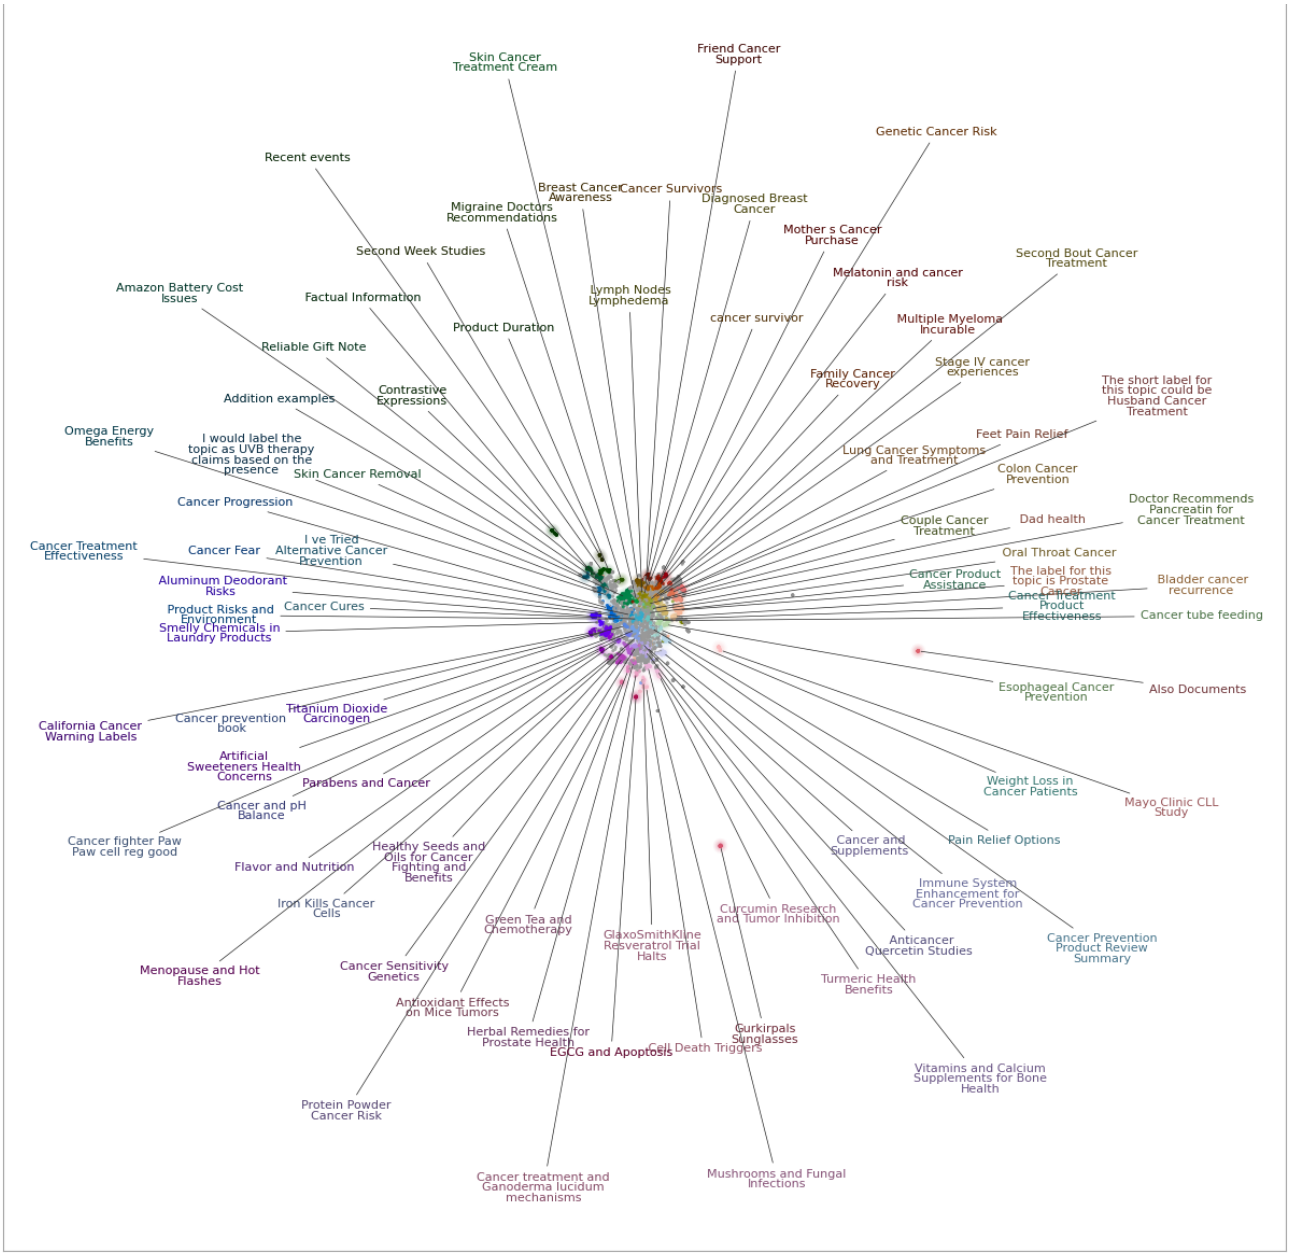
Results

Content Analysis

A total of 4703 sentences containing positive cancer mentions were identified, drawn from 3349 reviews associated with 2589 distinct products. These cancer-related reviews contained a total of 26,078 sentences and 500,087 words, with an average length of 149.3 words per review. For comparison, the broader Health & Personal Care category comprised 2,982,326 reviews, totaling 10,469,336 sentences and 199,501,964 words, with an average of 66.9 words per review. Table 1 shows the distribution of product categories with reviews that include cancer-related mentions.

Table S2 in Multimedia Appendix 2 shows the distribution of sentiment scores across the review sentences with cancer mentions, where scores 1 and 5 prevailed as the top sentiments. Temporarily, there were increasing trends for the average sentiment score of the sentences with cancer mentions from 2004 to 2014 before and after a dip around 2008.

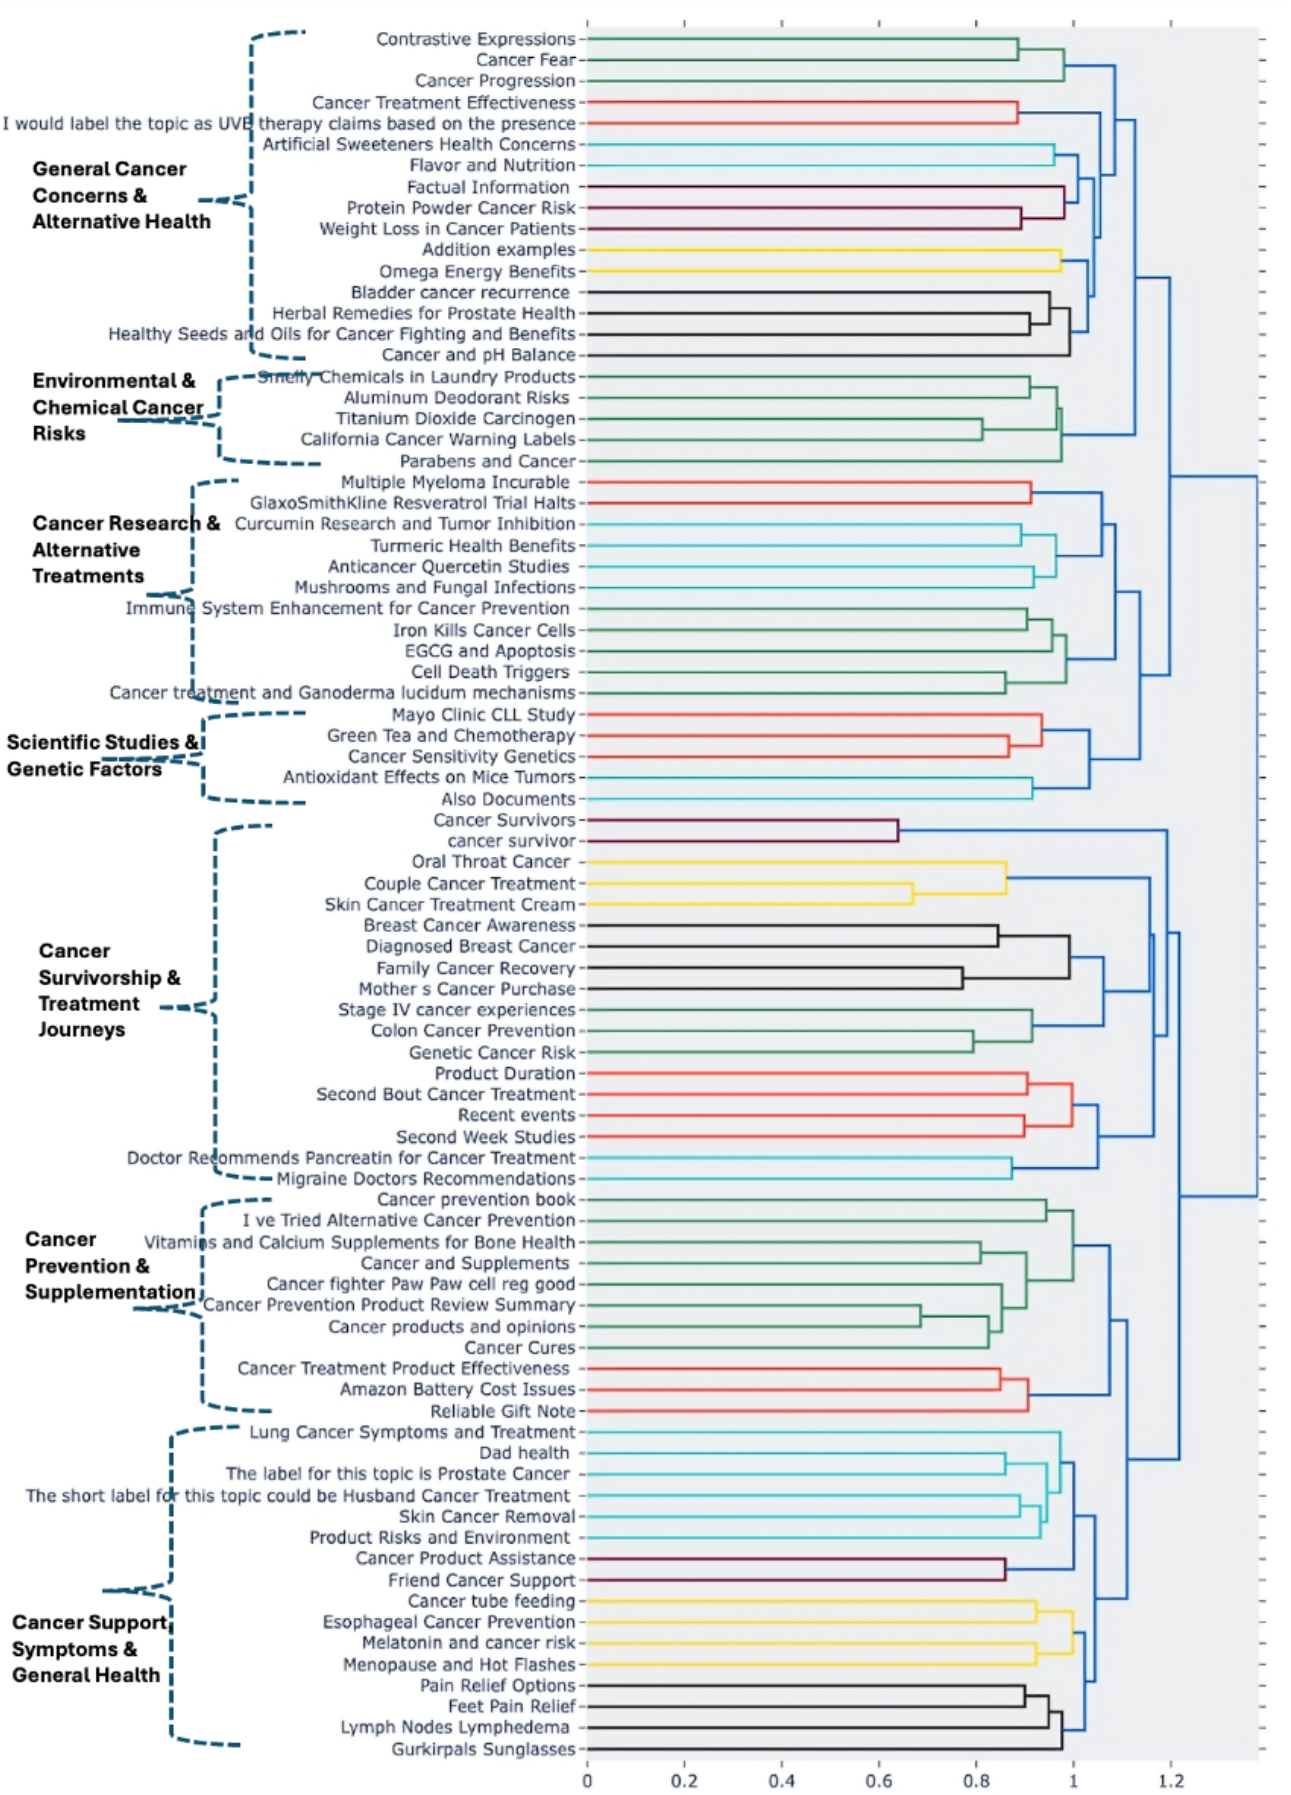
Table . Distribution of product categories in review sentences of cancer mentions.



Product categories	Number of review sentences with cancer mentions
Health & personal care	4703
Vitamins & dietary supplements	2758
Health care	675
Personal care	361
Sports nutrition	283
Medical supplies & equipment	268
Household supplies	99
Sexual wellness	45

Figure 2 shows the results of topic modeling applied to all sentences containing cancer mentions extracted using the dictionary method. The identified topics revealed meaningful insights into cancer symptom management and survivorship experiences. Examples included discussions of green tea use during chemotherapy, cancer prevention strategies, product recommendations for breast cancer; post-treatment oral health issues, and antioxidant effects on tumor vasculature. To further examine the thematic structure, we conducted hierarchical clustering of these topics, as shown in Figure 3. Cluster labels were generated using GPT-4o (prompting instructions are shown in Multimedia Appendix 3), resulting in the following high-level themes: General Cancer Concerns & Alternative Health; Environmental & Chemical Cancer Risks; Cancer Research & Alternative Treatments; Scientific Studies & Genetic Factors; Cancer Survivorship & Treatment Journeys; Cancer Prevention & Supplementation and Cancer Support, Symptoms & General Health. For example, the General Cancer Concerns &

XSL•FO
RenderX

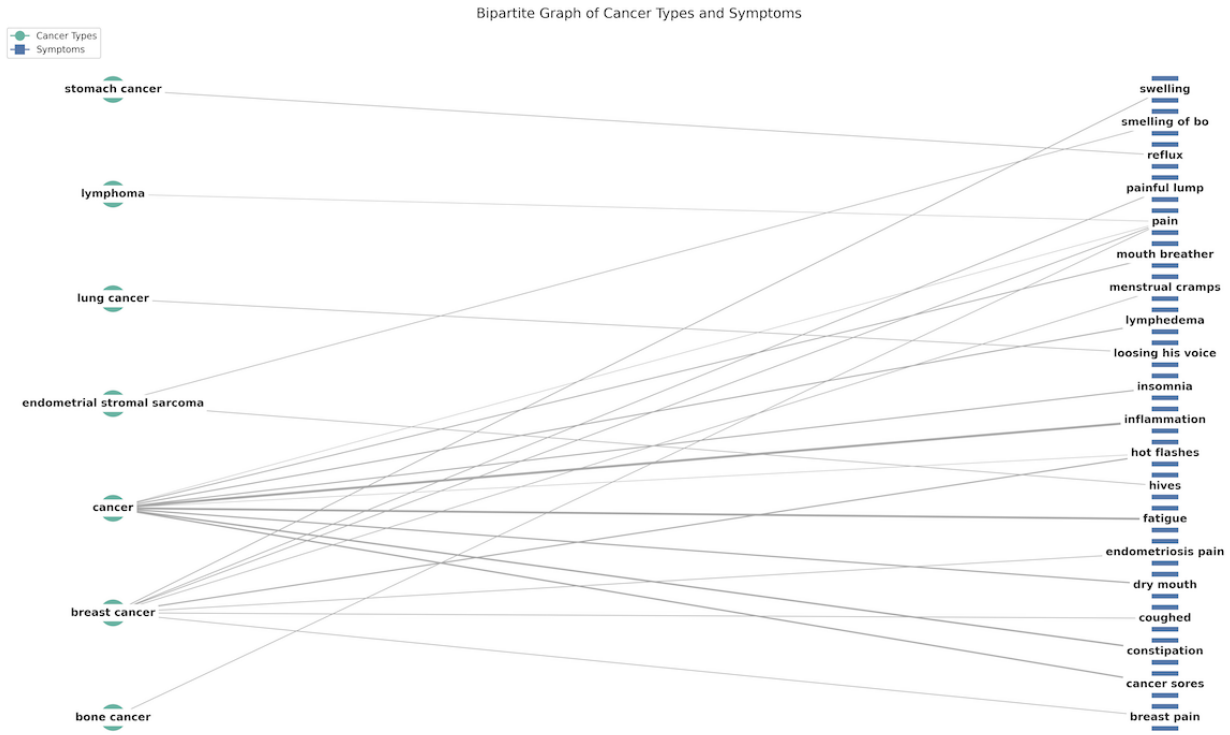


Alternative Health cluster includes discussions related to cancer-related fears and disease progression, while the Cancer Support, Symptoms & General Health cluster captures narratives related to pain management, lymph node involvement, and lymphedema. To quantify the distribution of content across these clusters, we further prompted GPT-4o to assign each sentence derived from topic modeling into one of the 7 clusters using an in-context prompt (Multimedia Appendix 3). As shown in Table S3 in Multimedia Appendix 2, the cluster Cancer Support, Symptoms & General Health accounted for the largest proportion of sentences, followed by Cancer Prevention & Supplementation.

Figure 2. Topic modeling with BERTopic based on all sentences with cancer mentions.

XSL•FO
RenderX

Figure 3. Hierarchical clustering of topics based on all sentences with cancer mentions.



XSL•FO
RenderX

Figures S1-S6 in Multimedia Appendix 4 display the results of hierarchical clustering and topic modeling conducted separately for review sentences grouped by sentiment score 1, 2, 3, 4, and 5. This stratified analysis revealed notable differences in thematic content across sentiment groups. For example, sentiment score group 1 (most negative) contained a higher concentration of topics related to cancer risks, including concerns about carcinogenic ingredients, California Proposition 65 warning labels, artificial sweeteners, product safety, and general ingredient toxicity. In contrast, sentiment score group 5 (most positive) featured a greater number of topics highlighting perceived benefits for cancer-related conditions. These included the purported benefits of iodine for thyroid health, calcium vitamin supplementation for bone health, flaxseed as a complementary therapy, narratives of cancer survivorship and thriving, use of sleep aids during cancer treatment, and various anticancer supplements used by survivors.

Figure 4 shows the bipartite graphs of cancer types with symptoms. The bipartite graph is used to show the association between cancer types and symptoms instead of causal relations in a sentence. The edge between cancer types and symptoms represented the frequency of the cancer type-symptom pairs, showing the strength of each association. Zero-shot LLM extracted detailed symptoms, such as pain, inflammation, fatigue, constipation, etc. Results showed associations between stomach cancer and reflux, breast cancer and menstrual cramps, bone cancer and pain, etc.

Figure 4. Bipartite graph of cancer types and symptoms extracted by large language model.

Top 15 symptoms in reviews were also identified, with pain being the most frequent symptom, followed by inflammation, fatigue, hot flashes, dry mouth, constipation, cancer sores, nausea, insomnia, neuropathy, lymphedema, incontinence, diarrhea, bloating, fever, and night sweats.

Annotation Corpus

Table 2 shows the statistics for the resulting annotated corpus for each concept and associated classes (type) and certainties. In total, 2067 labels were generated from 159 reviews. Table S4 in Multimedia Appendix 2 shows the inter-annotator agreements for each concept annotation, with the overall inter-annotator agreement being 0.86. IAA for cancer type is the highest (0.97), and harmful outcome is the lowest (0.63). The annotated corpus is publicly accessible through the OHNLP Github [13,35].

XSL•FO
RenderX

Table . Statistics of the resulting annotated corpus.

Concepts and class (type)[a]	Certainty			
	Positive	Negative	Hypothetical	Possible
Human				
Cancer_type	131	9	100	2
Pet				
Cancer_type	18	0	3	0
Cancer_related				
Indicated_symptom	105	1	1	0
Harmful_outcome	16	0	5	0
Favorable_outcome	145	0	51	1
Other				
Indicated_symptom	80	0	2	0
Harmful_outcome	23	0	1	0
Favorable_outcome	242	0	15	0

[a]There were 1,015 labels for Product (itself) and 98 for Product (other).

Baseline Model Development

In our study, the annotated data is used for two distinctive NLP tasks, ie, named entity recognition and text classification. The dataset for the NER task included 1054 annotated samples, with 80% (843 samples) used for training the model and 20% (211 samples) designated for testing its accuracy. For text classification, the dataset consists of 218 annotated samples, with 80% (174 samples) allocated for training the model and 20% (44 samples) reserved for testing its accuracy. Table 3 shows the statistics of annotation entity labels for model development.

Table 4 shows the performance of Bert-base-cased, Bio_ClinicalBERT, and gpt4-1106-preview-chat in NER. In general, bert-like models outperformed LLM, with 0.6692 weighted average F_1-score for bert-base-cased, 0.6558 for Bio_ClinicalBERT, and the best performance of gpt4-1106-preview-chat was 0.5077 weighted average F_1-score through many-shot strategy. Among the 3 entities, "indicated symptom" showed consistent lower performance across all baseline models compared with the other two entities, that is, "cancer type" and "product," implying the difficulty of extracting this entity.

Table 5 shows the performance of baseline models in text classification. The performance of LLM gpt4-1106-preview-chat using many-shot strategy exceeded bert-like models. Specifically, the performance of bert-base-cased and Bio_ClinicalBERT in classifying "Harmful outcome" was zero. This could be explained by the limited number, that is, 16, of "Harmful outcome" labels in the gold standard. In addition, the IAA of harmful outcome is the lowest during annotation, implying that "Harmful outcome" classification is the most difficult classification task among all. In contrast, LLM excelled in the scenario of the limited labels, achieving the highest F_1-score for the 3 classes, that is, 0.6667 for "Harmful outcome," 0.8846 for "Favorable outcome," and 0.7333 for "Ambiguous outcome."

[a]SFT: supervised fine-tuning.

Discussion

Principal Findings

Complementary therapies are increasingly used by cancer survivors to manage persistent symptoms and long-term side effects. Among breast cancer patients, for example, dietary supplement use has been reported in 67% to 87% of cases [36,37]. However, complementary therapies are often not integrated into routine oncology care, and clinical research evaluating their effectiveness remains limited. One contributing factor is that many patients do not disclose their use of such therapies to providers, creating a significant gap in understanding how survivors self-manage their health outside clinical settings [38,39].

XSL•FO
RenderX

In this study, we explored the potential of Amazon consumer reviews as a novel data source for capturing survivor-reported experiences with symptom management and complementary therapy use. Through content analysis, we identified several dimensions of cancer survivorship care reflected in these reviews.

First, topic clustering revealed meaningful subgroups related to survivorship experiences, including discussions of protein powders, cancer-related weight loss, breast cancer and estrogen receptor status, and vitamins for future cancer prevention.

Second, sentiment-stratified analysis revealed that reviews with lower sentiment scores more often focused on cancer-related risks (eg, toxic ingredients and product harms), while those with higher scores more often highlighted perceived benefits of supplements and other supportive products for managing cancer-related symptoms (Figures S1-S6 in Multimedia Appendix 4). These patterns provide insights into how survivors interpret and evaluate complementary therapies in relation to their health and recovery.

Third, associations between specific cancer types (identified via the rule-based dictionary method), and symptoms (identified using zero-shot LLM methods) surfaced detailed symptom management experiences, including pain, fatigue, and gastrointestinal symptoms. Notably, the top 15 symptoms included in these reviews reflect common survivorship challenges [40,41], with pain being the most frequent. Fourth, while the zero-shot LLM was not formally evaluated in this content analysis, it was effective in identifying symptom-related language at scale, which enabled exploratory symptom mapping across cancer types. These findings illustrate how publicly available consumer data can offer valuable insight into the lived experiences of survivors and their efforts to manage persistent symptoms using accessible, over-the-counter, or complementary therapies.

Beyond content analysis, our key contributions include the development of a manually annotated dataset with 159 reviews and baseline NLP models for NER and text classification. This resource was intentionally designed to capture nuanced mentions of cancer types (eg, “cancer in his bone”) and survivor-reported outcomes, laying the groundwork for future applications in survivorship research. These annotations provide a foundation for fine-grained analysis of survivor narratives and outcomes related to self-management of cancer and treatment-related side effects.

The baseline models demonstrated promising performance. The bert-base-cased model achieved the highest weighted average F_1-score for NER, while gpt4-1106-preview-chat achieved the highest F_1-scores across all text classification tasks. These results suggest that LLMs, while currently limited in NER performance [42,43], are highly effective for text classification. For instance, even in the limited Harmful outcome category (n=16), GPT-4 was able to generalize and achieve an F_1-score of 0.6667 in the zero-shot setting, compared with an F_1-score of 0 for fine-tuned BERT/Bio_ClinicalBERT models. This highlights the potential of LLMs for use in survivorship-related classification tasks where annotated data may be limited. To address the low performance of the NER task, data augmentation through synthetic data generation or fine-tuning models with a larger training dataset can be used.

Limitations

Our study has several limitations. First, the sentiment analysis component is constrained by the domain dependence of existing pretrained models [44]. While many general-purpose language models can classify sentiment, few are trained specifically on health or cancer-related content. To enable a high-level analysis of emotional tone, we used an existing sentiment model, which achieved 67% exact match accuracy between predicted sentiment and the number of stars assigned to product reviews containing cancer mentions. However, this approach occasionally produced mismatches. For instance, the sentence “My husband took this for early stage CLL and after 9 months is in remission.” was assigned a sentiment score of 1 (negative), despite clearly expressing a positive outcome. This misalignment reflects the complexity of interpreting sentiment in survivorship contexts, where emotional tone may be influenced by both product experience and the reviewer’s cancer journey. As such, sentiment scores may not consistently reflect product efficacy or survivor satisfaction. In addition, consumer reviews are inherently subjective and may reflect social influence biases (eg, other reviews) [45], or may come from users who are not representative of the broader survivor population [46]. Despite these limitations, sentiment analysis helped highlight broad differences in topics across emotional tone. In future work, we plan to fine-tune domain-specific sentiment models trained on health-related and survivorship-specific data to improve classification accuracy and interpretability.

Second, although the overall IAA was high (F_1=0.86), the IAA for the “Harmful outcomes” category was considerably lower (F_1=0.63). This is likely attributable to the small number of annotated instances (n=16), which may have contributed to reduced consistency. However, given the clinical and survivorship importance of identifying adverse outcomes, this remains a critical category. Future annotation efforts will involve expanded training, guideline refinement, and targeted oversampling of underrepresented classes to improve reliability.

Third, the dataset used for this study includes Amazon reviews posted between May 1996 and July 2014. Consumer behaviors, complementary therapy trends, and survivorship care practices have likely evolved in the past decade. This temporal limitation may restrict the contemporary relevance of some findings, particularly in light of recent shifts toward integrative oncology and growing digital health engagement among survivors. Fourth, our manually annotated dataset comprises only 159 reviews. While this proof-of-concept sample enabled initial model development and feasibility testing, the limited sample size constrains the generalizability and robustness of the resulting models. Ongoing annotation work will expand the dataset, with careful attention to balancing reviews across outcome types and sentiment categories to support more comprehensive model training.

Notably, a new version of the Amazon review dataset—spanning May 1996 to Sep 2023—has recently been released and is

XSL•FO
RenderX

245.2% larger than the version used in this study [47]. Future work will leverage the expanded dataset to scale annotation efforts, develop more robust models, and generate updated insights into cancer symptom management and complementary therapy use among cancer survivors. These analyses could also support regulatory efforts and health care interventions by highlighting potential product risks and unmet survivor needs reflected in real-world consumer narratives.

Conclusion

Our results demonstrate the potential of Amazon consumer reviews as a novel data source for identifying persistent symptoms, concerns, and self-management strategies among cancer survivors. We presented the design and implementation of a publicly accessible, manually annotated corpus available through the OHNLP GitHub focused on cancer type, symptoms, and symptom management outcomes. This corpus, along with the baseline NLP models developed for named entity recognition and text classification, lays the groundwork for future methodological advancements in cancer survivorship research. Importantly, insights derived from this study could be evaluated in relation to established clinical guidelines for symptom management in cancer survivorship care (eg, American Society of Clinical Oncologists and National Comprehensive Cancer Network). Such comparisons may help validate survivor-reported outcomes, reveal novel survivor concerns not routinely captured in clinical care settings, and inform the development of more patient-centered care models. By revealing the feasibility of using consumer-generated data for mining survivorship-related experiences, this study offers a promising foundation for future research and argumentation analysis aimed at improving long-term outcomes and support for cancer survivors.

Abstract

Background: Melanoma currently ranks as the fifth leading cancer diagnosis and is projected to become the second most common cancer in the United States by 2040. Melanoma detected at earlier stages may be treated with less-risky and less-costly therapeutic options.

Objective: This study aims to analyze temporal and spatial trends in melanoma incidence by stage at diagnosis (overall, early, and late) in Texas from 2000 to 2018, focusing on demographic and geographic variations to identify high-risk populations and regions for targeted prevention efforts.

Methods: We used melanoma incidence data from all 254 Texas counties from the Texas Cancer Registry (TCR) from 2000 to 2018, aggregated by county and year. Among these, 250 counties reported melanoma cases during the period. Counties with no cases reported in a certain year were treated as having no cases. Melanoma cases were classified by SEER Summary Stage and stratified by the following four key covariates: age, sex, race and ethnicity, and stage at diagnosis. Incidence rates (IRs) were calculated per 100,000 population, and temporal trends were analyzed using joinpoint regression to determine average annual percentage changes (AAPCs) with 95% CIs for the whole time period (2000 - 2018), the most recent 10-year period (2009 - 2018), and the most recent 5-year period (2014 - 2018). Heat map visualizations were developed to assess temporal trends by patient age, year of diagnosis, stage at diagnosis, sex, and race and ethnicity. Spatial cluster analysis was conducted using Getis-Ord Gi* statistics to identify county-level geographic clusters of high and low melanoma incidence by stage at diagnosis.

Results: A total of 82,462 melanoma cases were recorded, of which 74.7% (n=61,588) were early stage, 11.3% (n=9,352) were late stage, and 14% (n=11,522) were of unknown stage. Most cases were identified as males and non-Hispanic White individuals. Melanoma IRs increased from 2000 to 2018, particularly among older adults (60+ years; AAPC range 1.20%-1.84%; all *P* values were <.001), males (AAPC 1.59%; *P*<.001), and non-Hispanic White individuals (AAPC of 3.24% for early stage and 2.38% for late stage; *P*<.001 for early stage and *P* = .03 for late state). Early-stage diagnoses increased while the rates of late-stage diagnoses remained stable for the overall population. The spatial analysis showed that urban areas had higher early-stage incidence rates (*P*=.06), whereas rural areas showed higher late-stage incidence rates (*P*=.05), indicating possible geographic-based differences in access to dermatologic care.

Conclusions: Melanoma incidence in Texas increased over the study time period, with the most-at-risk populations being non-Hispanic White individuals, males, and individuals aged 50 years and older. The stable rates of late-stage melanoma among racial and ethnic minority populations and rural populations highlight potential differences in access to diagnostic care. Future prevention efforts may benefit from increasing access to dermatologic care in areas with higher rates of late-stage melanoma at diagnosis.

KEYWORDS

melanoma incidence; melanoma screening; geographic disparity; geospatial analysis; joinpoint regression; demographic variation; temporal trend analysis; stage at diagnosis

Introduction

Melanoma currently ranks as the fifth leading cancer diagnosis overall and is projected to become the second most diagnosed cancer in the United States by 2040 [1]. Nationally, melanoma incidence rates (IRs) have shown distinct temporal trends across age, sex, race, and ethnicity. Since 2006, IRs have decreased for adolescents and young adults but increased for older adults, with an annual percent change (APC) of 2.5% for individuals older than 65 years between 2006 and 2015 [2,3]. From 2006 to 2021, IRs have increased for non-Hispanic White and Hispanic individuals (APC of 1.7% and 0.6%, respectively) but decreased for non-Hispanic Black individuals (APC of –1.2%) [3]. Non-Hispanic White males older than 50 years have maintained the highest incidence over the last 2 decades [3].

Previous studies have reported that the areal-level social determinants of health (SDoH) are associated with disparities in melanoma incidence, stage at diagnosis, and survival outcomes. For example, using spatial cluster analysis and a multinomial logistic regression model, a study in Florida found that patients with melanoma who live in census tracts with higher percentage of poverty are more likely to have a late-stage diagnosis [4]. Another study examining the national cancer database from 2011 to 2020 used a chi-square test and found that patients from urban areas are more likely to have an early-stage melanoma (P<.001) [5]. Similarly, a study in Texas using a multinomial logistic regression model found that patients from counties with persistent poverty (≥20% of residents at or below the federal poverty level for the past two decennial censuses) have higher incidence-based melanoma mortality [6]. Melanoma survival rates vary dramatically depending on stage at diagnosis, with nearly guaranteed 5-year survival for early-stage (localized) diagnoses [3]. However, racial and ethnic minority groups are more likely to be diagnosed with melanoma at advanced stages when compared with stage-matched White patients (chi-square tests with P<.001) [3,7,8]. Therefore, understanding how stage-specific melanoma incidence varies across time by patient demographics and geographic location can inform data-driven early detection efforts to improve melanoma morbidity and mortality.

Although Texas had lower all-stage melanoma IRs compared with the national average during 2017 and 2021 (14.9 vs 22.7 cases per 100,000 population), it reported the highest percentage of late-stage cutaneous melanoma diagnoses in the contiguous United States (18.2% in Texas vs 14.1% nationally) [9]. One strategy to shift melanoma detection from late to earlier stages is to increase screening via dermatologists. However, many regions of Texas lack access to dermatologists [10,11]. Alternatively, primary care providers (PCPs) may provide essential skin-cancer detection services [12], yet significant training barriers often preclude early skin cancer diagnosis by PCPs [13]. Geographically targeted education and telementoring efforts to support PCP melanoma diagnosis [14] could potentially enhance early melanoma detection, particularly in areas with a high late-stage melanoma IR. However, the spatial and temporal distribution of stage-based melanoma incidence in Texas has yet to be thoroughly explored to identify these critical locations.

In this study, we analyzed Texas Cancer Registry (TCR) melanoma cases from 2000 to 2018. Using novel data visualizations, we identified trends in melanoma incidence by year of diagnosis, patient demographics, and stage at diagnosis. We also investigated county-level geographic patterns of melanoma incidence across Texas over time. Understanding these trends can guide the development of risk-based interventions to improve melanoma outcomes at the population level.

Methods

Data

Melanoma incidence data from 2000 to 2018 were obtained from the TCR and aggregated by 254 Texas counties and year. Among these, 250 counties reported melanoma cases during the period. Counties with no cases reported in a certain year were treated as having no cases. Melanoma cases were categorized by stage at diagnosis using the Surveillance, Epidemiology, and End Results (SEER) summary stage system, which differs from the more clinically oriented National Comprehensive Cancer Network melanoma-specific staging guidelines [10]. While SEER summary stage data categories have changed over time, we organized TCR melanoma cases into three groups: early stage (SEER stages 0 [in situ], 1 [localized], and 2 [regional by direct extension only]), late stage (SEER stages 3 to 5 [regional] and stage 7 [distant]), and unknown (SEER stage 9: unknown, unstaged, and unspecified).

For demographic stratification, we considered 7 age groups (18 - 29, 30 - 39, 40 - 49, 50 - 59, 60 - 69, 70 - 79, and ≥80 years old), 2 sex groups (female and male), and 4 racial and ethnic groups (non-Hispanic White, non-Hispanic Black, Hispanic, and non-Hispanic Others). Annual county-level population estimates stratified by age, sex, and race and ethnicity were obtained from the National Institutes of Health (NIH) SEER county population data [15].

Patient county of residence at the time of diagnosis was classified as rural or urban using the 2013 US Department of Agriculture Rural-Urban Continuum Codes (RUCCs) [16]. RUCCs 1 - 3 were classified as urban and RUCCs 4 - 9 were classified as rural. Counties were also classified as either with or without persistent poverty using the US Economic Development Administration's 2021 persistent poverty data [17].

Incidence Calculation and Trend Analysis

Annual melanoma incidence-based rates were calculated by sex, age, and racial and ethnic groups as described in the "Data" section. Given the substantial variation in melanoma incidence across different age groups, with higher rates typically observed in older age groups, previous analyses often reported age-adjusted rates to allow for more comparable temporal trends across different populations. However, in this study, we adopted a novel data visualization approach using temporal heat maps, which effectively incorporate known confounders such as age and provide a clearer and more intuitive representation of trends [18]. The heat maps display the year of diagnosis (x-axis), age at diagnosis (y-axis), and calculated stage-specific incidence per 100,000 population as a blue (lower rates) to red (higher rates) color gradient. The heat maps used the Akima interpolation method [19] to generate a smoothed surface from observed data points, providing a visually coherent presentation of temporal trends in IRs.

Spatial Cluster Analysis

We calculated the annual melanoma incidence-based rate for each county in Texas (n=254) using county-specific population data. Spatial cluster analyses were then performed using Getis-Ord Gi* statistics. The Gi* statistic indicates the degree of spatial clustering: positive values indicate that a county and its neighboring areas have higher-than-average rates, while negative values suggest lower-than-average rates. Statistical significance was assessed via Monte Carlo simulation, comparing the observed Gi* values to a reference distribution generated from simulated spatial data. The results categorize counties' spatial clustering significance as follows: Very High (Gi* stat>0 and $P<.01$), High (Gi* stat>0 and $0.01 \leq P<.05$), Somewhat High (Gi* stat>0 and $0.05 \leq P<.10$), Insignificant ($P>.10$), and Low (Gi* stat<0 and $P<.10$). These categorizations allow for the identification of counties with significantly higher or lower melanoma IRs than would be expected by random chance and represent successive thresholds for interpreting spatial clusters without implying a strict ranking of significance. Chi-square tests were used to examine the relationship between spatial clustering categories and urban-rural or poverty status. All data analyses and visualizations were conducted in R (version 4.2.1; R Core Team) [20].

Joinpoint Trend Analysis

To assess temporal changes in melanoma IR, we performed a state-level joinpoint trend analysis to identify years when significant shifts in trends occured. We calculated the APC in IR using the weighted least-squares method, stratified by stage at diagnosis and among different demographic groups [21]. The APC represents the annual rate of change in IR over a specified period, assuming a constant percentage change each year. For instance, an APC of 2% would indicate that an IR of 100 per 100,000 would increase to 102 per 100,000 in the following year. We allowed for a maximum number of two joinpoints over the 19-year study period. Using the Joinpoint Trend Analysis Software (Joinpoint Regression Program; version 5.3.0.0) from SEER [22], we identified specific years with significant changes in the temporal trends and determined the final number of joinpoints using permutation tests. In addition, we derived a summary measure, the average annual percentage change (AAPC), over three fixed time periods: 2000 - 2018 (entire study period), 2009 - 2018 (most recent 10 y), and 2014 - 2018 (most recent 5 y), based on the joinpoint regression model for the full period from 2000 to 2018. For example, an AAPC of 2% for the 2010 - 2018 period would indicate that the IR increased by an average of 2% annually during these years. The 95% CIs for both APC and AAPC were derived using empirical quantile methods.

Ethical Considerations

The study was approved by the institutional review board (IRB) at the University of Texas Health Science Center at Houston (IRB: HSC-SPH-23 - 0483). Melanoma TCR data were obtained from the Texas Department of State Health Services (DSHS) via a formal data request that included an IRB application. Upon IRB approval from the DSHS, a waiver of informed consent was granted because study constitutes secondary research using existing data, involves no more than minimal risk to the participants, and therefore does not require additional consent.

To protect participants' privacy and confidentiality, all data were de-identified prior to analysis. The dataset included only non-identifiable variables such as year of diagnosis, county of residence at diagnosis, demographic characteristics (e.g., sex, race/ethnicity), and birth year. No names, contact information, or medical record numbers were included. The research team adhered to all DSHS data use agreements and institutional data security protocols. Access to the data was limited to approved study personnel and stored on encrypted, password-protected servers within secure institutional networks.

Results

Overview

From 2000 to 2018, the TCR reported 82,462 melanoma cases (Table 1). Among these, 61,588 (74.7%) were diagnosed at an early stage, 9352 (11.3%) at a late stage, and 11,522 (14%) had an unknown stage at diagnosis. The demographic subgroups with the most cases included individuals aged 60 - 69 years (18,959 cases, 23.0%), males (49,058 cases, 59.5%), and non-Hispanic White individuals (74,943 cases, 90.9%). The demographic distribution of melanoma cases by stage largely mirrored these overall trends. The racial and ethnic distribution showed that non-Hispanic White individuals dominated both early- and late-stage cases, although their proportion was slightly lower in late-stage cases.

Figure 1 presents temporal heat maps of stage-specific population-adjusted melanoma IRs (cases per 100,000 population) across demographic subgroups (sex, age, and race and ethnicity) from 2000 to 2018 in Texas. When considering all stages, melanoma IRs slightly increased over time to around 90 per 100,000 population. The highest increase was observed in the 80+ age group from 79 in 2000 to 104 in 2018 (AAPC 1.84%, 95% CI 1.27-2.40), while the 70 - 79 age group saw the highest increase from 2014 - 2018 (AAPC 2.75%, 95% CI 1.84-5.03). Conversely, IRs for the 18 - 29 age group declined from 6 in 2014 to 4.6 per 100,000 in 2018 (AAPC 3.05%, 95% CI –3.66 to –2.46). IRs for those aged 30 - 49 years remained

XSL•FO
RenderX

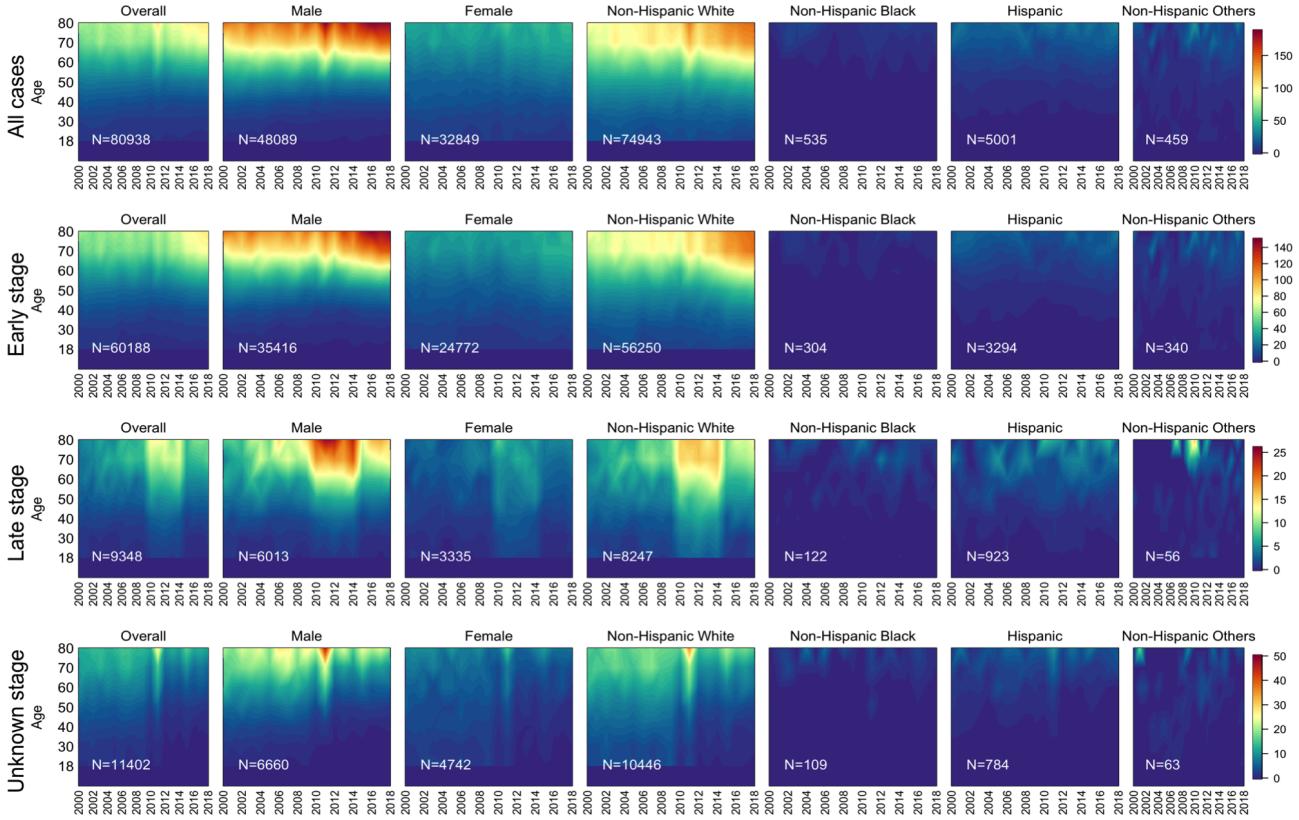
stable at approximately 10 throughout the study period (Figure 1and Multimedia Appendix 1).

Table . Summary of patient demographics by Surveillance, Epidemiology, and End Results (SEER) summary stage system groupings at diagnosis.

Variable	Early stage[a] (N=61,588), n (%)	Late stage[b] (N=9,352), n (%)	Unknown stage[c] (N=11,522), n (%)	All cases (N=82,462), n (%)
Age group (years)				
18 - 29	2,196 (3.6)	391 (4.2)	536 (4.7)	3,123 (3.8)
30 - 39	4,466 (7.3)	758 (8.1)	927 (8.0)	6,151 (7.5)
40 - 49	7,599 (12.3)	1,287 (13.8)	1,589 (13.8)	10,475 (12.7)
50 - 59	11,822 (19.2)	2,049 (21.9)	2,149 (18.7)	16,020 (19.4)
60 - 69	14,412 (23.4)	2,108 (22.5)	2,439 (21.2)	18,959 (23.0)
70 - 79	13,027 (21.2)	1,712 (18.3)	2,156 (18.7)	16,895 (20.5)
≥80	8,066 (13.1)	1,047 (11.2)	1,726 (15.0)	10,839 (13.1)
Sex				
Male	36,300 (58.9)	6,016 (64.3)	6,742 (58.5)	49,058 (59.5)
Female	25,288 (41.1)	3,335 (35.7)	4,780 (41.5)	33,403 (40.5)
Race and ethnicity				
Non-Hispanic White	56,250 (91.3)	8,247 (88.2)	10,446 (90.7)	74,943 (90.9)
Non-Hispanic Black	304 (0.5)	122 (1.3)	109 (0.9)	535 (0.6)
Hispanic	3,294 (5.3)	924 (9.9)	784 (6.8)	5,002 (6.1)
Non-Hispanic Others	340 (0.6)	56 (0.6)	63 (0.5)	459 (0.6)
Unknown	1,400 (2.3)	3 (0.0)	120 (1.0)	1,523 (1.8)

[a]Early stage: SEER stages 0 (in situ), 1 (localized), and 2 (regional by direct extension only).

[b]Late stage: SEER stages 3 to 5 (regional) and stage 7 (distant).



[c]Unknown stage: SEER stage 9: unknown, unstaged, unspecified.

IRs for males appear much higher than females among 50+ years, reaching over 140 per 100,000 in the 70+ age group and over 180 per 100,000 in the 80+ age group by 2018 (Figure 1). In contrast, among younger age groups (18-49), females showed slightly higher rates than males over time. In addition, melanoma incidence increased at a more rapid rate for males from 2009 to 2018, with an AAPC of 3.48% (95% CI 2.49-5.19) compared with 2.47% (95% CI 1.89-3.26) for females (Multimedia Appendix 1).

Stratifying by race and ethnicity, non-Hispanic White individuals displayed the highest rates across all age groups, with noticeable increases over the study period for those aged 50 years and older. The older non-Hispanic White patients (70+ years) showed rates over 130 per 100,000 by 2018. For the 18 - 29 age group, non-Hispanic White patients had a slight decrease in IRs from 16.5 per 100,000 in 2000 to 11.4 per 100,000 in 2018. Other racial and ethnic groups, such as non-Hispanic Black and Hispanic individuals, maintained much lower IRs mostly below 30 per 100,000 across all age groups and years (Figure 1).

XSL•FO
RenderX

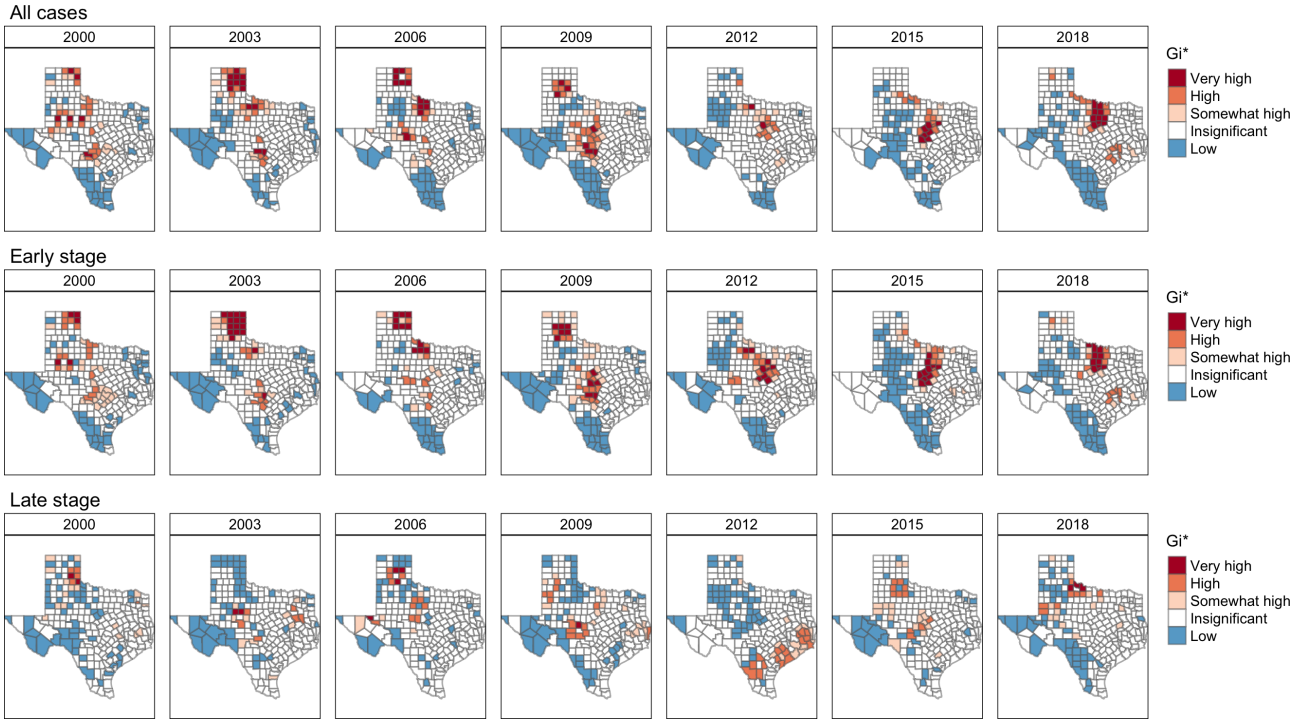
Figure 1. Temporal heat maps presenting melanoma incidence rates (per 100,000 population) by columns of overall population, sex, and racial and ethnicity groups. Each row panel shows a different stage at diagnosis: all cases, early stage, late stage, and unknown stage. Numbers in the lower left corner of each panel indicate the total number of melanoma cases in Texas from 2000 to 2018.

To facilitate comparison with national statistics, age-adjusted IRs (to the 2000 US standard population) are presented by stage at diagnosis, age, gender, and race and ethnicity in Multimedia Appendix 2.

The incidence of early-stage melanoma has increased more rapidly than late-stage melanoma incidence (Figure 1). Early-stage melanoma temporal trends mirrored those of overall cases, with the highest rates for non-Hispanic White males older than 70 years, reaching 114 cases per 100,000 by 2018. Other racial and ethnic groups displayed minimal variation over time, with rates remaining low throughout the study period (under 10 cases per 100,000 for non-Hispanic Black individuals and under 25 per 100,000 for Hispanic individuals). Late-stage melanoma IRs were lower than early-stage incidence across all demographics. The overall population showed rates below 15 cases per 100,000, with a slight increase over time in older males, peaking around 25 per 100,000 between 2011 - 2014 (refer to additional details in Discussion). Non-Hispanic White patients had the highest rates (maximum 16 per 100,000 in the 80+ age group), while non-Hispanic Black and Hispanic patients had consistently low late-stage IRs (mostly below 5 cases per 100,000). The IRs for unknown stage cases remained relatively stable over time across all demographic groups.

When investigating stage by race and ethnicity, early-stage diagnoses predominated across all races and ethnicities. However, Hispanic and non-Hispanic Black individuals had proportionately more late stage at diagnosis melanomas than non-Hispanic White patients (Multimedia Appendix 3). The AAPC for late-stage melanoma cases was similar for Hispanic (AAPC 2.38%, 95% CI 0.53-3.73) and non-Hispanic White patients (AAPC 2.66%, 95% CI –0.98 to 7.17) and higher for non-Hispanic Black patients (AAPC 5.79%, 95% CI 2.61-9.01; Multimedia Appendix 1).

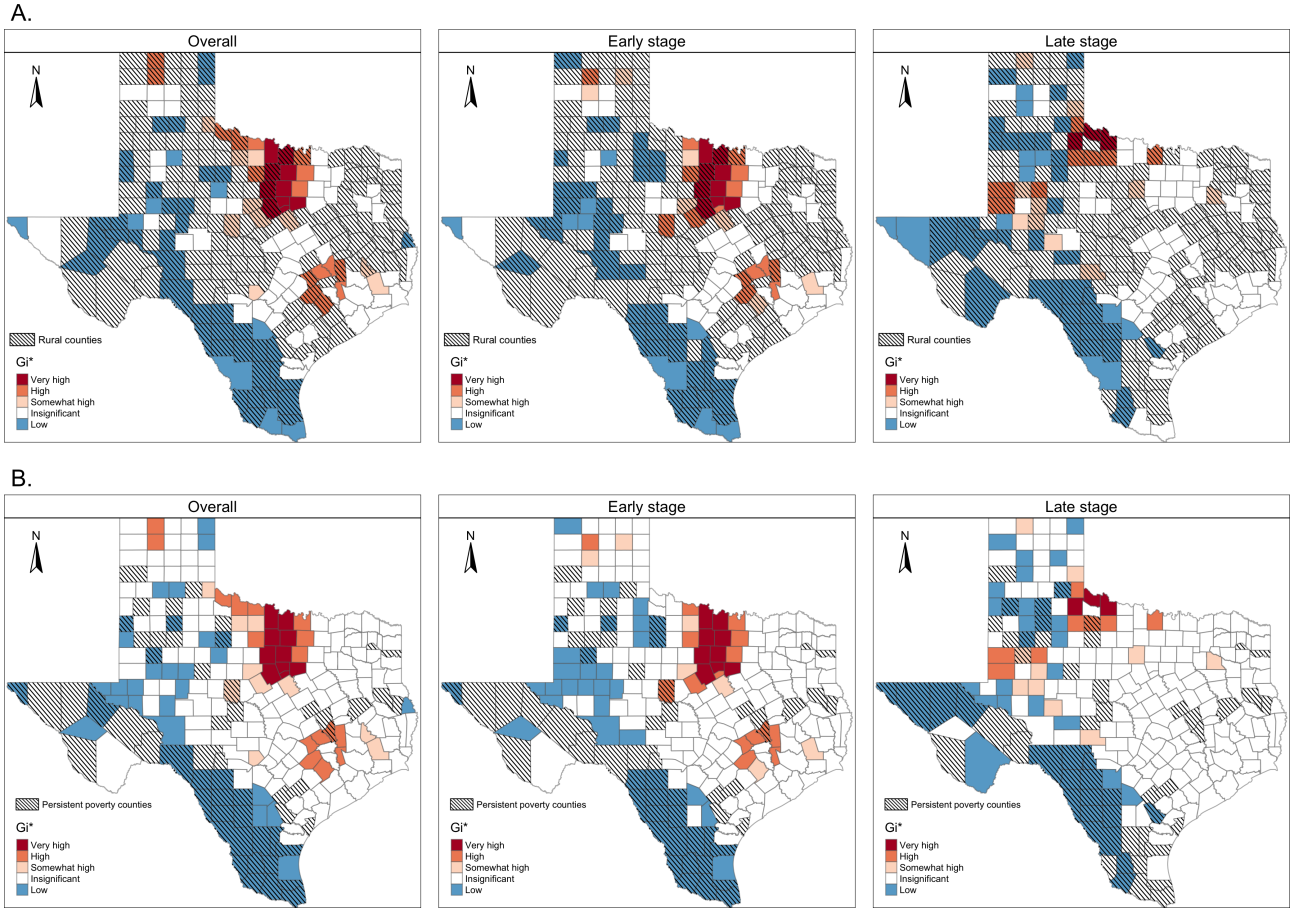
Spatial Cluster Analysis



Maps showing high- and low-melanoma incidence spatial clusters are presented in Figure 2. When considering all melanoma cases, spatial clusters with significantly higher-than-average melanoma incidence (median IR 42 per 100,000, IQR 23-62) were primarily in northwestern Texas from 2000 to 2006, with a shift to central Texas between 2007 and 2015, and then to counties surrounding Dallas by 2018. Spatial clusters with lower-than-average melanoma incidence were clustered near southern and western Texas (median IR 11, IQR 0-24). The spatial patterns for early-stage and overall melanoma cases were similar with median IRs of 35 per 100,000 (IQR 19-52) in high-incidence spatial clusters, and 6 per 100,000 (IQR 0-17) in low-incidence spatial clusters. However, the spatial clusters for higher-than-average late-stage cases showed distinct patterns with localization to northwestern Texas from 2000 to 2007, a shift toward southeast Texas between 2010 and 2014, and a return to central-northern Texas in 2015.

Overlaying the 2018 spatial clusters with rural counties (hatched lines), we observed that clusters of higher-than-average late-stage melanoma incidence significantly overlap with rural areas (P=.05; Figure 3A). Similarly, clusters of higher-than-average early-stage melanoma incidence appear to overlap with urban areas (P=.06; Figure 3A). In contrast, clusters of lower-than-average incidence for overall, early-stage, and

XSL•FO
RenderX



late-stage melanoma appear to overlap with persistent poverty counties (all *P* values were <.001; Figure 3B).

Figure 2. Spatial cluster analysis of melanoma incidence rates (cases per 100,000 population) by melanoma stage at diagnosis (all cases, early stage, and late stage) and selected years from 2000 to 2018 using Gi* statistics. Classifications were defined as follows: very high (Gi*>0 and *P*<.01), high (Gi*>0 and 0.01 ≤ *P*<.05), somewhat high (Gi*>0 and 0.05 ≤ *P*<.10), insignificant (*P*>.10), and low (Gi*<0 and *P*<.10). Red-shaded areas represent high-incidence clusters, depicting clusters of counties with significantly higher incidence rates compared with the statewide average incidence rate. Blue-shaded areas highlight clusters of counties with significantly lower incidence rates compared with the state average.

RenderX

Figure 3. Spatial clusters of melanoma incidence rates overlaid with (A) rural counties and (B) persistent poverty counties in 2018. Classifications were based on Gi* statistics as follows: very high (Gi*>0 and P<.01), high (Gi*>0and 0.01 ≤ P<.05), somewhat high (Gi*>0 and 0.05 ≤ P<.10), insignificant (P>.10), and low (Gi*<0 and P<.10).

Discussion

Principal Findings

Texas has the highest proportion of late-stage melanoma cases relative to the total number of reported melanoma cases in the contiguous United States and is the second most populated state. Identifying the regions and patient populations that disproportionately bear the burden of late-stage melanoma at diagnosis is crucial for developing targeted early detection efforts. Our spatial clustering analysis of Texas revealed that high-incidence clusters of early-stage melanoma were primarily localized in urban, well-resourced areas, whereas high-incidence clusters of late-stage melanoma were concentrated in rural areas . This disparity may be partly explained by the lower density of dermatologists in rural areas [11,23]. Patients with melanoma living in these areas may experience delayed diagnosis [24], need to travel longer distances to receive surgical management, and have decreased melanoma-specific survival [25]. These findings, while observational, highlight the importance of addressing structural disparities in health care access. Therefore, any early detection intervention must be tailored to be feasible in rural, lower-resourced settings.

Melanoma IRs exhibit substantial variation by age, with older patients experiencing significantly higher rates compared with younger patients. Because the age distribution of the population often shifts over time, age-adjusted rates are commonly used to compare trends across different time periods and geographic regions. These adjustments typically use a fixed reference year for the age distribution, which may lack the robustness to fully capture ongoing demographic change. As the population continue to age and shift in age structure, a static reference year may obscure important trends and fail to accurately reflect the current risk landscape. In this study, we used a novel visualization approach using temporal heat maps that directly incorporate age as a variable, providing a more adaptive and precise method for identifying shifts in melanoma incidence trends over time. This visualization highlighted pronounced incidence variations, particularly among late-stage male and non-Hispanic White patients from 2010 to 2014. We identified two TCR data sources which may explain this variation: Texas Health Care Information Collection (THCIC) and eMaRC Plus (Centers for Disease Control and Prevention [CDC]). THCIC, established by the Texas legislature, collects data on health care activities in hospitals and health maintenance organizations [26]. During a pilot from 2010 to 2013, THCIC identified melanoma cases not otherwise reported to TCR, leading to the inclusion of 559 cases in the TCR database, most of which were categorized as unknown stage at diagnosis. The second data source, eMaRC Plus, a software developed by the CDC to receive and process Health Level Seven files from pathology laboratories, was used from 2010 to 2018. eMaRC Plus identified 8,786 cases, with 93.1% being early-stage and 6.8% unknown stage. The peaks in early-stage and unknown-stage

XSL•FO
RenderX

incidence observed in 2011 and onward may be attributed to these two data sources. However, the increase in late-stage incidence from 2010 to 2014 could not be fully explained by these data sources, suggesting that temporary reporting inconsistencies may warrant further investigation to fully understand their impact on the identified temporal trends.

Despite these data source differences, descriptive trends also revealed that older non-Hispanic White men comprise the majority of late-stage melanoma cases at diagnosis. This specific demographic provides a clear target cohort for refining early melanoma detection efforts. Given that older men generally have lower rates of skin self-awareness [27], promoting early detection through their family members or PCPs may offer greater opportunity. Our analysis of race and ethnicity revealed that, while most melanoma cases were diagnosed at early stages across all groups, Hispanic and non-Hispanic Black patients experienced proportionately more late stage at diagnosis melanomas than non-Hispanic White counterparts. Although the absolute number of melanoma cases is small compared with other cancers, these findings reinforce the concept that melanoma can impact individuals of all races and ethnicities.

Strengths and Limitations

This study has several strengths and limitations. A key strength is the innovative visualization approach, which enabled a comprehensive analysis of temporal trends, stratified by age, sex, race and ethnicity, and stage at diagnosis. The use of TCR data allowed for the inclusion of patient residential information at the time of diagnosis, as well as additional data captures from pilot studies that would otherwise be unavailable. Furthermore, the geospatial analysis provided a comprehensive examination of patterns across all cases and by specific stages, offering valuable insights that could guide future interventions and educational efforts. The study also presents several limitations, particularly the large proportion of cases with an unknown stage at diagnosis. More precise data on these cases would enable better stage classification and improve the stage-specific analyses. In addition, the TCR data has limitations in capturing SDoH, which, if included, could provide a deeper understanding of the health disparities associated with melanoma outcomes.

Conclusions

Our study provides valuable guidance for future early melanoma detection efforts. Such efforts must be feasible in rural, lower-resourced areas of the state and focus on patients at highest risk of late-stage melanoma at diagnosis. Multimodal approaches, which combine foundational dermatology training for interested PCPs [14], telementoring to support PCP incorporation of skin cancer detection examinations into practice [28], and efficient store-and-forward eConsults [29] to reduce dermatology access gaps, offer promising pathways to improve early melanoma detection in low-resource settings.

Abstract

Background: Disparities in cancer burden between transgender and cisgender individuals remain an underexplored area of research.

Objective: This study aimed to examine the cumulative incidence and associated risk factors for cancer and precancerous conditions among transgender individuals compared with matched cisgender individuals.

Methods: We conducted a retrospective cohort study using patient-level electronic health record (EHR) data from the University of Florida Health Integrated Data Repository between 2012 and 2023. Transgender individuals were identified using a validated, computable phenotype algorithm that used structured data and clinical notes. They matched 1:10:10 by age and calendar year of index date with cisgender women and cisgender men. The index date was the first transgender-related record for transgender individuals and a matched diagnosis date for cisgender controls. Primary outcomes included new-onset cancers associated with human papillomavirus, human immunodeficiency virus, tobacco, alcohol, lung, breast, and colorectal sites. Secondary outcomes were precancerous conditions related to the same cancer types. We calculated cumulative incidence rates and conducted time-to-event analyses using the Fine-Gray method, treating all-cause death as a competing risk, to assess associations between gender identity and the presence of cancer or precancer, adjusting for demographic and clinical covariates. Interaction analyses evaluated if associations between cancer risk factors and precancer differed by gender identity.

Results: We identified 2745 transgender individuals (mean age at index date 25.1, SD 14.0 years) and matched them with 27,450 cisgender women and 27,450 cisgender men from the same health care system. The cumulative incidence of cancer did not differ significantly between transgender and cisgender cohorts (transgender n=28, 1.0% vs cisgender women, n=358, 1.3%; *P*=.13 and cisgender men, n=314, 1.1%; *P*=.64). However, transgender individuals exhibited significantly higher risks for precancerous conditions compared to cisgender women (subdistribution hazard ratios [sHRs] 1.1, 95% CI 1.0 - 1.3) and cisgender men (sHR 1.3; 95% CI 1.2 - 1.5). Specifically, transgender individuals were more likely to develop colorectal precancer (sHR 1.2; 95% CI 1.1 - 1.4) compared to cisgender women, as well as human papillomavirus–related precancer (sHR 1.8; 95% CI 1.4 - 2.3) and colorectal precancer (sHR 1.4; 95% CI 1.2 - 1.6) compared to cisgender men. Subgroup analyses showed similar patterns in both female-to-male and male-to-female individuals compared with their matched cisgender counterparts. Interaction analyses revealed stronger protective effects of private insurance or Medicare against precancers in transgender individuals than in cisgender peers, while being non-Hispanic Black or having substantial comorbidities were stronger risk factors among transgender individuals.

Conclusions: Transgender individuals showed a similar cancer incidence yet significantly higher precancer incidence compared with cisgender individuals, suggesting underdiagnosis or delayed detection. These findings highlight the need for tailored preventive care strategies, including targeted screenings and risk reduction interventions, to address cancer disparities in the transgender population.

KEYWORDS

transgender and gender nonconforming; cancer cumulative incidence; real-world data; electronic health records; health disparities

Introduction

Transgender persons are individuals whose gender identity or expression does not align with society's expectations based on the sex assigned at birth [1]. Global estimates suggest that 0.3% - 0.5% of adults self-identify as transgender [2], and a recent survey reported that as many as 1.6% of US adults identify as transgender [3]. Transgender individuals consistently experience a disproportionately high prevalence of adverse health outcomes, including human immunodeficiency virus (HIV), sexually transmitted infections, mental health distress, and substance use disorders [4]. Despite the growing literature on the unique health challenges faced by transgender individuals, our understanding of the cancer burden (eg, cumulative incidence of cancer) and risk in this population remains limited [5], primarily due to the lack of relevant data [6]. Reluctance to self-identify and participate in health surveys, along with the limited inclusion of gender identity measures in national surveillance systems, poses challenges in obtaining population-based representative samples and conducting longitudinal studies to examine cancer burden in this population. Current insights into cancer risk in transgender populations rely primarily on anecdotal evidence and small-scale studies [7,8], leading to inconsistent findings.

Evidence suggests that transgender individuals may face an elevated risk of certain cancers compared to the general population, including breast cancer [7], cancers linked to human papillomavirus (HPV) [9] and HIV [6], and those associated with tobacco and alcohol use [10,11]. For example, transgender women (male-to-female, MTF) undergoing prolonged hormone therapy are exposed to high estrogen levels, which may increase breast cancer risk [12-14]. Transgender populations are twice as likely to smoke as cisgender peers [15] and have higher rates of hazardous alcohol use [16], both known cancer risk factors. In addition, a higher prevalence of sexual health risk behaviors [17-20] increases the risk of acquiring cancer-related infections, including HPV and HIV. Studies have reported a higher cervicovaginal HPV prevalence among transgender individuals assigned female at birth compared to cisgender women (30.5% vs 20.0%) [17] and a global HIV prevalence of 19.9% for trans women and 2.6% for trans men, which are 66 and 6.8 times higher than the general population, respectively [18]. These infections further elevate the risk of virus-associated cancers.

However, due to disparities in health care access and screening, cancer is often diagnosed at later stages or underreported in transgender populations. Studies have shown that transgender men are less likely to be up to date on Pap tests compared to cisgender women, and transgender individuals overall have lower rates of cervical cancer screening [19,20]. These disparities are attributed to fear of discrimination in health care settings, lack of provider knowledge about transgender health needs, and the absence of inclusive screening guidelines [21-24]. As a result, transgender individuals frequently experience delayed diagnosis or remain undiagnosed. These challenges contribute to late-stage diagnoses, poorer health outcomes, and an underestimation of the true cancer burden in this population.

Given these challenges, investigating precancerous lesions offers a timely and meaningful opportunity to address cancer disparities. Precancerous lesions, or precancers, refer to abnormal cellular and tissue changes that have the potential to develop into cancer if left untreated [25]. The progression rates of these lesions vary depending on their type and location. For instance, cervical intraepithelial neoplasia, a common HPV-related precancerous condition, is a critical early indicator of cervical cancer risk [26]. Previous studies have shown that cervical intraepithelial neoplasia 3 is associated with a twofold increased risk of cervical cancer compared to the general female population [27]. Investigating the burden of precancer in transgender individuals is crucial for several reasons. First, many transgender individuals are relatively young, and while their cumulative cancer incidence may be low, a significant proportion may already harbor precancerous lesions, signaling increased future cancer risk. Second, studying precancer can reveal disparities missed by cancer diagnoses alone, especially in underserved populations. Even when detection is limited, observed lesions highlight underlying vulnerability and offer earlier opportunities for intervention. Thus, examining the cumulative incidence and risk factors for precancer among transgender individuals can uncover hidden disparities, inform targeted prevention strategies, and help reduce future cancer burden in this population.

Electronic health record (EHR) data have emerged as a vital tool for addressing knowledge gaps in cancer research within the transgender community. The widespread adoption of EHRs enables large-scale, longitudinal studies and comparisons with cisgender controls. EHRs offer both structured data (eg, diagnoses and procedures) and unstructured clinical notes, which can help identify transgender individuals and capture health profiles more comprehensively. Unlike traditional cancer registries, EHRs include detailed risk factor data, allowing for a more nuanced understanding of disparities. In addition, their broad population coverage allows for robust comparisons between transgender and cisgender individuals. In this study, we leveraged longitudinal EHR data to examine the cumulative incidence and risk factors for cancer and precancer by comparing transgender and cisgender individuals. We hypothesized that transgender individuals would have a heightened risk for cancer and precancer compared to cisgender individuals.

Methods

Data Source and Study Population

We conducted a retrospective cohort study using patient-level EHR data from 2012 - 2023, obtained from the University of Florida (UF) Health Integrated Data Repository (IDR). This clinical data warehouse aggregates data from UF's various clinical and administrative information systems, including the Epic EHR system. The IDR contains more than 1 billion observational facts for over 2 million patients. This study

followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) and RECORD (Reporting of Studies Conducted using Observational Routinely-Collected Data) guidelines (STROBE-RECORD; Checklist 1).

The study population included a cohort of transgender individuals and a matched cohort of cisgender individuals identified in the UF Health EHRs. Transgender individuals and their sex assigned at birth were identified using a previously developed and validated computable phenotype algorithm [28]. The algorithm classified individuals as transgender if they met at least one of the following criteria: (1) recorded gender identity as transgender, or (2) had at least one transgender diagnosis code from the diagnosis table, along with at least one transgender keyword (eg, "transgender," "MTF," and "FTM") from clinical notes. The complete list of keywords and codes is provided in Multimedia Appendix 1. Manual chart review of 300 records demonstrated high algorithm performance: precision=0.96, recall=0.95, F_1-score=0.96. In an independent test set, the algorithm achieved perfect precision and recall (F_1-score=1.0). We further classified transgender individuals into female-to-male (FTM), MTF, or unknown categories based on sex assigned at birth.

The index date for transgender individuals was defined as the date of the first recorded evidence of transgender status. Each transgender individual was matched to 10 cisgender men and 10 cisgender women, randomly selected from the IDR, based on age and calendar year of the index date. This dual matching approach enables comparisons with both cisgender groups to isolate disparities related to gender identity versus sex assigned at birth. Similar matching approaches have been used in prior transgender health research [29,30]. The index date for cisgender individuals was a randomly selected date of diagnosis. We excluded individuals who (1) had an age at first encounter of less than 3 years, (2) had no encounter after the index date, and (3) had a gap of longer than 2 years between any two encounters.

Study Outcomes

Primary outcomes were new-onset cancer cases between 2012 and 2023, assessed from the earliest available record until the date of cancer occurrence, loss to follow-up, or study termination. Cancer types included HPV-related, HIV-related, tobacco-related, and alcohol-related cancers [31-34], as well as lung, breast, and colorectal cancers, given the existence of clear screening guidelines for these types. Specifically, HPV-related cancers included oropharyngeal, cervical, anal, vaginal, vulvar, and penile cancers [31]. HIV-related cancers included Kaposi sarcoma, non-Hodgkin lymphoma, and cervical cancer [32]. Tobacco-related cancers encompassed lung, head and neck, liver, esophagus, bladder, kidney, stomach, pancreas, colorectal, and cervical cancers [34], while alcohol-related cancers comprised head and neck, esophageal, liver, breast, and colorectal cancers [33]. We also calculated cases of "any cancer," covering all 18 individual cancer sites mentioned above. Patients with these cancers were identified using *International Classification of Diseases (ICD)−9/10 CM* diagnosis codes from the UF Health EHRs.

Secondary outcomes were new-onset precancerous conditions for the same 18 cancer types, defined using criteria from the Canadian Cancer Society [25] and prior literature [35-42]. Similar to the cancer outcomes, we grouped these precancerous conditions into HPV-related precancer, tobacco-related precancer, alcohol-related precancer, prelung cancer, prebreast cancer, and precolorectal cancer categories. We curated ICD-9/10 codes from established sources and clinical review (Multimedia Appendix 2) to harmonize definitions and minimize misclassification, especially for less frequently documented conditions.

Covariates

Covariates included age at the index date, race-ethnicity, insurance payer, smoking status, family history of cancer, health care usage (ie, outpatient and inpatient visits), and Charlson Comorbidity Index (CCI). Race-ethnicity was categorized as non-Hispanic White (NHW), non-Hispanic Black (NHB), non-Hispanic Other, Hispanic, or Unknown. Insurance payers were categorized as Medicare, private insurance, self-pay, or Medicaid or other insurance (eg, charity and worker's compensation). Smoking status was determined from the most recent EHR entry before the index date and categorized as current, former, never smoker, or unknown. In addition, baseline measures of health care usage, family cancer history (ICD-9: V16 and ICD-10: Z80), and CCI were extracted from the EHR data within 12 months before the index date. Health care usage was measured based on the number of outpatient and inpatient visits. Family history of cancer and conditions in the CCI (eg, diabetes) were identified using relevant ICD-9/10-CM codes and confirmed with at least one inpatient or outpatient diagnosis. We calculated the CCI using the modified algorithm by Klabunde et al [43]. CCI was categorized into 3 groups: no comorbidity (CCI=0), some comorbidities (CCI=1), or substantial burden of comorbidities (CCI ≥2). For variables with missing values (eg, smoking status and insurance payer), we created an "unknown" category. We included it in both univariate comparisons and regression models to retain the full analytic sample. No other variables had missing values.

Statistical Analysis

We summarized baseline characteristics by gender identity and transgender subgroups. We calculated and compared cumulative incidence rates of cancer and precancerous conditions between transgender individuals and their matched cisgender male and female counterparts. Given the cohort's relatively young age and low baseline disease probability, cumulative incidence was an appropriate measure, reflecting new cases during follow-up as a proportion of the population at risk. Means (SDs) or medians (IQRs) were used for continuous variables. Categorical variables were summarized with counts and percentages. Normality was assessed using the Kolmogorov-Smirnov test. Between-group comparisons used *t* tests, Wilcoxon signed-rank tests, and chi-square or Fisher exact tests, as appropriate. To estimate the hazard of each cancer and precancer outcome, we used Fine-Gray competing risk models, treating all-cause death as a competing risk. Both univariable and multivariable models were constructed, adjusting for all covariates. Adjusted subdistribution hazard ratios (sHRs) with 95% CIs were

XSL•FO
RenderX

reported. Proportional hazard assumptions were verified using supremum tests. Interaction terms between gender identity and covariates were tested to evaluate differential effects. Subgroup analyses compared FTM individuals to cisgender women and MTF individuals to cisgender men using the originally matched cohort, without additional rematching to preserve statistical power and comparability. All tests were 2-sided with α=.05. Data processing was conducted in Python (version 3.9.4; Python Software Foundation), and statistical analyses were performed in SAS (version 9.4; SAS Institute Inc).

Ethical Considerations

This study was approved by the UF Institutional Review Board (IRB202100946). It used deidentified EHR data, exempting it from informed consent under institutional policy [44]. Sensitive gender identity data were stored and analyzed on secure servers with access limited to authorized study personnel. No identifiable personal information was included in the analytic dataset to ensure confidentiality and compliance with ethical standards. No participant compensation was provided.

Results

We identified 2745 transgender individuals, matched to 27,450 cisgender women and 27,450 cisgender men from the UF Health EHRs in a 1:10:10 matching ratio based on age and calendar year of the index date. Table 1 presents the distributions of patient characteristics stratified by gender identity. The mean age at index was 25.1 (SD 14.0) years across all three cohorts (P≥.99). Despite age matching, significant differences were observed in all other characteristics. Compared to cisgender individuals, transgender individuals were more likely to be NHW (transgender, n=1803, 65.7% vs women, n=14675, 53.5% and men, n=15,307, 55.8%; P<.001) and to have a substantial burden of comorbidities (transgender, n=191, 7.0% vs women, n=1148, 4.2% and men, n=1281, 4.7%, respectively; P<.001). In contrast, the transgender individuals were less likely to have private insurance (transgender, n=1147, 41.8% vs women, n=13,948, 50.8% and men, n=13,837, 50.4%, respectively; P<.001), to be never smokers (transgender, n=1569, 57.2% vs women, n=19656, 71.6% and men, n=17,330, 63.1%, respectively; P<.001), and to have outpatient visits [(mean 3.2, SD 6.1 vs women, mean 4.3, SD 6.8 and men, mean 3.5, SD 6.9) visits in the past year, respectively; P<.001]. Furthermore, transgender individuals were less likely to have a family cancer history than cisgender women (n=19, 0.7% vs n=416, 1.5%; P<.001) and had fewer inpatient visits in the past year than cisgender men (mean 0.15, SD 0.6 vs mean 0.2, SD 0.6; P<.001). Among the 2745 transgender individuals, 1324 (48.2%) were FTM, 1168 (42.6%) were MTF, and the remaining 253 (9.2%) had unknown natal sex (Table 2). Compared with MTF individuals, FTM individuals were younger [mean 22.4 (SD 11) vs mean 27.7 (SD 15.5) years; P<.001], more likely to be NHW (n=936, 70.7% vs n=752, 64.4%; P<.001), had higher rates of private insurance (n=600, 45.3% vs n=489, 41.9%; P<.001), were more likely to be nonsmokers (n=814, 61.5% vs n=673, 57.6%; P<.001), and had more outpatient visits (mean 3.4, SD 6.6 vs 3.3, SD 6.5; P=.004).

[a]FTM: female-to-male.

[b]MTF: male-to-female.

[c]NHW: non-Hispanic White.

[d]NHB: non-Hispanic Black.

[e]Other insurance: charity and worker's compensation.

[f]CCI: Charlson Comorbidity Index (0: no comorbidity; 1: some comorbidities; ≥2: substantial burden of comorbidities).

Median follow-up time for cancer was 1176 days (IQR 344 - 2579) in the transgender group, 1227 days (IQR 379 - 2669) for cisgender women, and 999 days (IQR 232 - 2406) for cisgender men. For precancer, the median follow-up was 1031 days (IQR 307 - 2289) for transgender individuals, 1090 days (IQR 321 - 2425) for cisgender women, and 931 days (IQR 199 - 2230) for cisgender men. Table 3 shows that the cumulative incidence of any cancer was similar between transgender individuals (n=28, 1.0%) and cisgender women (n=358, 1.3%; *P*=.13) and men (n=314, 1.1%; *P*=.64). The only significant difference was a higher rate of breast cancer in transgender individuals compared with cisgender men (n=7, 0.3% vs n=1, 0.004%; *P*<.001). For precancer cases, the cumulative incidence of any precancer was higher in transgender

XSL•FO
RenderX

individuals (n=306, 11.1%) than in cisgender men (n=2758, 10.0%; *P*=.07) but similar to cisgender women (n=3086, 11.2%; *P*=.88), although these comparisons were not statistically significant. Compared with cisgender men, transgender individuals had a significantly higher cumulative incidence of HPV-related precancers (n=76, 2.8% vs n=413, 1.5%; *P*<.001), prebreast cancer (n=2, 0.07% vs n=1, 0.01%; *P*=.02), and precolorectal cancer (n=184, 6.7% vs n=1472, 5.4%; *P*=.004). However, precancer incidence did not differ significantly between transgender individuals and cisgender women.

Table 4 shows subgroup results. Compared to cisgender women, FTM individuals had significantly lower cumulative incidence of any cancer (n=9, 0.7% vs n=358, 1.3%; *P*=.05) and any precancer (n=123, 9.3% vs n=3086, 11.2%; *P*=.03), including lower HPV-related (n=21, 1.6% vs n=877, 3.2%; *P*=.001) and alcohol-related precancers (1.1% vs 2.3%; *P*=.003). These lower rates may reflect reduced smoking and alcohol consumption in FTM individuals, as well as a reduced risk of HPV-related gynecologic cancers due to lower gynecologic health care engagement or differences in screening practices. In contrast, MTF individuals largely followed the overall transgender versus cisgender men trends, but with additional differences. They had a higher cumulative incidence of breast cancer (n=2, 0.2% vs n=1, 0.004%; *P*=.005), any precancer (n=171, 14.6% vs n=2758, 10.0%; *P*<.001), HPV-related precancers (n=53, 4.5% vs n=413, 1.5%; *P*<.001), and precolorectal cancer (n=99, 8.5% vs n=1472, 5.4%; *P*=.004), consistent with the overall transgender cohort. However, unlike the broader transgender comparison, MTF individuals also had higher cumulative incidence of tobacco-related (n=144, 12.3% vs n=2462, 9.0%; *P*<.001) and alcohol-related precancer (n=38, 3.3% vs n=599, 2.2%; *P*=.02), while prebreast cancer rates did not differ from cisgender men (n=0, 0.0% vs n=1, 0.01%; *P*≥.99).

Table . Cumulative incidence of cancer and precancer cases by gender identity (N=57,645).

[a]FTM: female-to-male.

[b]MTF: male-to-female.

[c]Any of the 18 cancer types: Kaposi sarcoma, non-Hodgkin lymphoma, cervical cancer, oropharyngeal, anal, vaginal, vulvar, penile, lung, head and neck, liver, esophagus, bladder, kidney, stomach, pancreas, colorectal, and breast cancer.

[d]HPV-related cancers include oropharyngeal, cervical, anal, vaginal, vulvar, and penile cancers.

[e]HIV-cancer includes Kaposi sarcoma, non-Hodgkin lymphoma, and cervical cancer. Tobacco-related cancers include lung, head and neck, liver, esophagus, bladder, kidney, stomach, pancreas, colorectal, and cervical cancers.

[f]Alcohol-related cancers include head and neck, esophageal, liver, breast, and colorectal cancers.

Figure 1 summarizes the main results from the Fine-Gray regression examining associations between gender identity and cancer or precancer outcomes. For cancer cases, the risk of developing any cancer or individual cancer types was statistically the same across the transgender and cisgender cohorts; none of the adjusted sHRs for gender identity were statistically significant after adjusting for covariates. For precancer cases, transgender individuals were significantly more likely to develop any precancer than cisgender women (adjusted sHR 1.1, 95% CI 1.0 - 1.3) and men (adjusted sHR 1.3, 95% CI 1.2 - 1.5). Compared with cisgender women, transgender individuals were more likely to develop precolorectal cancer (adjusted sHR 1.2, 95% CI 1.1 - 1.4). Compared with cisgender men, transgender individuals were more likely to develop HPV-related precancers (adjusted sHR 1.8, 95% CI 1.4 - 2.3) and precolorectal cancer (adjusted sHR 1.4, 95% CI 1.2 - 1.6) after adjusting for covariates.

The findings from the multivariable regression using the Fine-Gray method for subgroups are summarized in Figure 2. FTM individuals were significantly more likely to develop any precancer than cisgender women (adjusted sHR 1.1, 95% CI 1.0 - 1.3), and MTF individuals were significantly more likely to develop any precancer than cisgender men (adjusted sHR 1.5, 95% CI 1.2 - 1.8). Compared with cisgender women, FTM individuals were more likely to develop precolorectal cancer (adjusted sHR 1.2, 95% CI 1.0 - 1.4). Compared with cisgender men, MTF individuals were more likely to develop HPV-related precancers (adjusted sHR 2.5, 95% CI 1.9 - 3.4) and precolorectal cancer (adjusted sHR 1.6, 95% CI 1.3 - 1.9) after adjusting for covariates.

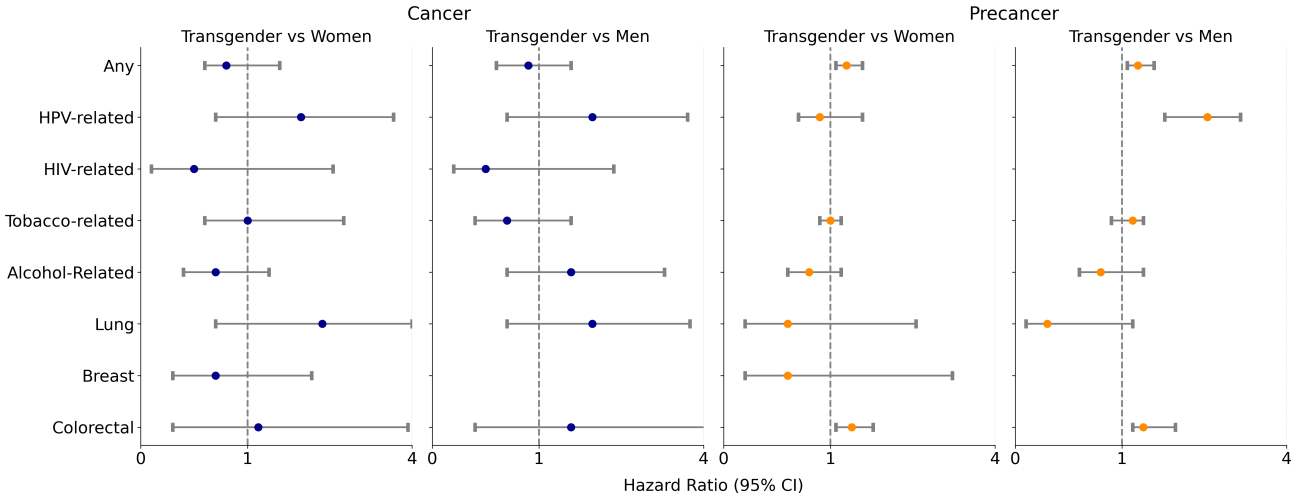
We assessed whether associations between cancer risk factors and precancer risk varied by gender identity using interaction analysis (Figure 3). Each x-axis position represents a gender group (transgender, cisgender women, and cisgender men), and each line represents one category of a risk factor (eg, insurance type, race, and smoking), labeled at the right. Markers (dots, squares, and triangles) indicate significant associations ($P<.05$), sHRs >1 indicate increased risk, and sHRs <1 indicate a protective effect. Interaction effects are identified by changes in sHRs across gender groups. For insurance coverage, having

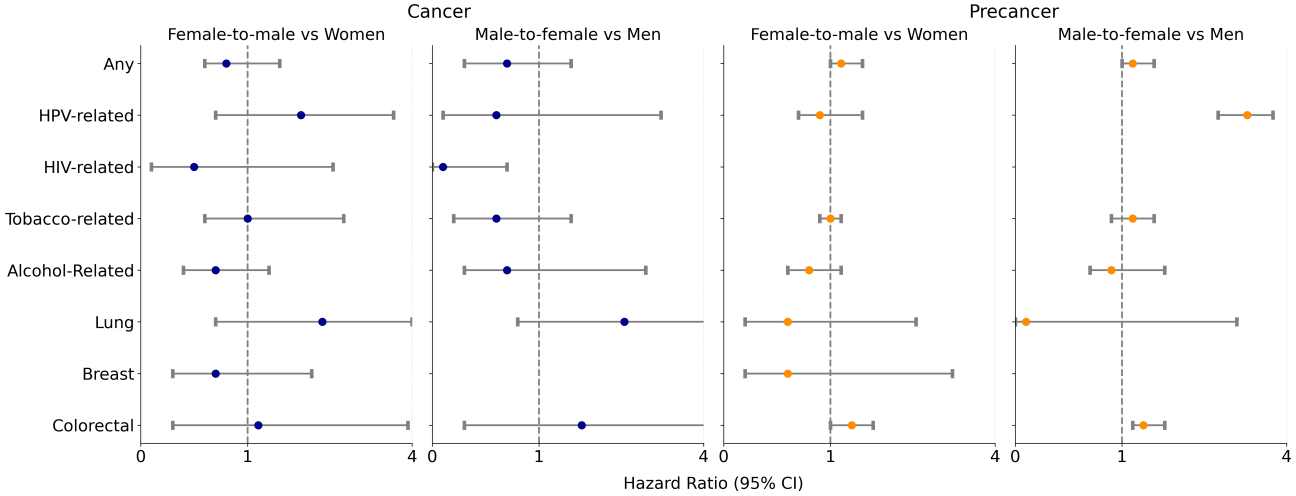
XSL•FO
RenderX

private insurance or Medicare was a protective factor against precancers, with a greater protective effect in transgender individuals than in cisgender individuals. Being NHB, compared with NHW, was a significant risk factor for any precancer in transgender individuals. For all precancer types analyzed, being NHB was a greater risk factor for transgender individuals than for cisgender individuals. Hispanic ethnicity was a significant risk factor for precancers only in cisgender individuals, with the risk being higher in men than in women. Having a substantial burden of comorbidities (CCI ≥2 vs CCI=0) was a greater risk factor for transgender individuals for any precancer and tobacco-related precancer. Regarding smoking status, being a former smoker, compared with a never smoker, was a significant risk factor for HPV-related precancers in cisgender individuals, with the risk being higher in women than in men. The effects of outpatient and inpatient visits on precancer risk were smaller in transgender individuals than in cisgender individuals.

X-axis position represents a gender group (transgender, cisgender women, and cisgender men). The y-axis represents sHRs values. Each line represents one category of a risk factor. The dots, squares, and triangles represent statistically significant sHRs for transgender, cisgender women, and cisgender men, respectively. The reference groups are Medicaid for insurance coverage, NHW for race-ethnicity, 0 for CCI, and never smoker for smoking status.

Figure 1. Adjusted hazard ratios estimating the association of gender identity with cancer and precancer cases. HIV: human immunodeficiency virus; HPV: human papillomavirus.





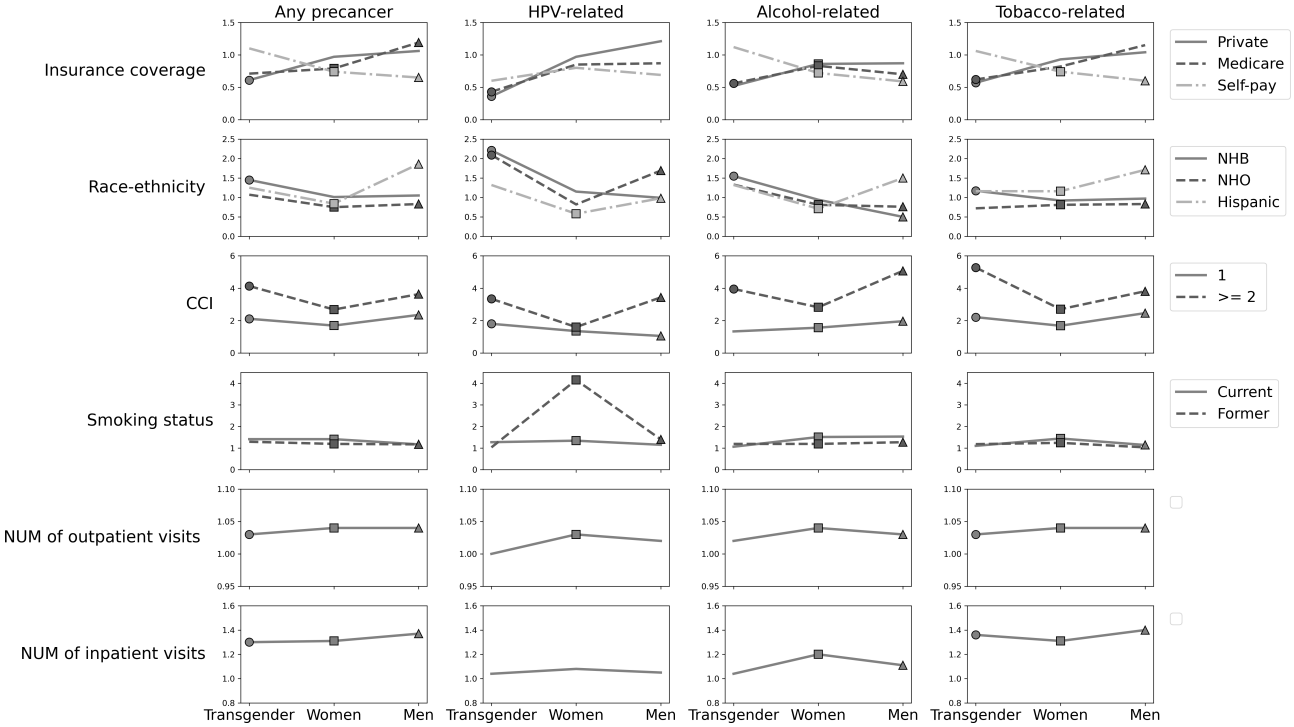


Figure 2. Adjusted hazard ratios estimating the association of subtype gender identity with cancer and precancer cases. HIV: human immunodeficiency virus; HPV: human papillomavirus.

Figure 3. Interaction plots of gender identity with cancer risk factors for precancer diseases. CCI: Charlson Comorbidity Index (0: no comorbidity, 1: some comorbidities, and ≥2: substantial burden of comorbidities); HPV: human papillomavirus; NHB: non-Hispanic Black; NHO: non-Hispanic Other; NUM: number.

Discussion

Principal Findings

In this study, we used EHR data from a large health care system to examine the risk of cancer and precancer and explore the impact of cancer risk factors across different gender identities. Our findings indicate that while the hazard of developing any cancer was similar between transgender and cisgender individuals, transgender individuals were more likely to develop precancer conditions than their cisgender counterparts. Specifically, transgender individuals showed elevated risks for colorectal precancers compared with cisgender women, and higher risks for HPV-related and colorectal precancers compared with cisgender men in the time-to-event analysis. These associations remained significant in MTF individuals compared with cisgender men and in FTM individuals compared with cisgender women after adjustment. Furthermore, our analysis identified private insurance or Medicare as protective factors against precancers in transgender individuals, while factors such as being NHB or having a substantial burden of comorbidities emerged as significant risk factors.

Interpretation and Comparison With Prior Work

Our study found no significant difference in overall cancer risk between transgender and cisgender individuals, but a significantly higher risk of precancerous lesions in transgender populations. While some previous studies suggest elevated cancer risks in transgender individuals, particularly hormone-sensitive cancers or those linked to infections such as HPV or HIV, our findings diverge from this [11]. Several factors may explain this discrepancy. First, our transgender cohort was relatively young (mean age=25.1, SD=14.0 years), whereas cancer risk increases substantially after age 50 [45]. Second, the small number of cancer cases limited statistical power. Third, disparities in health care access likely contributed to underdiagnosis. We found transgender individuals had fewer outpatient and inpatient visits compared with cisgender individuals at baseline, possibly reducing early detection opportunities. This aligns with previous research documenting lower health care usage and cancer screening rates among transgender individuals, potentially resulting in delayed diagnoses or underreported cases [46,47].

The elevated precancer risks observed in transgender individuals and subgroups align with recent findings. A JAMA Oncology review similarly reported higher HPV-related precancer rates among transgender individuals despite comparable cancer incidence, suggesting underlying vulnerabilities not fully captured by cancer diagnoses alone [10]. This suggests that while age may offer temporary protection against overt cancer, early-stage carcinogenic processes are already underway in this population. Biological factors such as prolonged hormone therapy, coupled with higher rates of smoking, alcohol use, and HIV, may accelerate precancerous changes at younger ages. Specifically, higher HPV-related precancer in MTF individuals likely reflects limited HPV screening and vaccination and greater HPV exposure [10]. Elevated colorectal precancer in both transgender subgroups could result from lower colorectal cancer screening uptake and health care engagement compared with cisgender populations [10]. These disparities underscore the need for targeted preventive care and screening interventions to mitigate cancer risk in transgender communities. Subgroup analyses comparing FTM to cisgender women and MTF to cisgender men revealed patterns consistent with the overall findings. While these associations remained significant after adjustment, the study was not powered to explore mechanistic differences. Detailed data on hormone therapy or other

XSL•FO
RenderX

gender-affirming interventions were not available, limiting our ability to evaluate their potential influence on these observed disparities.

Our analysis also revealed several risk factors associated with precancer risk among transgender individuals, revealing subtle differences in disparities. For instance, transgender individuals with private insurance or Medicare exhibited lower precancer risks compared with those with Medicaid. Transgender individuals with Medicaid insurance may face increased risks due to limited access to specialized care or preventative services. For example, prior research indicates that Medicaid enrollees had lower rates of breast, cervical, and colorectal cancer screening than those with commercial insurance [48]. In addition, NHB transgender individuals demonstrated elevated precancer risks compared with their NHW counterparts, possibly due to systemic inequalities in health care access and usage, as well as higher rates of underlying health conditions in NHB individuals. According to the National Transgender Discrimination Survey, Black transgender adults in the United States have higher rates of unemployment, poverty, sexual assault, negative experiences with health care providers, and HIV than cisgender Black people [49]. Furthermore, the presence of substantial comorbidities emerged as a significant predictor of precancer risk among transgender individuals, reflecting the complex interplay between health status and cancer susceptibility. For example, conditions such as HIV, which are often prevalent in transgender populations, can weaken immune function and contribute to precancerous lesions. To tackle these differences, specific actions are needed, including improving the availability of specialized care and preventative services in Medicaid coverage for transgender individuals, implementing culturally competent health care practices within NHB communities, and addressing underlying health issues to reduce precancer risk.

Strengths and Limitations

Our study has several strengths, including the use of comprehensive EHR data, which enabled a large-scale examination of cancer and precancer conditions among transgender individuals. The inclusion of matched cisgender cohorts enhances the validity of comparative analysis. However, our study also has limitations. First, the young age of our cohort limits generalizability to older transgender individuals, likely underestimating true cancer risks. Second, sample sizes for specific cancers were small, which limited the statistical power for subgroup analyses. Third, although health care usage measures were adjusted for in the analyses, residual confounding due to disparities in health care access and screening might persist. Fourth, our study may be influenced by residual confounding factors not fully captured in the EHR data, including socioeconomic status (eg, income and education), lifestyle behaviors (eg, smoking pack-years, alcohol use, and physical activity), sexual practices, environmental exposures, and hormone therapy use. Many of these factors are known to influence both cancer and precancer risk through complex, interrelated mechanisms. For example, limited financial resources and poor access to care may delay preventive screenings, while chronic stress or poor nutrition may increase biological vulnerability. Risky behaviors such as heavy alcohol use or tobacco smoking may also exert direct carcinogenic effects. Although EHRs may capture broad categories for some of these factors, they often lack granularity in terms of intensity, frequency, or timing, which limits our ability to adjust for their full impact in the analysis.

Future Directions

Future research should include older and more diverse transgender populations and conduct age-stratified analyses to better assess lifetime cancer risk. Studies integrating EHRs with detailed behavioral, lifestyle, and hormone-related data are needed to improve risk estimation. Advanced analytic methods, such as causal inference or instrumental variable approaches, may also help address unmeasured confounding.

Conclusion

This study offers important insights into cancer and precancer burden among transgender individuals and underscores the need for targeted interventions to reduce cancer disparities in this underserved population.

Abstract

Background: Effective prevention and treatment are urgently needed, since gastric cancer (GC) poses a grave threat to the health and well-being of patients. The 5 East Asian countries (China, Japan, North Korea, South Korea, and Mongolia) represent one of the most significant regions globally in terms of GC burden.

Objective: The goal of this study is to examine the patterns and trends of GC across 5 East Asian countries between 1990 and 2021.

Methods: We retrieved data from the Global Burden of Disease Study (GBD) 2021 regarding the prevalence, incidence, mortality, years lived with disability (YLDs), years of life lost (YLLs), and disability-adjusted life years (DALYs) associated with GC in 5 East Asian countries from 1990 to 2021. We further assessed the burden of GC according to age and sex. We used decomposition analysis to examine the changes in the number of new cases, patients, and deaths related to GC. We also used Joinpoint (Joinpoint Regression Program, Version 5.1.0) and age-period-cohort analysis methods to interpret the epidemiological characteristics of GC. Autoregressive integrated moving average model (ARIMA) and Bayesian age-period-cohort (BAPC) prediction models were used to forecast the GC burden by 2036.

Results: Among the 5 East Asian countries, China recorded the highest incidence, prevalence, death, YLLs, YLDs, and DALYs in both 1990 and 2021. From 1990 to 2021, the age-standardized rates for prevalence, mortality, incidence, YLDs, YLLs, and DALYs across the 5 East Asian countries showed an overall decline, though they remained higher than the global average. In all 5 East Asian countries, individuals aged 65 years and older consistently exhibited the highest rates for prevalence, incidence, mortality, YLDs, YLLs, and DALYs. The prevalence rate in South Korea, the incidence rate in North Korea and Mongolia, and the mortality rate in China are influenced by aging, surpassing the global aging average.

Conclusions: The disease burden of GC in the 5 East Asian countries has consistently ranked high over the past 3 decades, particularly among the older individuals. The burden of GC in the 5 East Asian countries is expected to present a major public health challenge, primarily driven by the large population size and the aging demographic.

Introduction

In 2022, gastric cancer (GC) accounted for 4.9% of all cancer cases, making it the fifth most commonly diagnosed cancer globally [1]. It is the fifth leading cause of cancer-related deaths, accounting for 6.8% of all cancer fatalities [1]. The incidence rate of GC remains high [2], particularly in Asian countries such as China [3,4]. It presents a significant challenge for both prevention and treatment, posing a serious threat to the life and health of affected individuals [5].

The 5 East Asian countries—China, Japan, North Korea, South Korea, and Mongolia—together account for about 22% of the global population and approximately 24% of the world's gross domestic product (GDP) [6]. The 5 East Asian countries share similar geographical locations, cultural influences, and dietary and lifestyle habits. Their traditional medicines, including traditional Chinese medicine (TCM) and traditional Mongolian medicine, have complemented Western medicine effectively [7].

However, the existing GC registries remain insufficient, and epidemiological reports from the 5 East Asian countries are limited. The 2021 Global Burden of Diseases (GBD), Injuries, and Risk Factors Study performed a cause-of-death analysis, estimating mortality rates and years of life lost for 288 different causes of death [6]. This analysis categorized data based on age, sex, and location across 204 countries and regions, as well as 811 subnational areas, covering the period from 1990 to 2021 [6,8]. This study provides a comprehensive analysis of the disease burden of GC in 5 East Asian countries from 1990 to 2021, examining key metrics such as prevalence, incidence, mortality, years lived with disability (YLDs), years of life lost (YLLs), and disability-adjusted life years (DALYs). We also use the autoregressive integrated moving average (ARIMA) and Bayesian age-period-cohort (BAPC) models to predict the disease burden of GC to 2036. The aim of this study is to provide key insights that will assist decision-makers in assessing the overall burden of GC across the 5 East Asian countries. This, in turn, will support the formulation of targeted prevention strategies and help ensure the equitable distribution of public health resources.

Methods

Data Source

The Global Health Data Exchange GBD Results Tool was used to collect data spanning from 1990 to 2021. The GBD platform provides access to all age-standardized and age-specific rates, along with data that includes 95% uncertainty intervals. Potential issues with GBD data include variability in data quality across countries and years, which can affect comparability. Some regions have limited or incomplete health data, leading to reliance on statistical estimates and models that introduce uncertainty. In addition, differences in data collection methods and reporting standards may impact the accuracy and consistency of results. These factors should be considered when interpreting GBD findings.

We retrieved data from the GBD 2021 regarding the prevalence, incidence, mortality, YLDs, YLLs, and DALYs associated with GC of all ages in 5 East Asian countries (China, Japan, North Korea, South Korea, and Mongolia) from 1990 to 2021.

Definition

In this study, we categorized all cancers coded as C16.902, following the *International Classification of Diseases, Tenth Revision* (*ICD-10*), as GC. By adhering strictly to *ICD-10* codes for cancer classification, the study ensured precise, reproducible identification of GC cases across different data sources and geographies, facilitating consistent burden measurement in GBD 2021.

Data Analysis

The statistical methods used in GBD 2021 are described in detail in a separate source [6], including cause of death ensemble modeling, Bayesian Meta-regression, covariate inclusion, uncertainty quantification, and data standardization and adjustment, etc. Trends in prevalence, incidence, mortality, YLDs, YLLs, and DALYs from 1990 to 2021 were analyzed based on year, sex, and age group.

The average annual percent change (AAPC) and annual percentage change, along with their corresponding 95% CIs, were calculated using Joinpoint regression analysis (Joinpoint Regression Program, Version 5.1.0) to assess trends in the age-standardized prevalence rate (ASPR), age-standardized incidence rate (ASIR), age-standardized mortality rate (ASMR), age-standardized years lived with disability rate, age-standardized years of life lost rate, and age-standardized disability-adjusted life years rate (ASDR). All age-standardized rates (ASRs) were calculated using the age standard of the GBD world population.

The decomposition method uses several established approaches to analyze the differences in total deaths, attributing them to 3 main components: population growth, population aging, and changes in mortality rates [9-14].

The ARIMA model combines both the autoregressive and moving average models [15]. The ARIMA model is based on the assumption that the data series consists of time-dependent random variables, with their autocorrelation patterns described by the model. Consequently, future values can be predicted using past observations [16].

The BAPC model was used to predict the burden of GC up to 2036, using the BAPC and INLA packages in R. All analyses were performed using R (version 4.4.1, R Foundation) and Zstats v1.0 (Weijun Zheng), with a two-tailed *P* value of less than .05 deemed statistically significant [17].

Ethical Considerations

The data used in this study are publicly accessible, and patient information was derived from aggregated data rather than individual-level records. This study aligns with an item considered exempt from review by the Ethics Committee of the Affiliated Hospital of Nanjing University of Chinese Medicine, specifically the category of "Previous data research." Data were used in accordance with GBD's terms of access for aggregated,

XSL•FO
RenderX

anonymized data. As a result, the Ethics Committee of the Affiliated Hospital of Nanjing University of Chinese Medicine determined that the study was exempt from ethical review. All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. Informed consent was obtained from all individual participants included in the study.

Results

Overall Burden

In 1990, Japan had the highest ASPR among the 5 East Asian countries. In 2021, South Korea had the highest ASPR among the 5 East Asian countries. The ASPR of the 5 East Asian countries, except for North Korea, was above the global ASPR and the ASPR of Asia in 1990. The ASPR of North Korea was both below the global ASPR and the ASPR of Asia in 1990. The ASPR of the 5 East Asian countries was both above the global ASPR and the ASPR of Asia in 2021 (Table S1 in Multimedia Appendix 1).

In 1990, South Korea had the highest ASIR among the 5 East Asian countries. However, by 2021, Mongolia had the highest ASIR in the region. In 1990, the ASIR for all 5 East Asian countries, except North Korea, was higher than both the global and the Asian level. In contrast, the ASIR for North Korea was above the global ASIR but lower than the ASIR for Asia. By 2021, the ASIR for all 5 East Asian countries exceeded both the global ASIR and the ASIR for Asia (Table S2 in Multimedia Appendix 1).

In both 1990 and 2021, Mongolia had the highest ASMR among the 5 East Asian countries. The ASMR of the 5 East Asian countries, except for North Korea, was above the global ASMR and the ASMR of Asia in 1990. The ASMR of Japan and South Korea was above the global ASMR but below the ASMR of Asia in 2021 (Table S3 in Multimedia Appendix 1).

In 1990, Japan had the highest age-standardized YLDs rate among the 5 East Asian countries. In 2021, Mongolia had the highest age-standardized YLDs rate among the 5 East Asian countries. The age-standardized YLDs rate of the 5 East Asian countries except for North Korea was above the global and the Asian level in 1990. The age-standardized YLDs rate of North Korea was above the global but below the Asian level in 1990. The age-standardized YLDs rate of the 5 East Asian countries was both above the global and the Asian level in 2021 (Table S4 in Multimedia Appendix 1).

In both 1990 and 2021, Mongolia had the highest age-standardized YLLs rate and ASDR among the 5 East Asian countries. The age-standardized YLLs rate and ASDR of 5 East Asian countries were above the global and the Asian level in 1990. The age-standardized YLLs rate and ASDR of Japan and South Korea were above the global level but below the Asian level in 2021 (Table S5 and S6 in Multimedia Appendix 1).

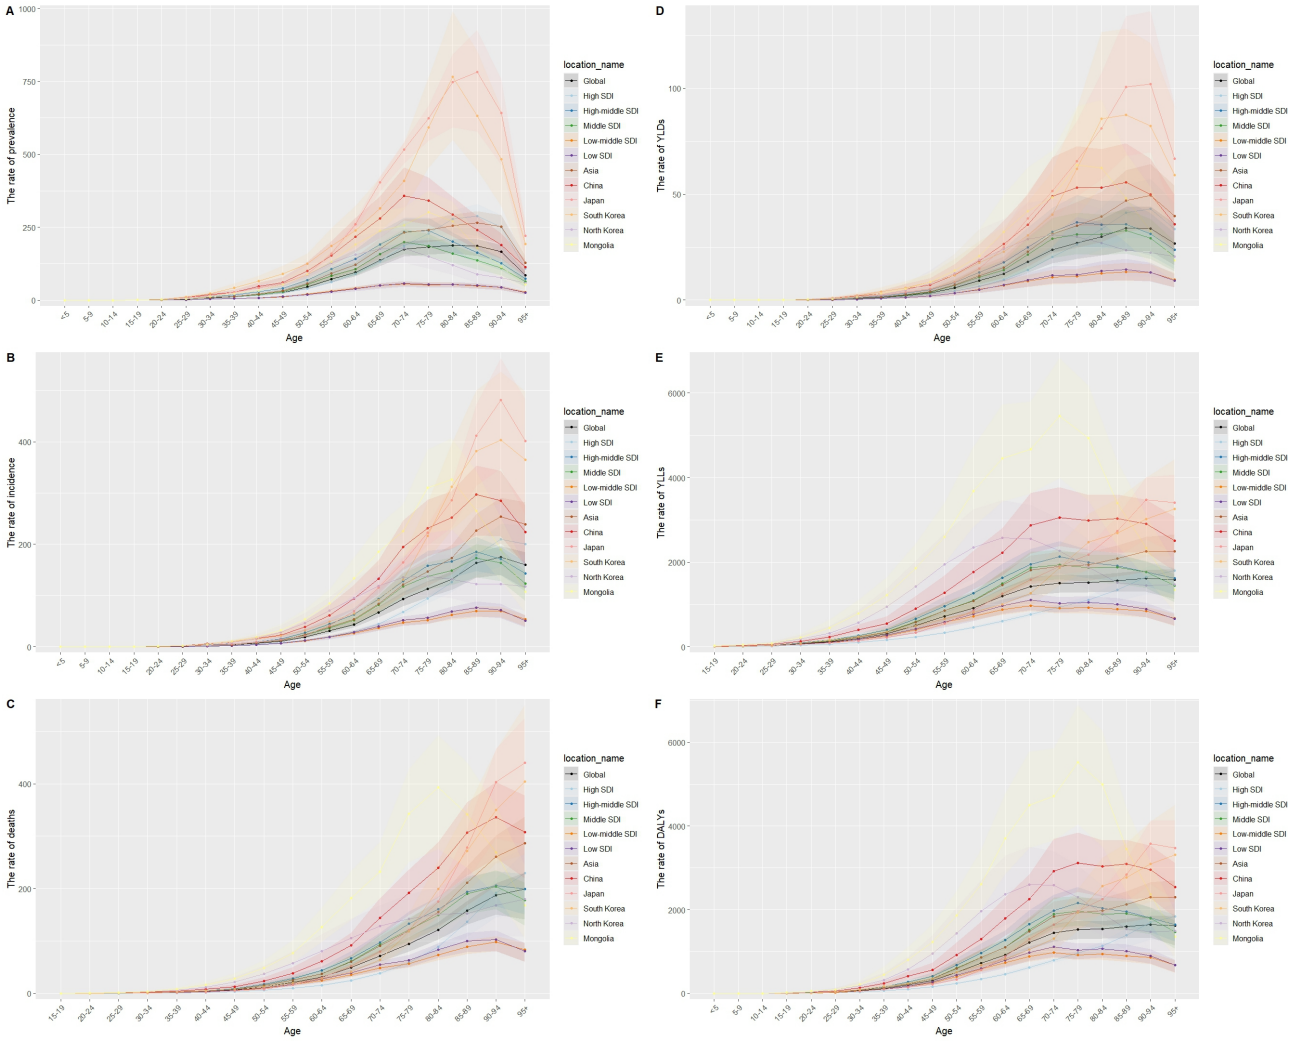
Descriptive Analysis From Age Perspective

In 2021, the age group with the highest prevalence numbers of females and males in China was 65 - 69 years. The age group with the highest prevalence numbers of females in Japan was 80 - 84 years, and the age group with the highest prevalence numbers of males in Japan was 70 - 74 years. The age group with the highest prevalence numbers of females in South Korea was 80 - 84 years, and the age group with the highest prevalence numbers of males in South Korea was 60 - 64 years. The age group with the highest prevalence numbers of females in North Korea was 60 - 64 years, and the age group with the highest prevalence numbers of males in North Korea was 55 - 59 years. The age group with the highest prevalence numbers of females in Mongolia was 60 - 64 years, and the age group with the highest prevalence numbers of males in Mongolia was 55 - 59 years (Figure S1 in Multimedia Appendix 2).

In 2021, the age group with the highest incidence numbers of females in China was 70-74 years, and the age group with the highest incidence numbers of males in China was 65-69 years. The age group with the highest incidence numbers of females in Japan was 85-89 years, and the age group with the highest incidence numbers of males in Japan was 70-74 years. The age group with the highest incidence numbers of females in South Korea was 80-84 years, and the age group with the highest incidence numbers of males in South Korea was 75-79 years. The age group with the highest incidence numbers of females in North Korea was 75-79 years, and the age group with the highest incidence numbers of males in North Korea was 60-64 years. The age group with the highest incidence numbers of females and males in Mongolia was both 60-64 years (Figure S2 in Multimedia Appendix 2).

In 2021, the age group with the highest mortality numbers of females and males in China was both 70 - 74 years. The age group with the highest mortality numbers of females in Japan was 85 - 89 years, and the age group with the highest mortality numbers of males in Japan was 80 - 84 years. In 2021, the age group with the highest mortality numbers of females and males in South Korea was both 80 - 84 years. The age group with the highest mortality numbers of females in North Korea was 75 - 79 years, and the age group with the highest mortality numbers of males in North Korea was 60 - 64 years. The age group with the highest mortality numbers of females in Mongolia was 75 - 79 years, and the age group with the highest mortality numbers of males in Mongolia was 60 - 64 years (Figure S3 in Multimedia Appendix 2).

In 2021, the age group with the highest YLDs numbers of females in China was 70 - 74 years, and the age group with the highest YLDs numbers of males in China was 65 - 69 years. The age group with the highest YLDs numbers of females in Japan was 85 - 89 years, and the age group with the highest YLDs numbers of males in Japan was 70 - 74 years. The age group with the highest YLDs numbers of females in South Korea was 80 - 84 years, and the age group with the highest YLDs numbers of males in South Korea was 60 - 64 years. The age group with the highest YLDs numbers of females in North Korea was 60 - 64 years, and the age group with the highest YLDs numbers of males in North Korea was 55 - 59 years. The age



XSL•FO
RenderX

group with the highest YLDs numbers of females and males in Mongolia was both 60 - 64 years (Figure S4 in Multimedia Appendix 2).

In 2021, the age group with the highest YLLs and DALYs numbers of females and males in China was 65 - 69 years. The age group with the highest YLLs and DALYs numbers of females in Japan was 85 - 89 years, and the age group with the highest YLLs and DALYs numbers of males in Japan was 70 - 74 years. The age group with the highest YLLs and DALYs numbers of females in South Korea was 80 - 84 years, and the age group with the highest YLLs and DALYs numbers of males in South Korea was 60 - 64 years. The age group with the highest YLLs and DALYs numbers of females in North Korea was 60 - 64 years, and the age group with the highest YLLs and DALYs numbers of males in North Korea was 55 - 59 years. The age group with the highest YLLs and DALYs numbers of females in Mongolia was 60 - 64 years, and the age group with the highest YLLs and DALYs numbers of males in Mongolia was 55 - 59 years (Figures S5 and S6 in Multimedia Appendix 2).

In 2021, the age group with the highest prevalence rate in China and North Korea was 70 - 74 years. The age group with the highest prevalence rate in Japan was 85 - 89 years. The age group with the highest prevalence rate in South Korea was 80 - 84 years. The age group with the highest prevalence rate in Mongolia was 75 - 79 years (Figure 1A).

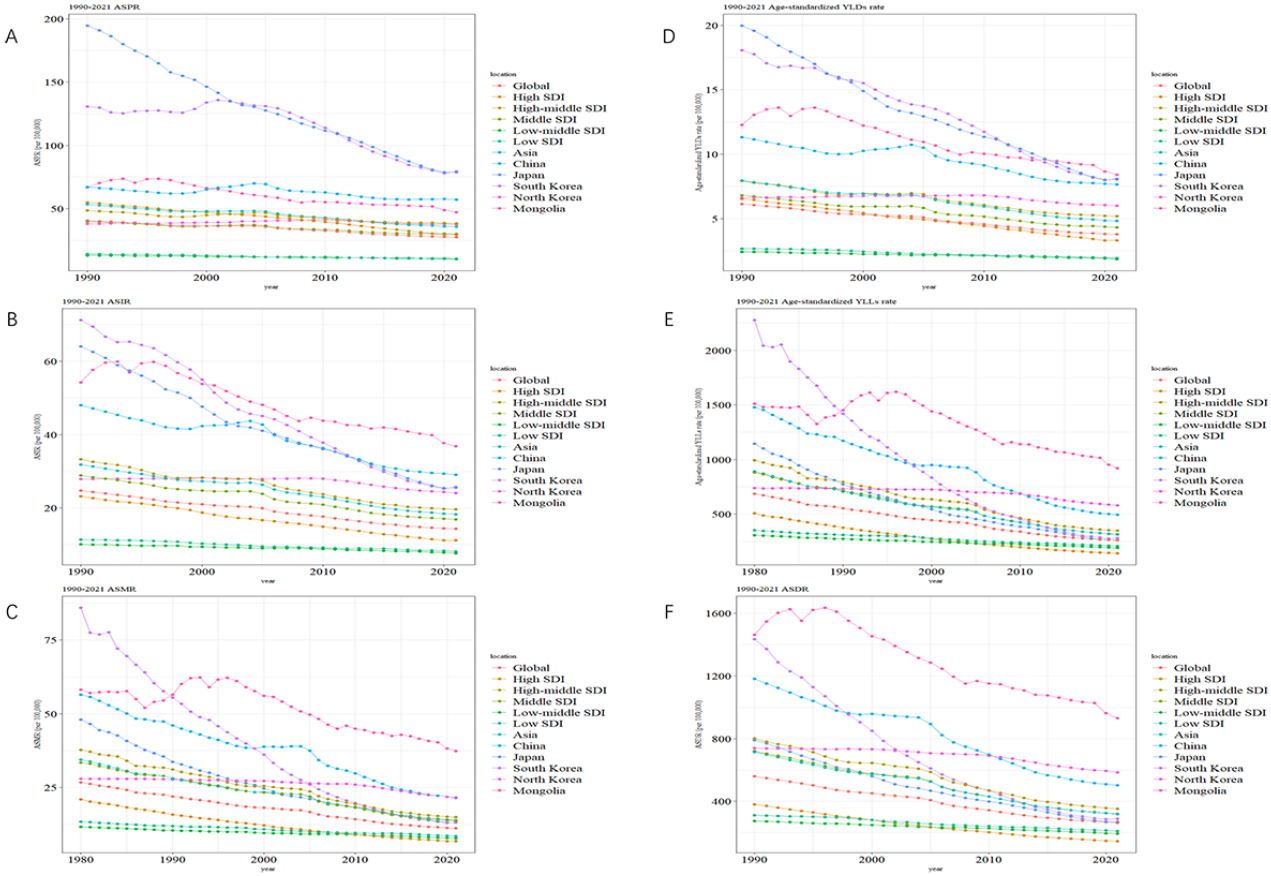
Figure 1. Age-specific rate in 5 East Asian countries. (A) The rate of prevalence. (B) The rate of incidence. (C) The rate of death. (D) The rate of YLDs. (E) The rate of YLLs. (F) The rate of DALYs. DALY: disability-adjusted life year; SDI: Sociodemographic Index; YLD: year lived with disability; YLL: year of life lost.

In 2021, the age group with the highest incidence rate in China was 85 - 89 years. The age group with the highest incidence rate in Japan and South Korea was 90 - 94 years. The age group with the highest incidence rate in North Korea was 75 - 79 years. The age group with the highest incidence rate in Mongolia was 80 - 84 years (Figure 1B).

In 2021, the age group with the highest mortality rate in China was 90 - 94 years. The age group with the highest mortality rate in Japan, South Korea, and North Korea was above 95 years. The age group with the highest mortality rate in Mongolia was 80 - 84 years (Figure 1C).

In 2021, the age group with the highest YLDs rate in China and South Korea was 85 - 89 years. The age group with the highest YLDs rate in Japan was 90 - 94 years. The age group with the highest YLDs rate in North Korea was 70 - 74 years. The age

XSL•FO
RenderX



group with the highest YLDs rate in Mongolia was 75 - 79 years (Figure 1D).

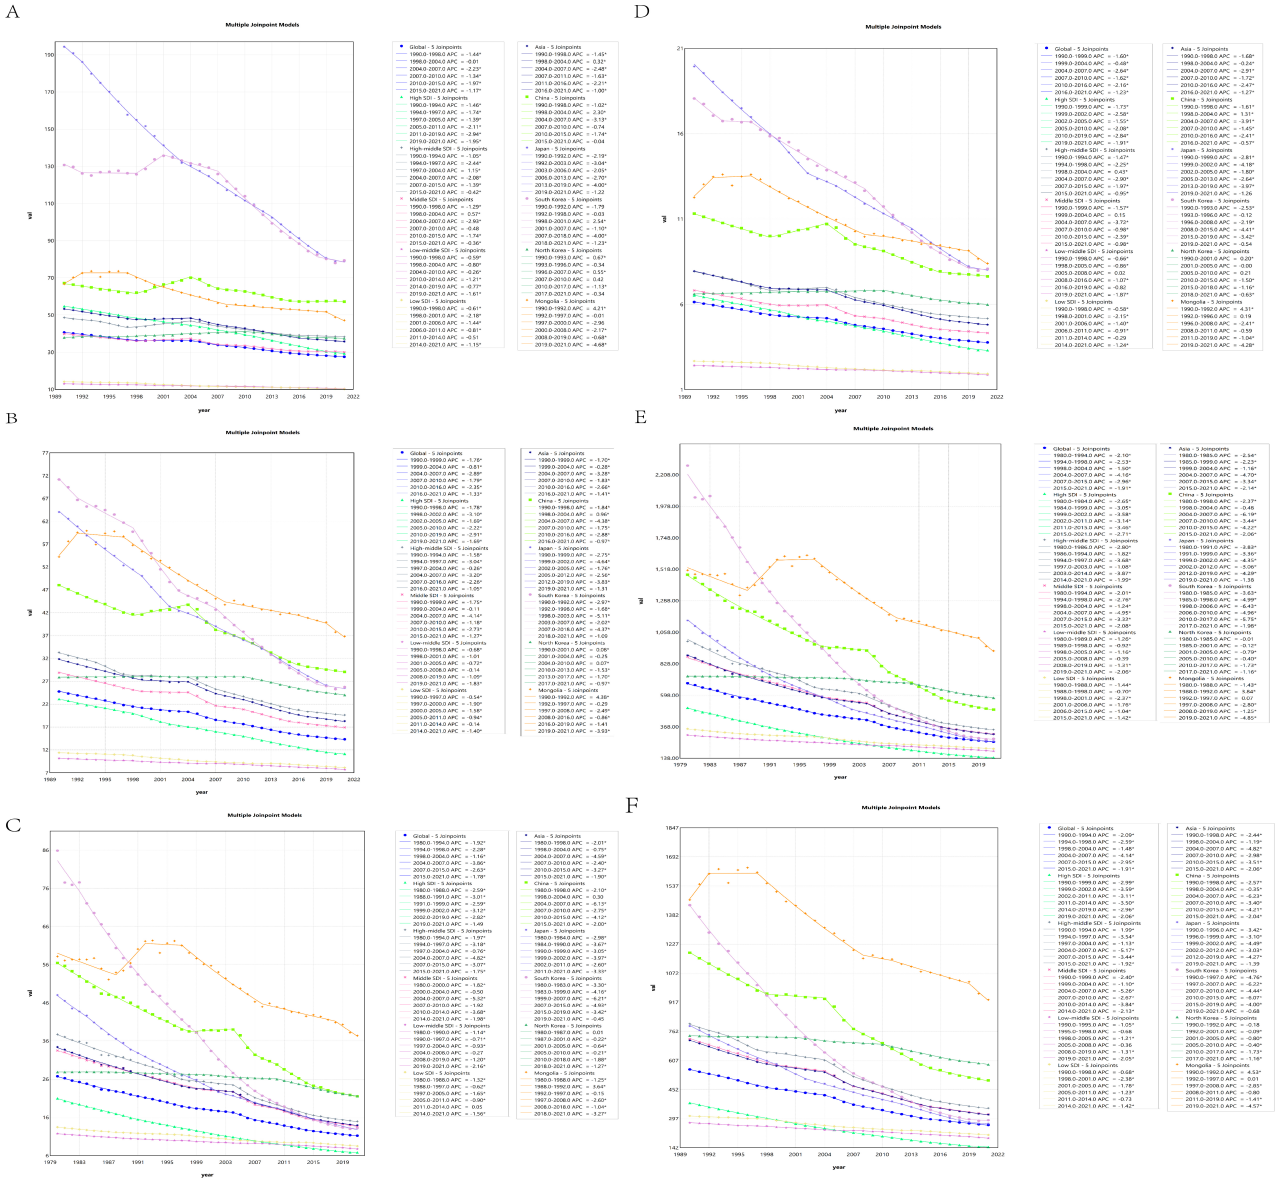
In 2021, the age group with the highest YLLs and DALYs rate in China and Mongolia was 75 - 79 years. The age group with the highest YLLs and DALYs rate in Japan was 90 - 94 years. The age group with the highest YLLs and DALYs rate in South Korea was above 95 years. The age group with the highest YLLs and DALYs rate in North Korea was 65 - 69 years (Figure 1E and F).

Descriptive Analysis From a Period Perspective

The ASPR, ASIR, ASMR, age-standardized YLDs rate, age-standardized YLLs rate, and ASDR of the 5 East Asian countries showed an overall downward trend from 1990 to 2021 (Figure 2). The ASPR, ASIR, ASMR, age-standardized YLDs rate, age-standardized YLLs rate, and ASDR for both females and males in the 5 East Asian countries showed an overall oscillating downward trend from 1990 to 2021 (Figures S7-12 in Multimedia Appendix 3).

Figure 2. Time trends in 5 East Asian countries. (A) Age-standardized prevalence rate. (B) Age-standardized incidence rate (C) Age-standardized mortality rate. (D) Age-standardized YLDs rate. (E) Age-standardized YLLs rate. (F) Age-standardized DALYs rate. DALY: disability-adjusted life year; SDI: Sociodemographic Index; YLD: year lived with disability; YLL: year of life lost.

The time trends of ASPR in Japan and South Korea ranked the top 2 among the 5 East Asian countries (Figure 2A). The time trends of ASIR in South Korea and Mongolia ranked the top 2 among the 5 East Asian countries (Figure 2B). The time trends of ASMR in South Korea and Mongolia ranked the top 2 among the 5 East Asian countries (Figure 2C). The time trends of YLDs in Japan, South Korea, and Mongolia ranked the top 3 among the 5 East Asian countries (Figure 2D). The age-standardized YLLs rate and ASDR in Mongolia ranked first among the 5 East Asian countries since 1990 (Figure 2E and F).



The ASPR in China and Mongolia was above the global level from 1990 to 2021 (Figure 2A). The ASPR in North Korea exceeded the global level in 1996 (Figure 2A). The ASIR, ASMR, age-standardized YLDs rate, age-standardized YLDs rate, age-standardized YLLs rate, and ASDR in the 5 East Asian countries were above the global level from 1990 to 2021 (Figure 2B-F).

Joinpoint Regression Analysis

The AAPCs of ASPR in China (−0.50, 95% CI −0.67 to −0.32), North Korea (−0.05, 95% CI −0.16 to 0.05) and Mongolia (−1.14, 95% CI −1.44 to −0.84) were above the global level (−1.26, 95% CI −1.40 to −1.12). The AAPCs of ASPR in Japan (−2.92, 95% CI −3.11 to −2.72) and South Korea (−1.65, 95% CI −1.91 to −1.38) were below the global level (Figure 3A and Table S7 in Multimedia Appendix 4).

XSL•FO
RenderX

Figure 3. Joinpoint regression analysis of the age-standardized rate in 5 East Asian countries from 1990 to 2021. (A) Age-standardized prevalence rate. (B) Age-standardized incidence rate. (C) Age-standardized mortality rate. (D) Age-standardized YLDs rate. (E) Age-standardized YLLs rate. (F) Age-standardized DALYs rate. DALY: disability-adjusted life year; YLD: year lived with disability; YLL: year of life lost.

The AAPCs of ASIR in China (−1.61, 95% CI −1.73 to −1.48), North Korea (−0.48, 95% CI −0.52 to −0.44) and Mongolia (−1.26, 95% CI −1.60 to −0.92) were all above the global level (−1.76, 95% CI −1.89 to −1.64). The AAPCs of ASPR in Japan (−2.95, 95% CI −3.16 to −2.74) and South Korea (−3.23, 95% CI −3.47 to −2.98) were below the global level (Figure 3B and Table S7 in Multimedia Appendix 4).

The AAPCs of ASMR in North Korea (−0.62, 95% CI −0.65 to −0.60) and Mongolia (−1.11, 95% CI −1.47 to −0.75) were above the global level (−2.11, 95% CI −2.27 to −1.95). The AAPCs of ASMR in China (−2.34, 95% CI −2.60 to −2.07), Japan (−3.12, 95% CI −3.33 to −2.90) and South Korea (−4.47, 95% CI −4.65 to −4.28) were below the global level (see in Figure 3C and Table S7 in Multimedia Appendix 4).

The AAPCs of age-standardized YLDs rate in China (−1.25, 95% CI −1.38 to −1.12), North Korea (−0.33, 95% CI −0.37 to −0.28) and Mongolia (−1.25, 95% CI −1.57 to −0.93) were all above the global level (−1.57, 95% CI −1.70 to −1.44). The AAPCs of age-standardized YLDs rate in Japan (−2.93, 95% CI −3.14 to −2.71) and South Korea (−2.61, 95% CI −2.92 to −2.31) were below the global level (see Figure 3D and Table S7 in Multimedia Appendix 4).

The AAPCs of age-standardized YLLs rate in North Korea (−0.58, 95% CI −0.61 to −0.56) and Mongolia (−1.24, 95% CI −1.59 to −0.89) were above the global level (−2.36, 95% CI −2.55 to −2.17). The AAPCs of age-standardized YLLs rate in China (−2.65, 95% CI −2.86 to −2.43), Japan (−3.55, 95% CI −3.78 to −3.32) and South Korea (−4.95, 95% CI −5.17 to −4.73) were below the global level (see Figure 3E and Table S7 in Multimedia Appendix 4).

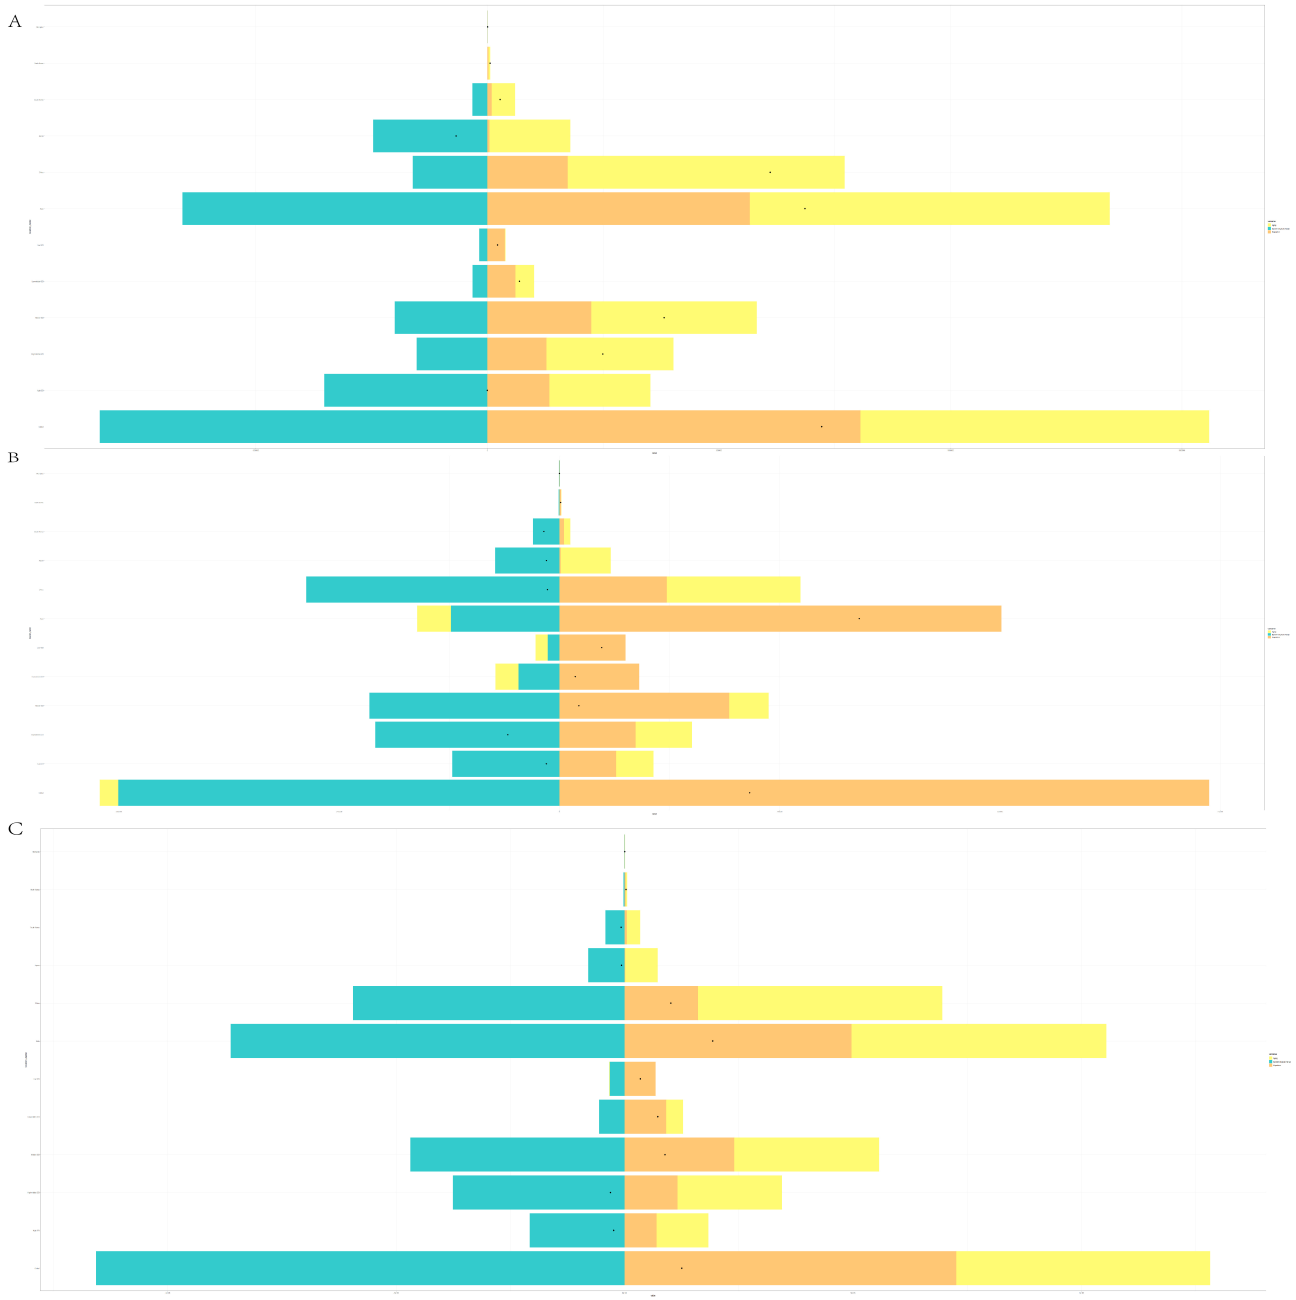
The AAPCs of ASDR in North Korea (−0.74, 95% CI −0.77 to −0.72) and Mongolia (−1.48, 95% CI −1.80 to −1.16) were above the global level (−2.42, 95% CI −2.52 to −2.33). The AAPCs of ASDR in China (−2.75, 95% CI −2.92 to −2.58),

XSL•FO
RenderX

Japan (−3.43, 95% CI −3.61 to −3.24) and South Korea (−5.06, 95% CI −5.32 to −4.79) were below the global level (see Figure 3F and Table S7 in Multimedia Appendix 4).

Age-Period-Cohort Analysis

The prevalence rate in China increased rapidly between the ages of 0 and 70 years, whereas the prevalence rate after age 70 years exhibited a gradual decline (Figure S13A in Multimedia Appendix 5). The prevalence rate in Japan increased rapidly between the ages of 0 and 80 years, while the prevalence rate after age 80 years displayed a gradual decline (Figure S13B in Multimedia Appendix 5). The prevalence rate in South Korea increased rapidly between the ages of 0 and 80 years, while the prevalence rate after age 80 years demonstrated a gradual decline (Figure S13C in Multimedia Appendix 5). The prevalence rate in North Korea rose rapidly between the ages of 0 and 70 years while the prevalence rate after 70 years showed a slowly decreasing trend (Figure S13D in Multimedia Appendix 5). In Mongolia, the prevalence rate surged significantly from ages 0 to 70 years, while the prevalence rate after age 70 years displayed a gradual decline (Figure S13E in Multimedia Appendix 5).



The incidence and death rate in China increased rapidly between the ages of 0 and 90 years, while the incidence and death rate after 90 years showed a slowly decreasing trend (Figure S14A-15A in Multimedia Appendix 5). In Japan, the incidence and death rate rose sharply from ages 0 to 90 years, while the incidence and death rate after age 90 years exhibited a gradual decline (Figure S14B-15B in Multimedia Appendix 5). The incidence and death rate in South Korea increased oscillably between the ages of 0 and 100 years (Figure S14C-15C Multimedia Appendix 5). In North Korea, the incidence and death rate surged significantly from ages 0 to 80 years, while the incidence and death rate after age 80 years exhibited a gradual decline (Figure S14D-15D in Multimedia Appendix 5). In Mongolia, the incidence and death rate rose sharply from ages 0 to 80 years, while the incidence and death rate after age 80 years displayed a gradual decline (Figure S14E-15E in Multimedia Appendix 5).

Decomposition Analysis

The prevalence rate in China is 97.93% affected by aging, 28.41% affected by population, and −26.34% affected by epidemiological change. The prevalence rate in Japan is −258.68% affected by aging, −6.87% affected by population, and 365.55% affected by epidemiological change. The prevalence rate in South Korea is 183.07% affected by aging, 33.95% affected by population, and −117.02% affected by epidemiological change. The prevalence rate in North Korea is 61.85% affected by aging, 39.24% affected by population, and −1.09% affected by epidemiological change. The prevalence rate in Mongolia is 87.92% affected by aging, 94.71% affected by population, and −82.63% affected by epidemiological change (Figure 4A).

XSL•FO
RenderX

Figure 4. Decomposition analysis. (A) Prevalence. (B) Incidence. (C) Death.

The incidence rate in China is −1108.04% affected by aging, −889.77% affected by population, and 2097.81% affected by epidemiological change. The incidence rate in Japan is −386.89% affected by aging, −10.57% affected by population, and 497.46% affected by epidemiological change. The incidence rate in South Korea is −41.33% affected by aging, −29.04% affected by population, and 170.37% affected by epidemiological change. The incidence rate in North Korea is 32.39% affected by aging, 135.40% affected by population, and −67.79% affected by epidemiological change. The incidence rate in Mongolia is 65.76% affected by aging, −1740.31% affected by population, and 1774.53% affected by epidemiological change (Figure 4B).

The death rate in China is 528.18% affected by aging, 159.04% affected by population, and −587.22% affected by epidemiological change. The death rate in Japan is −1075.28% affected by aging, −24.67% affected by population, and 1199.94% affected by epidemiological change. The death rate in South Korea is −382.19% affected by aging, −69.17% affected by population, and 551.36% affected by epidemiological change. The death rate in North Korea is 103.65% affected by aging, 78.25% affected by population, and −81.90% affected by epidemiological change. The death rate in Mongolia is 100.74% affected by aging, 154.25% affected by population, and −154.99% affected by epidemiological change (Figure 4C).

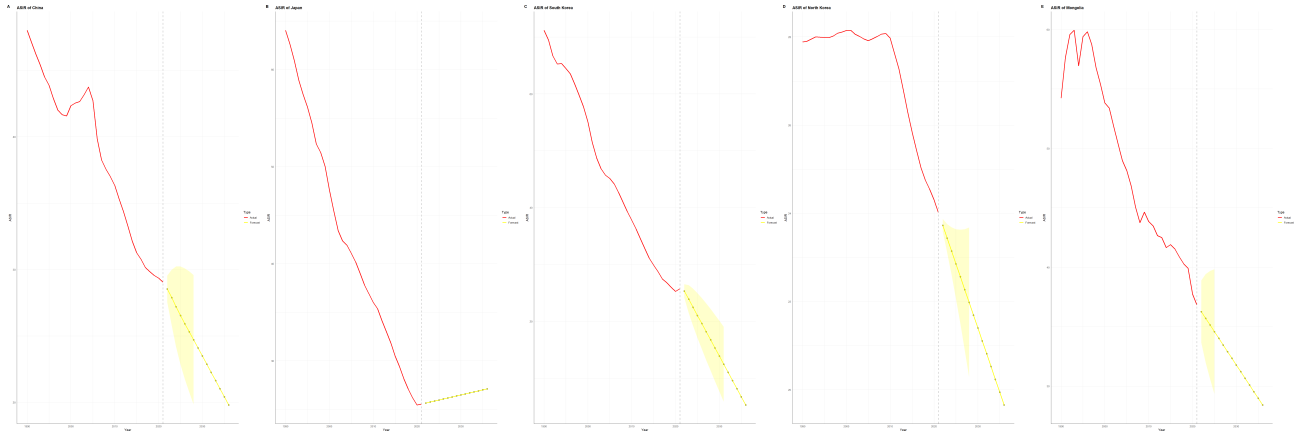
ARIMA and BAPC Prediction

We conducted ARIMA and BAPC models to predict the situation up to 2036 (Figures 5 and 6, S16-17 in Multimedia Appendix 6). The ASPR of China decreased from 1990 to 1997, increased from 1997 to 2004, and decreased after 2004. The ASPR of Japan demonstrated an overall downward trend from

XSL•FO
RenderX

1990 to 2036. The ASPR of South Korea gradually declined after reaching its peak around 2003 and rose again in 2021. The ASPR of North Korea gradually declined after reaching its peak around 2010 and rose again in 2024. The ASPR of Mongolia gradually declined after reaching its peak around 1993 and 1996 (Figure S16 and Table S8 in Multimedia Appendix 6).

Figure 5. Autoregressive integrated moving average model prediction of age-standardized incidence rate. (A) China. (B) Japan. (C) South Korea. (D) North Korea. (E) Mongolia.



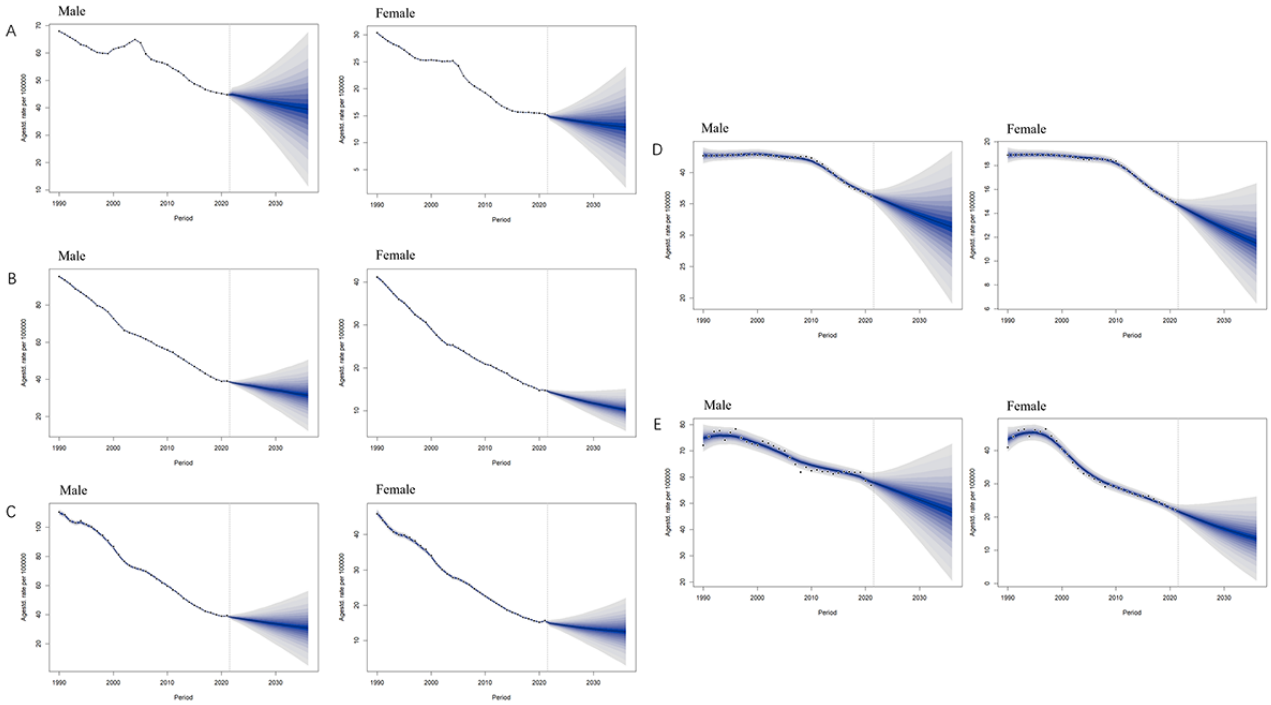


Figure 6. Bayesian age-period-cohort prediction of age-standardized incidence rate. (A) China. (B) Japan. (C) South Korea. (D) North Korea. (E) Mongolia.

The ASIR (Table 1) of China, South Korea, and North Korea demonstrated an overall downward trend from 1990 to 2036. The ASIR (Table 1) of Japan gradually declined and rose again in 2021. The ASIR (Table 1) of Mongolia gradually declined after reaching its peak around 1993 and 1996 (Figures 5 and 6, and Table S9 in Multimedia Appendix 6).

Table . Autoregressive Integrated Moving Average prediction ASIR[a] per 100,000 people in the 5 East Asian countries.

ASIR	China	Japan	South Korea	North Korea	Mongolia
1990	48.03	64.05	71.18	27.89	54.22
2021	29.05	25.54	25.76	24.02	36.83
2030	23.49	26.48	13.89	21.40	31.78
2036	19.80	27.11	5.30	19.65	28.41

[a]ASIR: age-standardized incidence rate.

XSL•FO
RenderX

The ASMR of China, Japan, South Korea, and North Korea demonstrated an overall downward trend from 1990 to 2036. The ASMR of Mongolia gradually declined after reaching its peak around 1993 and 1996 (Figure S17 and Table S10 in Multimedia Appendix 6).

Discussion

Principal Findings

This study offers a thorough analysis of the GC burden across 5 East Asian countries from 1990 to 2021. It highlights significant epidemiological trends and regional disparities, which are essential for guiding public health policies and optimizing resource allocation. Our findings indicate that China recorded the highest number of incidence, prevalence, death, YLLs, YLDs, and DALYs among the 5 East Asian countries in both 1990 and 2021. From an age perspective, in 2021, the age group with the highest prevalence numbers, incidence numbers, mortality numbers, YLD numbers, YLL numbers, and DALY numbers of females and males in the 5 East Asian countries was consistently those aged 55 and older. The age group with the highest prevalence rate, incidence rate, mortality rate, YLDs rate, YLLs rate, and DALYs rate in 5 East Asian countries was consistently those aged 65 years and older. The prevalence rate in South Korea was influenced by aging, surpassing global averages. The incidence rate in North Korea and Mongolia was influenced by aging and exceeds global averages. The mortality rate in China was influenced by aging, surpassing global averages. All of these factors indicate a significant disease burden on the older population.

In 1990, Japan had the highest ASPR among the 5 East Asian countries, but South Korea had the highest ASPR in 2021. In 1990, South Korea had the highest ASIR, and Japan had the highest age-standardized YLDs rate among the 5 East Asian countries, but Mongolia reported the highest ASIR and age-standardized YLDs rate in 2021. Mongolia also exhibited the highest ASMR, age-standardized YLLs rate, and ASDR among the 5 East Asian countries in both 1990 and 2021. The ASPR, ASIR, ASMR, age-standardized YLDs rate, age-standardized YLLs rate, and ASDR of the 5 East Asian countries demonstrated an overall downward trend from 1990 to 2021, but still higher than the global level. The AAPCs of ASPR, ASIR, ASMR, age-standardized YLDs rate, age-standardized YLLs rate, and ASDR in North Korea and Mongolia were above the global level. We used the ARIMA and BAPC models to project trends up to 2036. The ASIR and ASMR of Mongolia are predicted to be top 1 among 5 East Asian countries, while the ASPR of South Korea is predicted to be the highest. GC poses a substantial disease burden in 5 East Asian countries, particularly in China, Japan, South Korea, and Mongolia.

Gastrointestinal cancers account for nearly one-third of global cancer mortality [18]. GC demonstrated decreasing trends specifically in females from 2000 to 2019, but still at a high level [19]. The infection-noncommunicable disease pair with the largest burden was GC due to *Helicobacter pylori* [20]. The global incidence and mortality rates of both young- and late-onset GC have decreased since 1990, but the incidence rate of young-onset cancer has demonstrated a small but significant upward trend since 2015 [21]. From 1990 to 2019, the global incidence and mortality rates of GC declined in both sexes, across most GBD regions and countries, but the GC burden was still heavy in some GBD regions and countries, particularly within special age-specific groups [22]. In 2019, tracheal, bronchus, and lung (TBL), esophageal, stomach, colorectal, and pancreatic cancer were the top 5 neoplasms attributable to tobacco smoking, with different burdens in regions as per their development status [23]. The burden of stomach cancer worldwide, adjusted for age and related to smoking, has shown a decline from 1990 to 2019, but regional disparities have been identified, with some areas experiencing an increase in this burden [24]. ASIR and ASMR of GC in the total population, different regions, and countries in Asia from 1990 to 2019 showed an overall decreasing trend [25]. A study has found out that the GC burden attributed to high sodium intake still exists seriously and varies remarkably by regions, sex, and age across China [26]. Although the predicted age-standardized rates of mortality and DALYs due to dietary GC show downward trends, the absolute numbers are still predicted to increase in the next 25 years due to rapid population aging in China [27]. A considerable proportion of GC incidence might be preventable by healthy dietary habits in Korea [28].

GC susceptibility genes in East Asian populations differ from those in other regions [29-34]. To our knowledge, very few studies have focused on the epidemiological situation of GC in 5 East Asian countries. A study confirmed that ambient temperature has a significant impact on temperature-associated mortality, with cardiovascular mortality being especially vulnerable to both ambient temperature and diurnal temperature range [35].

Our study has several limitations. First, data within each iteration of GBD were comparable, but due to inherent limitations in the GBD methodology, results from different iterations, even for the same year, were not comparable. Differences in the GBD outcomes between iterations could be attributed to updates in data sources and improvements in methodology. Second, the accuracy of the estimated GC burden largely depends on the availability and quality of data acquired, which could be partially compensated by statistical methods. However, in regions with scarce data, especially in low-sociodemographic index countries, estimates could only rely on predictive covariates or global trends with consideration of sociodemographic index level and data from a single country, which is less representative. Extra caution should be taken when interpreting data from these areas. Additional high-quality population-based studies should be performed, especially in countries with scarce data. Third, some sources of uncertainty, including the covariates used in models, are not captured in our estimation process. The long-term impact of the COVID-19 pandemic may lead to deviation in the prediction model.

Conclusions

The disease burden of GC in 5 East Asian countries has been consistently substantial over the past 3 decades, particularly among older people. Considering the complexity of GC pathogenesis, the focus of current research should be on the

XSL•FO
RenderX

etiological research and the development of therapeutic strategies. Public health strategies need to enhance early diagnosis and prevention of GC, as well as optimize the regional distribution of health care resources and implement effective environmental health policies. Research on the epidemiology of GC in the 5 East Asian countries population should be strengthened, particularly focusing on differentiated management and precise prevention and control strategies for various regions, genders, and age groups. Meanwhile, rehabilitation and long-term care for patients with GC require greater attention to improve patients' quality of life and reduce the burden on society and the health care system [36]. Complementary and alternative medicine combined with modern medicine plays an active role in the treatment of GC [37-39].

Acknowledgments

We acknowledge the Institute for Health Metrics and Evaluation (University of Washington), the Global Burden of Disease (GBD) Collaborators, and all staff who provided the data necessary for this study. The opinions expressed here are those of the authors and do not necessarily represent the official position of the organizations with which they are affiliated. We thank associate professor Weijun Zheng and his team from Zhejiang Chinese Medical University for their important suggestions and valuable technical support in methodology and statistics. This study was supported by the National Key R&D Program of China (grants 2022YFC3500200 and 2022YFC3500202), Innovation Team and Talents Cultivation Program of National Administration of Traditional Chinese Medicine (grant ZYYCXTD-C-202208), NATCM's Project of High-level Construction of Key TCM Disciplines (grant [2023]85), Qing Lan Project of Jiangsu Higher Education Institutions (grant [2023]27), the Program for Leading Talents of Traditional Chinese Medicine of Jiangsu Province (grant SLJ0314), Postgraduate Research & Practice Innovation Program of Jiangsu Province (grant SJCX22_0706), and the General project of Universities' philosophy and social science in Jiangsu Province (grant 2024SJYB0564).

Data Availability

Data used for the analyses is deposited in publicly available repositories from the Global Burden of Disease Study 2021, the Institute of Health Metrics and Evaluation [40,41].

Authors' Contributions

TG led the conceptualization, funding acquisition, and supervision of the study and was responsible for data curation, formal analysis, investigation, methodology, project administration, resources, software development, validation, visualization, and drafting and revising the manuscript. TZ, Wenjie Zhu, YY, and YH contributed to data curation, formal analysis, investigation, methodology, project administration, software development, validation, visualization, and reviewing and editing the manuscript, with YY additionally contributing to drafting the original manuscript. Wenjian Zhu contributed to investigation, methodology, software development, validation, and visualization. WS, LL, and WW supported the study through methodology development, project administration, resource provision, and supervision, with LL and HC additionally securing funding. HC and XW further contributed to supervision, validation, and project administration, and XW also participated in methodology, funding acquisition, and manuscript review and editing.

Abstract

Background: Eastern Asia has historically had the highest global incidence and mortality rates of gastric cancer (GC) while substantial disparities exist between countries. The overall burden of GC remains insufficiently explored.

Objective: Using the Global Burden of Disease Study 2021, this research aims to estimate the burden and risk factors of GC in Eastern Asia from 1990 to 2021.

Methods: Incidence, age-standardized incidence rate (ASIR), deaths, age-standardized mortality rate (ASMR), disability-adjusted life years, age-standardized disability-adjusted life year rate (ASDR), and risk factor burdens for GC were analyzed in Eastern Asia from 1990 to 2021. Joinpoint analysis determined average annual percent change (AAPC) and annual percent change, while age-period-cohort analysis assessed temporal trends. The Bayesian age-period-cohort model projected GC burden from 2021 to 2035. All analyses used R software (version 4.4.1; R Foundation for Statistical Computing).

Results: In 2021, Eastern Asia reported 748,235 new GC cases and 527,054 deaths, accounting for 60.8% (748,235/1,230,232) of new cases and 55.2% (527,054/954,373) of deaths reported globally. From 1990 to 2021, South Korea showed the largest declines in ASIR, ASMR, and ASDR, with ASMR decreasing from 55.4 per 100,000 to 13.3 per 100,000 (AAPC −4.5, 95% CI −4.8 to −4.3). ASIR, ASMR, and ASDR also showed a downward trend in Japan and China, with an AAPC of −3.0 (95% CI −3.2 to −2.8) for ASMR in Japan and −2.4 (95% CI −2.6 to −2.3) in China. The GC burden of North Korea was basically stable, with an AAPC of ASMR of −0.8 (95% CI −0.8 to −0.8). Mongolia showed a slight decline, with an AAPC of ASMR of −1.4 (95% CI −1.7 to −1.0), and the burden of GC was the highest. High-sodium diets and smoking were the main risk factors for disability-adjusted life years of GC in 2021. Smoking contributed to a decline in ASDR as the sociodemographic index increased. Projections suggest continued ASDR reductions across Eastern Asia from 2022 to 2035, though Mongolia will maintain the highest burden.

Conclusions: Despite a decrease from 1990 to 2021, GC remains a significant public health issue in Eastern Asia. Addressing it necessitates prioritizing primary and secondary prevention, including reducing risk factors and enhancing early screening.

Introduction

According to the latest global cancer burden figures for 2022 released by the World Health Organization's (WHO) International Agency for Research on Cancer (IARC), gastric cancer (GC) is the fifth leading cause of death with the fifth most common cancer globally [1]. There were over 968,000 new cases of GC in 2022 and close to 660,000 deaths. Although the incidence and mortality of GC present a downward trend worldwide [2], incidence and mortality rates still are highest in Eastern Asia [1]. However, there is a large variability across Eastern Asia countries in both incidence and mortality, which might be associated with socioeconomic disparities, early GC screening, etc.

The risk of infection with *Helicobacter pylori*, a major confirmed cause of noncardia GC, is enhanced by poor hygiene; thus, the incidence of GC is closely related to socioeconomic differences [3]. A recently published cluster randomized

XSL•FO
RenderX

controlled trial with 11.8 years of follow-up from China showed a reduction in the incidence of GC among patients treated with anti–*H. pylori* [4]. In addition, smoking, heavy alcohol consumption, high-sodium diet, and insufficient intake of fresh vegetables and fruits may also increase the risk of GC [5]. In addition, because of the insidious symptoms in early GC, a high proportion of patients are already progressed into middle or late stage by the time it is detected, and the prognosis is poor with a 5-year survival rate of <25% [6]. However, due to the widespread implementation of national screening programs, some high-incidence Eastern Asia countries have shown relatively high 5-year survival rates for GC through early cancer detection (such as 64.6% in Japan and 71.5% in South Korea) [7]. Therefore, the comparison of the trend features of GC in Eastern Asia countries with a heavy burden of GC is helpful to reveal the epidemiological characteristics and risk factors of GC and provide information support for the formulation of public health policies.

In this study, we used Eastern Asia data from the Global Burden of Disease Study (GBD) 2021 to explore the changes in GC burden and its risk factors by sex and nation from 1990 to 2021. The findings aim to offer scientific evidence for the accurate screening and prevention of GC, ultimately reducing its disease burden.

Methods

Ethical Considerations

This study uses publicly available data from the Global Burden of Disease Study (GBD) database. The GBD data are anonymized and aggregated at the population level, and no individual-level information is included. Ethics approval and informed consent were not required for the use of these data. Access to the GBD database complies with all applicable data use agreements and guidelines provided by the Institute for Health Metrics and Evaluation [8].

Overview and Definition

GBD 2021 assesses health risks associated with 371 diseases, injuries, and 88 risk factors, and we conducted a secondary analysis of data from this collaborative endeavor. This study complies with the GATHER (Guidelines for Accurate and Transparent Health Estimates Reporting) checklist and has been registered in the GBD 2021 Paper Proposal Form. This analysis included patients with GC stratified by sex and age in Eastern Asia (containing 5 countries) from 1990 to 2021. Since GBD 2021 excludes data on the GC burden for individuals younger than 15 years of age, our main focus was on those aged 15 years and older. GC was classified according to the *International Classification of Diseases* (*ICD*), including *ICD-10* codes C16-C16.9 and *ICD-9* codes 151 - 151.9, 209.23, version 10.04 [9].

Data on the incidence, mortality, and disability-adjusted life years (DALYs) for GC in Eastern Asia, including their 95% uncertainty intervals (UIs), were obtained from GBD 2021. Eastern Asia population projections from 2022 to 2035 were also derived from the 2021 Global Health Data Exchange source tool. Sociodemographic index (SDI) is a comprehensive index to measure the socioeconomic development of a region. In this study, Eastern Asia was classified according to the quintile of SDI. The Institute for Health Metrics and Evaluation offers the regional SDI division [10]. The GBD 2021 companion paper explains the data input, processing, synthesis, and the final model used to estimate disease burden [11]. The estimates referenced in this study are publicly accessible through the GBD results tool [12].

Attributable Risk Factors

For the risk factors of GC in GBD 2021, exposure data were modeled using a Bayesian statistical model: either spatiotemporal Gaussian process regression or DisMod-MR 2.1.9 to estimate the exposure distribution of risk factors. Next, the general formula for continuous risk was used to compute the Population Attributable Fraction (PAF) between risk-outcome pairs by age-sex-location-year. To estimate attributable DALYs, the total DALY was multiplied by the PAF. Previous studies detail the exact calculation process [9]. Risk factors associated with GC in GBD 2021 include smoking and high-sodium diet. We showed shifts in the PAF for these risk factors between 1990 and 2021 and used locally weighted regression to explore the relationship between risk factors and SDI.

Statistics

Age-Standardized Incidence, Mortality, and DALY Estimates

The age-standardized incidence rate (ASIR), age-standardized death rate (ASMR), and age-standardized disability-adjusted life year rate (ASDR) were adopted to quantify the trends associated with morbidity, mortality, and DALYs for the all-age population in Eastern Asia. In this study, the direct methods were used to calculate age-standardized rates (per 100,000 population) [13], in which the actual rates of all groups of comparative data are known, and the rates are standardized by standard population or standard population composition. Standardization removes the effect of internal differences (such as age) and subsequently allows analysis of any substantial differences. Due to GBD 2021 only offering crude rates for specific age groups (eg, 15 - 19, 20 - 24, 25 - 29, and up to 95+ years), we used crude rates for such groups. All data are accessible on the web via the GBD results tool [12].

Joinpoint Analysis

In this study, we used the Joinpoint software (version 4.9.1.0) developed by the National Cancer Institute Division of Cancer Control & Population Sciences to calculate annual percent change (APC), average annual percent change (AAPC), and its 95% CI of the ASIR, ASMR, and ASDR of GC in Eastern Asia. The Joinpoint software used the Monte Carlo permutation test model optimization method to select the optimal number of joinpoints. Our data used the optimal number of joinpoints recommended by the software for analysis.

Joinpoint regression (selecting the log-linear model: lny=xb), also known as segmented line regression, is a statistical method to analyze trend changes in time series data. This method calculates the APC and its 95% CI for each segment by dividing

XSL•FO
RenderX

the long-term trend line into a number of segments to describe the time series trend by sex in Eastern Asia countries. Based on the trend of the APC, the AAPC was then computed. An upward trend is indicated when both the APC or AAPC estimate and its 95% CI upper and lower bounds are greater than 0. Alternatively, a downward trend occurs if both the APC or AAPC estimate and its 95% CI upper and lower bounds are less than 0.

Age-Period-Cohort Analysis

We used age-period-cohort modeling based on the Poisson distribution to assess the connections between age, period, and birth cohort with GC mortality [14], as an individual's birth cohort is evaluated using the time period of death and the individual's death age (birth cohort=period-age).

However, the age-period-cohort analysis experiences unidentifiable issues, so we used the intrinsic estimation method to estimate the age, period, and cohort effects. These estimates were validated with the use of the estimation function of the age-period-cohort network analysis tool developed by the National Cancer Institute.

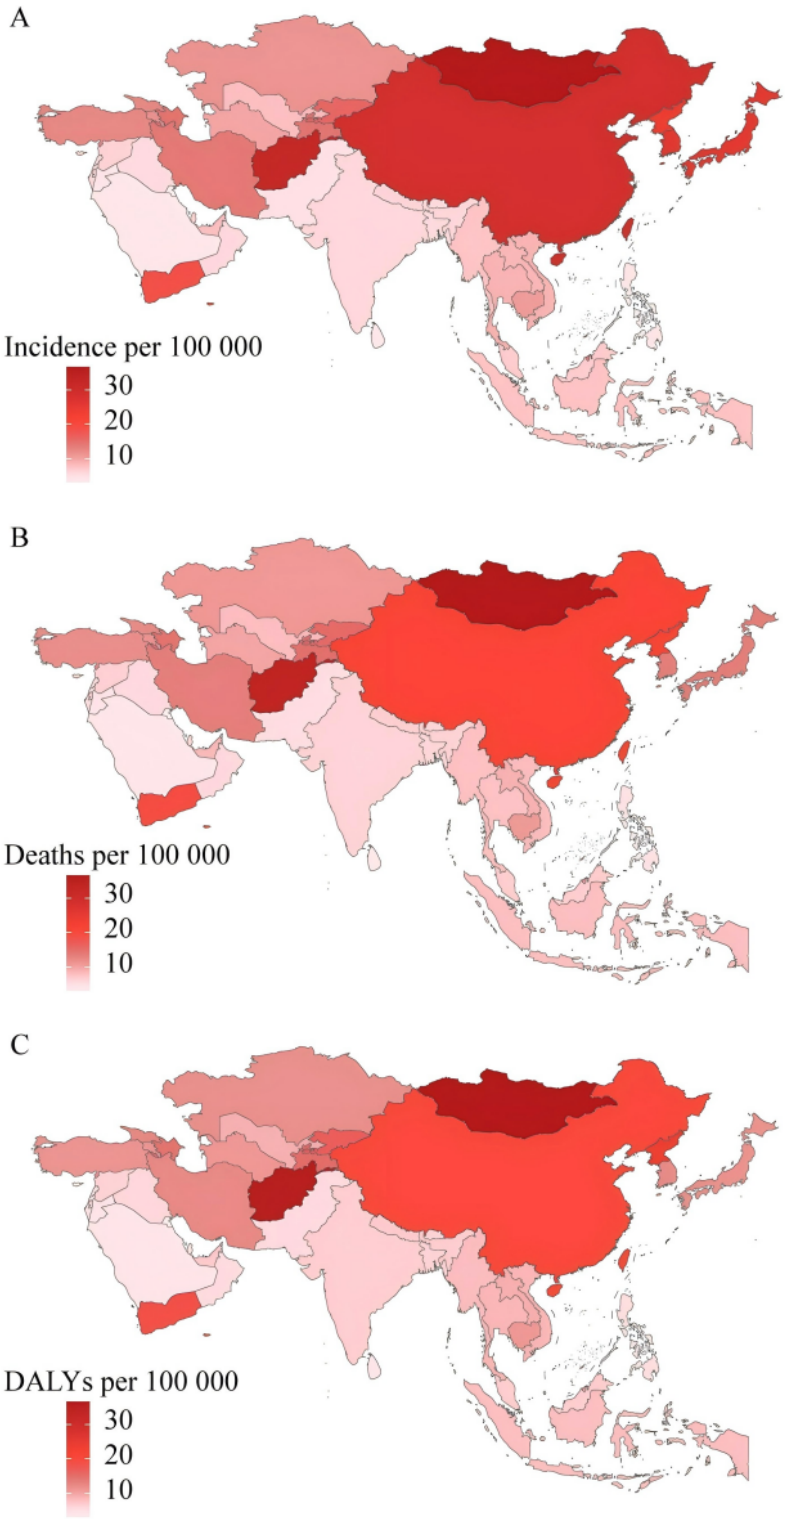
The estimable functions contained the longitudinal age curve, period or cohort relative risk (RR), and net or local drift. The longitudinal age curve shows the expected age-specific rate in a reference cohort adjusted for period effects. The period or cohort RR would be the relative death risk after being adjusted for age and nonlinear effects in a period or cohort compared with the reference period or cohort. Net and local drift indicate APC in all age groups and each age group, respectively.

Bayesian Age-Period-Cohort Analysis

For projecting future disease burden, the Bayesian age-period-cohort (BAPC) model provides the highest coverage and greater accuracy compared to other models [15,16]. The age-period-cohort model was used to assess the age, period, and cohort effects on GC mortality in Eastern Asia, and the BAPC model was used to estimate GC mortality from 2021 to 2035. The forecast was conducted using the BAPC model within the integrated nested Laplacian approximation (R packages BAPC and INLA) to adjust for overdispersion by assuming an inverse γ prior distribution for age, period, and cohort effects (modeled by a second-order random walk [RW2]) [17] .

The R software package (version 4.4.1; R Foundation for Statistical Computing) and JD_GBDR (version 2.22; Jingding Medical Technology Co, Ltd) were used for graphical drawing in this study. A 2-sided *P* value of .05 or less was used to define statistical significance.

Results



Burden of GC in 2021

In 2021, there were 748,235 new cases of GC and 527,054 deaths in Eastern Asia, with DALYs of 12.1 million, accounting for 60.8% (748,235/1230,232) new cases and 55.2% (527,054/954,373) deaths reported globally. Among the countries in Eastern Asia, the ASIR for GC was highest in Mongolia (36.8, 95% UI 29.4-45.3 per 100,000), the second was China (29.1, 95% UI 22.4-36.2 per 100,000), followed by South Korea, Japan, and North Korea (Figure 1A and Multimedia Appendix 1). The ASMR for GC was highest in Mongolia (37.4, 95% UI 29.4-45.9 per 100,000), followed by North Korea (21.6, 95% UI 16.4-27.1 per 100,000), China, South Korea, and Japan (Figure 1B and Multimedia Appendix 2). The highest ASDR for GC was Mongolia (930.4, 95% UI 747.5-1157.9 per 100,000), followed by North Korea (585.7, 95% UI 437.3-748.5 per 100,000), China, South Korea, and Japan (Figure 1C and Multimedia Appendix 3). Taiwan (Province of China) had the lowest ASIR (11.5, 95% UI 10.2-12.7 per 100,000), ASMR (8.9, 95% UI 7.8-9.8 per 100,000), and ASDR (193.7, 95% UI 174.5-213.3 per 100,000) deserve mentioning.

In Eastern Asia, the burden of GC was greater in the male population than the female population, including incidence, mortality, and DALYs. It is worth noting that the burden of GC was higher in the female population than the male population at age 90 years and older in Japan, 85 years and older in South Korea, and 75 years and older in North Korea. This phenomenon was caused by the different changes of incidence, mortality, and DALYs in the male and female population. For example, the incidence, mortality, and DALYs of GC rose with age among the female population, while the male population reached a peak and began to decline at 90 - 94 years in Japan (Figure 2).

Trend of GC Burden From 1990 to 2021

The results of the joinpoint regression analysis indicated that GC incidence, mortality, and DALYs in Eastern Asia showed trends of decrease from 1990 to 2021, where similar trends were noted. However, there was significant heterogeneity in the temporal trends across countries (Table 1 and Figure 3). South Korea presented the highest absolute AAPC values for incidence, mortality, and DALYs, which represented that ASIRs, ASMRs, and ASDRs experienced the greatest declines in Eastern Asia. For example, the mortality of GC for both sexes dropped from 55.4 (95% UI 44.1-62.4) per 100,000 to 13.3 (95% UI 10.9-16.5) per 100,000 between 1990 and 2021 in South Korea, with the AAPC of −4.5 (95% CI −4.8 to −4.3). Notably, South Korea experienced the most rapid decline in GC mortality between 1998 and 2007, with the APC of −6.1 (95% CI −6.3 to −5.9). However, this trend decelerated subsequently, resulting in the APC of −0.5 (95% CI −3.2 to 2.4) between 2019 and 2021. In Japan, ASIR, ASMR, and ASDR also showed downward trends, but the absolute AAPC was smaller than that of South Korea, and the AAPC of ASMR was −3.0 (95% CI −3.2 to −2.8). From 1990 to 2021, ASIR, ASMR, and ASDR in China presented decreasing trends, and the AAPC of ASMR was −2.4 (95% CI −2.6 to −2.3). During the period from 1998 to 2004, this trend maintained stable or increased slightly, followed by the most rapid decline between 2004 and 2007, with the APC of −6.2 (95% CI −7.3 to −5.1), and the APC was −2.0 (95% CI −2.3 to −1.7) between 2015 and 2021.

The overall trend of ASIR, ASMR, and ASDR in North Korea remained stable between 1990 and 2021, AAPC of ASMR was −0.8 (95% CI −0.8 to −0.8). The mortality of GC for both sexes changed from 27.8 (95% UI 20.5-35.6) per 100,000 to 21.6 (95% UI 16.4-27.1) per 100,000 between 1990 and 2021 in North Korea, increased rank across countries. ASIR, ASMR, and ASDR of GC in Mongolia increased significantly from 1990 to 1992, then showed stability between 1992 and 1997 and declined slightly from 1997. In Mongolia, the ASMR of GC showed an overall slight decreasing trend for both sexes combined from 1990 to 2021 (AAPC −1.4, 95% CI −1.7 to −1.0), and Mongolia had the highest burden of GC among Eastern Asia in 2021. The ASIR, ASMR, and ASDR of GC in Taiwan (Province of China) were the lowest between 1990 and 2021. Although ASMR showed slight upward trends between 1994 and 1997, the overall trends were downward.

Age-Specific Mortality Rates for GC

We arranged the mortality and population data into consecutive 5-year periods from 1992 - 1996 (median 1994, IQR 1993-1995) to 2017 - 2021 (median 2019, IQR 2018-2020) and 22 consecutive birth cohorts, including those born from 1895 - 1899 (median 1897, IQR 1896-1898) to 2000 - 2004 (median 2002, IQR 2001-2003). The results showed a declining trend in GC mortality among Eastern Asia during the period from 1992 - 1996 to 2017 - 2021.

The mortality rate of GC in South Korea, North Korea, and Japan basically increased with the age group, while in China, Taiwan (Province of China), and Mongolia, the mortality rate of GC reached the peak around the age of 90 years, then decreased (Figure 4A). Eastern Asia showed a generally decreasing trend of GC mortality across birth cohorts, but old age groups in some countries showed an increase and then a decrease, indicating a relatively lower risk of GC mortality in cohorts born more recently (Figure 4B). For example, the mortality rate of GC in China decreased in 60 - 64 years of age (median 62 years of age, IQR 61-63) across the periods of 1994, 1999, 2004, 2009, 2014, and 2019, with 138.0, 122.4, 116.4, 96.8, 74.6, and 64.4 per 100,000. In successive birth cohorts, the GC mortality rate gradually decreased in 60 - 64 years of age (median 62 years of age, IQR 61-63).

XSL•FO
RenderX

Figure 4. Age-specific mortality rates of gastric cancer (GC) by period and cohort-specific mortality rate of GC by age group in Eastern Asia, 1992 - 2021. (A) Survey years were arranged into consecutive 5-year periods and describe the relationship between GC mortality rates and age group. (B) The GC mortality rates were arranged into 22 consecutive birth cohorts and describe the relationship between GC mortality rates and birth cohorts.

Net Drift and Local Drift in Different Age Groups

Net drift refers to the overall APC across the whole study period, while local drift refers to the APCs in the mortality rate for each age group relative to net drift (Table 2). The results of net drift showed that GC mortality had a downward trend in Eastern Asia, with the greatest reduction in South Korea and the smallest in North Korea. In China and Mongolia, mortality of the female population decreased more than the male population; nevertheless, there were fewer substantial reductions in mortality among the female population than the male population in South Korea. Local drift showed that the most significant decrease in mortality was in the 25 - to 29-year age group for the male population in Korea (−7.3%, 95% CI −9.2 to −5.4), with the decline slowing as age groups increased. For the female population, the most pronounced decline seen was in the 65 - to 69-year age group (−7.1%, 95% CI −7.5 to −6.8). Among the female population in Mongolia, the mortality rate decreased more in age groups younger than 75 years, but the mortality rate of the male population showed little decline in all age groups.

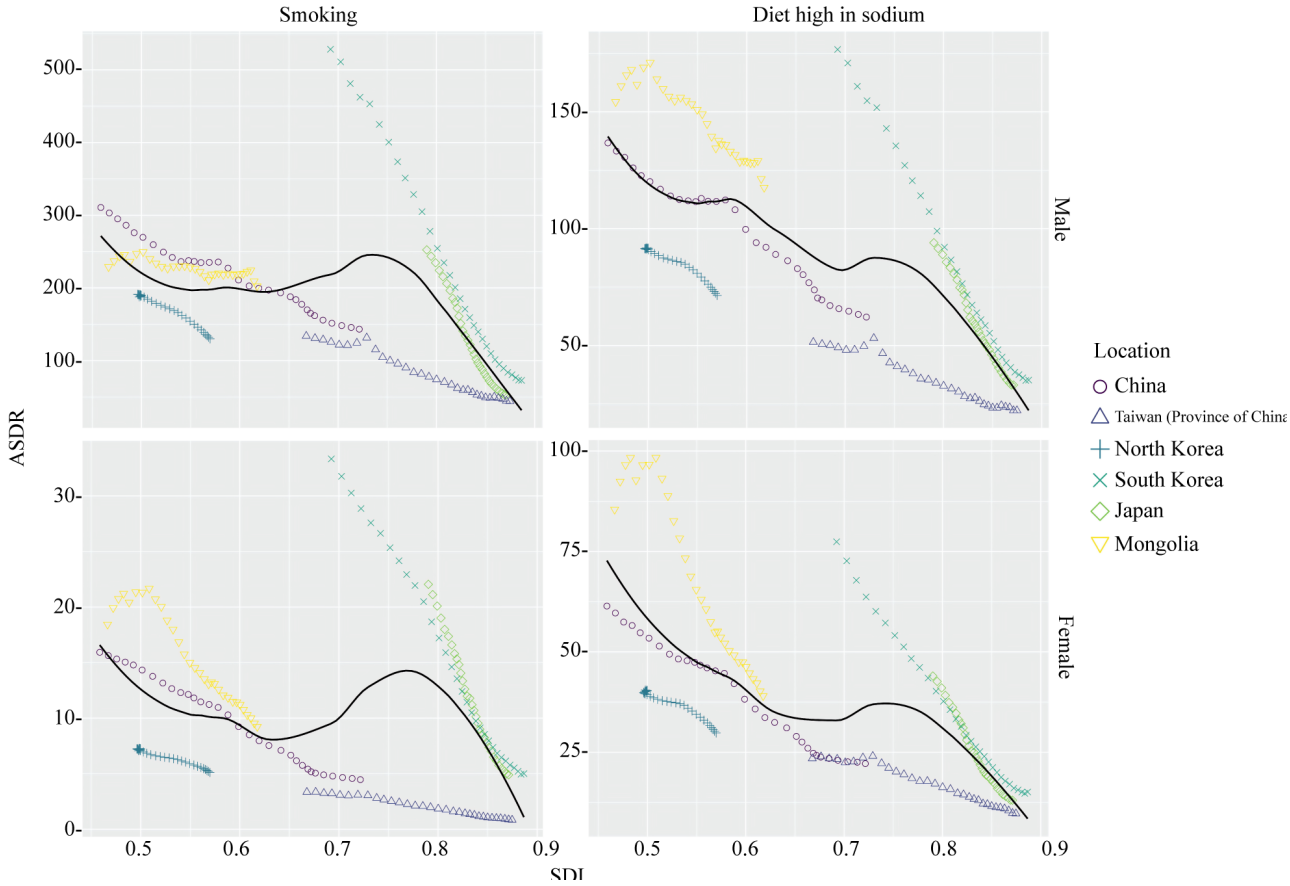
Age-Period-Cohort Effects on GC Mortality

Multimedia Appendix 4 shows the effect of age, period, and cohort on GC in Eastern Asia. With advancing age, the RRs of GC mortality increased in Eastern Asia, while the mortality rate of GC in Korea increased slowly with age. In Mongolia, the highest mortality rate was in the 80 - to 84-year age group, followed by a significant downward trend. Period and cohort effects in Eastern Asia tended to show similar trends. In Eastern Asia, the risk of GC mortality decreased compared with the control period set, indicating improvement in the health status of the whole population during the study period. The greatest improvement was in South Korea. In all birth cohorts, the most significant improvement compared to the reference cohort occurred among those born in South Korea before 1950. For the older cohorts, Taiwan (Province of China), China, and Japan all showed favorable improvements, while the improvement trends in North Korea and Mongolia were not evident. Among those born after 1950, there was an improvement trend in Eastern Asia, also with South Korea showing the most significant improvement, followed by Japan and China.

DALYs From GC Attributable to Risk Factors



The percentage of age-standardized DALYs attributable to high-sodium diets and smoking in Eastern Asia is shown in Multimedia Appendix 5. There was no significant change in the population attributable scores for the high-sodium diets factor in 2021 compared to 1990. The ASDRs attributed to smoking among the female population in Eastern Asia were decreasing, and the proportion was not high, all being less than 5%. For the male population, the ASDRs attributed to smoking increased in Mongolia, showed no significant change in China, and showed downward trends in Japan, South Korea, North Korea, and Taiwan (Province of China). Among them, Japan declined the most, dropping from 22.4% (95% UI 18.4-26.8) in 1990 to 13.3% (95% UI 10.9-15.9) in 2021. In 2021, the ASDRs attributed to smoking were the highest at 19.1% (95% UI 16.1-22.2) for the male population in China.

In Eastern Asia, the ASDRs for GC attributed to both factors showed overall downward trends with increasing SDI (Figure 5). As SDI increased year on year, from middle-high SDI in 1990 to high SDI in 2021, the ASDRs for both factors in Japan and South Korea decreased most rapidly. In Taiwan (Province of China), the rates of decline were slower because the ASDRs for both factors were already at relatively low levels in 1990.

XSL•FO
RenderX

Between 1990 and 2021, as China moved from low-middle SDI to middle-high SDI, the ASDR for smoking and high-sodium diets declined relatively rapidly. In Mongolia, from 1990 to 2021, as the SDI transitioned from low-middle to middle level, the impact of smoking on male ASDR showed no significant improvement trend, while other factors demonstrated more noticeable trends of improvement. In North Korea, although the SDI increased between 1990 and 2021, it remained within the low-middle SDI level, and the reductions in both factors were relatively small.

Figure 5. ASDR per 100,000 population for gastric cancer attributable to each risk factor for Eastern Asia by SDI, 1990 - 2021. Expected values based on SDI and ASDR in all locations are shown as the black line. For each region, points from left to right depict estimates from each year from 1990 to 2021. ASDR: age-standardized disability-adjusted life year rate; SDI: sociodemographic index.

Projections of GC Mortality Trends

The projections of GC ASMR trends for the male and female population in Eastern Asia from 2022 to 2035 are shown in Multimedia Appendix 6. The results showed that the ASMR of GC for both male and female populations in Eastern Asia will continue to decrease, with the ASMR remaining higher in the male population than in the female population by 2035. Because the baseline is low, the decrease in GC mortality in Japan will be modest, with the ASMR for the female population decreasing from 7.7 (95% CI 7.6-7.8) per 100,000 in 2021 to 4.2 (95% CI 3.7-4.8) per 100,000 in 2035. In Japan, the rate of GC mortality in the male population is projected to decrease from 20.3 (95% CI 20.1-20.5) per 100,000 in 2021 to 11.1 (95% CI 10.1-12.1) per 100,000 in 2035, showing a greater decrease than that observed in the female population.

In China, GC mortality was projected to drop significantly, particularly for the female population, from 12.1 (95% CI 12.1-12.2) per 100,000 in 2021 to 6.9 (95% CI 5.5-8.3) per 100,000 by 2035. Nevertheless, GC mortality in Mongolia was expected to decrease slowly. The mortality rate of GC among the Mongolian female population will decrease from 22.6 (95% CI 20.9-24.2) per 100,000 in 2021 to 13.6 (95% CI 10.1-17.1) per 100,000 in 2035. In the male population among Mongolia, the ASMR will decrease from 59.4 (95% CI 56.8-62.0) in 2021 to 51.6 (95% CI 46.1-57.1) in 2035. It is predicted that the burden of GC among the Mongolian male population will remain the highest in Eastern Asia by 2035.

Discussion

Principal Findings

GC has long been a significant global health concern, with Eastern Asia standing out as a critical area for investigation due to its disproportionately high disease burden and distinct epidemiological characteristics. Comprising multiple countries, Eastern Asia shares certain cultural and dietary habits as well as some common genetic background elements. These intertwined factors play a vital role in the incidence and mortality of GC. Investigating the incidence, mortality, and DALYs due to GC in Eastern Asia is essential for dissecting the variation in epidemiological trends and underlying mechanisms among different countries and population subgroups. It not only provides evidence for public health

XSL•FO
RenderX

decision makers to allocate resources more rationally but also formulates more effective strategies in prevention, screening, and treatment. In this study, we analyzed trends in mortality and ASMR of GC across Eastern Asia from 1990 to 2021 using data from the GBD and predicted the disease burden in 2035 that aimed to explore its spatiotemporal distribution patterns and identify potential intervention entry points, thereby laying a scientific theoretical foundation and practical guidance for reducing the burden of GC in this region.

In 2021, GC of Eastern Asia accounted for 53.2% (12,130,950/22,786,633) of total global DALYs, underscoring its substantial public health impact. Among the countries, Mongolia reported the highest ASIR, ASMR, and ADSR for GC, while Taiwan (Province of China) exhibited the lowest rates. These findings align with geographical distribution patterns in Eastern Asia previously noted in the 2019 GBD database [18]. GC presented a significantly greater risk to the male population compared to the female population in Eastern Asia, with the Chinese male population exhibiting the highest sex ratio of 2.4. This disparity was likely attributable to variations in lifestyle, environmental exposures, and genetic predispositions. The incidence, mortality, and DALYs of GC increased with age across both sexes, though the male population consistently exhibits higher rates—except in specific older age brackets, such as individuals older than 75 years in North Korea, older than 85 years in South Korea, and older than 90 years in Japan. These may be related to the protective effect of endogenous estrogen [19], so postmenopausal women were more at risk of GC. From 1990 to 2021, mortality rates for GC decreased across all of Eastern Asia. Analysis based on the AAPC revealed that declines in incidence and mortality were more pronounced in higher SDI countries, suggesting that economic development and health care improvements played pivotal roles in reducing GC disease burden.

However, the decline in incidence and mortality was not uniform across the countries. The steepest reduction was observed in South Korea, where mortality rates fell by 76% from 1990 to 2021. The local drift indicated the most significant decrease occurred within the 25 - to 29-year age group among the male population in South Korea (−7.3%, 95% CI −9.2 to −5.4). Japan demonstrated the second-largest decline, with a 60.9% reduction. South Korea and Japan reflected successful experience in GC prevention and control. These findings highlight the potential for other countries to adopt similar strategies to achieve comparable outcomes. In China, GC mortality decreased by 53%, with the joinpoint analysis revealing a more significant decline from 2015 to 2021 (APC −2.0, 95% CI −2.3 to −1.7) compared to South Korea and Japan. Although mortality rates have declined, GC in North Korea has risen in ranking across Eastern Asia, and mortality rates reached 21.6 per 100,000 population. Meanwhile, Mongolia experienced a 33.7% decrease in mortality; yet, it continues to bear the world's highest GC mortality rate at 38.2 per 100,000 population. This alarming statistic highlights the need for enhanced prevention strategies and early detection programs in Mongolia. In contrast, Taiwan has consistently maintained a lower burden, with a 54.2% reduction in GC mortality, reaching 8.86 per 100,000 population in 2021. The intrinsic estimation method was used to estimate the age, period, and cohort effects on Eastern Asia, which showed a generally decreasing trend of GC mortality in consecutive birth cohorts. Age-period-cohort analysis indicated a relatively lower risk of mortality from GC in individuals born in more recent cohorts. This pattern suggests that the decline in GC mortality is not only due to the improvement in medical treatment and early detection but also to the changes in lifestyle and dietary habits over the past few decades. The implementation of public health policies aimed at reducing the prevalence of *H. pylori* infection and the promotion of a balanced diet rich in fruits and vegetables may have contributed to this positive trend. Projections suggest a continued significant decrease in GC burden across Eastern Asia by 2035, although the Mongolian male population is expected to maintain the highest rates.

Our study showed that reductions in GC mortality across Eastern Asia have been driven by improved socioeconomic conditions, changes in key risk factors, and the introduction of cancer screening programs. The population-attributable scores for the high-sodium diet factor remained relatively unchanged in 2021 compared to 1990, maintaining a level of approximately 8% across all countries in Eastern Asia. However, the ASDR of GC from high-sodium diets decreased by 18.2% globally between 2007 and 2017 [20]. Therefore, it is pertinent to investigate the reasons underlying the lack of a downward trend in this risk factor across Eastern Asia over the past 3 decades. The WHO states that high-sodium diets raise the risk of GC [21]. It works by damaging the gastric mucosa with high salt concentrations, increasing susceptibility to *H. pylori* colonization and promoting gastric epithelial cell apoptosis in synergy with N-nitroso compounds and carcinogens [22]. A meta-analysis indicated that the risk of GC was increased by 12% per 5 g per day increment of dietary salt intake [23]. Traditional East Asian diets are high in salt when cooked or seasoned; despite countries having introduced policies to reduce salt intake, further efforts are needed. For example, sodium intake has decreased in South Korean people from 2012 but remains well above intake targets [24]. South Korean people consumed an average of 3.3 g of sodium daily in 2018, exceeding the WHO recommendation by over 1.5 times [25]. According to the data from the Korea National Health and Nutrition Examination Survey, the primary dietary sources of sodium intake among the South Korean people are salt, kimchi, and soy sauce, with daily kimchi consumption at 96.3 g [24]. In 2012, Japan formulated Health Japan 21 (the second term), with a target of consuming less than 8.0 g of salt per day [26]. However, the latest 2019 data showed that the average consumption was 9.7 g [27], well above the 5.0 g recommended by the WHO [21]. In Japan, sodium mainly comes from seasonings like soy sauce, table salt, and miso, as well as processed foods [26]. Sodium intake in China decreased from 6.3 g per day in 1991 to 4.1 g per day in 2015; yet, it remained twice the WHO's recommended limit. In 2015, over 67% of sodium intake came from salt used in cooking [28]. In Eastern Asia, it is important to enhance nutrition education and develop low-sodium seasonings while improving food preservation methods to reduce sodium intake [29].

Smoking presented different attributable patterns for GC development. For the male population, the ASDRs attributed

XSL•FO
RenderX

to smoking increased in Mongolia, showed no significant change in China and North Korea, and showed downward trends in Japan, South Korea, and Taiwan (Province of China). For the female population, smoking-related ASDRs decreased across Eastern Asia, even though the proportion was less than 5%. The Basic Plan to Promote Cancer Control programs, including tobacco control, was launched in 2017 in Japan [27]. Smoking prevalence among Japanese people has been decreasing gradually since 2004; it was 27.1% for the male population and 7.6% for the female population in 2019 [27]. Similarly, Taiwan (Province of China) implemented the Tobacco Hazards Prevention Act in 2009, reducing smoking prevalence in adults older than 40 years of age from 12.25% in 2001 to 8.18% in 2013 [30]. In contrast, after implementing various tobacco control measures, China reduced age-standardized smoking prevalence among men by 22.4%; it was still 37.5% in 2015 [31]. Smoking is an established cause of GC and was categorized as a class I carcinogen by the IARC [32]. Smoking significantly elevated GC risk, with meta-analyses indicating RRs of 1.30 (95% CI 1.23 - 1.37) for current smokers and 1.53 (95% CI 1.44 - 1.62) for former smokers compared to never-smokers [33]. The risk of GC intensified with increased smoking dosage and reached an RR of 1.69 for individuals smoking 20 cigarettes per day [33]. Another meta-analysis also confirmed this conclusion, with RRs for male and female population being 1.61 (95% CI 1.49-1.75) compared to those who never smoked [34]. Indeed, 16.5% of male and 1.9% of female patients with GC were estimated to be attributable to smoking globally in 2020 [35]. Consequently, it is imperative to enhance policy formulation and implementation to effectively achieve the objective of reducing smoking prevalence by 2030 [31].

As the proportion of DALYs attributed to high-sodium diet and smoking was not high, there were still risk factors outside the GBD data, such as *H. pylori* infection. The interaction between smoking and *H. pylori* infection further amplifies GC risk. For example, a 22.3-year follow-up study in Linqu County, a high-incidence area for GC in China, revealed that smoking significantly elevated the risk of GC incidence (odds ratio 1.72) and mortality (hazard ratio 2.01), but only among those infected with *H. pylori* [4]. This finding suggested a synergistic interplay between smoking and *H. pylori* infection in the pathogenesis of GC, underscoring the imperative for *H. pylori* eradication as a cornerstone of prevention, particularly in populations with high smoking prevalence. *H. pylori*, classified as a group I carcinogen by the IARC, remains a pivotal driver of GC. Notably, the cytotoxin-associated gene A positive strains of *H. pylori* in Eastern Asia are linked to a substantially greater risk of GC compared to Western populations [36]. Substantial evidence indicated that the eradication of *H. pylori* can reduce GC incidence by 46% (RR 0.54) in the general population and can also prevent progression in patients with mild to moderate atrophic gastritis [37,38]. The rs9607601 variant in the 22q13.1 region is associated with BAIAP2L2 expression, which is significantly overexpressed in GC tissues. BAIAP2L2 promotes the activation of the AKT/mTOR and Wnt/β-catenin pathways and may be involved in the development and progression of GC. Individuals carrying the rs9607601 T allele exhibit more pronounced therapeutic effects against *H. pylori* infection [39]. In 2015, the prevalence of *H. pylori* infection in Mongolia was strikingly high at 74.1%, surpassing rates in China (55.8%), Japan (51.7%), and South Korea (53.9%) [16]. Taiwan (Province of China) government launched an *H. pylori* eradication program and showed a strong association between the number of patients treated with *H. pylori* treatment and ASIR of GC (r=0.72) from 2005 to 2016 [30]. These results emphasize the need for targeted public health strategies in high-risk regions, focusing on smoking cessation, *H. pylori* screening and treatment, and sodium intake reduction to reduce the burden of GC.

Endoscopic screening represents a critical intervention for early detection and treatment of GC, with well-documented efficacy in high SDI countries such as Japan and South Korea. In Japan, nationwide GC screening began in the 1960s using radiography, evolving into a national program by 1983. Endoscopic screening was incorporated into the Japanese Guidelines for Gastric Cancer Screening in 2008, with biennial screening for individuals aged 50 years and older becoming the gold standard [40]. Hamashima et al [41] reported a significant reduction in mortality among the endoscopic screening cohort in Japan, with ASMR of 0.43 (95% CI 0.30-0.57). Similarly, in South Korea, the National Cancer Screening Program (NCSP), launched in 2001, offers biennial endoscopic or radiographic screening for individuals aged 40 years and older. NCSP started with free GC screening for Medical Aid recipients, then included lower-income NHI beneficiaries in 2005, and screenings are offered at 10% cost to the upper-income bracket thereafter. By providing low-cost or free screening options, the NCSP achieved high participation rates, contributing to a notable decline in GC mortality and an increase in the 5-year survival rate, which now surpasses that of Japan [40]. Jun et al [42] demonstrated that individuals who underwent endoscopic screening experienced a 21% lower risk of GC mortality compared to those who were not screened. Notably, frequent endoscopic examinations yielded a dose-dependent reduction in mortality, with odds ratios of 0.60, 0.32, and 0.19 for 1, 2, and 3 or more screenings, respectively [42]. The latest synthetic control study showed that the average RRs were 0.83 (95% CI 0.71-0.96) for GC mortality in South Korea. The RR reached 0.59 by the 15th year after the initiation of nationwide screening, while for Japan, the average RRs were 0.97 (95% CI 0.88-1.07) for GC mortality [43]. The benefits of South Korea's countrywide GC screening were evident, but the success of Japan's program was uncertain. Other countries in Eastern Asia could look to the experiences of South Korea and Japan as a reference.

It is worth mentioning that in China, since the inception of the National Key Public Health Projects in 2005, endoscopic screening programs have been implemented across more than 110 high-risk regions. Therefore, the mortality rate of GC in China increased slightly from 1998 to 2004 but had resumed the downward trend since 2005. China developed cancer screening guidelines of GC in 2022 on the basis of studies within the Chinese population [44]. Recent evidence from the National Cancer Center's multicenter cohort study in China (2005 - 2015) demonstrated that a single endoscopic screening significantly reduced the incidence and mortality of esophageal and noncardia GC as well as the mortality from cardia cancer, particularly among individuals aged 40 - 69 years [45]. The local drift of this study showed that the mortality rate of the age group 40 - 69

XSL•FO
RenderX

years decreased more than that of other age groups in China. Moreover, findings from Peking University Cancer Hospital's research in Linqu County confirmed that endoscopic screening not only reduced the risk of invasive GC but also improved 5-year survival rates [46]. Repeated screenings further amplified these benefits, and the risk of GC death decreased more significantly in the repeat screening group than in the 1-time screening group. In addition, for individuals with a prior diagnosis of intestinal metaplasia or low-grade intraepithelial neoplasia, repetitive screening within 2 years can significantly improve the detection rate of early GC [46]. These findings underscore the importance of optimizing screening protocols, including the frequency and target population, to enhance early detection and treatment outcomes. Although China started GC screening later than South Korea and Japan, it has implemented effective screening programs and *H. pylori* prevention and treatment strategies and targeted attention to high-risk individuals. Therefore, the mortality of GC in China is expected to decrease significantly by 2035. However, although GC screening has been conducted for decades, it still faces some challenges. First, the coverage of GC screening remains relatively limited, and the compliance of target populations with screening is relatively low. Second, the quality of screening technologies varies significantly, and the process of screening, early diagnosis, and treatment is not sufficiently smooth.

Mongolia, where GC is the leading cause of cancer-related mortality, presents unique epidemiological challenges. The age of GC diagnosis is approximately a decade earlier than in other Eastern Asia countries, and projections indicate that Mongolia will remain the highest GC burden in Eastern Asia by 2035. Mongolia has a high prevalence of *H. pylori* infection significantly increasing the risk of GC [47]. In addition, dietary and lifestyle factors such as the consumption of excessively hot foods and beverages, a red meat-dominant diet, and frequent consumption of reheated leftovers may all exacerbate gastric carcinogenesis. Alarmingly, over 80% of GC cases in Mongolia are diagnosed at advanced stages, resulting in poor survival outcomes [48]. Addressing this pressing public health challenge will require a multifaceted approach, including public education campaigns to improve awareness about GC, increased access to affordable endoscopic screening, and enhanced health care infrastructure to facilitate timely diagnosis and treatment. The low level of socioeconomic development is a potential risk factor affecting the incidence and prognosis of GC [49]. As Mongolia is still considered to have a middle SDI, it is necessary to increase medical security to reduce the burden of GC. Encouragingly, the Mongolian government launched a nationwide noncommunicable disease screening program in 2019 [48], which holds promise for mitigating the rising burden of GC.

Strengths and Limitations

Our study has some strengths, including the ability to visually display the risk of GC in Eastern Asia and its territories through risk area classification. This study has several limitations. First, the availability and quality of raw data restricted our ability to estimate the disease burden and the risk-attributed GC burden to a certain extent. Second, GCs exhibit heterogeneity in their pathogenesis, pathological characteristics, and epidemiological trends. We are unable to distinguish these subtypes for detailed statistical analysis.

Conclusions

This analysis represents the first comprehensive evaluation of the GC burden in Eastern Asia using the latest GBD data. While ASIR, ASMR, and ASDR have declined over the past 3 decades, the absolute number of new cases, deaths, and DALYs attributable to GC has increased due to population growth and aging. These epidemiological trends highlight the enduring public health challenge posed by GC in Eastern Asia. To combat this burden effectively, a dual focus on primary and secondary prevention is paramount. Interventions should prioritize modifiable risk factors, including improved hygiene, dietary changes (eg, reduced sodium intake and increased consumption of fruits and vegetables), and the widespread adoption of *H. pylori* eradication strategies. Concurrently, enhanced screening programs and early diagnostic interventions must be implemented to achieve substantial reductions in mortality and improve survival outcomes. In the future, it is necessary to improve the detection rate of GC screening by accurately stratifying and identifying high-risk populations for GC. Artificial intelligence–assisted diagnostic technology and high-quality endoscopic examination are crucial for accurate diagnosis [50].

Abstract

Background: The noninvasive imaging examinations of mammography (MG), low-dose computed tomography (CT) for lung cancer screening (LCS), and CT colonography (CTC) play important roles in screening for the most common cancer types. Internet search data can be used to gauge public interest in screening techniques, assess common screening-related questions and concerns, and formulate public awareness strategies.

Objective: This study aims to compare historical Google search volumes for MG, LCS, and CTC and to determine the most common search topics.

Methods: Google Trends data were used to quantify relative Google search frequencies for these imaging screening modalities over the last 2 decades. A commercial search engine tracking product (keywordtool.io) was used to assess the content of related Google queries over the year from May 1, 2022, to April 30, 2023, and 2 authors used an iterative process to agree upon a list of thematic categories for these queries. Queries with at least 10 monthly instances were independently assigned to the most appropriate category by the 2 authors, with disagreements resolved by consensus.

Results: The mean 20-year relative search volume for MG was approximately 10-fold higher than for LCS and 25-fold higher than for CTC. Search volumes for LCS have trended upward since 2011. The most common topics of MG-related searches included nearby screening locations (60,850/253,810, 24%) and inquiries about procedural discomfort (28,970/253,810, 11%). Most common LCS-related searches included CT-specific inquiries (5380/11,150, 48%) or general inquiries (1790/11,150, 16%), use of artificial intelligence or deep learning (1210/11,150, 11%), and eligibility criteria (1020/11,150, 9%). For CTC, the most common searches were CT-specific inquiries (1800/5590, 32%) or procedural details (1380/5590, 25%).

Conclusions: Over the past 2 decades, Google search volumes have been significantly higher for MG than for either LCS or CTC, although search volumes for LCS have trended upward since 2011. Knowledge of public interest and queries related to imaging-based screening techniques may help guide public awareness efforts.

Introduction

Worldwide, an estimated 20 million new cancer diagnoses and 9.7 million deaths occurred in 2022. The 3 most common types of newly diagnosed malignancies were lung cancer (12.4%), female breast cancer (11.6%), and colorectal cancer (9.6%). Lung cancer and colorectal cancer were the most common causes of cancer-related mortality, with breast cancer in fourth place after liver cancer [1]. Noninvasive imaging, such as mammography (MG), low-dose computed tomography (CT) for lung cancer screening (LCS), and CT colonography (CTC), plays important roles in the early detection of the most common cancer types and has demonstrated efficacy in reducing cancer-related and all-cause mortality rates [2,3]. Encouraging results from large screening trials in several countries [4-6] have

XSL•FO
RenderX

driven global interest in imaging-based lung, breast, and colorectal screening [7-12] and have prompted efforts to initiate and optimize screening worldwide [13-15].

A 2013 Pew Research Center survey found that 72% of adults had pursued web-based health information over the past year, with 77% performing an initial search using an internet search engine [16]. Analysis of internet search volumes for topics related to these imaging examinations may identify opportunities for improved patient outreach and education. Google search trends have been shown to correlate with both epidemiological data and public interest [17-19]. However, few studies have looked at general search volumes for each screening method [20-22], and to our knowledge no publication has documented a detailed topic-level analysis comparing all 3 types of image-based screening.

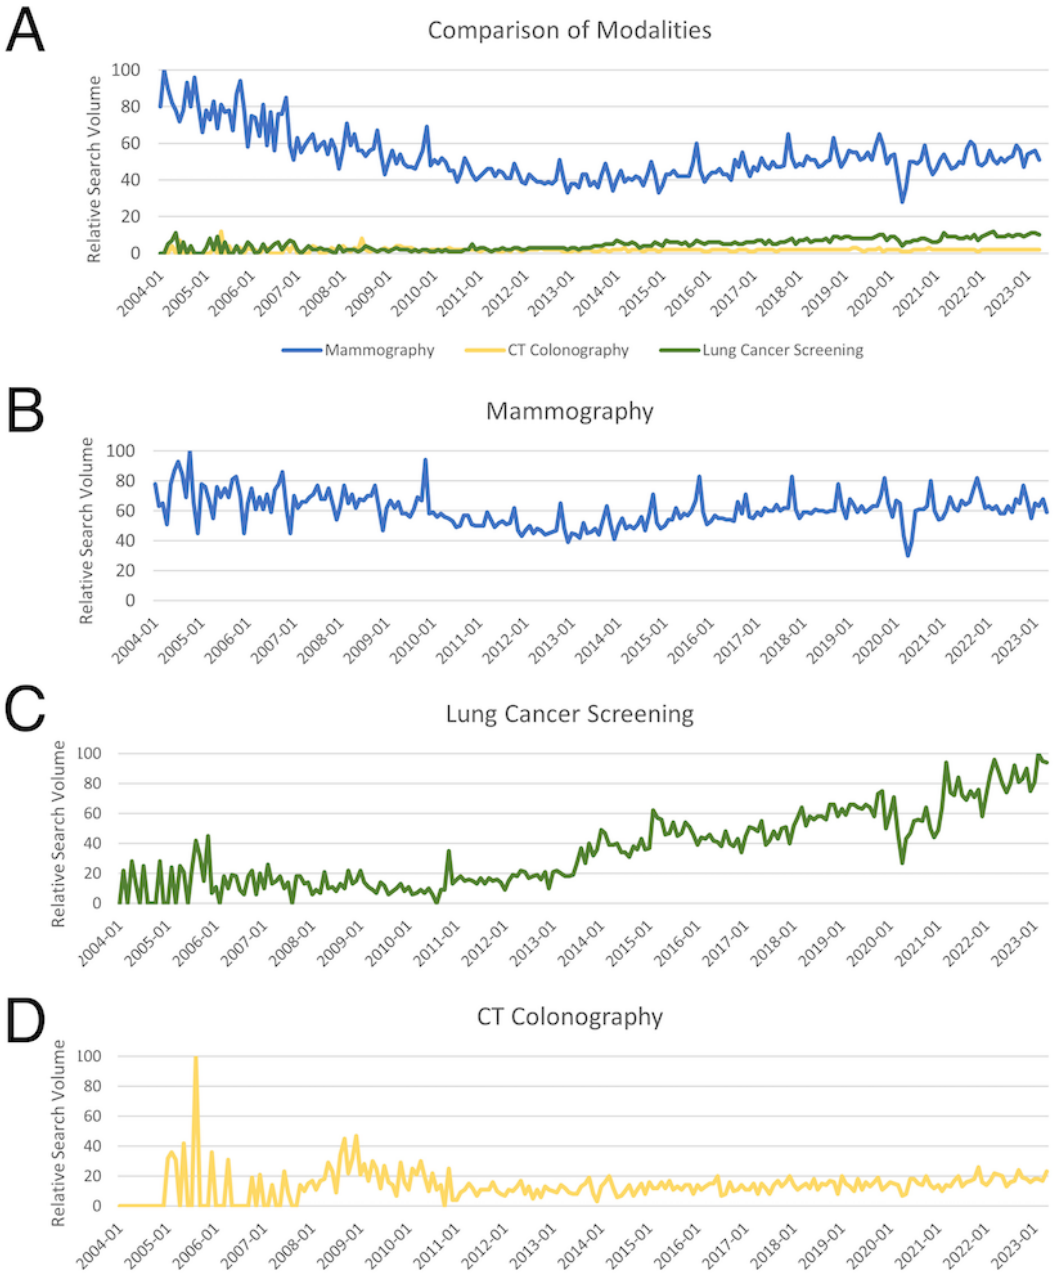
Methods

Overview

Google Trends was used to assess long-term variation in worldwide relative search volumes for the terms "mammography," "lung cancer screening," and "CT colonography" for the period January 1, 2004 (the earliest date for which Google Trends data were retrievable) to April 1, 2023. Google was chosen, as it is the most frequently used internet search engine, consistently capturing more than 80% of the worldwide internet search market [23].

Keyword tool (keywordtool.io), a commercial search engine tracking product, was used to query average volumes of monthly Google searches in English worldwide for the period May 1, 2022, to April 30, 2023 [24]. Keyword tool uses the output of the Google autocomplete tool to extract the most common entries at the search prompt, which made it optimal to use for this study design [24]. All questions and question-like queries entered at the Google search prompt relating to the terms "mammography," "lung cancer screening," and "CT colonography" were extracted. Two of the authors (ZDZ and BPL) used an iterative process to agree upon a list of thematic categories for queries. Search results with at least 10 monthly searches were independently assigned to the most appropriate category by the 2 graders, with disagreements resolved by consensus.

Data Analysis



Search volumes for each screening type were plotted as normalized values (relative search volumes comprising the format of Google Trends data output), with 100 representing the highest relative search volume and 1 representing the lowest, with 0 representing a search volume of zero or insufficient search volume to calculate. Average monthly search volumes for each category were grouped by screening modality and presented in tabular format as the number of searches and as a percentage of total searches for the corresponding modality.

Results

A plot of Google Trends data from 2004 to 2023 comparing MG, LCS, and CTC Google searches is shown in Figure 1. The median 20-year relative search volume was 50 (SD 13; IQR 43-57) for MG, 5 (SD 3; IQR 2-7) for LCS, and 2 (SD 1.2; IQR 1-2) for CTC. On average, the search frequency for LCS was only one-tenth of that for MG, and CTC search volume was only one–twenty-fifth of MG search volume. Search volumes for LCS steadily increased from 2011 to 2023, while searches for MG and CTC plateaued.

XSL•FO
RenderX

Figure 1. Relative worldwide monthly Google search volumes for imaging-based screening examinations. Graph A compares the relative average worldwide monthly search volumes for mammography, lung cancer screening, and CT colonography from January 1, 2004, to April 1, 2023. Graphs B, C, and D illustrate search volumes for the modalities taken independently. All data were obtained from Google Trends for worldwide searches in English. CT: computed tomography.

The relative search volumes for MG alone (Figure 1) across the period ranged from 30 to 100 (median 60; IQR 54-67); there was an overall decrease in relative search volume from the high in 2004 (100) to 2013 (39), followed by an overall increase from 2013 to 2019 (82), with the nadir in 2020 (30) corresponding to the onset of the COVID-19 pandemic. Relative search volumes for LCS alone ranged from 0 to 100; there was an overall decrease in relative search volumes from 2005 (90) to 2010 (0), and a subsequent uptrend after 2011, culminating in a high of 100 in 2019. Relative search volumes for CTC alone ranged from 0 to 100 with the highest volume in 2005, with a secondary peak in 2008 (47), and a plateau from 2010 to 2023 with an average of 14.

XSL•FO
RenderX

Topic analysis using Keyword tool data for the period from May 1, 2022, to April 30, 2023, showed that MG-related topics had the highest total monthly search volume (621,810 searches/month), followed by those related to LCS (23,250 searches/month), and CTC (17,690 searches/month). From these searches, a total of 751 queries classified as questions or question-like queries by the Keyword tool interface were extracted as follows: 442 for MG, 178 for LCS, and 131 for CTC. Of these, 332 had a search volume of >10 per month. The reviewers identified 39, 14, and 11 thematic categories for MG, LCS, and CTC, respectively. The most common categories of queries for MG were nearby screening locations (60,850/253,810, 24%), general inquiries (52,460/253,810, 21%), pain associated with screening (28,970/253,810, 11%), and eligibility criteria (ages) (16,160/253,810, 6%) (Table 1). For LCS, the most frequent categories of queries were CT-specific inquiries (5380/11,150, 48%), general inquiries (1790/11,150, 16%), artificial intelligence (AI) or deep learning use in lung screening (1210/11,150, 11%), screening eligibility criteria (ages or pack-years) (1020/11,150, 9%), and nearby screening locations (750/11,150, 7%) (Table 1). The most common categories of queries related to CTC were CT-specific inquiries (1800/5590, 32%), screening procedural details (1380/5590, 25%), performance compared with colonoscopy (870/5590, 16%), and screening preparation (such as colon preparation and sedation) (720/5590, 13%) (Table 1). Examples of the most common queries for each image-based screening are presented in Table 2.

Table . The table shows examples of the 5 most common inquiries for each imaging-based cancer screening examination from May 1, 2022, to April 30, 2023. All data were obtained from Keyword tool (keywordtool.io) for worldwide searches performed in English.

	Example #1	Example #2	Example #3
Mammography			
Nearest screening locations	"mammography near me"	"mammogram without referral near me"	"mammogram near me now"
General inquires	"what is the mammography"	"why mammography is important"	"mammography versus mammogram"
Pain associated with screening	"is mammography painful"	"do mammograms hurt"	"what does a mammogram feel like"
Cancer imaging characteristics	"mammogramof breast cancer"	"mammography of breast cancer images"	"mammography of fibroadenoma"
Screening eligibility criteria	"mammography at what age"	"when should mammograms be done"	"mammography before 40"
Lung cancer screening			
CT[a]-specific inquiries	"lung cancer screening with low dose ct"	"low dose lung cancer screening"	"lung cancer detection using ct scan images"
General inquires	"lung cancer screening tests"	"what is a lung cancer screening"	"lung cancer screening for smokers"
Artificial intelligence and deep learning in LCS[b]	"lung cancer detection using image processing"	"lung cancer detection using deep learning"	"lung cancer detection using machine learning"
Screening eligibility criteria	"lung cancer screening ages"	"criteria for lung cancer screening"	"who should be screened for lung cancer"
Nearest screening locations	"lung cancer screening near me"	"mobile lung cancer screening near me"	"private lung cancer screening near me"
CT colonography			
CT-specific inquiries	"what is a ct colonography"	"ct colonography with contrast"	"ct colonography without contrast"
Screening procedural details	"ct colonography procedure"	"does ct colonography use contrast"	"how is ct colonography performed"
Imaging modality comparison (colonoscopy versus CTC[c])	"ct colonography versus colonoscopy cost"	"ct colonography versus colonoscopy sensitivity"	"is ct colonography as good as colonoscopy"
Prescreening procedural preparation	"what is the prep for a ct colonography"	"what is the prep for a ct colonography nhs"	—[d]
Coding (*ICD*[e]/CPT[f])	"ct colonography cpt code"	"ct colonography cpt"	—

[a]CT: computed tomography.

[b]LCS: lung cancer screening.

[c]CTC: computed tomography colonography.

[d]Not available.

[e]*ICD*: *International Classification of Diseases*.

[f]CPT: current procedural terminology.

Discussion

Principal Findings

Overview

Our study revealed much higher Google search volumes for MG topics over the past 2 decades than for LCS and CTC. The average search frequency for LCS was only approximately one-tenth of that for MG, and CTC search volume was only one–twenty-fifth of MG search volume. LCS average search volumes increased from 2011 to 2023, while searches for MG and CTC plateaued. MG-related topics had the highest total monthly search volume, followed by those related to LCS and CTC. Frequently searched topics varied across modalities and included nearby screening locations, procedural details or associated pain, and eligibility criteria.

MG consistently exhibited higher levels of search interest compared with LCS or CTC, possibly reflecting the longer history of MG and various longstanding initiatives focused on breast screening and women's health [25,26]. Despite the higher

XSL•FO
RenderX

absolute mortality for lung cancer than for breast cancer globally, search volumes for topics related to LCS have remained much lower than those for MG, although LCS search volumes have experienced an uptrend since 2011, when the National Lung Screening Trial was published [3]. MG was first established in 1913 and fully adopted in the 1970s [25], in contrast to low-dose CT for LCS, which gained widespread recognition in 2011. The early peak of interest in LCS in the 2004‐2006 period coincides with attention generated by early CT LCS programs, followed by a decline in interest until 2011 [27,28]. The relative search volumes for CTC have been persistently low over the last 2 decades, especially compared with MG (2%). While CTC is recognized by the national medical societies and formal guidelines of several countries as a viable screening option [29-31], other organizations have raised concerns regarding the strength of evidence supporting CTC or cost-effectiveness compared with colonoscopy [32,33]. The low search volumes might reflect a lack of awareness or desire for this screening option among the public.

Our topic analysis of recent volumes for queries related to image-based screening techniques showed both similarities and differences across imaging modalities. For example, in the case of MG, a substantial portion of searches (60,850/253,810, 24%) involved the nearest screening center, a topic with substantial although lower percentages of search volumes for LCS (750/11,150, 7%) and CTC (230/5590, 4%), highlighting a possible target of increased or more effective publicity. A relatively high volume of searches related to procedural aspects of CTC (1380/5590, 25%) may suggest a relative unfamiliarity with details of this specific imaging modality. A common topic of searches was potential procedural discomfort or pain in MG (28,970/253,810, 11%), with a lower percentage for CTC (220/5590, 1%), suggesting an opportunity for providers to better address procedural comfort that might otherwise decrease screening uptake. Cost or insurance coverage for screening was in the top 10 most-searched topics for all 3 screening modalities but comprised a minority of searches in terms of percentage; although cost and coverage pose concerns for some individuals, it is notable that several other topics, such as the nearest screening locations, procedural pain, and eligibility criteria, had on average 2- to 3-fold higher search volumes. AI and deep learning were common search topics for LCS (1210/11,150, 11%) but were not common queries for MG or CTC; this is somewhat surprising, as AI in the form of computer-aided detection is commonly used in MG.

Comparison to Prior Work

Previous research has examined internet search trends for cancer screening examinations. Snyder et al [20] examined Google search volume trends for cancer screening terms during the first stages of the COVID-19 pandemic, finding a temporary decline in searches for terms related to MG, LCS, colonoscopy, and pap smear. Rosenkrantz and Prabhu [22] performed a Google Trends analysis of the relative frequency of Google searches for MG, LCS, CTC, and prostate magnetic resonance imaging from 2004 to 2014, finding a slight progressive decline over the decade in searches for MG, a decrease from 2004 to 2010 in searches for LCS, followed by a persistent increase beginning in 2011, and an overall decade-long decline in searches for CTC; these findings are consistent with our analysis, although we show that searches for LCS continued to rise from 2014 to 2023 and that searches for MG and CTC have continued to plateau. Our analysis also has the advantage of comparing both the relative and absolute volumes of searches across modalities (MG, LCS, and CTC) instead of relying solely on relative search volumes, showing that searches related to MG greatly exceeded those related to LCS and CTC.

A variety of other methods have been used to assess public interest in and knowledge of cancer screening, including interviews, focus group discussions, questionnaires, and news coverage analysis [10,34,35]. Raju et al's [34] survey of LCS-eligible individuals who chose not to participate in screening found that 19% of individuals had concerns about the distance to the screening site, and 14% of individuals had concerns about insurance coverage, recalling some of the frequent search topics for LCS in our study. In a Google News analysis of news coverage of MG from 2006 to 2015 [21], the most frequently covered topics included screening MG controversies (29%), new breast imaging technology (23%), imaging of dense breasts (11%), and public screening initiatives (11%), topics that were not among the most common MG searches in our study.

Strengths and Limitations

To our knowledge, our study is the first to use internet search engine data to gauge both general and topic-level public interest across imaging-based screening modalities by providing both relative search frequencies and estimates of absolute search volumes. We examined 2 decades of Google search volumes across 3 key imaging-based cancer screening examinations and documented the most common themes of recent related search queries.

Our study had several limitations. First, there are limitations inherent in any method of search volume estimation. Google Trends reports search data in relative terms and may report a value of 0 when search frequencies are low. For topic analysis, we captured data representing a snapshot of queries over a year, while queries may change over time. Search volumes were also estimated through a proprietary tool that uses Google autocomplete as a proxy for search volumes, as actual absolute search volumes are not available from Google Trends. However, our goal was not to measure exact search volumes but rather to analyze and compare trends across modalities and to discern the topics of the most frequent searches. Second, the analysis of thematic categories is intrinsically subjective; we attempted to mitigate this by using 2 observers, with final decisions rendered by consensus. Third, we analyzed worldwide Google searches in English and did not perform a country or region-specific analysis; while such comparative analyses are potentially of interest because of differences in screening guidelines and behavior across countries, our main objectives were to provide a general and comprehensive analysis of search interest across modalities and to determine the main topics of search queries. Future studies may incorporate comparisons of search queries across countries. Finally, internet search volumes may not directly translate to individual concerns, real-world behaviors, or screening uptake; however, individuals frequently

XSL•FO
RenderX

turn to the internet as a source of medical information [16], and internet searches have often been used as a proxy of public interest in a wide variety of health-related topics [17-20,22].

Conclusions

In conclusion, MG has generated consistently higher Google search volumes over the past 2 decades than LCS and CTC, but search interest in LCS has been on an upward trend since 2011. Frequently searched topics varied across modalities and included nearby screening locations, procedural details or associated pain, and eligibility criteria. These search trends might inform the development of communication strategies related to screening and aid in addressing frequently asked questions from the public.

Acknowledgments

Generative artificial intelligence was not used for any portion of the study or for any portion of manuscript writing.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the proprietary nature of one of the search analysis tools used but are available from the corresponding author on reasonable request.

Authors' Contributions

ZDZ and BPL contributed to data curation, formal analysis, and methodology. ZDZ, IOC, RAG, EMJ, MRM, PJM, SKS, JTS, and BPL were involved in conceptualization, drafting the original manuscript, and reviewing and editing the final version.

Abstract

Background: Esophageal and gastric cancer were among the top 10 most common cancers worldwide. In addition, sex-specific differences were observed in the incidence. Due to their anatomic proximity, the 2 cancers have both different but also shared risk factors and epidemiological features. Exploring the potential correlated incidence pattern of them, holds significant importance in providing clues in the etiology and preventive strategies.

Objective: This study aims to explore the spatiotemporal correlation between the incidence patterns of esophageal and gastric cancer in 204 countries and territories from 2010 to 2019 so that prevention and control strategies can be more effective.

Methods: The data of esophageal and gastric cancer were sourced from the Global Burden of Disease (GBD). Spatial autocorrelation analysis using Moran I in ArcGIS 10.8 (Esri) was performed to determine spatial clustering of each cancer incidence. We classified different risk areas based on the risk ratio (RR) of the 2 cancers in various countries to the global, and the correlation between their RR was evaluated using Pearson correlation coefficient. Temporal trends were quantified by calculating the average annual percent change (AAPC), and the correlation between the temporal trends of both cancers was evaluated using Pearson correlation coefficients.

Results: In 2019, among 204 countries and territories, the age-standardized incidence rates (ASIR) of esophageal cancer ranged from 0.91 (95% CI 0.65-1.58) to 24.53 (95% CI 18.74-32.51), and the ASIR of gastric cancer ranged from 3.28 (95% CI 2.67-3.91) to 43.70 (95% CI 34.29-55.10). Malawi was identified as the highest risk for esophageal cancer (male RR=3.27; female RR=5.19) and low risk for gastric cancer (male RR=0.21; female RR=0.23) in both sexes. Spatial autocorrelation analysis revealed significant spatial clustering of the incidence for both cancers (Moran I>0.20 and P<.001). A positive correlation between the risk of esophageal and gastric cancer was observed in males (r=0.25, P<.001). The ASIR of both cancers showed a decreasing trend globally. The ASIR for esophageal and gastric cancer showed an AAPC of −1.43 (95% CI −1.58 to −1.27) and −1.76 (95% CI −2.08 to −1.43) in males, and −1.93 (95% CI −2.11 to −1.75) and −1.79 (95% CI −2.13 to −1.46) in females. In addition, a positive correlation between the temporal trends in ASIR for both cancers was observed at the global level across sexes (male r=0.98; female r=0.98).

Conclusions: Our study shows that there was a significant spatial clustering of the incidence for esophageal and gastric cancer and a positive correlation between the risk of both cancers across countries was observed in males. In addition, a codescending incidence trend between both cancers was observed at the global level.

Introduction

Globally, cancer is a leading cause of mortality, with its significance continually rising [1-4]. It was estimated that in 2019, cancer accounted for 250 million disability-adjusted life years [3]. Concurrently, according to the Global Cancer Statistics 2020, esophageal and gastric cancer were among the top 10 most common cancers worldwide [5]. In addition, sex-specific differences were observed in the incidence [5]. Due to their anatomic proximity, esophageal and gastric cancer have both different but also a number of shared risk factors and epidemiological features [6-8]. Several published articles have demonstrated that frequent consumption of hot beverages and poor oral hygiene are risk factors for esophageal cancer [9,10], while a high-sodium diet and *Helicobacter pylori* infection are risk factors for gastric cancer [11,12]. Smoking and heavy alcohol consumption are associated with the incidence of both esophageal and gastric cancer [13,14]. There are also some pathological injuries involving both esophagus and stomach, such as gastroesophageal reflux disease and Barrett esophagus, which is related to reflux [15,16]. Furthermore, the high-incidence regions for esophageal cancer are primarily distributed in East Asia, Southeastern Africa, and Northern Europe, while the high-incidence regions for gastric cancer are mainly distributed in East Asia and Eastern Europe [5]. The spatial distribution of these 2 cancers exhibits certain overlapping patterns. However, there has been no global-level spatiotemporal correlation analysis simultaneously examining the incidence of both esophageal and gastric cancer [17-22]. Therefore, systematic exploring the spatiotemporal correlation in the incidence of esophageal and gastric cancer holds significant importance.

Through the spatiotemporal correlation analysis of global incidence of esophageal and gastric cancer, we aim to provide insightful information that would contribute to the prevention and control of these cancers worldwide and the rational allocation of global public health resources.

Methods

Data Sources

The Global Burden of Diseases, Injuries, and Risk Factors Study 2019 (GBD 2019), coordinated by the Institute for Health Metrics and Evaluation (IHME) offers comprehensive and comparable data on the epidemiological burden of esophageal and gastric cancer, which includes age-standardized incidence rates (ASIR) recorded annually spanning from 1990 to 2019 [4]. The data of esophageal and gastric cancer were sourced from the Global Health Data Exchange (GHDx) query tool [23]. The GHDx query tool in the GBD 2019 database includes data from 204 countries and territories by sex from 1990 to 2019. Furthermore, according to the geographic location, the world was divided into 21 regions such as East Asia in GBD 2019 database. The quality and integrity of data can be significantly influenced by advancements in medical records and data collection technologies. Therefore, we extracted data on the ASIR (per 100,000 person-years) with 95% uncertainty interval (UI) of esophageal and gastric cancer from 2010 to 2019 due to the higher quality and integrity of recent data in our study. The ASIR was calculated by the direct method. Standardization was crucial in this study as it eliminates the bias when comparing rates. The 95% UI is a range of values that reflects the certainty of an estimate. The sociodemographic index (SDI) is a composite indicator developed by GBD researchers to characterize the developmental status of countries and territories, and it is closely associated with health outcomes. It is the geometric mean of 0 to 1 indices of total fertility rate under the age of 25, mean education for those ages 15 and older, and lag distributed income per capita [24]. The IHME provides publicly available SDI Reference Quintiles and the SDI values for all locations from 1950 to 2020 [24]. Based on the provided SDI Reference Quintiles, all locations can be classified into 5 categories, including low SDI (SDI≤0.46), low-middle SDI (0.46<SDI≤0.61), middle SDI (0.61<SDI≤0.69), high-middle SDI (0.69<SDI≤0.81), and high SDI (SDI>0.81).

Statistical Analysis

Spatial Distribution and Correlation of Esophageal and Gastric Cancer

In the analysis of spatial distribution and correlation of the ASIR of esophageal and gastric cancer, we used ArcGIS 10.8 (Esri) to calculate Global Moran I [25,26], which was used to evaluate whether the incidence of each cancer exhibited spatial clustering. Global Moran I measure spatial autocorrelation based on both feature locations and feature values simultaneously, where the feature here refers to different countries and territories. The tool calculates the Moran I value and both a zI-score and *P* value to evaluate the significance of that Index. The Moran I statistic for spatial autocorrelation was given as Multimedia Appendix 1.

Moran I values range between −1 and +1. For the Global Moran I statistic, the null hypothesis states that the attribute being analyzed is randomly distributed among the features in the study area. When the *P* value is statistically significant, we may reject the null hypothesis, and a positive value indicates the spatial distribution of high values and low values in the dataset is more spatially clustered than would be expected if underlying spatial processes were random; a negative value indicates the spatial distribution of high values and low values in the dataset is more spatially dispersed than would be expected if underlying spatial processes were random. A dispersed spatial pattern often reflects some type of competitive process—a feature with a high value repels other features with high values, and it is similar in a feature with a low value. When the *P* value is not statistically significant, we cannot reject the null hypothesis, indicating a random spatial distribution. In spatial autocorrelation analysis, the conceptualization of spatial relationships adheres to the Inverse_Distance rule.

In addition, by comparing the ASIR levels of esophageal and gastric cancer in each country and territory against those of the global ASIR levels, we obtained the corresponding risk ratio (RR) to quantify the level of relative risk. Countries and territories with an RR value≤0.50 were classified as low-risk area, while an 0.50<RR value<2.00 and RR value≥2.00 were classified as medium-risk area and high-risk area, respectively.

XSL•FO
RenderX

We then used the Pearson correlation coefficient to evaluate the correlation between the RR of esophageal and gastric cancer in both sex groups. We also evaluated the relationship between SDI quintiles and the distribution of different risk areas.

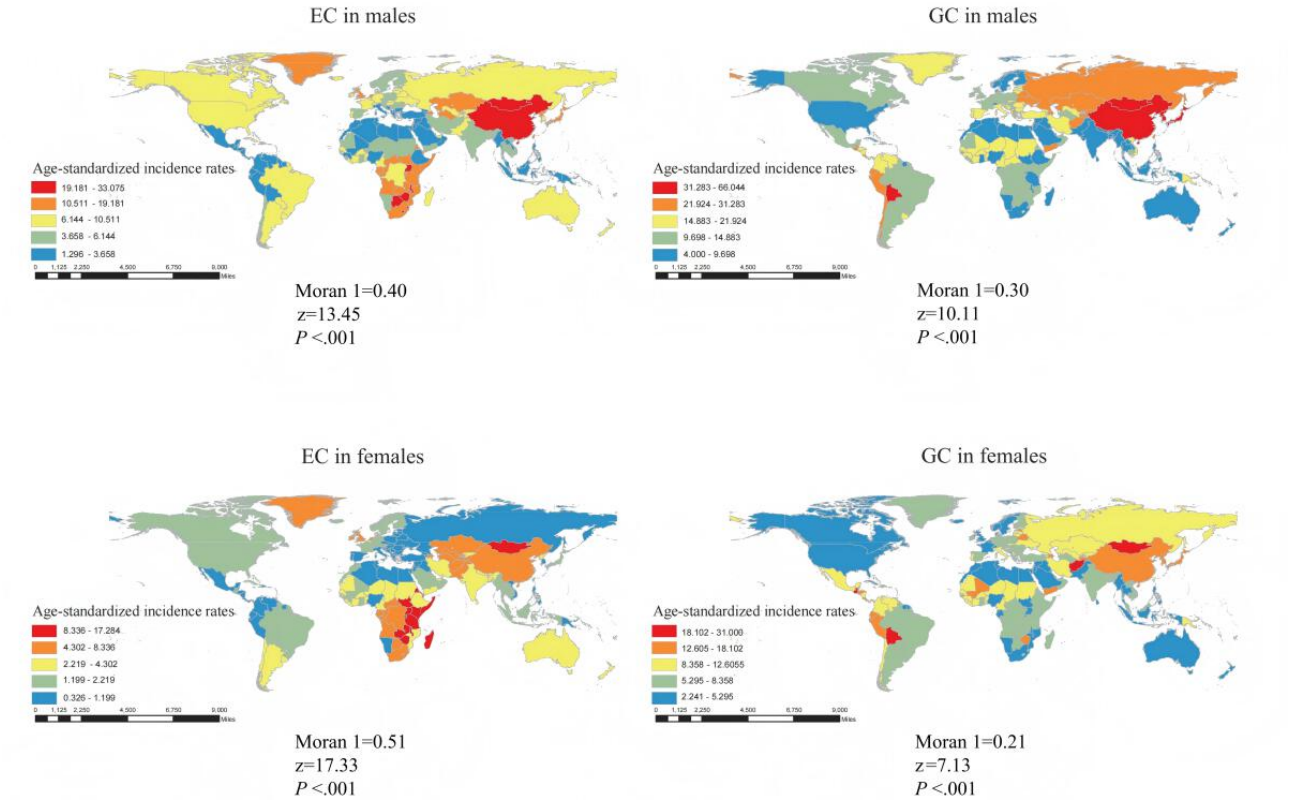
Temporal Trend and Correlation of Esophageal and Gastric Cancer

In the analysis of temporal trends and correlation of the ASIR of esophageal and gastric cancer, we used the National Cancer Institute Joinpoint Regression Program (version 5.0.2) to calculate the average annual percent change (AAPC) of the ASIR for esophageal and gastric cancer across 204 countries and territories during 2010 - 2019. The CI was set at 95%. AAPC is a statistical indicator used to describe the average annual change rate of the ASIR over a certain period. It provides a comprehensive assessment of the overall trend of ASIR over the entire study period by weighting the annual percentage change over multiple time periods. If both the estimation of AAPC and its lower boundary of 95% CI were >0, the ASIR was considered to be in an increasing trend; if both the estimation of AAPC and its upper boundary of 95% CI were <0, the ASIR was considered to be in a decreasing trend. Otherwise, the ASIR was considered to be stable over time. In the correlation analysis, the Pearson correlation coefficient was used to evaluate the correlation between the temporal trends in the ASIR of esophageal and gastric cancer. A Pearson correlation coefficient >0 with a *P* value less than the specified significance level indicated a significant positive correlation, while a coefficient <0 with a *P* value less than the specified significance level indicated a significant negative correlation. In addition, we assessed the correlation between the temporal trends in the ASIR of both cancers across SDI quintiles.

Given the significant sex differences in the incidence of esophageal and gastric cancer [27,28] and the lifestyle disparities, all analyses were stratified by sex. ArcGIS (version 10.8) and Joinpoint Regression Program (version 5.0.2) were used for spatial autocorrelation analysis and temporal trend analysis of ASIR respectively. All data analyses were conducted in software R (version 4.3.2; R Foundation for Statistical Computing) and R Studio (Posit). A *P* value of less than .05 was considered statistically significant.

Ethical Considerations

This study did not involve human participants and animals. Ethics approval was not applicable for this study, as this study used existing good quality data that were aggregated at the population level. Data available for download on IHME websites are publicly available and can be used, shared, modified or built upon by noncommercial users in accordance with the IHME Free-of-Charge Non-Commercial User Agreement [29].



Results

Spatial Distribution and Correlation Between the Esophageal and Gastric Cancer Incidence in 2019

The study included data on the incidence of esophageal and gastric cancer from 204 countries and territories and 21 geographic regions. In 2019, the global ASIR of esophageal and gastric cancer were 6.51 (95% CI 5.69-7.25) and 15.59 (95% CI 14.11-17.15) per 100,000 person-years, respectively, with considerable variation observed across regions and sex groups. Among the 204 countries and territories provided by the GBD dataset, the ASIR of esophageal cancer ranged from a minimum of 0.91 (95% CI 0.65-1.58) in Nigeria to a maximum of 24.53 (95% CI 18.74-32.51) in Malawi, while the ASIR of gastric cancer ranged from a minimum of 3.28 (95% CI 2.67-3.91) in Malawi to a maximum of 43.70 (95% CI 34.29-55.10) in Mongolia. Overall, the ASIR of esophageal and gastric cancer was significantly higher in males than in females, and within the sex group, the ASIR of gastric cancer was significantly higher than that of esophageal cancer at the global level (Figure 1). In 2019, Malawi had the highest ASIR of esophageal cancer in both sexes (male: 33.08, 95% CI 24.44-44.43; female: 17.28, 95% CI 12.64-23.50), and Mongolia was ranked the top 5 for both esophageal (male: 30.48, 95% CI 22.58-37.90; female: 16.03, 95% CI 7.50-21.37) and gastric cancer (male: 66.04, 95% CI 51.50-82.68; female: 28.18, 95% CI 21.53-36.56) in both sexes (Table S1 in Multimedia Appendix 2). In a broader scale, among males, the ASIR of esophageal and gastric cancer in East Asia, Central Asia and high-income Asia Pacific all ranked within the top 6 among 21 geographic regions. Among males, East Asia had the highest ASIR for both esophageal (21.70, 95% CI 16.37-26.61) and gastric cancer (46.67, 95% CI 37.63-56.82), while High-income Asia Pacific ranked fifth for esophageal cancer (10.68, 95% CI 8.87-12.89) and second for gastric cancer (41.91, 95% CI 35.58-49.40), and Central Asia ranked sixth (9.51, 95% CI 8.37-11.53) and fifth (24.08, 95% CI 21.82-26.57), respectively. Similarly, in females, the regions with the top 6 ASIR for esophageal and gastric cancer were East Asia and Central Asia. East Asia ranked second for esophageal cancer (6.67, 95% CI 4.39-8.38) and third for gastric cancer (15.65, 95% CI 12.80-19.05), while Central Asia ranked fifth (4.70, 95% CI 4.19-5.29) and sixth (10.76, 95% CI 9.81-11.87), respectively (Figures S1 and S2 in Multimedia Appendix 2). The spatial autocorrelation analysis also showed that there was a significant clustering phenomenon in the spatial distribution of the incidence of esophageal and gastric cancer in both sex groups (all Moran I>0.20 and *P* value <.001; Figure 1).

RenderX

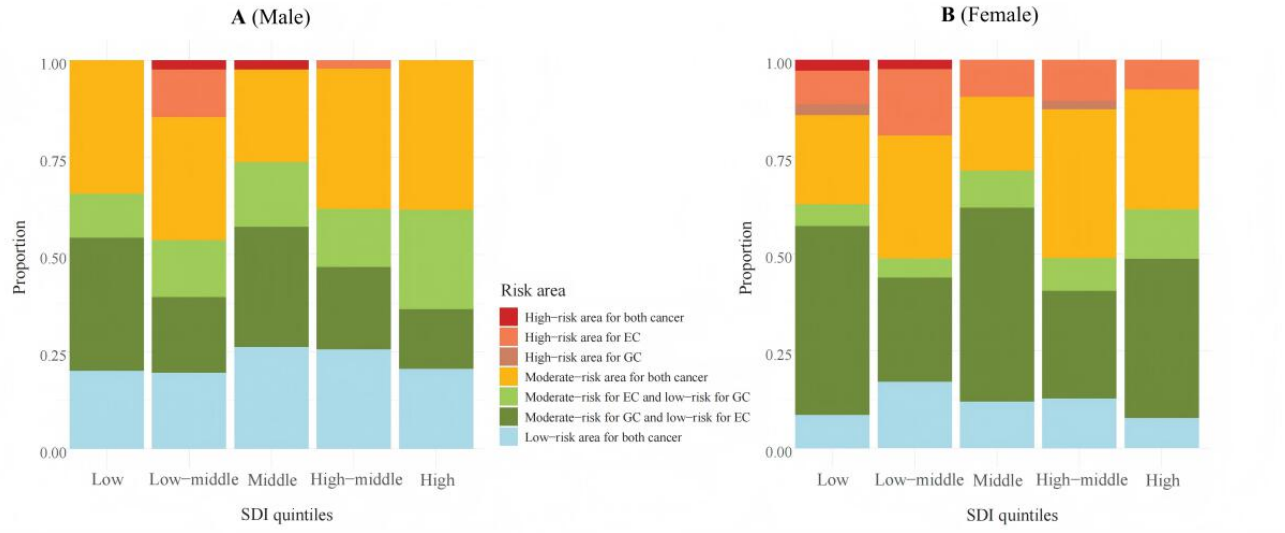
Figure 1. ASIR of esophageal cancer (EC) and gastric cancer (GC) in 204 countries and territories in 2019, by sex. EC: esophageal cancer; GC: gastric cancer; ASIR: age-standardized incidence rate.

The 2019 risk area classification results were shown in Figure 2. In 2019, China and Mongolia belonged to the high-risk area for both esophageal and gastric cancer in males (Figure 2), while Afghanistan and Mongolia belonged to the high-risk area for both cancers in the females (Figure 2). Mongolia was identified as an overlapped high-risk area for both esophageal cancer and gastric cancer in males and females. In addition, the number of countries and territories belonging to the high-risk area for esophageal cancer alone was significantly higher in females than in males, and the number of countries and territories belonging to the low-risk area for both esophageal and gastric cancer was much lower in females than in males. Furthermore, no country or territory in males belonged to the high-risk area for gastric cancer alone, while in females, there were 2 countries (Guatemala and Bolivia). It is noteworthy that Malawi had the highest RR value for esophageal cancer (male RR=3.27; female RR=5.19) and a low RR value for gastric cancer (male RR=0.21; female RR=0.23) in both males and females. We further conducted Pearson correlation analysis for the RR values of esophageal and gastric cancer, and found that there was a positive correlation between the RR values of esophageal and gastric cancer in males (r=0.25; P<.001), but no significant correlation was found in females (r=0.02; P=.77).

Risk area classification map of EC and GC for 204 countries and territories in males. B. Risk area classification map of EC and GC for 204 countries and territories in females. EC: esophageal cancer; GC: gastric cancer; ASIR: age-standardized incidence rates; RR: risk ratio; obtained by comparing the ASIR levels of esophageal and gastric cancer in each country and territory against those of the global ASIR levels.

XSL•FO
RenderX

Temporal Trend and Correlation Between Esophageal and Gastric Cancer Incidence From 2010 to 2019



From 2010 to 2019, at the global level, the ASIR of esophageal cancer ranged from a peak of 7.50 (95% CI 6.10-8.02) in 2010 to a lowest point of 6.44 (95% CI 5.79-7.00) in 2017, while the ASIR of gastric cancer ranged from a peak of 18.25 (95% CI 17.14-19.22) in 2010 to a lowest point of 15.59 (95% CI 14.11-17.15) in 2019. And the ASIR of esophageal and gastric cancer decreased significantly in both sex groups globally. The AAPC for esophageal and gastric cancer in males was −1.43 (95% CI −1.58 to −1.27) and −1.76 (95% CI −2.08 to −1.43), respectively, while in females, the AAPC for esophageal and gastric cancer was −1.93 (95% CI −2.11 to −1.75) and −1.79 (95% CI −2.13 to −1.46), respectively. We selected all the high-risk countries and territories which had the top 5 ASIR of esophageal or gastric cancer in 2019 in both sex groups (14 countries and territories were finally presented in the table due to partial overlap; Table S2 in Multimedia Appendix 3). In males, the ASIR for esophageal and gastric cancer both showed a decreasing trend in 10 countries and territories, while in females, this trend was observed in 11 countries and territories. Furthermore, in all countries and territories except Bolivia, there was a strong positive correlation between the temporal trends in the ASIR of esophageal and gastric cancer (Pearson correlation coefficient>0.5). In addition, it is noteworthy that despite Cabo Verde being among the top 5 countries for ASIR of esophageal and gastric cancer in males, the ASIR for these cancers continued to show a significant increasing trend in males, with an increasing trend also observed in females.

We also performed Pearson correlation analyses for the temporal trends between esophageal and gastric cancer ASIR at the global level and across all 204 countries and territories. At the global level, the Pearson correlation coefficient (r) for the temporal trends in the ASIR for both cancers were 0.98 in males and 0.98 in females. The results also showed that a positive correlation between temporal trends in the ASIR of the 2 cancers was observed in most countries and territories, regardless of sex (Figure 3 in Multimedia Appendix 3). A normality test on the distribution of Pearson correlation coefficients across 204 countries and territories for both males and females indicated that the distributions were not normal. Wilcoxon rank-sum test results showed that there were differences (P<.001) in the distribution of Pearson correlation coefficient data between males and females in these 204 countries and territories, and the median Pearson correlation coefficient was higher for females than for males.

The Correlation Between SDI and Both Risk Areas and Temporal Trend

Based on the SDI Reference Quintiles publicly provided by the IHME and the SDI values for all locations since 1950 [24], we collected the SDI for 204 countries and territories in 2019, and classified these countries and territories into different SDI quintiles according to the SDI Reference Quintiles. The composition of risk areas for different SDI quintiles was shown in Figure 3. As shown in Figure 3, the high-risk area for both cancers all distributed in the middle and below SDI quintiles. In males, high-risk areas were distributed only in the low-middle, middle, and high-middle SDI quintiles (Figure 3), while high-risk areas were distributed across all SDI quintiles in females (Figure 3). The chi-square test results show that there was no difference in the composition ratio of risk areas among various SDI quintiles in both sex groups.

Figure 3. Stacked bar plot of sociodemographic index (SDI) quintiles and different risk areas, by sex. (A) The stacked bar plot of SDI quintiles and different risk areas in males. (B) The stacked bar plot of SDI quintiles and different risk areas in females. EC: esophageal cancer; GC: gastric cancer; SDI: sociodemographic index.

As shown in Table 1, the ASIR of esophageal and gastric cancer both showed a downward trend in all SDI quintiles from 2010 to 2019, with all 95% CI excluding 0. In both sexes, the average annual percentage decrease in ASIR for esophageal and gastric cancer in the middle SDI quintile was both substantial. In addition, the decrease in ASIR for esophageal cancer in this quintile over the past decade was significantly more substantial than in other SDI quintiles. In the middle SDI quintile, the average annual percentage decrease in ASIR for esophageal cancer over the decade was more substantial than that for gastric cancer across both sexes. Conversely, in other SDI quintiles except for females in the low-middle SDI, the decrease in ASIR

XSL•FO
RenderX

for esophageal cancer was less substantial than that for gastric cancer. Pearson correlation analysis indicated that the correlation between the temporal trends in the ASIR for esophageal and gastric cancer was high in all SDI quintiles (Table 1 and Figure S4 in Multimedia Appendix 4). Since the distributions of Pearson correlation coefficients in each SDI quintile was nonnormal in both sex groups after normality test, the Kruskal-Wallis test was used to assess the differences in correlation coefficients among these SDI quintiles. The Kruskal-Wallis test indicated no significant differences in the correlation between the temporal trends in the ASIR of esophageal and gastric cancer across various SDI quintiles in both sex groups.

Table . Average annual percent change (AAPC) in age-standardized incidence rates (ASIR) of esophageal cancer (EC) and gastric cancer (GC) among different sociodemographic index (SDI) quintiles, 2010 - 2019 (AAPC, %).

Location	Male (95% CI)	*r* [a]	Female (95% CI)	*r* [a]
Low SDI		0.85		0.94
EC	−0.27[b] (−0.42 to −0.12)		−0.39[b] (−0.46 to −0.33)	
GC	−1.37[b] (−1.53 to −1.21)		−0.74[b] (−0.84 to −0.65)	
Low−middle SDI		0.88		0.95
EC	−0.21[b] (−0.34 to −0.09)		−0.43[b] (−0.74 to −0.12)	
GC	−1.19[b] (−1.41 to −0.98)		−0.67[b] (−0.82 to −0.52)	
Middle SDI		0.87		0.94
EC	−2.56[b] (−2.77 to −2.35)		−3.79[b] (−4.04 to −3.53)	
GC	−1.90[b] (−2.13 to −1.67)		−2.26[b] (−2.64 to −1.88)	
High−middle SDI		0.76		0.94
EC	−0.95[b] (−1.28 to −0.62)		−1.58[b] (−1.84 to −1.31)

[b]Indicates that 95% CI did not include 0.

Discussion

Principal Results

This study is the first to simultaneously report on the global temporal trends and spatial distribution of the ASIR for esophageal and gastric cancer, as well as their correlation based on GBD 2019 data. Our results show that there was a significant spatial clustering of the incidence for both cancers and a positive correlation between the risk of esophageal and gastric cancer across countries was observed in males. In addition, a codescending incidence trend between both cancers was observed in most countries and territories.

Due to the significant differences in the incidence of esophageal and gastric cancer between males and females [27,28], and the disparities in lifestyle, sex stratification was conducted in all analysis. In consistent with the previous studies, the risk of both esophageal and gastric cancer was high in Asia (especially East Asia and Central Asia) [5,30,31]. In addition, among Asian countries, the incidence of esophageal and gastric cancer was particularly serious in Mongolia (in 2019, the ASIR of both esophageal and gastric cancer ranked in the top 5 among both sexes). For Mongolia, the high incidence of esophageal cancer may be associated with high levels of fluoride in drinking water or drinking hot milk tea [32]. In addition, local cooking and heating mainly rely on coal and wood, resulting in high levels of fine particulate matter (diameter<2.5 μm), may also be one of the main reasons for the high incidence of esophageal cancer [33]. The spatial clustering phenomenon and the variation of geographical distribution in ASIR of esophageal and gastric cancer may be due to different lifestyles and environmental factors caused by differences in geographical and socioeconomic factors, as well as different histological subtypes of both cancers [34]. Compared with gastric cancer, there were more countries and territories with extremely high ASIR for esophageal cancer relative to the global level, which may be the reason why there were more countries and territories classified as the high-risk area for esophageal cancer than gastric cancer in this study. Although females were generally considered to have a lower risk of esophageal and gastric cancer than males, there were more countries and territories where females were at extremely high risk of esophageal and gastric cancer relative to the global

XSL•FO
RenderX

level. Those countries and territories, where the risk of esophageal and gastric cancer was much higher than the global level should be taken seriously. In addition, it is noteworthy that Malawi exhibited the highest risk for esophageal cancer alongside a very low risk for gastric cancer in both sex groups. The previous studies found that African countries with a higher incidence of esophageal cancer tend to have a lower estimated supply of selenium in their diets [35]. Therefore, the generally low selenium intake of the population in Malawi mainly caused by the reduced soil-to-crop selenium transfers in the local typical low pH soils may be one of the reasons for this phenomenon [35-37]. Since Malawi is one of the major tobacco producers in Africa, smokers have easier access to self-rolled tobacco (without filters), which will lead to smokers of this form of tobacco receive a higher dose of the carcinogenic products within the tobacco in comparison to store-bought cigarettes, thereby increasing the risk of developing esophageal cancer [38]. In addition, it has been reported that mycotoxins such as fumonisin B-1 stored in grain are fairly common in maize samples from Malawi, and although a direct causal relationship has not been established, this may be one of the reasons for the high incidence of esophageal cancer there [38]. The main source of energy in Malawian households is wood burning, which produces incomplete combustion products such as polycyclic aromatic hydrocarbons and may also be responsible for the high incidence of esophageal cancer [39]. In Pearson correlation analysis on the RR values for esophageal and gastric cancer among males and females, a positive correlation between the risk of incidence for esophageal and gastric cancer was observed in males, whereas no such correlation was found in females. Taking into account the possibility that the results may be influenced by a greater number of extreme values in females, we conducted a correlation analysis after removing some outliers. Nevertheless, no statistically significant correlation was found. One possible explanation is that smoking, as a primary common risk factor for both esophageal and gastric cancer, occurs at a significantly higher prevalence in males than in females (about 4 - 5 times higher) [40].

From 2010 to 2019, there was a global trend of decline in the ASIR for both esophageal and gastric cancer among males and females. The decline in the incidence of both cancers may be attributed to the improvements in the socioeconomic level and population health awareness in recent years [41-43]. It is worth mentioning that there were still some countries and territories, even some high-risk countries and territories including Cabo Verde, exhibited an increasing trend in the ASIR of esophageal and gastric cancer from 2010 to 2019. Although the significant increase of cancer registers compared with the past may be one of the reasons, it is necessary to actively control the incidence of esophageal and gastric cancer for those countries and territories showing an increasing trend. The reason for the stronger positive correlation between the temporal trends of esophageal and gastric cancer in females compared to that in males is unclear. However, it is certain that a significant positive correlation exists, which may be related to the shared risk factors due to their anatomic proximity.

When exploring the correlation between SDI and risk areas classified by RR values of esophageal and gastric cancer, no statistically significant difference was found in the composition ratio of risk areas across various SDI quintiles. This may be related to the low number of countries and territories belonging to the high-risk area for both cancers and gastric cancer alone. Consistent with the global trend, all SDI quintiles exhibited a decreasing trend in the ASIR of esophageal and gastric cancer, which indicated that, overall, the incidence of esophageal and gastric cancer had been improving in regions with different SDI quintiles from 2010 to 2019. Compared with other quintiles, the ASIR of esophageal and gastric cancer in middle SDI quintile both showed a substantial decreasing trend, which may be related to the high ASIR of both esophageal and gastric cancer in middle SDI quintile. Although the ASIR of gastric cancer was significantly higher than that of esophageal cancer, in contrast to other SDI quintiles, the decreasing trend in ASIR for esophageal cancer over the decade was more substantial than that for gastric cancer in middle SDI quintile. This opposite phenomenon, observed in the middle SDI quintile, calls for more rational public policies to strengthen the control of gastric cancer related risk factors. The correlation between the temporal trends in the incidence of esophageal and gastric cancer was strong among different SDI quintiles, and no statistically significant difference of this correlation was found across various SDI quintiles.

Strengths and Limitations

Our study has numerous strengths, including the ability to visually display the risk of both esophageal and gastric cancer in various countries and territories through risk area classification. This aids in developing prevention strategies tailored to shared or distinct risk factors of the 2 digestive cancers, while also considering local characteristics. Our study also has some limitations. First, the data we analyzed is sourced from the GBD 2019, the quality of some data, especially that from low-income or low SDI countries, is difficult to be guaranteed. Second, esophageal cancer includes 2 histological subtypes—esophageal squamous cell carcinoma and esophageal adenocarcinoma [44,45], while gastric cancer includes cardia gastric cancer and noncardia gastric cancer subtypes [46,47]. There are analogous and distinct etiologies with modifiable risk factors between these subtypes, as well as epidemiological characteristics [48-51]. However, due to the limitations of the GBD database, our study did not differentiate the subtypes of esophageal cancer and gastric cancer. Third, the results of Moran I are highly dependent on the choice of the conceptualization of spatial relationships. For global analysis, selecting an appropriate conceptualization is challenging, especially when regions are separated by natural barriers such as oceans. Contiguity measure may fail to capture spatial relationships across such barriers, while distance measure requires careful consideration of distance thresholds. In addition, Moran I is typically calculated for a single time point, which does not account for dynamic changes in spatial patterns over time. Furthermore, more detailed work is required to identify the primary modifiable risk factors in high-risk areas for each cancer, which will aid in more precisely reducing the global incidence of esophageal and gastric cancer.

XSL•FO
RenderX

Conclusions

This spatiotemporal correlation study simultaneously investigates esophageal cancer and gastric cancer, which share many risk factors. The results shows that there was a significant spatial clustering of the incidence for esophageal and gastric cancer and a positive correlation between the risk of both cancers across countries was observed in males. In addition, a codescending incidence trend between both cancers was observed at the global level. Despite the overall declining trend in the incidence rates of both esophageal and gastric cancer, they still pose a heavy disease burden worldwide. Analyzing the correlations in the global distribution and temporal trends of the incidence of esophageal and gastric cancer can help to gain a deeper understanding of the homogeneity and heterogeneity in the incidence pattern of these 2 cancers to optimize the allocation of global public health resources.

Abstract

Background: Cancers of the bladder, kidney, and prostate are the 3 major genitourinary cancers that significantly contribute to the global burden of disease (GBD) and continue to show increasing rates of morbidity and mortality worldwide. In mainland China, understanding the cancer burden on patients and their families is crucial; however, public awareness and concerns about these cancers, particularly from the patient's perspective, remain predominantly focused on financial costs. A more comprehensive exploration of their needs and concerns has yet to be fully addressed.

Objective: This study aims to analyze trends in online searches and user information–seeking behaviors related to bladder, kidney, and prostate cancers—encompassing descriptive terms (eg, "bladder cancer," "kidney cancer," "prostate cancer") as well as related synonyms and variations—on both national and regional scales. This study leverages data from mainland China's leading search engine to explore the implications of these search patterns for addressing user needs and improving health management.

Methods: The study analyzed Baidu Index search trends for bladder, kidney, and prostate cancers (from January 2011 to August 2023) at national and provincial levels. Search volume data were analyzed using the joinpoint regression model to calculate annual percentage changes (APCs) and average APCs (AAPCs), identifying shifts in public interest. User demand was assessed by categorizing the top 10 related terms weekly into 13 predefined topics, including diagnosis, treatment, and traditional Chinese medicine. Data visualization and statistical analyses were performed using Prism 9. Results revealed keyword trends, demographic distributions, and public information needs, offering insights into health communication and management strategies based on online information-seeking behavior.

Results: Three cancer topics were analyzed using 39 search keywords, yielding a total Baidu Search Index (BSI) of 43,643,453. From 2011 to 2015, the overall APC was 15.2% (P<.05), followed by –2.8% from 2015 to 2021, and 8.9% from 2021 to 2023, with an AAPC of 4.9%. Bladder, kidney, and prostate cancers exhibited AAPCs of 2.8%, 3.9%, and 6.8%, respectively (P<.05). The age distribution of individuals searching for these cancer topics varied across the topics. Geographically, searches for cancer were predominantly conducted by people from East China, who accounted for approximately 30% of each cancer search query. Regarding user demand, the total BSI for relevant user demand terms from August 2022 to August 2023 was 676,526,998 out of 2,570,697,380 (15.74%), representing only a limited total cancer-related search volume.

Conclusions: Online searches and inquiries related to genitourinary cancers are on the rise. The depth of users' information demands appears to be influenced by regional economic levels. Cancer treatment decision-making may often involve a family-centered approach. Insights from internet search data can help medical professionals better understand public interests and concerns, enabling them to provide more targeted and reliable health care services.

KEYWORDS

bladder cancer; kidney cancer; prostate cancer; Baidu Index; infodemiology; public interest; patients' concern

Introduction

Cancer poses a significant burden on global public health [1]. In urology, bladder, kidney, and prostate cancers are the 3 primary genitourinary cancers contributing to the global burden of disease (GBD), with persistently high morbidity and mortality rates [1,2]. According to a GBD report from 2019, the annual global incidence rates of bladder, kidney, and prostate cancers have risen by 154.78%, 123.34%, and 169.11%, respectively, over the past 2 decades, making them the most prominent cancers in the field of urology [3,4]. In mainland China, the incidence rates of bladder, kidney, and prostate cancers in 2019 had doubled compared with 1990 and are projected to triple by 2030 [2], with 192,390 cases of bladder cancer, 126,980 cases of kidney cancer, and 315,310 cases of prostate cancer. Therefore, precautionary measures are essential in addition to gathering information and assessing the disease burden using real-world data.

Infodemiology was defined as "The framework for an emerging set of public health informatics methods to analyze search, communication and publication behavior on the Internet." It has been shown to effectively highlight public health issues, assess the impact of health care policies, and uncover public concerns during global pandemics, as well as in chronic and contagious diseases, along with related public acceptance [5-9]. Examining underlying trends in user behavior and the specific demands associated with major genitourinary cancers could potentially provide insights into regional health information–seeking behaviors and population-level interests.

Cancer imposes a significant burden on patients and their families, typically measured in terms of financial costs and clinical outcomes [10,11]. However, there is limited understanding of its broader impacts, such as public awareness, emotional well-being, and social participation. In China, previous studies have examined prevalent noncancer urological issues and their online visibility using data from the Baidu Index [6,12,13], a tool that analyzes search behaviors to reflect public interest in health topics. While prior research has explored general cancer-related searches, these studies primarily focused on incidence correlations and population-level disparities across 28 cancer types [14], offering limited insights into specific user demands or temporal and geographic patterns.

This study aims to address this gap by focusing on 3 major genitourinary cancers: bladder cancer, kidney cancer, and prostate cancer. Using Baidu Index data, we analyzed internet search trends, user needs, and associated geospatial and temporal patterns. By identifying search behaviors and topics of interest, we seek to provide actionable insights into public health awareness and address unmet needs, potentially contributing to the improvement and guidance of health care strategies.

Methods

Keyword Selecting and Data Retrieving

Baidu (Baidu, Inc.), the leading search engine in mainland China, accounts for 92.1% of the search volume and 93.1% of user coverage [15]. Its analytics platform, Baidu Index, allows for tracking keyword popularity trends and analyzing related user demands [6,7,14]. Comparable to Google's platform on a global scale, Baidu has been validated as a reliable tool for studying online search trends and user behavior in infodemiology research within China [16,17].

This study primarily focuses on analyzing the temporal search trends of cancer-related terms associated with kidney, bladder, and prostate cancers. Based on defined criteria, these terms are characterized as compounds [6], combining morphemes denoting a urological organ with those indicating tumor-related concepts. The key morphemes identified were (1) "肾脏" or "肾" (the kidney), (2) "膀胱" (the bladder), (3) "前列腺" (the prostate), and (4) "肿瘤" (the tumor). The Baidu Index platform automatically matched these combinations with all available search keywords, including synonyms and complex derivatives. Measures were implemented to prevent duplication and omissions, following approaches detailed in previous studies [6,18]. Synonyms and complex derivatives were screened and selected to minimize ambiguity and bias arising from language habits, as previously described [6,13]. All available search keywords related to these 3 cancer types were categorized based on their connotations and are listed in Multimedia Appendix 1.

The Baidu Index platform consists of 3 key modules: (1) the search trend module, (2) the user demand module, and (3) the demographic portrait module. These modules enable the analysis of search demand from multiple perspectives, including popularity trends, topic-related concerns, and geodemographic features [6,13]. Search popularity is quantified using the Baidu Search Index (BSI), a key metric based on daily recorded search demand. With integrated data on location, gender, age, and other elements, trends and demographic profiles of the population can be visualized and retrieved [6,13]. Search trend data, available since 2011, were retrieved from the search trend module of the Baidu Index platform [14]. Data at both provincial and national scales were collected for the period from January 1, 2011, to July 31, 2023. The most recent data from the geodemographic and user demand modules were obtained from the user demand module on the Baidu Index official website [9,19].

Data Processing and Statistical Analysis

The Baidu Index is a data-sharing platform that leverages extensive user behavior data to measure search trends. By tracking the frequency of unique keyword searches and their weighting within Baidu's overall search volume, it provides a metric for keyword popularity. This study collected data on a daily, weekly, monthly, and yearly basis to capture a

XSL•FO
RenderX

comprehensive view of cancer-related search patterns. Sequential plotting of BSI data for each term was conducted to illustrate trends in public interest. Changes in trends over time were analyzed using the Joinpoint Regression Model (program version 4.7.0.0; Statistical Research and Applications Branch, National Cancer Institute). This model, well-suited for time-series analysis of large data sets, identifies statistically significant shifts in trends. The annual percentage change (APC) was calculated to summarize yearly trends within specified intervals, measuring year-over-year percentage changes. The average APC (AAPC) was used to evaluate trends over extended periods, providing a more stable estimate of the overall trend direction and rate of change [20,21]. For each topic—bladder cancer, kidney cancer, and prostate cancer—the public demand trend was illustrated through sequentially plotted BSI data. Intergroup differences were analyzed using the Student *t* test and Kruskal-Wallis test, as appropriate. A *P* value of <.05 was considered statistically significant.

In the user demand section, the top 10 most frequently mentioned words related to each search keyword were listed weekly and sorted by cancer type. This allowed for the identification and analysis of the most prominent and commonly discussed topics for each cancer type. In line with previous findings, we used a 13-topic system to categorize user demand–related terms, helping to clarify users' main concerns and implied intentions [13]. Aside from some random or off-topic terms, these categories were defined as follows: (1) complaint, (2) inquiry, (3) treatment and decision, (4) health issue, (5) diagnosis, (6) hospital and service, (7) symptom confirmation, (8) tests and examinations, (9) prognosis, (10) traditional Chinese medicine (TCM) complaint, (11) TCM inquiry, (12) TCM ingredient, and (13) TCM regimen.

All databases were constructed using Excel 2019 (Microsoft Corporation). The APC was calculated with the Joinpoint Regression Model, program version 4.7.0.0 (Statistical Research and Applications Branch, National Cancer Institute). Statistical analysis and figure creation were performed using Prism 9 for macOS (version 9.5.0 (525); GraphPad Software).

Ethical Considerations

We used publicly available, anonymized data that can be accessed without special permissions. As the data are aggregated and publicly accessible, IRB approval or exemption was not required.

Results

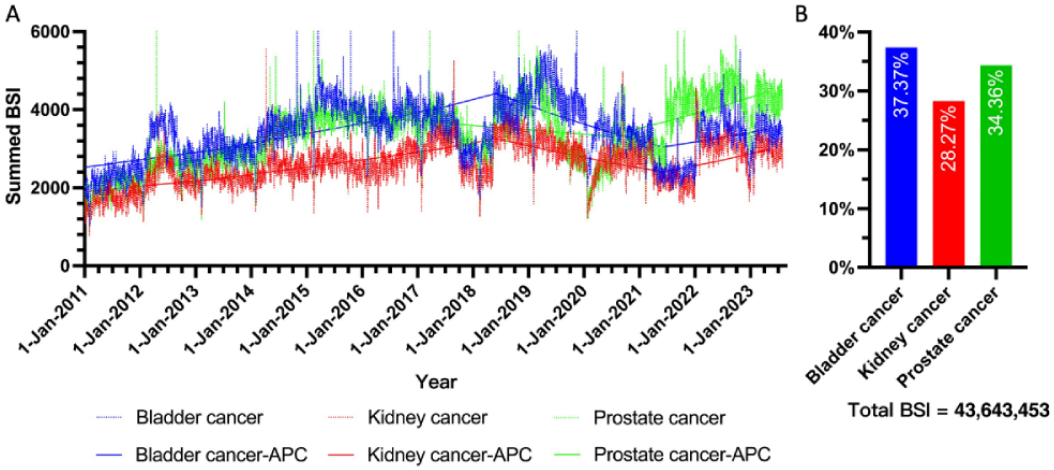
Available Trends Data in Urology Cancer Topics

We identified and confirmed 39 valid search keywords on the Baidu Index platform. These keywords are theme-based synonyms and moderate derivative terms that convey specific motives or demands. Among these, 13 keywords pertained specifically to bladder cancer, while 15 and 11 keywords were related to kidney cancer and prostate cancer, respectively. For theme categorization, 4 topics were identified: (1) complaint, with 9 keywords; (2) inquiry, with 23 keywords; (3) treatment, with 4 keywords; and (4) prognosis, with 3 keywords. All available search keywords related to these 3 urological cancers, along with their English equivalent translations, are listed in Multimedia Appendix 1.

The general search volume for all 3 urological cancers increased to a mean of 10,737.74 (SD 1026.29) from an initial mean of 5975.68 (SD 770.42). Specifically, the average daily search volume for bladder cancer rose to 3453.09 (SD 337.44) in 2023 from an initial average of 2275.72 (SD 302.17). For kidney cancer, the average daily search volume increased to 2976.78 (SD 319.64) from an initial average of 1706.84 (SD 262.95). Similarly, the search volume for prostate cancer grew to a mean of 4307.87 (SD 417.68) from 1993.12 (SD 297.99). According to the trend module, the total BSI for these top 3 urological cancers was 43,643,453. Specifically, the 13-year summed BSI ratio was 37.37% (15,972,271/43,643,453) for bladder cancer, 28.27% (12,079,106/43,643,453) for kidney cancer, and 34.36% (15,592,076/43,643,453) for prostate cancer (Figure 1). Regarding topic preferences for each cancer, the BSI ratio for complaint and inquiry was dominant, accounting for 90.26%, 96.10%, and 79.53% across all 4 topics for bladder cancer, kidney cancer, and prostate cancer, respectively (Figure 2).

To illustrate search trends over time since January 1, 2011, the daily request–based BSI for each cancer was analyzed both overall and by specific topics. The significance of these trends was evaluated using the APC model, as shown in Figures 1 and 2.

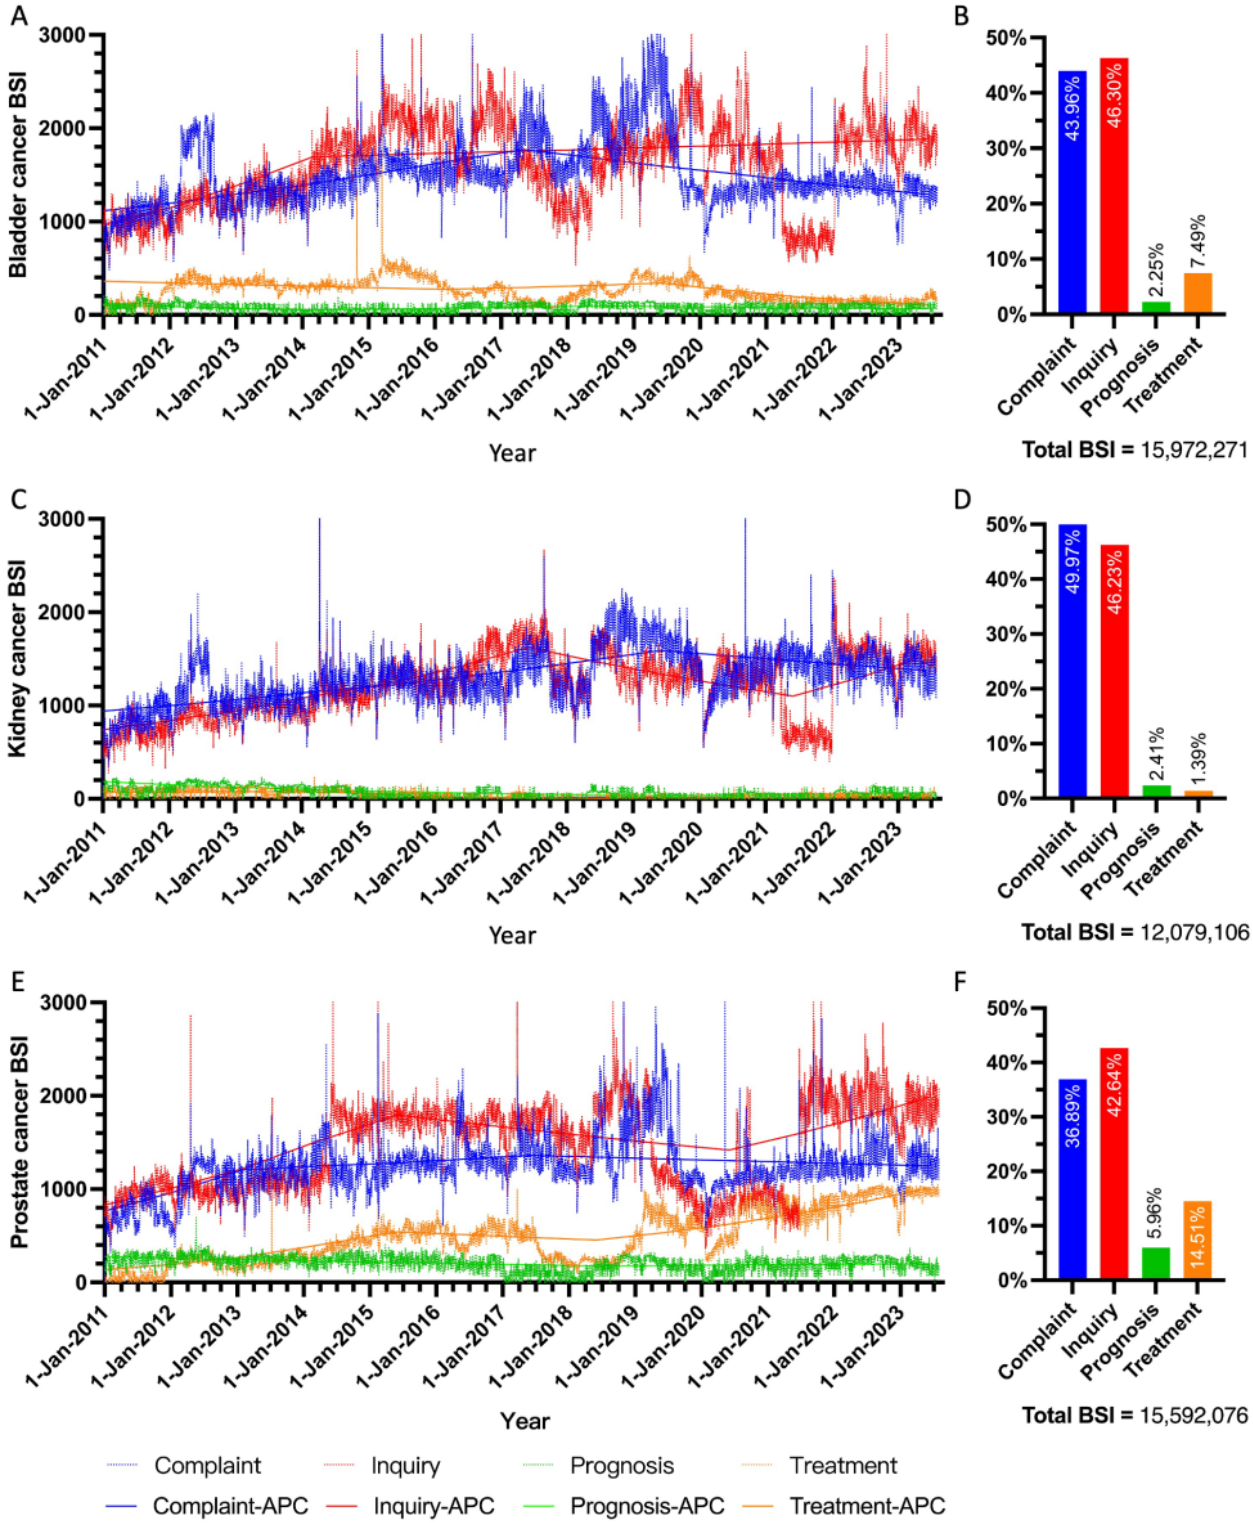
Based on the average annual BSI counts, a general growth in search requests for all 3 urological cancers was observed. The overall APC was 15.2% (*P*<.05) from 2011 to 2015, –2.8% from 2015 to 2021, and 8.9% from 2021 to 2023, resulting in an AAPC of 4.9%. For bladder cancer, the APC was 8.3% (*P*<.05) from 2011 to 2019, –11.7% from 2019 to 2021, and 7.4% from 2021 to 2023, with an AAPC of 2.8%. For kidney cancer, the APC was 8.0% (*P*<.05) from 2011 to 2019, –9.6% from 2019 to 2021, and 11.4% from 2021 to 2023, resulting in an AAPC of 3.9%. For prostate cancer, the APC was 17.7% (*P*<.05) from 2011 to 2015, –3.1% from 2015 to 2020, and 10.4% from 2021 to 2023, yielding an AAPC of 6.8% (*P*<.05).



Specifically within the bladder cancer theme, the APCs for the *complaint* topic were 8.0% (*P*<.05) from 2011 to 2021 and –5.1% from 2021 to 2023, with an AAPC of 1.2%. For the *inquiry* topic, the APCs were 20.8% (*P*<.05) from 2011 to 2014 and 1.2% from 2014 to 2023, with an AAPC of 4.8% (*P*<.05). For the *prognosis* topic, the APCs were –20.8% (*P*<.05) from 2011 to 2014, 15.6% from 2014 to 2018, and –6.9% from 2018 to 2023, resulting in an AAPC of –4.4%. For the *treatment* topic, the APCs were –5.4% from 2011 to 2016, 7.6% from 2016 to 2019, and –23.9% (*P*<.05) from 2019 to 2023, with an AAPC of –9.4%.

In the kidney cancer theme, the APCs for the *complaint* topic were 6.8% (*P*<.05) from 2011 to 2019 and –3.6% from 2019 to 2023, with an AAPC of 3.2% (*P*<.05). For the *inquiry* topic, the APCs were 14.0% (*P*<.05) from 2011 to 2017, –9.2% (*P*<.05) from 2017 to 2021, and 17.8% from 2021 to 2023, resulting in an AAPC of 6.2% (*P*<.05). For the *prognosis* topic, the APCs were –19.0% (*P*<.05) from 2011 to 2019 and 15.7% from 2019 to 2023, with an AAPC of –11.0% (*P*<.05). For the *treatment* topic, the APCs were 2.5% from 2011 to 2014,

XSL•FO
RenderX



–47.1% from 2014 to 2018, and 42.6% from 2019 to 2023, with an AAPC of –12.2% (*P*<.05). In the prostate cancer theme, the APCs for the *complaint* topic were 25.4% (*P*<.05) from 2011 to 2013, 3.1% from 2013 to 2017, and –1.4% from 2017 to 2023, resulting in an AAPC of 4.2%. For the *inquiry* topic, the APCs were 21.2% (*P*<.05) from 2011 to 2015, –4.6% from 2015 to 2020, and 11.8% from 2020 to 2023, with an AAPC of 11.8%. For the *prognosis* topic, the APCs were –6.2% (*P*<.05) from 2011 to 2018 and 2.5% from 2018 to 2023, with an AAPC of –3.0% (*P*<.05). For the *treatment* topic, the APCs were 41.6% (*P*<.05) from 2011 to 2015, –5.8% from 2015 to 2018, and 17.4% (*P*<.05) from 2018 to 2023, resulting in an AAPC of 18.2% (*P*<.05).

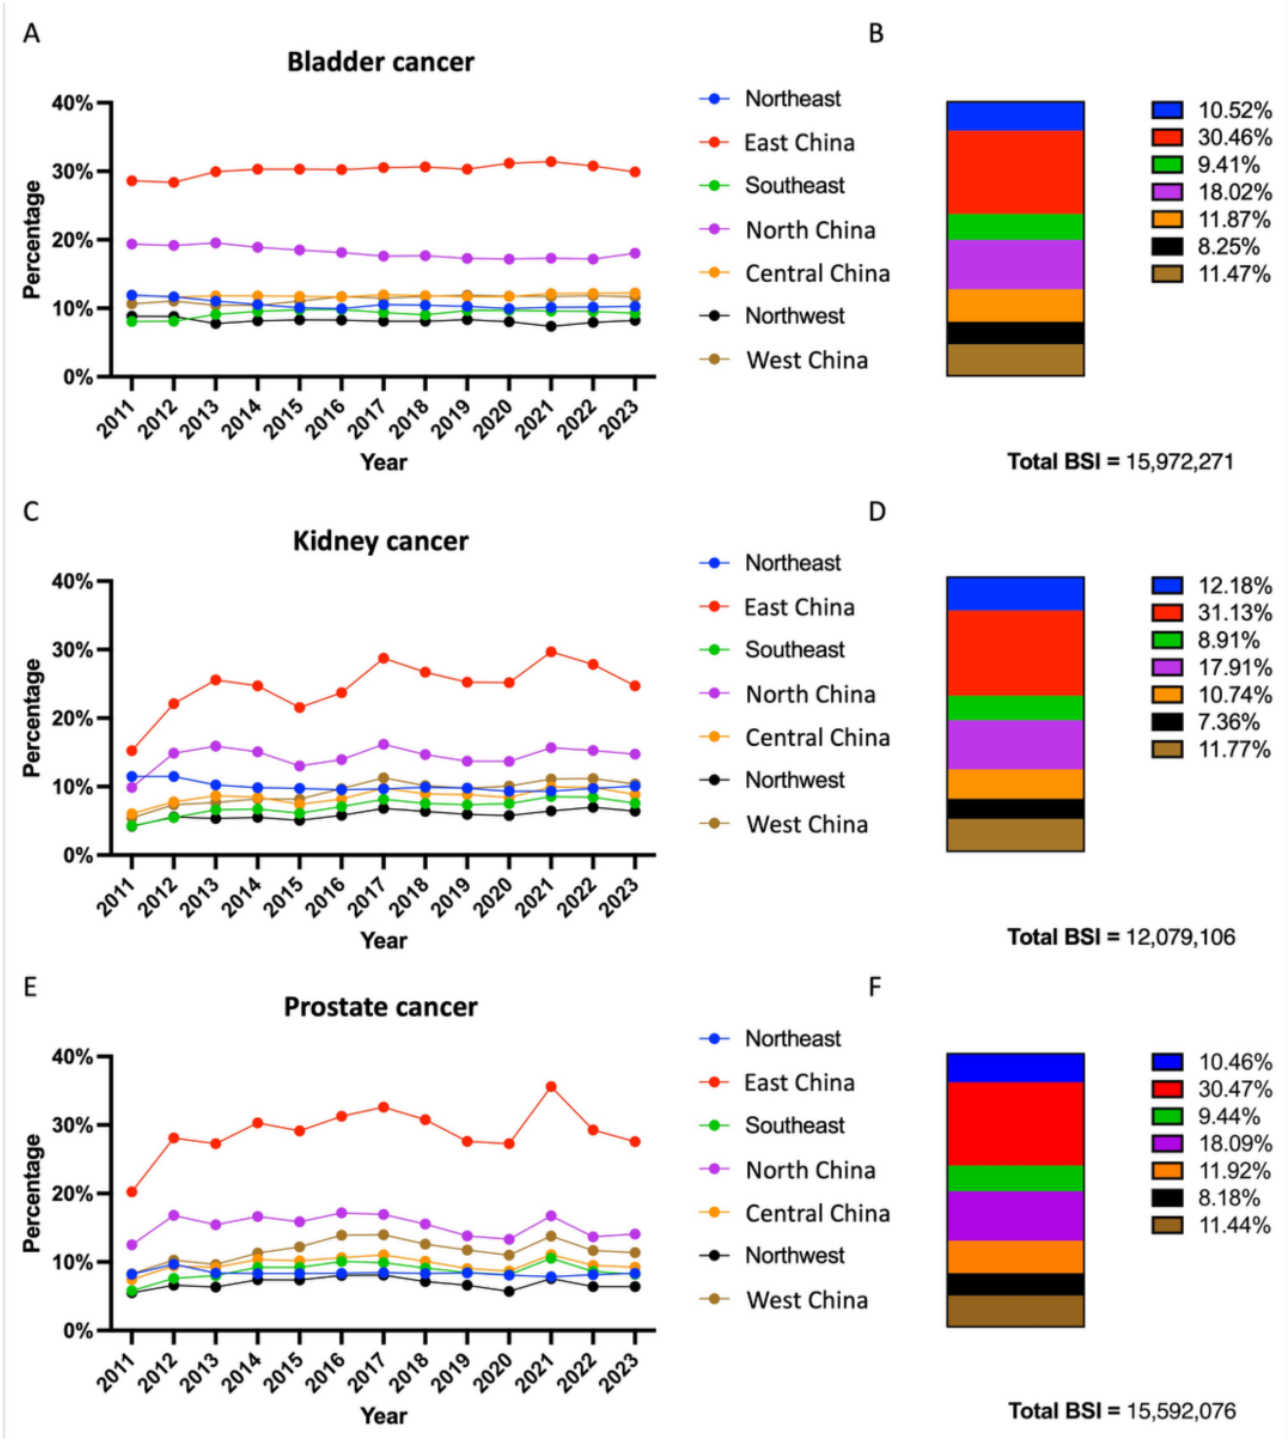
Figure 2. Online search trends for specific topics related to bladder, kidney, and prostate cancer since 2011. (A) Searching trend of specific topics in bladder cancer. (B) Sum BSI proportion of specific topics in bladder cancer. (C) Searching trend of specific topics in kidney cancer. (D) Sum BSI proportion of specific topics in kidney cancer. (E) Searching trend of specific topics in prostate cancer. (F) Sum BSI proportion of specific topics in prostate cancer. APC: annual percentage change; BSI: Baidu Search Index.



Geographic Differences

The geographic distribution of each cancer type was calculated based on provincial BSI data and categorized according to the 7 Chinese administrative divisions [6]. Figure 3 shows the 13-year regional BSI proportions for each cancer type with valid search records. Search requests were predominantly from East China, accounting for 30.46%, 31.13%, and 30.47% of bladder, kidney, and prostate cancer searches, respectively, followed by North China. Search demand from Central China, South China, and West China was comparable, each contributing around 11%. The Northeast and Northwest regions ranked the lowest, collectively accounting for approximately 8% of searches for each urological cancer.

Figure 3. Regional distribution of online search in bladder, kidney, and prostate cancer topics. (A) Annual BSI trend for each region in the topic of bladder cancer. (B) Total search rates for each region on the topic of bladder cancer. (C) Annual BSI trend for each region in the topic of kidney cancer. (D) Total search rates for each region on the topic of kidney cancer. (E) Annual BSI trend for each region in the topic of prostate cancer. (F) Total search rates for each region on the topic of prostate cancer. BSI: Baidu Search Index.

Demographic Differences

From the demographic distribution analysis, variations in age and gender distribution were observed across each cancer theme and specific topic. In the bladder cancer theme, search requests for each topic were primarily made by individuals aged 20-29 and 30-39 years. For kidney cancer, the topics of complaint, inquiry, and prognosis were predominantly searched by the 20-29-year age group, whereas the topic of treatment was mainly searched by individuals aged 40-49 years. In the prostate cancer theme, the topics of inquiry and treatment were primarily requested by the 30-39-year age group, while searches for prognosis were mainly made by those aged 40-49 years. Notably, no dominant age group was identified for searches in the complaint topic for prostate cancer (Table 1).

Keywords, Related Terms, and Search Frequency

During the data-providing period from August 15, 2022, to August 13, 2023, 27,065 out of 31,200 words were identified as in-topic, representing valid user demand. The total BSI for these relevant user demand terms was 676,526,998, accounting for only 676,526,998 of 2,570,697,380 (15.74%) total search requests. Detailed distributions of these relevant terms and their search frequencies are shown in Figure 4. The valid search ratio and demand distribution were also summarized overall (Figure 4) and specifically for each cancer theme (Figures 5 and 6). Additionally, the 3 most representative user-demand issues were identified and ranked based on frequency and search popularity (Tables 2 and 3).

[a]TCM: traditional Chinese medicine.

Discussion

Principal Findings

To the best of our knowledge, this study is the first infodemiology research to explore patients’ awareness and demand for primary urologic cancers (bladder, kidney, and prostate) within China’s vast population, particularly from clinical and health care perspectives [12,22]. By analyzing the most widely used local search platform, with billions of daily active queries, we identified consistent shifts in search trends, dominant regions for searches, and key demographic groups. Furthermore, we examined the most sought-after topics, reflecting user-initiated care-seeking behaviors and decision-making patterns [13].

We observed that while the overtime search trends fluctuate, the overall search volume for each cancer type has shown a general increase, as indicated by the overtime AAPC. Across all urologic cancer themes, the 4 main topics—“complaint,” “inquiry,” “treatment,” and “prognosis”—remain consistent, indicating that user queries focus on key aspects of disease-related decision-making. Notably, there is a strong demand for information on diagnostic criteria, etiology, treatment options, and realistic expectations for each cancer. Among tumor-related keywords, symptom-related searches account for 43.95%, 49.97%, and 36.89% of the total search volume for bladder, kidney, and prostate cancers, respectively. Inquiries, comprising 23 search keywords, account for 46.30%, 46.23%, and 42.64% of the total search volume for bladder, kidney, and prostate cancers, respectively. In terms of treatment-related searches, prostate cancer leads with 14.51% of the total search volume, followed by bladder cancer at 7.49% and kidney cancer at 2.41%. The prominence of searches related to complaints and inquiries is unsurprising, as the complaint

XSL•FO
RenderX

category primarily includes diagnostic keywords, reflecting users' initial, exploratory searches when they are uncertain about the specific information they require [22].

The main concerns in user inquiries revolve around early signs, primary indications, etiologies, specific symptoms, and other cancer-related issues. These topics represent a comprehensive collection of the most common challenges patients face during health care–seeking sessions, particularly in cancer-related scenarios.

In bladder cancer, search keywords frequently reflect concerns about symptoms, particularly in the early or late stages, with hematuria being a primary focus [23]. While hematuria does not definitively indicate bladder cancer, prompt attention to this visible symptom facilitates early detection and diagnosis.

For prostate cancer, user queries often center on symptoms, staging, and metastasis. Lower urinary tract symptoms are commonly reported but frequently stem from benign causes, making symptom-based identification challenging. Prostate cancer detection primarily relies on prostate-specific antigen-magnetic resonance imaging-biopsy combinations, though the screening sensitivity (0.93) and specificity (0.20) underscore limitations and adherence challenges [24-27]. Furthermore, concerns about skeletal metastasis and staging highlight the importance of enhanced education and communication strategies.

Kidney cancers, characterized by diverse carcinomas, are often identified through imaging as "space-occupying lesions," resulting in ambiguous search terms like "mass (肿物)." Compared with bladder and prostate cancers, users frequently lack precise diagnostic information [28]. Advances in imaging technology have increased renal cell carcinoma detection rates by 3.1% annually over the past decade [29,30]. However, diagnostic accuracy remains limited by tumor size and the high cost of imaging. Emerging machine learning systems offer promise, with diagnostic precision ranging from 84.18% to 90.83%, supporting cancer identification and surgical decision-making [29,30]. Addressing misdiagnosis and delays in renal carcinoma detection remains a critical priority for health care providers.

Life expectancy is a primary concern in users' inquiries about the 3 cancers. The standard query, "How long can one live with the diagnosis?" highlights that the most significant need for patients with cancer, in terms of treatment or intervention, is to minimize the negative impact of cancer on life expectancy. Currently, the growing population in Mainland China exacerbates the challenges posed by the morbidity and mortality of urologic cancers, affecting both the national health care system and personal lives [2]. As of 2019, the death rates for bladder cancer, kidney cancer, and prostate cancer in China were 50.39/1000, 40.09/1000, and 23.95/1000, respectively, with mortality rates gradually increasing with age [2]. Predictive models suggest that the morbidity and mortality rates for these 3 genitourinary cancers will continue to rise, although health care facilities are becoming more accessible in traditionally less-developed regions [31]. With improvements in perioperative management and increasing proficiency among surgeons in primary health care facilities, internet users have expressed concerns that could be addressed more promptly and validated by local health care professionals [31,32].

The search trend patterns across each cancer theme showed similarities, with an overall upward trend primarily driven by the topics of complaint and inquiry. The demand for cancer treatment and prognosis has generally declined, with the only exception being observed in prostate cancer treatment topics. Specifically, the search trends for bladder and kidney cancers increased until 2019, followed by a decline until a resurgence in 2021. For prostate cancer, turning points occurred in 2015 and 2020. The rising search trends may partly reflect real-world cancer incidence. Data from the GBD 2019 database indicated that the counts for bladder, kidney, and prostate cancers in 2019 were at least four times higher, with age-standardized incidence rates at least double those of 1990 [2]. This period also marked Baidu's "golden age," during which it became the primary source of information for internet users [13]. Although Baidu's marketing strategies for channeling information have been criticized, they do not appear to have affected its dominant role in providing cancer-related information to users [13].

Despite the COVID-19 pandemic's significant impact on regular medical activities and the shift in public attention toward outbreak management, online demand for information on tumor diseases, including genitourinary cancers, persisted and even increased in 2019 [6,33]. This demand was temporarily suppressed during the 2020-2021 pandemic peak but rebounded as government policies and health care responses evolved [34,35]. Search terms highlighted unresolved issues and user concerns about genitourinary cancers, emphasizing Baidu's role as a trusted source of health-related information. These trends underscore the need to address user-identified health care gaps in future health policy optimization.

Geographically, searches for the 3 cancers were led by East China, accounting for approximately 30%, followed by North China at around 18%. Other regions showed similar levels of interest, each at approximately 10%, while the northwest region ranked last with about 8%.

Socioeconomic inequalities significantly influence health-seeking behavior and online health information searches [33,36]. In China, disparities in medical center density, health care costs, social security policies, and household finances shape patients' decisions, with individuals from disadvantaged backgrounds often hesitating to seek treatment due to financial constraints [37]. Similarly, socioeconomic and educational factors affect online search behavior: higher-income individuals tend to exhibit greater digital literacy, use precise medical terminology, and seek reliable sources [38,39]. By contrast, lower-income groups face barriers such as limited internet access and lower trust in online information, often relying on symptom-based searches [40]. These differences underscore the impact of socioeconomic status on health awareness and access to accurate medical information [39,41].

Demographic data revealed similar interest in cancer topics across genders, though females expressed greater concern about kidney cancer prognosis. Bladder and kidney cancers have significantly higher incidence rates in males, at 5-fold and 2.5-fold, respectively. Interest in prostate cancer, despite being

XSL•FO
RenderX

male-specific, indicates engagement extending beyond patients alone [2]. Agewise, searches for bladder and kidney cancers were common among users aged 20-39 years, with kidney cancer treatment queries peaking in the 40-49-year age group. Prostate cancer searches followed a similar pattern, except prognosis-related queries, which were predominantly from users aged 40-49 years. Bladder and kidney cancer incidence rates in individuals aged 20-39 years (25.48/100,000 and 1.51/100,000, respectively) were half of those observed in the 40-59-year age group, while prostate cancer incidence peaked in individuals over 60 years [2].

The disparity between incidence rates and concern levels across gender and age groups highlights the importance of health consciousness and awareness. The high cost, complex nursing requirements, and strict follow-up schedules associated with cancer treatment underscore that the disease burden affects not only individuals but also entire families [42]. Research indicates that women play a prominent leadership role within families, making approximately 80% of health care–related decisions [43-45]. The concerns and demands of women, as key decision makers within families, should not be underestimated. Although older adults are increasingly integrating internet technology into their daily routines, including health care–seeking activities, the persistent digital divide among older users remains a significant challenge [46]. Therefore, joint decision-making involving family members, rather than focusing solely on the patients' needs, should be taken into account.

Our study found that only 15.74% of user search queries were categorized as relevant, reflecting a focus on trending topics, nonhealth issues, or vague terms, such as medication-related words. This low percentage suggests that public attention often shifts toward less scientifically grounded information, driven by societal trends, misinformation, or curiosity about lifestyle, diet, or alternative medicine [47,48]. The findings highlight the need for more effective dissemination of accurate cancer information and targeted educational campaigns to enhance public understanding of critical cancer issues. Furthermore, many users rely on general or indirect language in their searches, which may prevent their queries from being classified as relevant. This underscores the importance of promoting more precise health communication.

Overall, frequency, diagnosis, and symptom confirmation issues ranked among the top categories, accounting for 30.17% and 30.16%, respectively. Regarding popularity, interest in symptom confirmation ranked first, followed by diagnosis and health-related issues, each comprising approximately 15%. Similar patterns were observed in bladder and kidney cancers. However, in prostate cancer, while interest in diagnosis and symptom confirmation was dominant in terms of frequency, health care–related issues in prognosis garnered the most actual popularity.

In the topics of complaints and etiology inquiries, the most common concerns related to bladder and kidney cancers were hematuria and questions about its causes. As a marker of cancer risk, hematuria is often associated with underlying urologic malignancies. The standardized incidence ratio for overall urologic cancer risk peaks within the first 3 months following a hematuria diagnosis, reaching 14.15% [49]. Specifically, the standard incidence ratios for bladder, kidney, and prostate cancers at 3 months are 186.43%, 81.40%, and 14.18%, respectively [49]. Reports indicate that delayed responses to initial hematuria often lead to missed cancer diagnoses. Therefore, heightened awareness and timely investigation of its causes are recommended to prevent delays in cancer diagnosis [50,51].

We observed that several differential diagnoses were listed within the diagnosis topic. For bladder cancer, cystitis and prostate cancer were frequently mentioned. In the context of kidney cancer and prostate cancer, the most commonly referred differential diagnoses included renal cysts, renal kidney disease, prostatitis, and benign prostatic hyperplasia. These conditions must be ruled out before confirming a tumor diagnosis, suggesting the potential for users to engage in self-assisted cyber diagnosis [52].

Accurate evidence is essential for the correct diagnosis of cancer, as it helps identify tumor characteristics. In some cancer cases, even experienced experts may find judgment and decision-making complicated due to varying test results [53]. The risk of internet self-diagnosis in cancer warrants greater attention, as diagnosis delays and misleading treatments can have serious consequences [52]. For users with limited medical knowledge, it becomes even more challenging to identify accurate and useful information while maintaining reasonable and objective expectations [54]. Therefore, online health care information should be more instructive, neutral, and objective, enabling potential patients to better follow guidance from medical professionals [55].

Limitations

Several limitations of this study should be acknowledged. First, although Baidu is the largest search engine in mainland China, its dominance is increasingly challenged by emerging search platforms and social media, which restricts the scope of online search behavior captured. Consequently, the daily BSI may not fully reflect the demands of all internet users. Second, regional differences in user preferences and political regulations result in the exclusion of searches by individuals legally accessing international platforms. Furthermore, as Baidu is a Chinese platform, searches conducted in foreign languages or by ethnic minorities may be systematically omitted, potentially introducing bias. Third, the absence of a real-time public cancer database is a significant limitation, as it prevents the integration of search data with clinical data for more accurate disease prediction and forecasting. These factors underscore biases in internet access and usage across different demographic groups, which should be considered when interpreting the results in the context of broader cancer awareness and digital health information–seeking behavior.

Future Directions

This study is the first to address public concerns regarding the 3 major genitourinary cancers within the Chinese-speaking population. These cancers were selected due to their complexity and subtle onset, which often lead to delayed diagnoses and severe outcomes. By analyzing online search trends, this

XSL•FO
RenderX

research provides valuable insights into patient perceptions and needs, offering a broader understanding of public demand. Future infodemiology studies should incorporate data from multiple search engines, social media platforms, and multilingual or minority groups to achieve a more comprehensive analysis of public health trends. Integrating such a system into a national cancer database could significantly enhance disease tracking, forecasting, and public health decision-making.

Conclusions

Online searches and inquiries related to genitourinary cancers are on the rise. The depth of users' information demands appears to be influenced by regional economic levels. Cancer treatment decision-making may often involve a family-centered approach. Insights from internet search data are potentially beneficial for medical professionals to better understand public interests and concerns, enabling them to provide more targeted and reliable health care services.

Data Availability

Abstract

Background: Previous studies have found and confirmed a correlation between cognitive disorder and chemotherapy. As genetic testing becomes more routine in clinical practice, targeted therapies are increasingly gaining prominence. The relationship between targeted treatment and cognitive function is not yet clear. This study aimed to investigate the correlation between cognitive disorder and targeted treatment by evaluating the changes in cognitive function before and after targeted therapy.

Objective: This study aims to explore whether targeted therapy affects cognitive function in patients with advanced lung cancer and to explore the association between cognitive function, the inflammatory biomarker C-reactive protein, and psychological stress.

Methods: From the screened cohort of 150 patients with advanced non–small cell lung cancer (NSCLC) with gene mutations, 87 (58%) were rigorously selected for the study. The evaluation instruments used were the Mini-Mental State Examination scale, the Distress Thermometer, and the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 for assessing quality of life.

Results: A significantly lower progression-free survival (PFS) was observed in the group of patients surviving advanced NSCLC with cognitive disorder under targeted therapy in contrast to survivors in the group with no cognitive disorder (hazard ratio=0.347, 95% CI 0.209-0.578; *P*<.001). Furthermore, the objective response rate and disease control rate for the group with cognitive disorder were noted to be 37.8% and 86.7%, respectively, contrastingly lower than those in the group with no cognitive disorder, recorded at 78.6% and 97.6%, respectively. Significant variances were also noted in the Mini-Mental State Examination scores between patients with and without cognitive disorder both before and after targeted therapy (*P*<.001 in both cases), with a decreasing trend observed in both groups after targeted therapy. Noteworthy differences were found in quality of life scores both before and after targeted therapy (*P*<.001 in both cases). In addition, notable disparities were apparent in C-reactive protein levels among the 2 groups before and after treatment (*P*=.03 and *P*=.048 for each time point, respectively), with an upward trend observed in both groups after targeted therapy. The multivariate Cox regression analysis demonstrated that cognitive function is an independent risk factor for PFS in patients with NSCLC receiving targeted therapy.

Conclusions: Cognitive disorder may lead to lower quality of life scores and shorter PFS in patients undergoing targeted therapy. Early screening and intervention for such patients could effectively improve clinical outcomes and quality of life.

Introduction

Background

Lung cancer has become the leading cause of death worldwide, with non–small cell lung cancer (NSCLC) accounting for 85% of all cases [1]. NSCLC has various types, such as adenocarcinoma, squamous cell carcinoma, large cell carcinoma, and sarcomatoid carcinoma, with adenocarcinoma being predominant [2]. Surgery remains the definitive treatment for early-stage lung cancer; however, in clinical practice, most cases are diagnosed at an advanced stage. Platinum-based chemotherapy stands as the first-line treatment for NSCLC, yielding a median overall survival of 9.1 months and a median progression-free survival (PFS) period of 5 to 6 months [3]. The survival rate 1 year after chemotherapy is 37% [4].

Notably, the emergence of targeted therapy has improved the overall survival and PFS, as well as the quality of life (QoL), for some patients with advanced NSCLC. This population harbors sensitive gene mutations and has been recommended specific targeted therapies [5]. Epidermal growth factor receptor (EGFR) gene mutations, particularly those occurring at positions 18 to 21, are the most common, with those at positions 19 to 21 constituting over 90% of all EGFR mutations [6]. EGFR tyrosine kinase inhibitors, with their proven effectiveness, low toxicity, good tolerance, and ease of administration, are commonly used for advanced NSCLC. They function by entering the cells' tyrosine kinase catalytic domain, blocking adenosine triphosphate binding, and inhibiting the EGFR signaling pathway, which in turn promotes tumor cell apoptosis; hampers tumor cell proliferation; and, ultimately, impedes tumor growth, thereby prolonging patient survival [7].

Classic studies such as IPASS (Iressa Pan-Asia Study) [8], First-SIGNAL (first-line single-agent Iressa versus gemcitabine and cisplatin trial) [9], WJTOG 3405 [10], EURTAC (erlotinib versus standard chemotherapy as first-line treatment for European patients with advanced EGFR mutation–positive NSCLC) [11], NEJ002 [12], OPTIMAL [13], and LUX-Lung 6 [14] have confirmed the improved PFS, overall survival, and objective response rate (ORR) in EGFR mutation–positive patients treated with tyrosine kinase inhibitors compared to the group treated with chemotherapy. Anaplastic lymphoma kinase (ALK) fusion gene mutations, common in NSCLC, are detected in 1.4% to 11.6% of cases. Among East Asians, the ALK fusion gene positivity rate is approximately 4.1% [15]. Currently, first-generation ALK inhibitors such as crizotinib [16] and second-generation ALK inhibitors such as alectinib [17] are commonly used for ALK fusion gene–positive patients, whereas the third-generation ALK inhibitor lorlatinib [18] was approved by the China National Medical Products Administration in April 2022 but is still less commonly used in clinical practice. ALK inhibitors have shown better efficacy than chemotherapy, resulting in prolonged PFS and improved ORRs [19].

Objectives

In previous studies exploring the relationship between cognitive function and treatment, we have found that the cognitive function of patients with cancer is associated with chemotherapy and radiotherapy. For example, research by Simó et al [20] on cognitive function in patients with lung cancer has revealed declines in visuospatial ability and verbal fluency after chemotherapy, along with structural changes in gray and white matter in bilateral paralimbic integration areas. Radiotherapy can damage surrounding normal brain tissue during treatment, leading to cognitive dysfunction, especially when combined with chemotherapy [21]. This has been confirmed in studies on small cell lung cancer, where prophylactic cranial irradiation was associated with an increased risk of neurocognitive decline [22]. However, this presents a therapeutic dilemma. To avoid cognitive impairment, techniques such as hippocampal avoidance have been used during radiotherapy [23]. With the increasing prominence of targeted therapy for advanced NSCLC, its therapeutic efficacy has become a key focus of attention. Previous research has shown that the effectiveness of targeted therapy is influenced by the type of gene mutation [24], tumor type [25], presence of brain metastasis [26,27], and other factors. The relationship between targeted therapy efficacy and cognitive function remains unclear, warranting further investigation. In our study, we selected psychological distress, QoL, and C-reactive protein (CRP) as key variables based on previous research evidence. Both psychological distress and QoL are established critical factors influencing cognitive function [28-30]. Meanwhile, the inflammatory biomarker CRP plays a pivotal role in predicting and mediating cognitive function alterations [31,32]. This tripartite approach aligns with the biopsychosocial model, allowing for integrated analysis of psychological, functional, and biological pathways in cancer-related cognitive impairment.

Methods

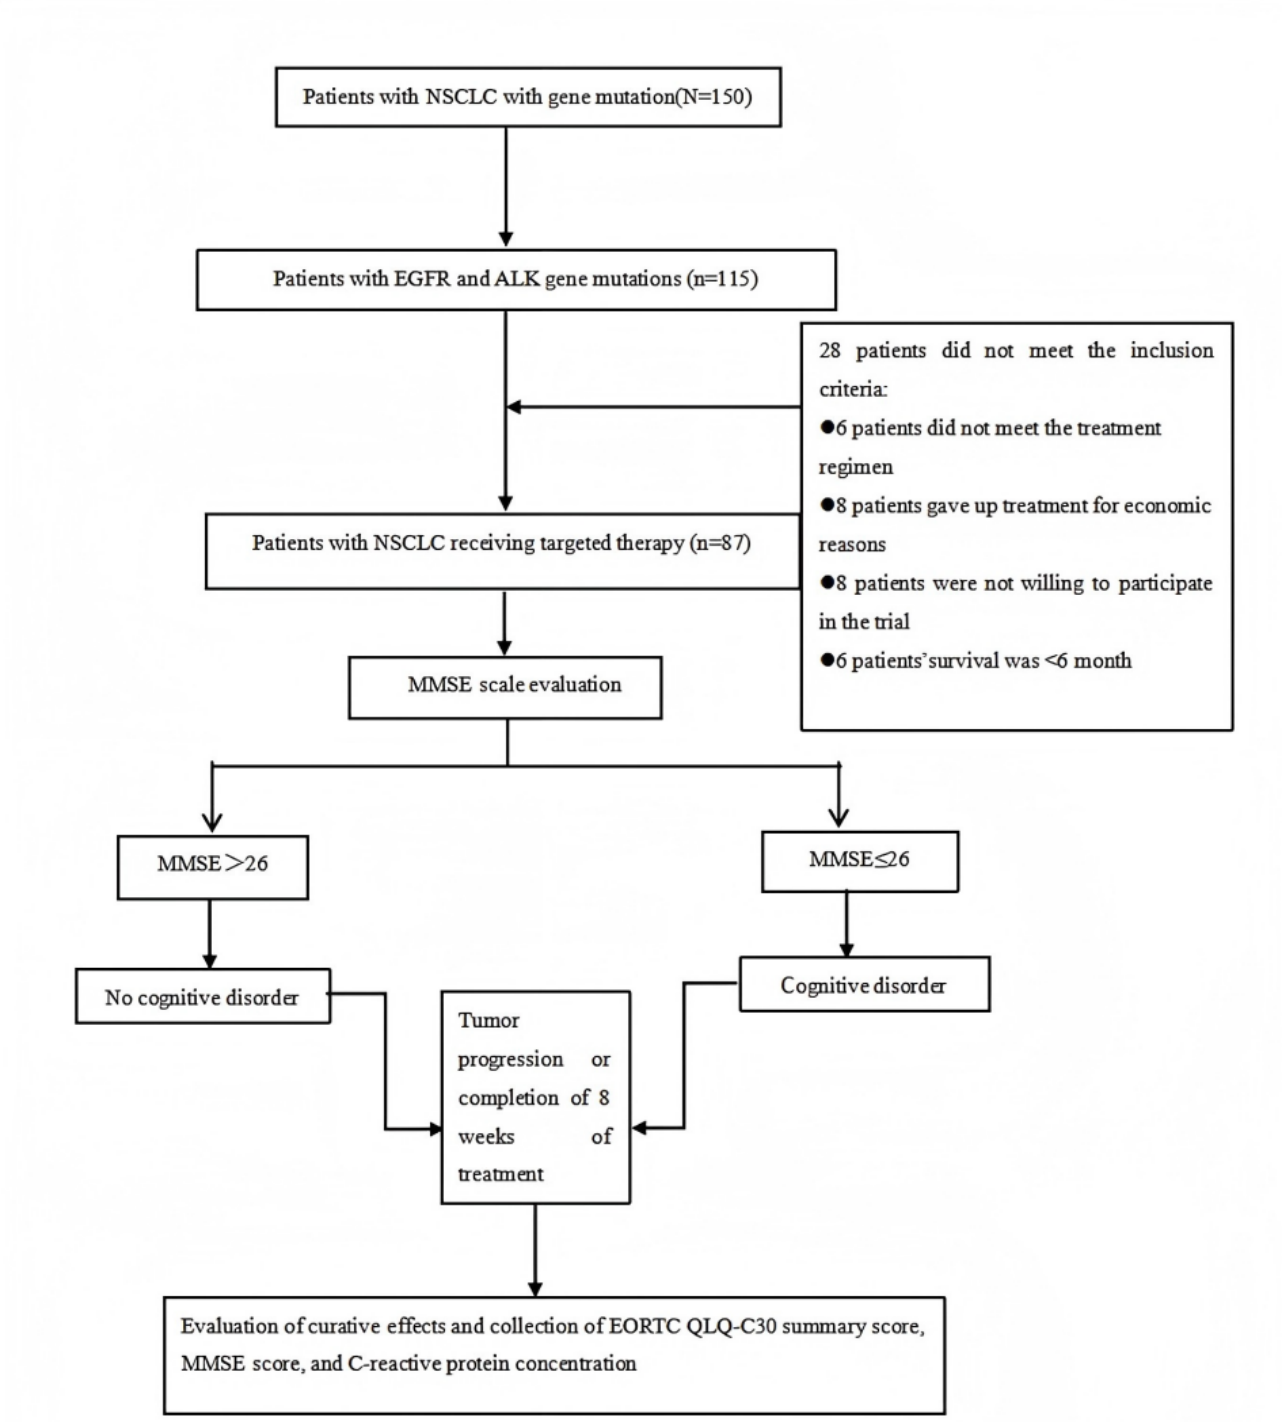
Overview

This prospective cohort study explored the impact of changes in cognitive function during targeted therapy on therapeutic effect and the relationship with QoL, inflammatory markers, and psychological distress. The recruitment period for this study was from May 1, 2020, to December 31, 2023. We screened patients who were pathologically diagnosed with NSCLC and selected for analysis those with concomitant EGFR and ALK gene mutations who had not received any antitumor therapy. A total of 87 cases met the inclusion criteria. During the baseline period, we collected basic information; clinical data; and scores on the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC QLQ-C30), the Distress Thermometer (DT), and Mini-Mental State Examination (MMSE) scales from all participants. The MMSE is a well-validated and globally recognized tool for screening cognitive impairment widely used in both clinical and research settings due to its strong operational feasibility.

XSL•FO
RenderX

Its reliability and validity have been extensively documented across diverse populations, including patients with cancer, assessing key cognitive domains affected by cancer treatments, such as orientation (time and place), memory (immediate and delayed recall), attention (serial subtraction and spelling), language abilities (naming and repetition), and visuospatial skills (figure copying) [33-35]. Consistent with previous research reports, an MMSE score of 26 or below is established as the cutoff threshold for identifying functional impairment; hence, the cutoff value was set at 26 for our study [36-38]. At 8 weeks of treatment, or when the tumor had progressed, the QoL questionnaire (EORTC QLQ-C30), DT, and MMSE scales were administered again. Informed consent was obtained by a professional oncologist.

Participants



The inclusion criteria for this study were as follows: (1) patients with a confirmed initial pathological diagnosis of lung adenocarcinoma, with genetic testing (histological specimen) indicating EGFR or ALK mutations; (2) patients who had not received any previous treatment and were eligible for first-line targeted therapy, with targeted therapy dosage and duration in line with National Comprehensive Cancer Network guidelines, and an expected survival period of >6 months; and (3) patients with no history of mental or neurological diseases, able to communicate normally, without hearing or language impairments, and with a Karnofsky Performance Scale score of ≥80. The exclusion criteria for this study were as follows: (1) diagnosis of a mental illness (such as depression, anxiety, or dementia) and (2) severely debilitating diseases unrelated to the tumor that significantly impacted the patient's QoL (such as heart failure, stroke, or disabilities).

Procedure

This study was conducted at the Anhui Provincial Chest Hospital tracking patients who were diagnosed with lung cancer for the first time, and we screened 150 cases of patients with lung adenocarcinoma and gene mutations for evaluation, of whom 115 (76.7%) were detected as having mutations in EGFR and ALK genes. Informed consent was obtained through personal communication with the patients and their families, and ultimately, 87 cases participated in this study. Professional oncologists evaluated the patients; collected clinical data; and conducted assessments using the EORTC QLQ-C30, DT, and MMSE. The aforementioned 3 assessments were administered before the first treatment and after 8 weeks of targeted therapy or when the disease progressed, and the therapeutic effect was evaluated with respect to solid tumors (Response Evaluation Criteria in Solid Tumors). During the COVID-19 pandemic, patients who had difficulty visiting the hospital completed the questionnaire via video communication, and all data collected via the questionnaire were completed by professionally trained oncologists. Figure 1 shows the study design flowchart.

Figure 1. Study design flowchart. ALK: anaplastic lymphoma kinase; EGFR: epidermal growth factor receptor; EORTC QLQ-C30: European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30; MMSE: Mini-Mental State Examination; NSCLC: non–small cell lung cancer.

Evaluation Measures

Gene Testing

All participants underwent histology biopsy, including lung puncture, bronchoscopy biopsy, lymph node biopsy, and surgical resection. The pathology was diagnosed by the pathology expert of the Anhui Provincial Chest Hospital pathology department, and the diagnosis was carried out by 2 individuals for diagnostic reports. The gene testing method used was high-throughput sequencing (next-generation sequencing), and the detection scope covered 139 lung cancer–related genes based on Chinese big data and the authoritative The Cancer Genome Atlas database, comprehensively covering hot spot mutations related to lung cancer (mutation, insertion, deletion, fusion, or copy number variation) and covering lung cancer therapeutic targets recommended by the National Comprehensive Cancer Network guidelines.

XSL•FO
RenderX

Cognitive Function Assessment

The MMSE was used for cognitive function assessment. The assessment using the MMSE questionnaire was conducted by trained professionals and consisted of 30 items covering 6 aspects. The total score out of 30 was recorded, with a score of 26 or below indicating cognitive disorder and a score above 26 indicating no cognitive disorder. The assessment was conducted twice after diagnosis, with the first assessment conducted before the first targeted therapy (time 1). The second assessment (time 2) was conducted at 8 weeks of treatment or upon tumor progression.

Important considerations included (1) ensuring that both tests were conducted in the same environment as much as possible, (2) establishing good communication, and (3) ensuring that each test item was only allowed to be attempted once (the time taken for each item may be appropriately extended to avoid the anxiety and resistance of the patient).

Evaluation of Targeted Therapy Efficacy

Each participant had measurable target lesions, and the Response Evaluation Criteria in Solid Tumors were used to evaluate the efficacy of targeted therapy. The efficacy assessment was divided into 4 categories: complete response, partial response, stable disease, and progressive disease. The efficacy assessments were reviewed and evaluated by 2 oncology experts.

Assessment Method for Psychological Distress

The DT is a tool used to assess psychological distress. It is globally applicable and convenient for clinical applications and self-assessment. It uses an 11-point visual analog scale ranging from 0 (no distress) to 10 (extreme distress) to visually represent the level of distress of the individual being tested. The DT often uses a cutoff point of 4 to distinguish between the presence and absence of distress, with higher scores indicating greater distress. When assessing the source of distress, a questionnaire consisting of 39 items is used, covering practical, familial, physical, emotional, and spiritual or religious issues. The assessments were carried out before the initiation of targeted therapy and after 8 weeks of targeted therapy or upon disease progression after targeted therapy.

EORTC QLQ-C30 Scale

The assessment of QoL used the EORTC QLQ-C30. The EORTC QLQ-C30 is summarized into 5 functional scales, 3 symptom scales, a global QoL scale, and 6 single items (decreased appetite, diarrhea, dyspnea, constipation, insomnia, and economic impact). The questions are divided into 4 levels, with the scores recorded as 1 to 4 points, but the global QoL scale questions adopt a 7-level answer format, with the ends being “very poor” and “excellent” and the score recorded as 1 to 7 points. The calculation method is to add the number of entries included in a specific scale or domain and divide by the number of included entries to obtain the score of each field. To make the scores of each field comparable, the scores can be linearly transformed into standardized scores within the range of 0 to 100. The comprehensive score of the EORTC QLQ-C30 is calculated as the average of the combination of 13 EORTC QLQ-C30 scale and item scores (excluding the global QoL scale and financial impact item).

Method for the Detection of CRP

We used a highly sensitive CRP testing kit that adopts the latex-enhanced immunoturbidimetric method to detect the content of CRP in human samples, which is used clinically as a nonspecific inflammation marker and for assessing cardiovascular disease risk. The sample requirement is fresh human ethylenediaminetetraacetic acid anticoagulated whole blood. Contaminated samples cannot be used.

The testing principle is that the reagent and sample are mixed, and the antibody-marked latex microparticles in the reagent and the CRP in the sample produce an agglutination reaction, leading to an increase in the turbidity of the solution. The concentration of CRP in the sample is obtained through turbidity analysis. This concentration is further converted into the concentration of CRP in the serum or plasma based on the proportion of blood cell volume in the sample.

Statistical Analysis

All statistical analyses in this study were conducted using SPSS (version 24; IBM Corp). Continuous variables were tested for normal distribution using the Kolmogorov-Smirnov test. Nonparametric tests were used for variables that did not conform to the normal distribution. Baseline differences in demographic and medical characteristics between groups were independently analyzed using 2-tailed *t* test or chi-square analysis. The QoL scores in the group with cognitive disorder and the group with no cognitive disorder were compared using 2 independent-sample *t* tests. Nonparametric tests were used to compare cognitive function changes and CRP concentration changes between the 2 groups, and linear regression was used to assess the correlation between MMSE scores and CRP concentration, QoL, and psychological distress, as well as the correlation between psychological distress and CRP concentration. We used Cox regression analysis to study the impact of relevant factors on the survival rates of the 2 groups and analyze the risk factors in all participants. All statistical tests were 2-tailed, and the significance level was set at $P<.05$. Results were expressed as means and SDs.

Ethical Considerations

This study was approved by the Biomedical Ethics Committee of Anhui Medical University (20200428). This study was conducted in accordance with the principles outlined in the Declaration of Helsinki. All patients were informed that the collected data would be used for research purposes and were assured that the study involved no invasive examinations or investigational drugs. Written informed consent was obtained from all participating patients. Participants retained the right to withdraw from the trial at any time without penalty or retaliation, and researchers were prohibited from influencing patients' decisions. Non-anonymized study data are accessible exclusively to investigators, with all data undergoing de-identification procedures prior to processing and analysis

Results

Demographic and Clinical Characteristics

As shown in Figure 1, there was a total of 150 patients with confirmed NSCLC and gene mutations during the screening phase of this study. Ultimately, 58% (87/150) of the patients met the inclusion criteria. The patients were divided into 2 groups, a group with no cognitive disorder (42/87, 48%) and a group with cognitive disorder (45/87, 52%), based on the MMSE assessment scores.

Table 1 shows the demographic and clinical characteristics of the study population. There were no significant differences between the 2 groups, including in age (t_{79}=0.543; *P*=.59), sex (χ^2_1=0.03, *P*=.86), educational level (χ^2_3=1.2; *P*=.76), tumor stage (χ^2_2=1.2; *P*=.55), presence of distant metastasis (χ^2_1=0.2; *P*=.63), distribution of distant metastatic sites (χ^2_2=1.1; *P*=.57), targeted therapy drugs (χ^2_4=4.0; *P*=.41), and Karnofsky Performance Scale (χ^2_1=0.3; *P*=.59).

Therapeutic Effect Between the Groups With and Without Cognitive Disorder

Table 2 shows the differences in the efficacy of targeted therapy between the groups with and without cognitive disorder. Neither group had participants reach complete response. In the group with cognitive disorder, the efficacies were partial response for 38% (17/45) of the patients, stable disease for 49% (22/45) of the patients, and progressive disease for 13% (6/45) of the patients, resulting in an ORR of 37.8% and a disease control rate (DCR) of 86.7%. In the group with no cognitive disorder, the efficacies were partial response for 79% (33/42) of the patients, stable disease for 19% (8/42) of the patients, and progressive disease for 2% (1/42) of the patients, resulting in an ORR of 78.6% and a DCR of 97.6%. There was a significant difference in the efficacies of targeted therapy between the 2 groups (χ^2_2=15.1; *P*=<.001).

Correlation Between Cognitive Disorder and Targeted Therapy

Table 3 shows changes in the cognitive function scores of patients with NSCLC before and after targeted therapy. Before targeted therapy, the mean MMSE score of the group with no cognitive disorder was 27.93 (SD 0.75), whereas the mean MMSE score of the group with cognitive disorder was 25.51 (SD 0.63). The difference between the groups was statistically significant (z=−8.245; P<.001). After targeted therapy, the mean MMSE score of the group with no cognitive disorder was 27.48 (SD 1.06), and the mean MMSE score of the group with cognitive disorder was 24.62 (SD 1.50). The difference between the groups was statistically significant (z=−7.118; P<.001). After targeted therapy, both groups' MMSE scores decreased, with the mean change in the group with no cognitive disorder being −0.45 (SD 1.09) and that in the group with cognitive disorder being −0.89 (SD 1.25). The group with cognitive disorder showed a more significant decrease than the group with no cognitive disorder, and the difference between the 2 groups was significant (z=−4.689; P<.001). The group with no cognitive disorder had a significant difference from before to after targeted therapy (z=−2.534; P=.01) and the cognitive disorder group also had a significant difference from before to after targeted therapy (z=−3.944; P<.001). As shown in Figure 2, there was a negative correlation between the MMSE score and the psychological distress score after targeted therapy (R^2=0.426; P<.001).

Table 3. Differences in Mini-Mental State Examination (MMSE) score at different time points.

	No CD[a] group (n=42), mean (SD)	CD group (n=45), mean (SD)	*z* score	*P* value
MMSE score at time 1[b]	27.93 (0.75)	25.51 (0.63)	−8.245	<.001

XSL•FO
RenderX

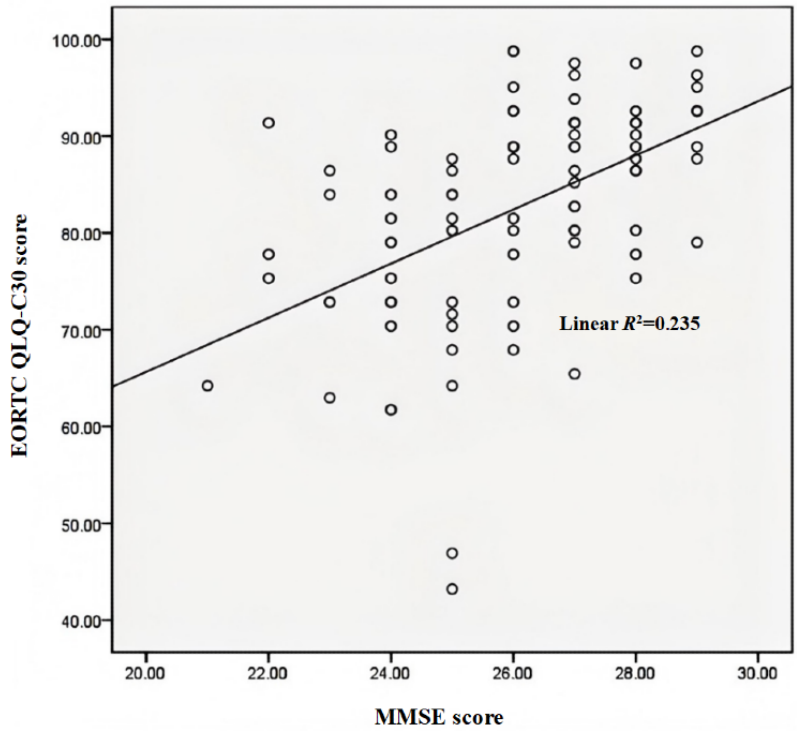

Figure 2. Correlation between the Mini-Mental State Examination (MMSE) score and psychological distress after targeted therapy (R^2=0.426; P<.001).

Correlation Between QoL and Cognitive Disorder

Before targeted therapy, the QoL score (mean 88.83, SD 5.69) of the group with no cognitive disorder was higher than that of the group with cognitive disorder (mean 80.30, SD 9.62), and there was a significant difference between the 2 groups (t=–5.073; P<.001). After targeted therapy, the QoL score (mean 90.04, SD 5.48) of the group with no cognitive disorder was higher than that of the group with cognitive disorder (mean 75.31, SD 10.40), and the difference between the 2 groups was significant (t=−8.337; P<.001). As shown in Figure 3, the MMSE score was positively correlated with QoL scores after targeted therapy (R^2=0.235; P<.001).

Figure 3. Correlation between the Mini-Mental State Examination (MMSE) score and the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC QLQ-C30) score after targeted therapy (R^2=0.235; P<.001).

XSL•FO
RenderX

Correlation Between CRP Concentration and Cognitive Disorder

Table 4 shows that, before targeted therapy, the CRP concentration (mean 7.05, SD 10.26 mg/L) of the group with no cognitive disorder was significantly lower than that of the group with cognitive disorder (mean 16.04, SD 19.88 mg/L), and there was a significant difference between the 2 groups (z=−2.175; P=.03). After targeted therapy, the CRP concentration (mean 10.64, SD 15.37 mg/L) in the group with no cognitive disorder was also significantly lower than that of the group with cognitive disorder (mean 20.09, SD 27.37 mg/L), and there was a significant difference between the 2 groups (z=−1.975; P=.048). After targeted therapy, the changes in CRP concentration in both groups showed an increasing trend compared to before targeted therapy, and the difference between the 2 groups was significant (z=−3.365; P=.001). There is a significant difference in CRP concentration before and after targeted therapy between the group with no cognitive disorder and the group with cognitive disorder (P=.01 and P=.03, respectively). As shown in Figure 4, the psychological distress score was correlated with CRP concentration after targeted therapy (R^2=0.058; P=.03).

Table 4. Differences in C-reactive protein concentration at different time points.

C-reactive protein concentration (mg/L)	No CD[a] group (n=42), mean (SD)	CD group (n=45), mean (SD)	*z* score	*P* value
At time 1[b]	7.05 (10.26)	16.04 (19.88)	−2.175	.03
At time 2[c]	10.64 (15.37)	20.09 (27.37)	−1.975	.048
Difference between time 1 and time 2[d]	3.59 (11.12)	4.05 (18.85)	−3.365	.001

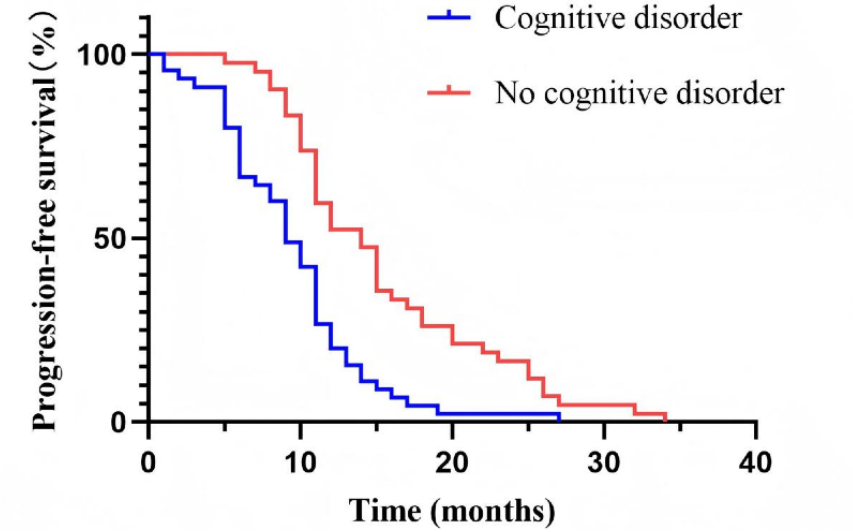
Figure 4. Correlation between C-reactive protein concentration and psychological distress after targeted therapy (R^2=0.058; P=.03).



PFS in Patients Receiving Targeted Therapy

Figure 5 shows that the PFS in patients with no cognitive disorder was significantly better than that in patients with cognitive disorder after targeted therapy (hazard ratio=0.347, 95% CI 0.209-0.578; P<.001). The median PFS for the group with cognitive disorder was 9 months (95% CI 7.36-10.64; IQR: 6-12 months), and the median PFS for the group with no cognitive disorder was 14 months (95% CI 11.46-16.54; IQR: 10-20 months).

XSL•FO
RenderX

Figure 5. Progression-free survival in patients receiving targeted therapy for advanced non–small cell lung cancer with gene mutation.

Factors Influencing PFS After Targeted Therapy

As shown in Table 5, Cox proportional hazard regression analysis revealed that sex (*P*=.67), age (*P*=.27), educational level (*P*=.85), EORTC QLQ-C30 score (*P*=.49), type of targeted drug (*P*=.56), CRP concentration (*P*=.37), and brain metastasis(*P*=.66) had no significant impact on PFS. However, cognitive dysfunction level was significantly associated with PFS. Cognitive disorder had a negative effect—worse cognitive function was correlated with reduced PFS (*P*=.03). Furthermore, cognitive dysfunction was identified as an independent risk factor for shorter PFS.

Table 5. Cox proportional hazard regression model analysis for progression-free survival in patients receiving targeted therapy.

Influence factor	Hazard ratio (95% CI)	*P* value
Cognitive function	1.946 (1.051-3.605)	.03
Sex	1.116 (0.679-1.833)	.67
Age	1.323 (0.807-2.168)	.27
Educational level	1.028 (0.765-1.382)	.85
EORTC QLQ-C30[a] score	1.228 (0.684-2.205)	.49
Targeted drug	0.939 (0.759-1.161)	.56
Brain metastasis	0.877 (0.494-1.560)	.66
C-reactive protein concentration	1.249 (0.769-2.029)	.37

[a]EORTC QLQ-C30: European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30.

Discussion

Principal Findings

This study suggests that cognitive disorder is associated with QoL and clinical outcomes in patients with advanced NSCLC receiving targeted therapy. The ORR was 37.8%, and the DCR was 86.7% in patients with cognitive disorder compared to 78.6% (ORR) and 19% (DCR) in patients with no cognitive disorder, demonstrating statistically significant differences in treatment efficacy between groups (*P*<.05). These results indicate superior therapeutic outcomes in patients with no cognitive disorder. Our analysis revealed a positive correlation between QoL and MMSE scores in patients with advanced NSCLC with driver gene mutations following targeted therapy (R^2=0.235; *P*<.001), suggesting an association between cognitive function and posttreatment QoL. This finding aligns with those of previous studies demonstrating that cognitive decline adversely affects QoL [39-42]. Furthermore, PFS was significantly shorter in patients cognitive disorder (median 9 months) than in patients with no cognitive disorder (median 14 months), with a statistically significant between-group difference (*P*<.05).

Cancer-related cognitive disorder is not just manifested in memory loss but also in declines in language and executive functions [43]. Previous studies have confirmed that cognitive disorder is present in patients with tumors before treatment. For example, in a study of cognitive function in patients with breast cancer, compared with a healthy control group, lower cognitive function was exhibited before treatment [44,45]. In colorectal cancer cognitive function research, Cruzado et al [40] also found that 37% of patients had cognitive disorder before treatment. Similarly, Vardy et al [46] also reported in a study of colon cancer that approximately 40% of patients compared with the healthy group had cognitive disorder before treatment. In lung cancer research, 35.4% of patients with advanced lung cancer had perceptual attention disorders before treatment, and 58.4%

XSL•FO
RenderX

of patients had perceptual memory disorders [29]. In this study, 52% (45/87) of patients showed cognitive disorder before treatment. As for the mechanisms of cognitive function changes in patients with cancer, Zhang et al [47] found that changes in cognitive function may be related to increased blood-brain barrier leakage. Compared to a healthy control group, patients with advanced lung cancer without brain metastasis had higher leakage rates in both temporal and whole brain lobes, primarily in visual space and executive function as well as delayed recall impairments. This could further cause brain metastasis and cognitive deterioration with the increase of blood-brain barrier leakage [47]. The research by Vannorsdall et al [48] indicates that not only does disease progression affect a patient with cancer's perception of cognitive function, but cancer treatment also leads to deteriorating cognitive function. Increasingly, studies have found that commonly used chemotherapy in tumor treatment can cause changes in a patient's cognitive function [49-51]. Cognitive changes are not limited to chemotherapy. There are cognitive changes even in targeted treatment. For example, previous studies have found an impact on cognitive function when vascular endothelial growth factor inhibitors are used, mainly affecting working memory and information processing speed [52]. In patients with EGFR mutations, after using EGFR tyrosine kinase inhibitor drugs, an increase in brain white matter damage and loss of gray matter volume were observed when testing using the modified Scheltens visual rating scale and voxel-based morphometry method. This reflects a possible negative impact of targeted treatment on cognitive function, which might explain the cognitive decline after targeted treatment [53]. In this study, after targeted treatment, the MMSE scores of the groups both with and without cognitive disorder decreased, with the group with cognitive disorder showing a larger decrease. Meanwhile, multivariate Cox analysis also demonstrated that cognitive disorder was an independent risk factor for PFS in patients. This step indicates that cognitive disorder impairs the therapeutic effect of targeted treatment and targeted treatment, in turn, aggravates the degree of cognitive dysfunction.

In this study, a change in the concentration of CRP was also observed. Before targeted therapy, the group without cognitive disorder had a lower concentration of CRP, with a significant difference between the 2 groups. An increasing trend in CRP levels was observed in both groups after targeted therapy. Wersching et al [54] also found a correlation between CRP levels and cognitive function, where higher CRP levels were associated with poorer executive function. This may be due to low-grade inflammation affecting the disintegration of the cerebral microstructure, hence influencing the frontal lobe pathway and corresponding executive functions and, consequently, impacting cognitive function [54]. In a large cohort study conducted by Arce Rentería et al [55] on individuals over the age of 45 years, higher CRP levels were found to be correlated with poorer memory and language fluency; CRP levels can serve as biomarkers for cognitive disorder in individuals over the age of 45 years [55]. CRP is a significant inflammatory and vascular disease biomarker. Inflammation can cause endothelial cell dysfunction, reflected in alterations in the white matter signal, which serves as a radiographic marker for cerebral vascular disease, playing a pivotal role in monitoring cognitive disorder [56,57]. Other brain regions controlling cognitive function are similarly affected by inflammation, for instance, the hippocampus. The hippocampus, located between the thalamus and medial temporal lobe and part of the limbic system, is primarily responsible for memory functions. Its volume can decrease under inflammatory conditions, closely tied to a decrease in cognitive function [58]. Hence, it can be inferred that an increase in CRP concentration is a critical indicator to predict cognitive disorder. In this study, an increasing trend in CRP was observed after targeted therapy, serving as a risk precursor for changes in cognitive function. However, no statistically significant correlation was observed between MMSE scores and fluctuations in CRP levels. The MMSE provides a composite score encompassing multiple cognitive domains (including orientation, memory, attention, language, and visuospatial function) without distinguishing specific subdomain impairments. Consequently, this global assessment metric may fail to detect subtle yet potentially clinically relevant cognitive changes associated with inflammatory processes. Future studies incorporating domain-specific neuropsychological assessments or more sensitive biomarkers of neuroinflammation may help elucidate this relationship. Targeted therapy might have promoted changes in CRP levels, resulting in changes in cognitive function.

Psychological distress is also a common psychological factor of concern in advanced lung cancer. In this study, psychological distress was positively correlated with concentrations of CRP (R^2=0.058; P=.03) and negatively correlated with MMSE scores (R^2=0.426; P<.001). Psychological distress is closely related to changes in cognitive function and inflammatory mediators during the onset and progression of cancer. Inflammatory cytokines are involved in the development of neuropsychiatric symptoms and depression and the risk factors associated with increased circulating inflammatory cytokines and CRP [59]. In patients with cancer as well as depression and fatigue, there are also elevated circulating inflammatory cytokines, and peripheral blood interleukin (IL)-1β, IL-6, tumor necrosis factor, and CRP levels show an increasing trend [60,61]. Among them, high plasma levels of IL-6 are related to accelerated tumor progression, high-stress states, depression, and abnormal behavior [62]. Therefore, CRP as an important indicator of inflammation is closely related to the psychological factors of patients with cancer. Similarly, clinical studies have found a correlation between psychological distress and cognitive disorder. In a large study, the higher the severity of psychological distress in young patients with cancer, the greater the probability of cognitive disorder [63]. Among patients with breast cancer, compared with those without depression, those in the depressed group scored higher on the Cognitive Error Questionnaire, indicating cognitive decline [64]. Moreover, research by Ando-Tanabe et al [65] has also confirmed that patients with greater psychological distress have higher levels of cognitive disorder. For patients with cancer during diagnosis and treatment, sufficient attention must be paid to psychological and cognitive issues, which have a certain impact on the diagnosis and treatment of tumors. Screening, consultation, and intervention involving professional oncology psychologists are necessary.

XSL•FO
RenderX

With the widespread promotion of gene testing technology in clinical applications, patients with advanced lung cancer have more treatment opportunities. Throughout the clinical treatment process, we observed changes in patients' cognitive function. For patients with EGFR or ALK mutations, we adopted the MMSE assessment scale, EORTC QLQ-C30 scale, and DT scale to evaluate the relationship between changes in cognitive function during targeted treatment and QoL and psychological distress and cognitive function's impact on treatment outcomes. In future treatments, patients requiring targeted therapy should routinely undergo cognitive function assessments. Adjuvant neuroprotective agents should be used to mitigate cognitive decline. Comprehensive supportive care should be implemented involving a multidisciplinary team approach with specialties such as psycho-oncology and neurology to collaboratively participate in the treatment. The EORTC QLQ-C30 should be integrated with cognitive scales to comprehensively capture treatment efficacy.

Limitations

This study is a small-sample investigation that conducted exploratory observational research based on clinically observed phenomena. The sample size of this study is similar to that of previous clinical trials assessing cognitive function [66-68]. However, a small sample size may reduce the study's statistical power and increase the likelihood of false-negative results. The reasons for the limited sample size are as follows. First, economic constraints played a role as some patients declined genetic testing due to the high costs, thereby losing the opportunity for targeted therapy. Second, delays in genetic test results led some patients to opt for chemotherapy before targeted therapy was available rather than receiving targeted treatment alone. Third, selection bias may have been introduced as socioeconomic factors and individual patient preferences influenced the demographic undergoing testing, potentially skewing the study sample. Fourth, the increasing number of clinical trials for lung cancer may have led some patients to participate in free clinical studies, further reducing the sample size of this trial.

Future Directions

Moving forward, it is imperative to conduct more in-depth investigations into the precise molecular mechanisms underlying the association between targeted anticancer therapies and treatment-related cognitive dysfunction. A particularly critical area of inquiry involves elucidating the pathophysiological pathways through which molecularly targeted agents may induce or exacerbate neurocognitive impairments, potentially through blood-brain barrier disruption, neuroinflammation, or direct neuronal toxicity.

Furthermore, the potential synergistic neurotoxic effects of combination regimens incorporating both traditional chemotherapeutic agents and novel targeted therapies warrant rigorous scientific exploration. This line of investigation should use comprehensive neuropsychological assessments coupled with advanced neuroimaging and biomarker analyses to determine whether such combination therapies produce additive or multiplicative adverse effects on cognitive function. These research directions have significant clinical implications for optimizing treatment strategies while preserving patients' QoL and neurocognitive health. In the future, we need to further investigate the molecular mechanisms linking targeted therapy and cognitive disorder. Moreover, whether chemotherapy combined with targeted therapy exacerbates cognitive disorder is also a valuable aspect requiring further exploration and research.

Conclusions

The findings confirmed that, following targeted therapy, patients with preexisting cognitive disorder showed markedly reduced QoL metrics and inferior PFS outcomes relative to cognitively intact patients. Substantial correlation was found among psychological factors, cognitive impairment, and CRP concentration in patients with advanced lung cancer. For such patients, early screening, counseling, and effective intervention measures are crucial for enhancing clinical efficacy and QoL.

Abstract

Background: Thyroid cancer is one of the most commonly diagnosed malignancies in South Korea, with incidence rates among the highest globally. Young women, in particular, represent a high-risk group, likely due to a combination of biological, occupational, and environmental factors. However, the specific risk factors contributing to thyroid cancer development in this population remain poorly understood.

Objective: This study aims to identify the risk factors associated with thyroid cancer among young female nurses using longitudinal survival analysis.

Methods: This longitudinal study used data from the Korea Nurses' Health Study (KNHS), a prospective national cohort of female nurses. Data from the first, fifth, seventh, and ninth surveys were used to construct a person-period data set. Female nurses aged in their 20s at baseline were included. Time-varying explanatory variables included age, marital status, BMI, smoking, alcohol consumption, perceived stress, sleep problems, nursing position, night shift work, working unit, and duration of radiation exposure. The dependent variable was self-reported physician-diagnosed thyroid cancer. Kaplan-Meier survival analysis and Cox proportional hazards regression were performed to examine the association between risk factors and thyroid cancer occurrence.

Results: A total of 22,759 person-period cases were analyzed, and 105 thyroid cancer events were identified. Kaplan-Meier analysis showed significant associations between thyroid cancer occurrence and age (χ^2_1=51.6, P<.001), marital status (χ^2_1=25.1, P<.001), sleep problems (χ^2_1=20.3, P<.001), night shift work (χ^2_1=20.1, P<.001), working unit (χ^2_1=13.0, P<.001), and duration of radiation exposure (χ^2_1=91.0, P<.001). In the Cox regression model, nurses aged in their 20s had a significantly higher risk of thyroid cancer than those aged in their 30s (hazard ratio [HR] 4.602, 95% CI 1.893-11.188). Those who worked night shifts were also at an increased risk (HR 1.923, 95% CI 1.127-3.280). Compared with no exposure, radiation exposure showed a dose-response relationship: <1 year: HR 3.449, 95% CI 1.474-8.074; ≥1 year: HR 4.178, 95% CI 2.702-6.461.

Conclusions: Younger age, night shift work, and duration of radiation exposure were significantly associated with an increased risk of thyroid cancer in young female nurses. These findings highlight the importance of early screening and occupational risk management, including regular radiation monitoring and support for circadian health, in health care settings.

KEYWORDS

cohort studies; occupational exposure; longitudinal studies; nurses; thyroid neoplasms; women's health

Introduction

In recent decades, thyroid cancer (TC) has emerged as the most rapidly increasing type of cancer worldwide, ranking ninth in incidence in the United States in 2020 [1]. The reported incidence rate of TC has doubled in the United States, rising from 7.62 per 100,000 people in 2000 to 13.83 per 100,000 in 2017, partly due to advancements in diagnostic technology [2]. Although TC has the highest 5-year survival rate among all cancers (98.3%), it imposes a substantial burden on the health care system and affected individuals due to psychological and financial challenges, especially given its recurrence rate of 4.3%-13.6% [3,4]. Among the global increase in TC incidence, South Korea reported especially high rates, ranging from 6.5 per 100,000 in 1999 to 40.2 per 100,000 in 2018—the highest reported values globally [5].

Notably, women in South Korea had higher age-standardized incidence (62.2 per 100,000 for women vs 18.8 per 100,000 for men) and mortality (0.4 per 100,000 for women vs 0.2 per 100,000 for men) in 2018 [6]. Specifically, women aged 15 years to 34 years are considered an at-risk group, accounting for 50% of all cancers diagnosed in South Korea [6]. TC is of particular concern for young adults aged in their 20s, as it is the second most commonly diagnosed cancer during pregnancy and up to 1 year postpartum [7]. Although concerns have been raised about overdiagnosis of TC—especially in South Korea, where improved access to health care has increased tumor detection rates [8]—and despite the low mortality rate of TC, all cancer survivors are subject to lifelong surveillance for disease recurrence. Furthermore, it is necessary to consider the changes associated with modern industrialized lifestyles, such as increased exposure to medical radiation, along with environmental and behavioral factors, which may serve as carcinogenic risk factors contributing to TC occurrence in young adult women [9].

As the etiology of TC remains poorly understood, researchers have explored potential risk factors to facilitate the development of preventive strategies. The most widely recognized contributor to the development of TC is exposure to ionizing radiation, and this risk is aggravated when individuals are exposed in their younger years [9]. Globally, 7.35 million medical professionals, including nurses, are exposed to occupational low-dose ionizing radiation, which may be associated with TC development [10]. However, the literature remains inconclusive, with conflicting findings on the statistical significance of the association between radiation exposure and TC risk among nurses [9,11]. Moreover, being female has been historically associated with an increased risk of papillary TC, likely due to the influence of reproductive hormones such as estrogen and progesterone [12]. As with all other cancer types, a family history of the disease—particularly the nonmedullary type—also contributes to the risk because genetic mutations increase an individual's susceptibility to tumor formation [13,14].

Sociodemographic and lifestyle factors have long been the focus of research aimed at TC prevention in the general population. Large-scale cohort studies have demonstrated an association between obesity—typically measured via BMI—and TC risk [15], particularly among women, regardless of geographical or age differences [16]. Moreover, sleep disturbances have been associated with TC incidence. For example, a systematic review reported that night shift work may affect thyroid-stimulating hormone levels, which may contribute to the development of thyroid malignancies [17]. Traditional cancer risk factors such as cigarette smoking, alcohol consumption, and stress have also been investigated as risk factors for TC; however, the findings have been inconsistent. These discrepancies underscore the importance of exploring multiple lifestyle factors that may be implicated in TC risk [18].

Considering the inconsistent results regarding the potential risk factors for TC occurrence and the high incidence of TC observed among young adult Korean women, further investigation of these factors is needed to better understand their contribution to TC in women. Therefore, leveraging a large longitudinal data set from the ongoing Korea Nurses' Health Study (KNHS), we investigated the risk factors that may be predictors of TC among female nurses aged in their 20s. We believe that the TC risk factors identified in this well-characterized population will be broadly representative of those identified in all South Korean women.

Methods

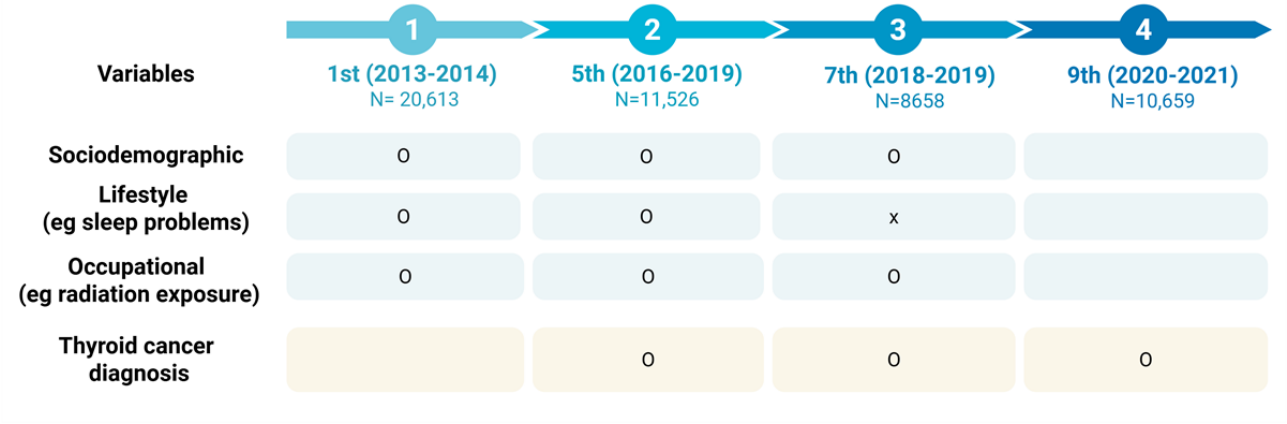
To enhance the transparency and quality of observational studies, this study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist for cohort studies.

Data Source and Study Population

In this study, we used data from the KNHS, an ongoing prospective cohort study designed to investigate the determinants of women's health and illness. The initial KNHS survey was conducted from 2013 to 2014, enrolling 20,613 female nurses. Participants have since been followed through online surveys [19]. This analysis explored the influence of sociodemographic, lifestyle, and occupational characteristics on the occurrence of TC over time, using data from the first and fifth surveys in 2016-2019 (n=11,526), seventh survey in 2018-2019 (n=8658), and ninth survey in 2020-2021 (n=10,659). These 4 surveys were selected for the longitudinal analysis due to their high number of participants and consistency in question items. From the first survey, we identified a subset of women aged in their 20s (n=12,055). An overview of the measurement timeline across the surveys and the survival analysis structure are shown in Figures 1 and 2, respectively.

XSL•FO
RenderX

Figure 1. Measurement timeline across the Korea Nurses' Health Study. Created with BioRender [20].



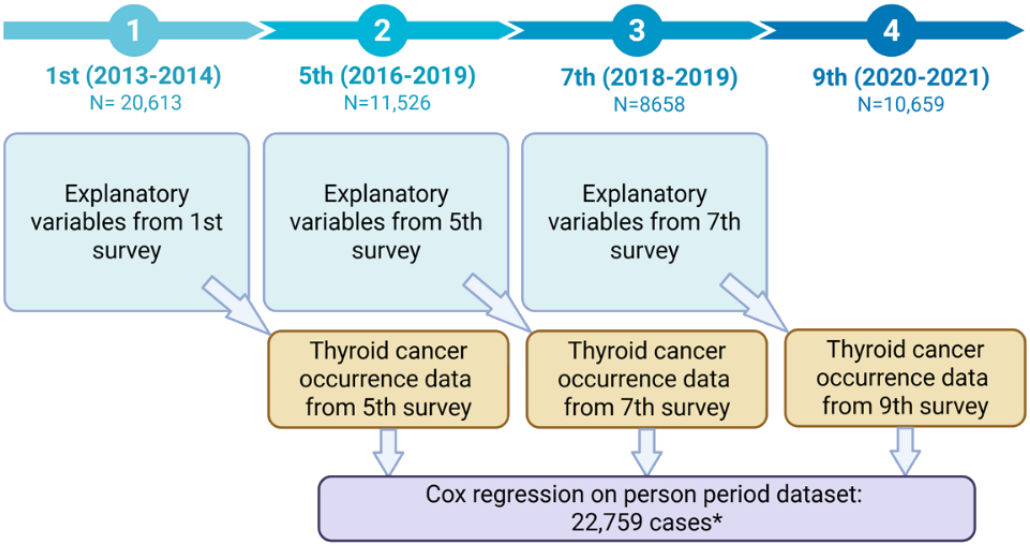


Figure 2. Person-period data structure. *Cases with missing data on explanatory or dependent variables were excluded by default. Created with BioRender [20].

In longitudinal data sets, explanatory variables should precede the occurrence of a dependent variable to establish potential causal relationships between these variables. Accordingly, in this study, TC occurrence in the fifth survey was analyzed in relation to explanatory variables from the first survey, TC occurrence in the seventh survey was analyzed based on explanatory variables from the fifth survey, and TC occurrence in the ninth survey was analyzed based on explanatory variables from the seventh survey. This design allowed for the assessment of how time-varying explanatory variables influence TC occurrence (a dependent variable) over time.

The first, fifth, seventh, and ninth surveys were selected because the dependent variable—physician-diagnosed TC—was assessed in all but the second and sixth surveys. Additionally, the duration of radiation exposure in hospitals—a key explanatory variable for TC—was specifically addressed in the first, fifth, and seventh surveys.

Measures

The dependent variable was defined as a dichotomized indicator of TC diagnosis made by a medical professional, as reported in the fifth, seventh, and ninth surveys. These surveys assessed the occurrence of TC before 2017, between 2018 and 2019, and between 2020 and 2021, respectively.

In this study, the explanatory variables were classified as sociodemographic, lifestyle, and occupational factors. Sociodemographic variables included age, marital status, and BMI in the first, fifth, and seventh surveys. Age was dichotomized as <30 years and ≥30 years. Marital status was categorized as married and unmarried/divorced/separated/widowed. BMI, calculated using height and weight, was categorized into underweight/normal (<23 kg/m^2) and overweight or obese (23 kg/m^2) groups.

Lifestyle variables included smoking status, alcohol consumption, perceived stress, and sleep problems. Smoking and alcohol consumption were assessed in the first and fifth surveys and categorized as yes or no. We analyzed whether smoking and alcohol consumption in the fifth survey could affect the occurrence of TC in the ninth survey because this information was not collected in the seventh survey. Perceived stress was measured on a 2-point scale. A 4-item perceived stress scale was used in the first survey, whereas a 10-item scale was used in the fifth and seventh surveys [21,22]. Both the 4-item and 10-item scales have been proven reliable and valid. The cutoff scores were determined based on the literature, with the top tertile categorized as high stress and the remaining tertiles as low stress [23]. The Cronbach α for the perceived

XSL•FO
RenderX

stress scales was 0.52, 0.70, and 0.73 in the first, fifth, and seventh surveys, respectively. Sleep problems were measured using the Jenkins Sleep Scale [24]. Based on a cutoff point of 12 out of a total score of 20, sleep problems were dichotomized as yes or no. The Cronbach α for sleep problems was 0.88 and 0.83 in the first and fifth surveys, respectively. We analyzed whether sleep problems in the fifth survey could affect the occurrence of TC in the ninth survey because this information was not collected in the seventh survey.

Occupational variables included nursing position, night shift work, working unit, and duration of radiation exposure in the hospital during the first, fifth, and seventh surveys. Nursing positions were dichotomized into staff nurses, nursing unit managers, and administrative supervisors. Night shift work was categorized as yes or no. Working units were classified into general ward/outpatient ward/hospital administration or special care units (eg, intensive care or emergency, anesthesia, operating room). To assess radiation exposure in hospitals, we surveyed the exclusive use of X-ray rooms, portable X-rays, computed tomography scans, fluoroscopes, radioactive isotopes, and radioactive materials. The duration of radiation exposure was surveyed among patients who were exposed to radiation in the hospital. Responses were classified as no-exposure, <1 year, and ≥1 year.

Statistical Analysis

Descriptive and cross-tabulation analyses were performed to compare sociodemographic, lifestyle, and occupational characteristics by TC status, using baseline data from the first survey (n=20,613). Longitudinal survival analysis was conducted using data from the first, fifth, seventh, and ninth surveys of the KNHS based on the literature, demonstrating that survival analysis can be performed using survey data with at least one follow-up [25]. Based on the findings of a previous study [26], explanatory variables in the first, fifth, and seventh surveys and the dependent variable TC in the fifth, seventh, and ninth surveys were used to construct a person-period data set. The data set was transformed into a long format with one row per person to capture temporal changes. After excluding cases with missing data on either explanatory or dependent variables (n=39,260), a total of 22,759 patients were included in the final analysis.

For the univariate analysis, a cumulative survival function test and Kaplan-Meier analysis were performed. The cumulative survival function test was performed to identify the effect of radiation exposure on TC occurrence. Kaplan-Meier analysis was performed to explore the relationship between each explanatory variable and the dependent variable, TC.

For the multivariate analysis, Cox regression analysis was conducted to identify the hazard ratios (HRs) of the explanatory variables affecting the dependent variable TC over time [25]. This approach accounted for the time-varying nature of explanatory variables and their influence on subsequent TC development. In multivariate analysis, there was no collinearity among the variables selected in the model. Furthermore, the Cox regression assumption—that the influence of independent variables on an event is constant over time—was confirmed [25].

Ethical Considerations

This study was approved by the institutional review board overseeing the KNHS (approval number 2013-03CON-03-P). Detailed descriptions of KNHS data collection procedures are available in the study by Kim et al [19]. In brief, participants provided electronic informed consent after securely logging into the KNHS website using their names and nurse registration numbers. Consent included agreement to use de-identified survey data for research purposes, prospective follow-up through national databases, and the protection of personal information in compliance with Korea's Privacy Protection Act. Additional consent was obtained for the use of contact information for follow-up and distribution of participation incentives. Survey data were anonymized for analysis, and personal identifiers were stored securely. Participants received a mobile gift card valued at approximately US $4.00 (₩4000) as compensation.

Results

Study Participant Characteristics

The results of the baseline descriptive analysis are presented in Table 1. This includes thyroid occurrence categorized by sociodemographic, lifestyle, and occupational variables.

Cumulative Survival Analysis

The results of the cumulative survival function test for assessing the association between TC occurrence and duration of radiation exposure in the hospital are shown in Figure 3. The survival curves for TC occurrence significantly differed by the duration of radiation exposure. Specifically, the cumulative survival rate of TC decreased with increasing duration of radiation exposure in the hospital.

Figure 3. Cumulative survival rates for thyroid cancer by the duration of radiation exposure in the hospital. Created with BioRender [20].

Univariate Analysis

Transformation of the KNHS data into a person-period data set yielded 22,759 cases with 105 occurrences of TC. The results of the Kaplan-Meier analysis are summarized in Table 2. Among the sociodemographic variables, age (χ^2_1=51.6, *P*<.001) and marital status (χ^2_1=25.1, *P*<.001) were associated with TC occurrence. Among lifestyle variables, sleep problems were significantly associated with TC occurrence (χ^2_1=20.3, *P*<.001). Among the occupational variables, night shift work (χ^2_1=20.1, *P*<.001), working units (χ^2_1=13.0, *P*<.001), and duration of radiation exposure in the hospital (χ^2_1=91.0, *P*<.001) were associated with TC occurrence.

Multivariate Analysis

The results of the Cox regression analysis are presented in Table 3. The value of –2 log-likelihood was 1850.002 (χ^2_1=65.5, *P*<.001) in the Cox regression model. Among the sociodemographic variables, participants aged in their 20s were significantly more likely to be diagnosed with TC than their older counterparts (HR=4.602, 95% CI 1.893-11.188). Among the occupational variables, those who worked night shifts were more likely to be diagnosed with TC than those who did not work night shifts (HR=1.923, 95% CI 1.127-3.280). In addition, those with radiation exposure in the hospital were more likely to be diagnosed with TC than those not exposed (<1 year: HR=3.449, 95% CI 1.474-8.074; ≥1 year: HR=4.178, 95% CI 2.702-6.461).

Discussion

Principal Findings

This longitudinal cohort study of female nurses in South Korea indicated that a longer duration of radiation exposure in the hospital, younger age, and night shift work were significantly associated with the occurrence of TC. These findings suggest that early occupational exposure and circadian disruption play important roles in the development of TC among young women, emphasizing the need for targeted prevention efforts in the health care workforce.

Comparison With Prior Research

Our results align with findings from major international nursing cohorts. For example, the Nurses' Health Study II [12] examined the impact of night shift work, sleep disruption, and reproductive factors on TC risk among female nurses in the United States over several decades of follow-up. Similarly, studies from the Danish Nurse Cohort [26] explored the association between occupational exposure, such as job strain, and cancer development, although direct links to TC have not been established. In contrast to these international studies, our investigation specifically focused on young adult nurses in South Korea, a population with one of the highest global incidences of TC, thereby providing important complementary evidence in an under-represented group.

These findings are also consistent with those of a meta-analysis investigating the association between female sex, radiation exposure, younger age, and TC occurrence [27]. Female nurses exposed to radiation in a hospital for more than 1 year had a >4.2-fold higher risk of developing TC than those who did not. This finding is consistent with that of previous large cohort studies on radiation-exposed workers reporting elevated rates of TC and thyroid abnormalities [28]. With the growing use of radiation-based procedures for diagnosis and treatment, occupational radiation exposure is a serious concern for nurses who are often accidentally or unavoidably exposed to radiation. However, as some studies have indicated, thyroid abnormalities related to radiation exposure are often underestimated or under-reported, and low-dose radiation exposure may not always be clearly linked to TC [29]. Chronic low-level exposure to such radiation may have cumulative effects on genetic mutations and rearrangements that contribute to TC development [30], and women tend to be more radiosensitive than men [31]. To reduce the risk of TC development among medical radiation workers in Korea, a regulation requiring a radiation monitoring system and increased radiation protection was enacted, effectively decreasing the occupational radiation dose per calendar year.

Age has long been a key prognostic factor in cancer staging; however, studies have reported inconsistent results concerning the effects of age on TC occurrence. Consistent with our findings, prior studies have revealed that young female adults (age at diagnosis: <30 years) are likely to have a high risk of TC owing to reproductive hormonal changes and high susceptibility to lymph node positivity, which plays an important role in predicting papillary TC recurrence [12]. However, in other Korean studies using a nationwide hospital-based cancer registry, the 30-year to 50-year age group showed the highest TC risk [6]. These inconsistencies underscore the complexity of TC risk factors; however, our findings support the importance of considering earlier TC screening in young adult women.

Univariate analysis indicated that working night shifts and sleep problems were associated with increased TC risk among female nurses. We acknowledge that our cohort of female nurses with sleep problems was shift workers, for whom disruptions in normal circadian rhythms could lead to sleep deprivation [32]. The etiology of sleep disturbances in TC development is not fully understood. However, a possible explanation is that chronic circadian disruption induced by sleep problems plays a role in hypothalamic-pituitary-adrenal axis dysfunction, resulting in tumor development [33]. Nevertheless, sleep disturbance appears to be a common health concern in the general population [34], and previous studies have reported that older women with insomnia or obstructive sleep apnea are at a higher risk of TC [35]. Although our study did not address sleep characteristics in terms of sleep quantity or quality, our findings highlight the importance of circadian health interventions in occupational settings.

In contrast to previous literature suggesting a positive association between obesity and TC risk [15,36], our analysis found no significant link between BMI and TC occurrence. These contradictory findings may be attributed to demographic differences across the study populations. For example, our study sample was limited to female nurses of Korean ethnicity, whereas other studies have examined more diverse racial and ethnic populations. Notably, in a meta-analysis of obesity and TC occurrence, being overweight was associated with a significant increase in TC among non-Asians but not among Asians [36]. Nevertheless, given that overweight or obesity is a major risk factor for TC, additional studies on the association between BMI and TC in Korean women are warranted.

Strengths and Limitations

This study has several strengths. We leveraged a large-scale, prospective cohort of young female nurses—a medically knowledgeable population known to provide high-quality and reliable self-reported health information. The use of longitudinal data from the KNHS enabled us to examine the effects of time-varying exposures on TC occurrence across multiple survey waves. To appropriately model the temporal relationships between changing exposures and TC risk, we used a longitudinal survival analysis framework using a person-period data structure, which is a widely recommended approach for evaluating time-dependent covariates in event history analyses [37]. Furthermore, this study specifically focused on young adult women aged in their 20s, a high-risk and understudied group in South Korea, contributing novel insights into occupational and lifestyle risk factors for TC development in early life stages.

However, this study has several limitations. First, the KNHS relied on self-reported medical history, such as TC diagnoses, without verification through medical records. Although nurses are generally reliable reporters of health conditions because of their medical knowledge and commitment to research, the possibility of misclassification cannot be entirely excluded [38].

XSL•FO
RenderX

Therefore, the selection of nurses may have enhanced the internal validity of this study. Second, the study did not collect data on TC subtypes or history of benign thyroid diseases, which may have strengthened our assessment of TC risk factors. Third, a detailed quantification of radiation exposure was not possible because radiation-related variables were based on self-reported occupational histories rather than objective dosimetry measurements. Finally, unmeasured confounding factors such as diet, environmental exposure, or detailed sleep characteristics, which could influence the observed associations, were not captured.

Future Directions

These findings have crucial implications for health care administrators and policymakers. Understanding these risk factors will facilitate informed clinical decision-making and foster a safer working environment. Early thyroid screening protocols for young nurses exposed to radiation or who work night shifts may facilitate early detection and intervention. Hospitals and health care systems should implement rigorous radiation safety programs, provide education on circadian health, and consider scheduling strategies to minimize exposure during long-term shifts. To mitigate the risk of TC, nursing administrators should implement comprehensive risk management strategies for their personnel. Such strategies may encompass regular assessments of both the dose and duration of ionizing radiation exposure, ensuring the availability of appropriate personal protective equipment and facilitating rigorous training on its consistent use. Furthermore, it is essential to inform nurses about the potential TC risks associated with night shift work. Education should also encompass the recognition of sleep deprivation symptoms and recommended interventions when these symptoms manifest.

From a public health perspective, prevention efforts should prioritize TC prevention initiatives targeting young female health care workers, focusing on occupational risk mitigation and health monitoring, starting early in their careers. Future research should aim to quantify cumulative occupational radiation exposure through objective dosimetry; explore dose-response relationships with TC risk; and incorporate detailed sleep measures such as sleep quantity, quality, and circadian chronotype. Such research will help clarify modifiable risk factors and guide the development of evidence-based occupational health guidelines to reduce TC risk in vulnerable populations.

Conclusion

In this longitudinal cohort study of young female nurses, we identified significant associations between TC occurrence and a longer duration of radiation exposure in the hospital, younger age, and night shift work. These findings underscore the importance of establishing vigilant measures to protect this vulnerable population. In particular, there is an urgent need for consistent monitoring of radiation exposure, especially among younger nurses engaged in nighttime shift duties. Based on these findings, health care institutions should ensure the availability of appropriate personal protective equipment as well as provide comprehensive radiation safety education and circadian health support. These preventive efforts may reduce the occupational burden of TC among young health care professionals.

Acknowledgments

We would like to express our gratitude to all the nurses who participated.

Abstract

Background: Androgen receptor axis-targeting reagents (ARATs) have become key drugs for patients with castration-resistant prostate cancer (CRPC). ARATs are taken long term in outpatient settings, and effective adverse event (AE) monitoring can help prolong treatment duration for patients with CRPC. Despite the importance of monitoring, few studies have identified which AEs can be captured and assessed in community pharmacies, where pharmacists in Japan dispense medications, provide counseling, and monitor potential AEs for outpatients prescribed ARATs. Therefore, we anticipated that a named entity recognition (NER) system might be used to extract AEs recorded in pharmaceutical care records generated by community pharmacists.

Objective: This study aimed to evaluate whether an NER system can effectively and systematically identify AEs in outpatients undergoing ARAT therapy by reviewing pharmaceutical care records generated by community pharmacists, focusing on assessment notes, which often contain detailed records of AEs. Additionally, the study sought to determine whether outpatient pharmacotherapy monitoring can be enhanced by using NER to systematically collect AEs from pharmaceutical care records.

Methods: We used an NER system based on the widely used Japanese medical term extraction system MedNER-CR-JA, which uses Bidirectional Encoder Representations from Transformers (BERT). To evaluate its performance for pharmaceutical care records by community pharmacists, the NER system was first applied to 1008 assessment notes in records related to anticancer drug prescriptions. Three pharmaceutically proficient researchers compared the results with the annotated notes assigned symptom tags according to annotation guidelines and evaluated the performance of the NER system on the assessment notes in the pharmaceutical care records. The system was then applied to 2193 assessment notes for patients prescribed ARATs.

Results: The F_1-score for exact matches of all symptom tags between the NER system and annotators was 0.72, confirming the NER system has sufficient performance for application to pharmaceutical care records. The NER system automatically assigned 1900 symptom tags for the 2193 assessment notes from patients prescribed ARATs; 623 tags (32.8%) were positive symptom tags (symptoms present), while 1067 tags (56.2%) were negative symptom tags (symptoms absent). Positive symptom tags included ARAT-related AEs such as “pain,” “skin disorders,” “fatigue,” and “gastrointestinal symptoms.” Many other symptoms were classified as serious AEs. Furthermore, differences in symptom tag profiles reflecting pharmacists’ AE monitoring were observed between androgen synthesis inhibition and androgen receptor signaling inhibition.

XSL•FO
RenderX

Conclusions: The NER system successfully extracted AEs from pharmaceutical care records of patients prescribed ARATs, demonstrating its potential to systematically track the presence and absence of AEs in outpatients. Based on the analysis of a large volume of pharmaceutical medical records using the NER system, community pharmacists not only detect potential AEs but also actively monitor the absence of severe AEs, offering valuable insights for the continuous improvement of patient safety management.

Introduction

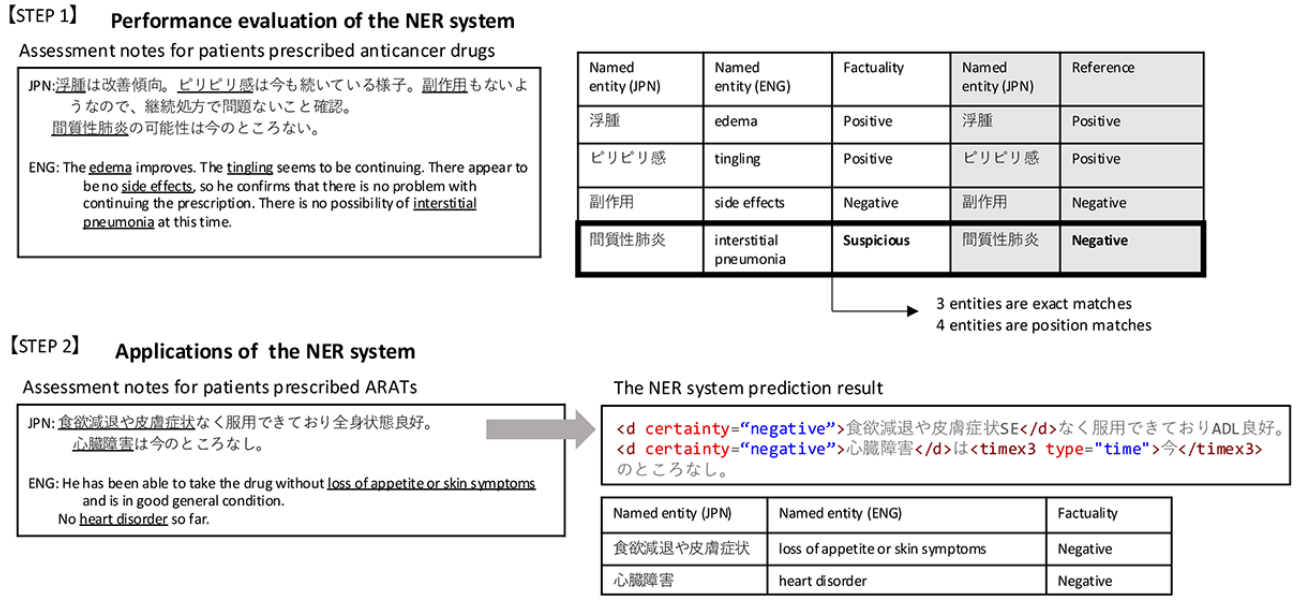
According to the International Agency for Research on Cancer, 20 million new cancer cases were reported in 2022 [1]. In particular, an increasing number of patients are receiving chemotherapy at home [2], driven by the increasing availability of oral anticancer drugs over the past 20 years [3]. Outpatient chemotherapy offers advantages such as reduced invasiveness of administration and fewer hospital visits. However, compared with inpatient chemotherapy, the lack of direct and frequent observation by health care professionals can present safety challenges. In practice, ensuring the safety of oral anticancer drugs prescribed to patients is never easy for treating physicians [4,5]. Additionally, for patients, the adverse events (AEs) experienced after the initiation of treatment may be more burdensome than those reported in clinical trials [6]. Therefore, continuous medical support is essential, extending beyond the hospital setting and involving collaboration with community health care services. Community pharmacies, as the most accessible health care providers, play a crucial role in monitoring AEs in outpatients using oral anticancer drugs [7].

Among outpatient chemotherapy options, endocrine therapy is a common treatment for patients with prostate cancer. In particular, for patients with castration-resistant prostate cancer (CRPC), androgen receptor axis-targeting reagents (ARATs)—abiraterone acetate, apalutamide, darolutamide, and enzalutamide—are taken long term in outpatient settings. Therefore, effective AE monitoring can contribute to prolonged treatment duration [8]. Furthermore, ARATs exhibit distinct AE profiles depending on their pharmacological mechanisms [9,10]. Abiraterone acetate, an androgen synthesis inhibitor, has been reported to cause AEs such as hypertension, gastrointestinal symptoms, fatigue, and liver dysfunction [11]. On the other hand, apalutamide, darolutamide, and enzalutamide, which act through androgen receptor (AR) signaling inhibition, have been associated with AEs such as fatigue and dermatologic disorders [12-15].

In Japan, outpatients prescribed ARATs typically have their prescriptions filled at community pharmacies. Pharmacists at these pharmacies dispense medications, provide patient counseling, monitor for potential AEs, and document pharmaceutical care records. Pharmaceutical care records are commonly written in the SOAP (subjective, objective, assessment, and plan) format [16]. In particular, the assessment section contains pharmacists' evaluations related to the patient's pharmacotherapy and thus may be a fruitful source of information about AEs experienced by patients. By systematically collecting and analyzing the AEs and pharmacists' assessments accumulated in pharmaceutical care records, it could be possible to clarify the AEs experienced outside the hospital by outpatients prescribed ARATs.

However, pharmaceutical care records comprise huge amounts of unstructured text data, including medical terms, accumulated over time for individual patients, making them difficult to analyze manually. Therefore, natural language processing technology, particularly named entity recognition (NER), offers a solution by enabling the extraction of patients' illnesses and symptom data from unstructured medical records [17,18]. Although studies using the NER system to analyze medical texts in hospital inpatients have been reported in the past, few studies have focused on outpatient care, especially in community pharmacy settings, where pharmacists contribute to the safe delivery of pharmacotherapy.

This study aimed to determine whether pharmacotherapy monitoring of outpatients prescribed ARATs can be carried out using NER to systematically collect AEs from pharmaceutical care records, with a particular focus on assessment notes, which may contain detailed records of AEs experienced by patients.



Methods

Outline

An overview of the experimental method is shown in Figure 1. First, we evaluated the performance of the NER system using assessment notes from pharmaceutical care records (STEP 1). The NER system was then used to extract symptoms from the pharmaceutical care records of patients prescribed ARATs (STEP 2).

Figure 1. Outline of the experimental method, including manual annotation on a data set, examination of the model's performance in terms of "position match" and "exact match," and use of the named entity recognition (NER) system to extract symptoms from the pharmaceutical care records of patients prescribed androgen receptor axis-targeting agents (ARATs). ENG: English; JPN: Japanese.

Model Description

System

Our objective was to evaluate the utility of pharmacist-assessed symptoms extracted from pharmaceutical care records kept by community pharmacies. To extract terms, we applied MedNER-CR-JA, an existing Japanese medical term-extraction system based on Bidirectional Encoder Representations from Transformers (BERT) and that was trained using Japanese case reports [19]. Given the input (pharmaceutical care records), the NER system output the symptoms with the factuality (e.g., positive symptom, negative symptom). The factuality was classified into 4 categories as shown in Table 1.

Table 1. Certainty attributes of symptom tags.

Symptom tags	Definition
Positive	The symptom is observed in the patient.
Suspicious	The symptom is suspected to be present in the patient.
Negative	The symptom is not observed in the patient.
General	The symptom is described without reference to the patient's condition.

Materials

This study used data from patients at community pharmacies (n=291,150) belonging to the Nakajima Pharmacy Group in Japan from April 2020 to December 2021. The patients' data consisted of medication orders (structured data) and pharmaceutical care records written in Japanese (unstructured data, n=2,180,902).

First, to evaluate the performance of the NER system (STEP 1), we selected pharmaceutical care records of patients with at least one prescription for anticancer drugs according to the structured data, using the drug codes (YJ codes). YJ codes starting with "42" in Japan indicate anticancer drugs. To evaluate the NER system, we took data recorded during October 2021 through December 2021 at 11 randomly selected pharmacies from the pharmacies with a history of anticancer drug prescriptions. Second, to apply the NER system to pharmaceutical care records (STEP 2), we extracted data for patients prescribed ARATs at least once from April 2020 through December 2021 using individual YJ codes (Multimedia Appendix 1) and used their assessment notes.

In both experiments (STEP 1 and STEP 2), we input the preprocessed text into the NER system. For text preprocessing, we removed line breaks and full-width and half-width spaces from the target text and normalized the text (Unicode). Furthermore, structured sections with template-based input were excluded, and only free-text sections were used.

Performance Evaluations and Metrics for Pharmaceutical Care Records

To evaluate the performance of the NER system on the assessment notes in the pharmaceutical care records, we performed manual annotation on a data set. We verified that the NER system was able to assign symptom tags according to existing annotation guidelines [20] with manual annotation performed by 3 pharmaceutically proficient researchers (SY, YY, KS). These researchers were selected based on their pharmaceutical expertise. Two of them were licensed pharmacists with over 5 years of experience in hospitals or

XSL•FO
RenderX

pharmacies, while the third was a pharmacy student who had completed a clinical internship in both a hospital and a pharmacy. To ensure consistency and reliability in the study, all researchers were expected to be familiar with the existing guidelines regarding the study objectives, task procedures, and evaluation criteria. The existing guidelines were standardized to enable annotation even by nonmedical professionals. To evaluate the consistency and generalizability of the annotation guidelines across annotators, we randomly extracted 100 cases from the target data, and these were annotated. Label agreement was evaluated using the Fleiss kappa (κ) coefficient to assess the concordance rate among the 3 researchers. Let *Po* be the mean of the raters' agreement and *Pe* the degree of concentration for each rating, then the calculation formula is as follows:

For a difficult task like NER, a score of around 0.6 is considered a substantial match, and the obtained evaluations are considered reasonably reliable [21].

After evaluating their agreement, the 3 researchers (SY, YY, KS) annotated the entire data set. The model's performance was evaluated using "position match" and "exact match." Position match is a method that accepts a match with the correct data if the tag's position and name are correct, while exact match requires the tag's position, name, and attributes to match with the correct data. In the position match evaluation, if the position is correct but the predicted tag name is different from the correct tag name, it is considered incorrect. Therefore, in the exact match, we calculated evaluation metrics separately for tags and attributes, while in the position match, we calculated metrics only for the tags. In both methods, the performance was evaluated in terms of precision, recall, and F_1-score:

Ethical Considerations

This study was conducted with anonymized data following approval by the ethics committee of the Keio University Faculty of Pharmacy (approval number: 240618-1) and was conducted in accordance with the relevant guidelines and regulations and the Declaration of Helsinki. Informed consent specific to this study was waived due to the retrospective observational design of the study based on the approval by the ethics committee of the Keio University Faculty of Pharmacy. To respect the will of each stakeholder, however, we provided patients and pharmacists of the pharmacy group with an opportunity to refuse the sharing of their pharmaceutical care records by posting an overview of this study at each pharmacy store or on their websites.

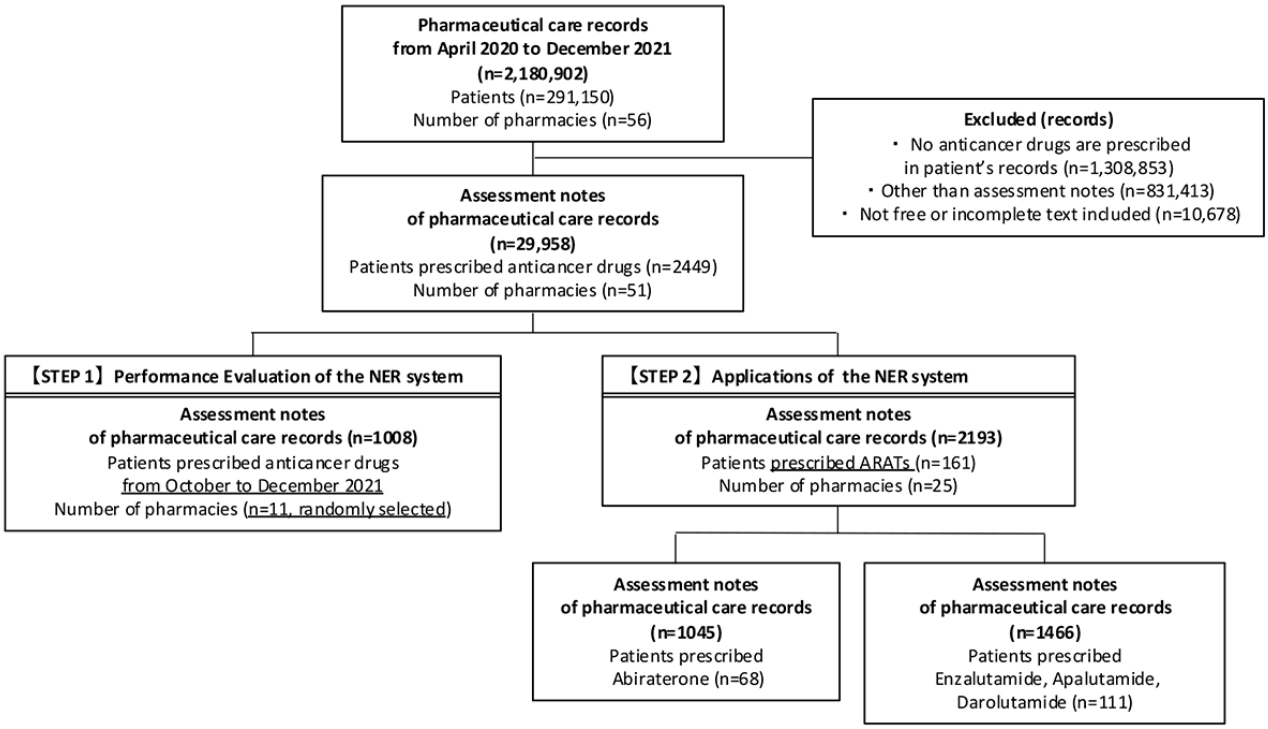
Results

Model Performance and Statistics

The data set used to evaluate the performance of the NER system consisted of 1008 assessment notes. The average word count per text in the target data was 48.3 words, with a median of 42.0 words and minimum and maximum values of 4 and 292 words, respectively. The κ coefficient among the 3 annotators for 100 randomly extracted texts was 0.62.

The F_1-score (NER excluding position matches and attribute classification) was 0.72. This score is the macro-average of the F_1-scores for all attribute classifications (positive, suspicious, negative, and general). For positive and negative symptom tags, the F_1-scores were 0.70 and 0.78, respectively (Table 2). The F_1-scores for all attribute classifications are shown in Multimedia Appendix 2. The position matches showed an excellent F_1-score of 0.86 (Multimedia Appendix 2).

Table 2. Exact matches between the named entity recognition system and annotators.



Tags	Precision	Recall	F_1-score
All symptom tags	0.66	0.78	0.72
Positive symptom tags	0.60	0.85	0.70
Negative symptom tags	0.73	0.83	0.78

Assessment Notes for Patients Prescribed Antiandrogens

Figure 2 shows the flowchart of the procedure for selecting pharmaceutical care records. From April 2020 through December 2021, 161 patients had at least one ARAT prescription and corresponding assessment notes in their pharmaceutical care records. There were 2193 assessment notes recording pharmacists' assessments. Additionally, 68 patients had a history of prescriptions for the androgen synthesis inhibitor abiraterone acetate, with 1045 assessment notes. There were 111 patients with a history of prescription for AR signal transduction inhibitors enzalutamide, apalutamide, and darolutamide, with 1466 assessment notes. On average, each extracted assessment note contained 39.8 words.

Prediction by the NER System

From 2193 assessment notes of patients prescribed ARATs, the NER system automatically assigned 1900 symptom tags. Among these 1900 symptom tags, 623 (32.8%) were positive symptom tags, predicting the presence of symptoms, while the majority, 1067 (56.2%), were negative symptom tags, predicting the absence of symptoms. Additionally, of the 1900 symptom tags, there were 131 (6.9%) general symptom tags and 79 (4.2%) suspicious symptom tags. Specifically, the positive symptom tags were commonly assigned to notes describing "pain," "skin disorders," "fatigue," and "gastrointestinal symptoms." The negative symptom tags frequently appeared in descriptions indicating general side effects such as "SE" or "side effects," accounting for 13.9% (148/1067) of the total. Furthermore, entities with nonpositive symptom tags were AE expressions related to ARATs, such as gastrointestinal symptoms, neuropsychiatric symptoms, and cardiovascular symptoms (Table 3). Other extracted symptoms included seizures and other neuropsychiatric symptoms, cardiovascular symptoms, and hepatic dysfunction. There were also descriptions of severe AEs, including myelosuppression, interstitial pneumonia, and rhabdomyolysis.

Next, the results were examined according to the pharmacological mechanism of action of the ARATs. For patients prescribed the androgen synthesis inhibitor abiraterone acetate, 876 symptom tags were automatically assigned to 1045 assessment notes. The most common symptom tag was negative, with 488 tags (488/876, 55.7%), while 283 positive symptom tags were assigned (283/876, 32.3%; Multimedia Appendix 3). Of the 876 tags, there were 64 (7.3%) general symptom tags and 41 (4.7%) suspicious symptom tags. Regarding characteristic expressions for patients taking abiraterone acetate, "congestive heart failure" was frequently noted among the positive symptom tags. Entities related to skin disorders, which occur frequently in patients taking AR signal transduction inhibitors, appeared infrequently in the top 20 entities. Additionally, entities such as "congestive heart failure," "drug-induced liver injury," and "hyperglycemia" were extracted among nonpositive symptom tags.

For patients prescribed the AR signal transduction inhibitors enzalutamide, apalutamide, and darolutamide, 1466 symptom tags were automatically assigned to 1274 assessment notes. Negative symptom tags were most common, amounting to 692 (692/1466, 47.2%), while positive symptom tags amounted to 438 (438/1466, 29.9%; Multimedia Appendix 4). Of the 1466 tags, there were 96 (6.5%) general symptom tags and 48 (3.3%) suspicious symptom tags. Among the positive symptom tags, characteristic entities for AR signal transduction inhibitors such as "skin disorders" and "fatigue" were frequently noted. Additionally, entities such as "seizures," "psychiatric symptoms," and "cardiovascular diseases" were extracted among the nonpositive symptom tags.

The differences in symptom entities collected based on the pharmacological mechanism of prescribed ARATs are illustrated in Figure 3.

Discussion

Overview

We evaluated the performance of the NER system on pharmaceutical care records and successfully extracted symptoms, including AEs, from the free-text assessment notes of community pharmacists. This study is the first to report the use of the NER system to systematically identify AEs from pharmaceutical care records of patients prescribed ARATs.

Predictive Performance of the NER System

The NER system exhibited robust performance on the pharmaceutical care records analyzed. Although the kappa statistics for annotation (0.62) indicate substantial agreement, the following factors were considered to have contributed to the decrease in the kappa. The most common type of disagreement among annotators was related to the selection range of the entity. Specifically, the annotation guidelines [16] we referenced set the standard for selecting the entire range when symptoms were expressed in parallel. However, discrepancies in the interpretation of the range occurred among the annotators. For example, for text such as “gastrointestinal symptoms, hypoglycemia present,” disagreements arose over whether to annotate this as “gastrointestinal symptoms” and “hypoglycemia” or as “gastrointestinal symptoms, hypoglycemia.”

The F_1-score for symptom tagging (NER and attribute classification) was 0.72, and the F_1-scores for positive and negative predictive performance ranged from 0.70 to 0.78. These results indicate that the system is effective for analyzing the pharmaceutical care records used in this study. Notably, the system outperformed prior work by Ohno et al [22], who reported an F_1-score of 0.64 for assessment notes among the SOAP format descriptions in Japanese hospital-based pharmaceutical care records using MedNER-J (NER and positive and negative classification). The NER evaluation method used in this study assumed that entities that completely matched the annotations were correct. In addition, many types of tags were used, and the evaluation was conducted under more stringent conditions.

Several factors may have affected model performance. In particular, there were specific expressions in pharmaceutical care records that we recognized as causing frequent errors in NER predictions during the performance evaluation. First, pharmacist assessment records often include descriptions related to medication adherence. The NER system sometimes incorrectly recognized terms such as “adherence” and “compliance” as symptom entities (for example, the entity “adherence” was predicted as a symptom expression). Second, pharmacist assessment records frequently included descriptions related to AE confirmation, often using nuanced expressions characteristic of Japanese, such as “no suspicion of XX.” As a result, the NER system occasionally predicted “suspicious” for negative symptom expressions (for example, the entity “interstitial pneumonia” was predicted as suspected in the sentence “no suspicion of interstitial pneumonia,” whereas the correct status should be negative). Additionally, the system showed low extraction rates for entities related to hypertension,

XSL•FO
RenderX

which is a side effect specific to enzalutamide acetate, as well as blood glucose–related expressions associated with concomitant corticosteroids and expressions related to hypokalemia, possibly because vital sign–related terms like "blood pressure" and "blood glucose" were treated as test values rather than symptoms. Another challenge was interpreting negation patterns, such as "No symptoms: XX (Symptoms)" and "Symptoms (-)," which may have led to incorrect symptom tagging.

AEs Identified in Pharmaceutical Care Records for Patients Prescribed ARATs

Our analysis of pharmacists' assessment records for outpatients prescribed ARATs revealed that over 90% of the records contained symptom tags. The extracted entities predominantly indicated symptoms related to AEs commonly seen in patients treated with ARATs. Common positive symptom entities included "pain," "skin disorders," "fatigue," "anorexia," and other typical side effects of ARATs. "Pain" was the most frequently identified symptom, reflecting the high prevalence of bone metastases in patients with CRPC requiring ARAT therapy. A study using the Frankfurt Metastatic Cancer Database of the Prostate reported that 78% of patients with CRPC had bone metastases [23].

On the other hand, the fact that the top 20 entities accounted for less than one-third of the total positive symptom tags suggests that many symptoms occur with low frequency, resulting in a long-tail distribution. This indicates that a large portion of symptom tags is dispersed across numerous less-frequent entities. This distribution indicates that the NER system has the sensitivity to capture a wide range of symptoms. However, it also suggests the need for standardization if the aim is to extract specific symptom expressions.

Entities other than positive symptom tags were serious AEs such as "interstitial pneumonia," "myelosuppression," and "rhabdomyolysis." Interestingly, many of the negative symptom tags indicated the absence of severe AEs, suggesting that pharmacists were actively monitoring for signs of AEs and documenting the absence of signs. These negative assessments, particularly for rare but serious AEs, highlight the thoroughness of pharmacists in ensuring the safety of outpatient pharmacotherapy.

Drug-Specific Monitoring by Community Pharmacists

There are two types of ARATs with different pharmacological mechanisms of action: androgen synthesis inhibition and AR signaling inhibition. Each category is associated with distinct AEs, which require tailored care. Despite the common indication for ARATs, this study highlights the differences in pharmacists' monitoring based on drug type.

The most characteristic positive symptom extracted for abiraterone acetate, an androgen synthesis inhibitor, was "heart failure," a critical AE requiring close monitoring. In addition, "cardiovascular symptoms," "congestive heart failure," "rhabdomyolysis," and "drug-induced liver injury" were also identified as nonpositive symptoms.

For patients prescribed AR signaling inhibitors (enzalutamide, apalutamide, darolutamide), the most frequently extracted positive symptoms included "skin problems," "fatigue," and "gastrointestinal symptoms," which are common AEs that are important to monitor. "Skin disorder" was more frequently reported as a symptom for AR signaling inhibitors, whereas it was less commonly reported for abiraterone acetate, an androgen synthesis inhibitor. In addition, "gastrointestinal symptoms" and "neuropsychiatric symptoms" were extracted from the nonpositive symptom tags. "Seizures" were also extracted from the nonpositive symptom tags. Seizures are a serious AE specifically associated with AR signaling inhibitors [15,24,25].

These results indicate that, even though ARATs are used for the same purpose, pharmacists should pay particular attention to certain AEs depending on the pharmacological mechanism of each type of ARAT.

Comparison With Prior Work

The NER system used in this study has previously been reported to be applicable to medical records documented in electronic medical records within hospitals in Japan [22,26,27]. For example, Ohno et al [22] reported an F_1-score of 0.64 for an NER system applied to hospital-based pharmaceutical records. In contrast, this study applied the NER system to pharmaceutical records documented in community pharmacies outside hospitals and achieved an F_1-score of 0.72 under more stringent evaluation conditions.

A key feature of this study is its focus on pharmaceutical care records by community pharmacists, which tend to include more diverse and nuanced expressions of outpatients than electronic medical records. Furthermore, our previous studies have demonstrated that patients with hand-foot syndrome and serious AEs can be identified using NLP applied to pharmaceutical care records by community pharmacies [28]. In this study, the NER system enabled the extraction of a wide range of AEs, not limited to specific side effects. These results highlight advancements in NER methodologies and underscore their applicability in real-world outpatient settings.

Limitations

This study has several limitations. First, the content of pharmaceutical care records may vary depending on the pharmacists' experience, the role of each pharmacy, and the condition of the patients. Second, this study focused on the extraction of AEs and did not include symptom normalization. As a result, synonymous entities such as "pain" were counted separately. Third, the pharmacies included in this study were part of a single pharmacy group, which may limit the generalizability of the findings to other pharmacy settings.

Prospects

The NER system used in this study enabled the automated analysis of a large volume of records accumulated by community pharmacists. This system can extract symptoms from text, determine their factuality, and monitor patients' symptoms over time. Additionally, error analysis of the NER system applied to pharmaceutical medical records by community pharmacists

XSL•FO
RenderX

can contribute to the appropriate and effective use of NER systems in the future.

Our findings support the idea that NER technology offers the potential for real-time and longitudinal monitoring of patients' symptoms through the seamless integration of local health care systems, including community pharmacies. In hospital electronic health records, it has been demonstrated that the accuracy of detecting AEs improves when physicians' notes are combined with records from nurses and pharmacists [23]. Similarly, for outpatients, AEs identified by community pharmacists may play a key role in effective monitoring. This approach would extend beyond the confines of hospital-based electronic medical record systems. By using NER technology, it should be possible to gain detailed insights into drug efficacy and the progression of AEs. Moreover, it should enable earlier interventions and timely adjustments to treatment plans, particularly for outpatients who may otherwise have limited direct interaction with health care providers

Conclusions

We evaluated the performance of the NER system on Japanese medical text, focusing on pharmaceutical care records by community pharmacists. The NER system successfully extracted AEs from pharmaceutical care records. This is the first study to apply NER to the pharmaceutical care records of patients prescribed ARATs in community settings. Our analysis of pharmacists' assessment records for outpatients prescribed ARATs revealed that over 90% of the records contained symptom tags. Notably, ARATs have distinct pharmacological mechanisms and exhibit different AE profiles, and the NER system successfully captured these variations. Furthermore, it highlights the role of community pharmacists in monitoring specific AEs related to ARAT therapy and, importantly, in documenting the absence of severe AEs as well. This study demonstrates that NER can effectively capture symptoms reported by outpatients and documented by community pharmacists, complementing hospital records and contributing to a more comprehensive understanding of AEs in outpatient settings. The NER system is expected to be a valuable tool for enhancing pharmacotherapy monitoring in outpatient settings.

Abstract

Background: Electronic health records contain inconsistently structured or free-text data, requiring efficient preprocessing to enable predictive health care models. Although artificial intelligence–driven natural language processing tools show promise for automating diagnosis classification, their comparative performance and clinical reliability require systematic evaluation.

Objective: The aim of this study is to evaluate the performance of 4 large language models (GPT-3.5, GPT-4o, Llama 3.2, and Gemini 1.5) and BioBERT in classifying cancer diagnoses from structured and unstructured electronic health records data.

Methods: We analyzed 762 unique diagnoses (326 International Classification of Diseases [ICD] code descriptions, 436 free-text entries) from 3456 records of patients with cancer. Models were tested on their ability to categorize diagnoses into 14 predefined categories. Two oncology experts validated classifications.

Results: BioBERT achieved the highest weighted macro F_1-score for ICD codes (84.2) and matched GPT-4o in ICD code accuracy (90.8). For free-text diagnoses, GPT-4o outperformed BioBERT in weighted macro F_1-score (71.8 vs 61.5) and achieved slightly higher accuracy (81.9 vs 81.6). GPT-3.5, Gemini, and Llama showed lower overall performance on both formats. Common misclassification patterns included confusion between metastasis and central nervous system tumors, as well as errors involving ambiguous or overlapping clinical terminology.

Conclusions: Although current performance levels appear sufficient for administrative and research use, reliable clinical applications will require standardized documentation practices alongside robust human oversight for high-stakes decision-making.

KEYWORDS

natural language processing; large language model; electronic health record; cancer diagnosis; BioBERT; bidirectional encoder representations from transformers

Introduction

Electronic health records (EHRs) generate vast volumes of data, providing a valuable resource for clinical decision-making and policy development [1]. Today, many prediction and prognostic models embedded within EHRs aid clinicians and policymakers by delivering data-driven insights [2,3]. However, a significant portion of the data in EHRs is either categorized inconsistently or stored as free text, requiring extensive manipulation before it can be utilized effectively in predictive models to support decision-making. This manual structuring process is often labor-intensive, time-consuming, and error-prone, especially when dealing with large datasets or ambiguous language [4]. Automating data structuring through natural language processing (NLP) is, therefore, essential to scale predictive health care applications.

With the advent of generative artificial intelligence (AI) and large language models (LLMs) [5], there has been a transformative leap in the capacity to process and interpret text with near-human accuracy. LLMs are advanced AI systems that

XSL•FO
RenderX

use vast datasets and sophisticated transformer-based neural networks to understand and generate human language [6]. By leveraging deep learning, these models capture nuances in syntax, semantics, and context, supporting a range of language-related tasks such as text completion, translation, and summarization. This has positioned LLMs as powerful tools for automating the structuring of unstructured data [7]. Through application programming interface access, LLM capabilities can be applied to large datasets, including in real-time applications. However, ensuring the accuracy and reliability of these models is critical [8].

Although there have been several efforts to apply NLP to EHR data and cancer diagnosis [9-11], few studies have directly compared emerging general-purpose LLMs with specialized models like BioBERT (where BERT stands for bidirectional encoder representations from transformers). In particular, there is limited research evaluating their performance in a clinically relevant setting that includes both structured International Classification of Diseases (ICD) codes and unstructured free-text diagnoses. This study addresses that gap by benchmarking multiple LLMs and BioBERT using real-world oncology data, with expert validation to assess clinical relevance.

In this context, this study examines the potential of 4 LLMs—GPT-3.5, ChatGPT-4o, Llama 3.2, and Gemini 1.5—along with BioBERT, a specialized biomedical language model, to structure extracted EHR data in a case study focused on radiation therapy. Although the LLMs are general-purpose models capable of diverse language tasks, BioBERT is a domain-specific model pretrained on biomedical texts. We evaluate the effectiveness of these models in classifying patient diagnoses in ICD and free-text formats, with expert oncology review to validate model outputs. Our primary aim is to assess their capabilities for EHR data structuring, which is crucial for incorporating unstructured medical data into predictive models that forecast interruptions in radiation therapy.

Methods

Dataset

This study uses a dataset comprised of records of 3456 patients with cancer from the Research Enterprise Data Warehouse, originally sourced from the University of Tennessee Medical Center in Knoxville from 2017 to 2021. This dataset forms part of a larger research project focused on predicting interruptions in radiation therapy. It includes detailed demographic data (age, gender, race), administrative information (treatment dates, insurance type), and social determinants of health (eg, socioeconomic indicators), which are critical for understanding factors influencing treatment continuity.

Among these patients, 720 lacked standardized ICD codes for their cancer diagnoses, leaving only unstructured text descriptions from treatment plan forms. This gap offered a unique opportunity to evaluate the effectiveness of LLMs in structuring unstructured data. Examples of structured ICD codes and descriptions and unstructured free-text diagnoses include the following:

- ICD descriptions: “Malignant neoplasm of lower lobe, right bronchus or lung,” “Benign neoplasm of cerebral meninges,” “Malignant neoplasm of glottis.”
- Free-text descriptions: “56-year-old female with an anal canal/perianal squamous cell carcinoma,” “66-year-old male with metastatic esophageal adenocarcinoma,” “b/1 GBM,” “left RMT.”

Category Definition

To ensure clinically relevant cancer type categorizations, a comprehensive literature review was conducted, followed by a focus group session with two oncology experts (DLS and CLB). This collaborative process resulted in the identification of 14 clinically relevant categories for this study: “Benign,” “Breast,” “Lung or Thoracic,” “Prostate,” “Gynecologic,” “Head and Neck,” “Gastrointestinal,” “Central Nervous System,” “Metastasis,” “Skin,” “Soft Tissue,” “Hematologic,” “Genitourinary,” and “Unknown.” These categories were designed to align with the clinical requirements of oncology treatment planning and the predictive modeling of radiation therapy interruptions.

Unlike standard ICD ontologies, this categorization was customized for the specific needs of the project. For example, all benign tumors were grouped into a single category, regardless of location or ICD hierarchy, to reflect their distinct impact on treatment interruption. Therefore, we required language models capable of interpreting both ICD code descriptions and free-text entries and classifying them into this custom set, rather than relying solely on structured ICD code mapping.

Model Selection

Four prominent LLMs were selected for this study based on their reputation for processing unstructured data in health care contexts, along with BioBERT, a domain-specific biomedical model chosen for its specialization in biomedical text:

- GPT-3.5 (OpenAI): A general-purpose LLM trained on diverse datasets.
- GPT-4o (OpenAI): An advanced iteration, GPT-4o (“o” for omni) offers enhanced capabilities, including support for both text and image inputs. It is available through a paid subscription and is designed to process complex inputs with greater intelligence and versatility.
- Llama 3.2 (Meta): An open-source model, it is designed for efficient processing. The 70B parameter version was deployed locally using 4-bit quantization, available freely for research purposes.
- Gemini 1.5 (Google): Accessed through the Google Cloud Vertex AI platform. The model was configured with a temperature of 1 for creative outputs and set to generate responses of up to 8192 tokens to accommodate lengthy medical descriptions.
- BioBERT (dmis-lab): A specialized biomedical language model built on BERT architecture; it was accessed through the Hugging Face Transformers library. Unlike the LLMs, BioBERT was specifically pretrained on biomedical corpora for domain-specific tasks. The dmis-lab/biobert-base-cased-v1 model was deployed with

XSL•FO
RenderX

a maximum token length of 128 and batch size of 8, and it was trained for 3 epochs with a weight decay of 0.01.

These models were chosen for their accessibility and integration capabilities in clinical data processing pipelines. Each model was tested on its ability to classify unstructured diagnosis descriptions into predefined categories.

Prompt Design

Prompt design is crucial for enhancing the accuracy of LLM outputs, particularly in clinical applications. Working iteratively with the data science and clinical teams, we refined various prompt formulations, ultimately defining the following optimal prompt for diagnosis categorization:

> *Given the following ICD-10 description or treatment note for a radiation therapy patient: {input}, select the most appropriate category from the predefined list: {Category list}. Respond only with the exact category name from the list. If the description indicates a benign tumor, categorize it as 'Benign.' Use 'Unknown' if it does not match any category. If the description overlaps multiple categories, select the closest matching category.*

Model Implementation

Each model was implemented in Python 3, but while most models were accessed via their respective cloud application programming interfaces, Meta's Llama 3.2 was implemented locally using Ollama. The models were integrated into the data processing pipeline to enable automated categorization of unstructured diagnosis data.

Postprocessing and Category Standardization

To ensure consistency in model outputs, we implemented a 2-step category cleaning function in Python. The function first standardizes input by converting all text to lowercase and removing excess white space, then attempts to match the processed text against predefined categories. If no direct match is found, the function uses the difflib library to identify the matching category using string similarity metrics. This approach helps standardize variations in spellings and minor discrepancies in model outputs while maintaining classification accuracy. Cases without sufficient similarity to any predefined category are labeled as "No match."

Diagnostic Category Verification

To evaluate model accuracy, the categorized diagnoses were independently reviewed by oncology experts (DLS and CLB). Each model's performance was quantified by measuring alignment between its outputs and expert classifications, with accuracy calculated based on agreement rates. Patterns of misclassification were examined to highlight common errors and areas for potential model improvement.

Validation

We evaluated model performance using two primary metrics: accuracy and weighted macro F_1-score. Accuracy was calculated by directly comparing each model's predicted diagnosis to the true label, without adjusting for class frequency. Weighted macro F_1-score provided a complementary measure that balances precision and recall across all diagnosis categories while assigning greater influence to frequently occurring diagnoses via sample weights. This ensured that performance on common categories meaningfully impacted the overall score while still considering the model's ability to classify less frequent diagnoses.

To assess the statistical robustness of our estimates, we computed 95% confidence intervals for both metrics using nonparametric bootstrapping. This resampling approach quantifies the uncertainty around each point estimate, allowing for more reliable comparisons between models.

Ethical Considerations

This study was approved by the institutional review board of the University of Tennessee Health Science Center (institutional review board number 16 - 04888-XP) as exempt under 45 CFR 46.104(d)(4), as it involved the secondary analysis of deidentified clinical data. Because the data were fully deidentified and the research involved no direct patient interaction, informed consent was not required. Data privacy was maintained through secure institutional servers and restricted access for authorized personnel only.

Results

From our dataset of 3456 patients with cancer, we analyzed 762 unique diagnoses: 326 structured ICD code descriptions and 436 free-text entries from clinical notes. Each unique diagnosis was mapped to one category based on expert-defined criteria, and the frequency of each diagnosis across patient records was tallied. Table 1 summarizes the number of unique diagnoses per category alongside their total frequency in the dataset.

Model evaluation revealed varied performance patterns across data formats (Table 2). BioBERT achieved the highest weighted macro F_1-score on ICD codes (84.2, 95% CI 78.4 - 89.7), demonstrating the effectiveness of biomedical-specific pretraining for interpreting structured data. Its ICD code accuracy was also strong at 90.8 (95% CI 87.7 - 93.9). However, for free-text diagnoses, accuracy dropped to 81.6 (95% CI 78.0 - 85.3) and weighted macro F_1-score to 61.5 (95% CI 53.3 - 69.1). This drop reflects challenges in processing unstructured clinical narratives, even with strong performance on standardized medical terminology. BioBERT particularly struggled with cases involving abbreviations and multicondition diagnoses.

XSL•FO
RenderX

Table . Distribution of cancer diagnosis categories defined by oncology experts, showing the number of unique diagnosis descriptions and their total frequency across 3456 patient records.

Cancer category	Total frequency, n	Unique diagnoses, n
Breast	539	23
Lung or thoracic	516	67
Head and neck	485	133
Metastasis	466	94
Gastrointestinal	329	94
Prostate	304	3
Benign	178	32
Gynecologic	174	81
Central nervous system	155	77
Hematologic	91	44
Soft tissue	59	24
Genitourinary	58	22
Skin	56	33
Unknown	46	35
Total	3456	762

Table . Accuracy and weighted macro F_1-score of different language models in categorizing medical diagnoses for ICD[a] code and free-text analysis (mean, 95% CI).

Model	ICD code analysis		Free text analysis	
	Accuracy (%)	Weighted macro F_1-score (%)	Accuracy (%)	Weighted macro F_1-score (%)
GPT-3.5	88.9 (85.6 - 92.3)	61.6 (55.9 - 79.7)	75.9 (71.8 - 79.8)	52.5 (46.5 - 58.4)
GPT-4o	90.8 (87.7 - 93.9)	81.2 (74.9 - 87.2)	81.9 (78.0 - 85.1)	71.8 (62.1 - 78.1)
Gemini	81.0 (76.7 - 85.0)	70.2 (62.5 - 76.5)	64.2 (59.6 - 68.8)	51.6 (43.9 - 57.8)
Llama	77.6 (73.0 - 81.9)	64.5 (54.6 - 73.7)	64.2 (59.4 - 68.8)	43.9 (38.0 - 50.3)
BioBERT	90.8 (87.7 - 93.9)	84.2 (78.4 - 89.7)	81.6 (78.0 - 85.3)	61.5 (53.3 - 69.1)

[a]ICD: International Classification of Diseases.

Among the LLMs, GPT-4o matched BioBERT's ICD code accuracy at 90.8 (95% CI 87.7 - 93.9) and achieved the second-highest weighted macro F_1-score for ICD codes at 81.2 (95% CI 74.9 - 87.2). In free-text performance, GPT-4o outperformed BioBERT in weighted macro F_1-score, reaching 71.8 (95% CI 62.1 - 78.1) versus BioBERT's 61.5 (95% CI 53.3 - 69.1), while maintaining slightly higher accuracy at 81.9 (95% CI 78.0 - 85.1) compared to 81.6 (95% CI 78.0 - 85.3).

GPT-3.5 delivered competitive accuracy on ICD code descriptions (88.9, 95% CI 85.6 - 92.3) but showed a sharper decline for free-text diagnoses (75.9, 95% CI 71.8 - 79.8). Its weighted macro F_1-score dropped from 61.6 (95% CI 55.9 - 79.7) for ICD codes to 52.5 (95% CI 46.5 - 58.4) for free text, highlighting limitations in unstructured note processing. Gemini and Llama both trailed the top performers, with ICD code accuracies of 81.0 (95% CI 76.7 - 85.0) and 77.6 (95% CI 73.0 - 81.9), respectively, and further reductions for free text (64.2, 95% CI 59.6 - 68.8 for both). Weighted macro F_1-score followed the same pattern, with Gemini scoring 70.2 (95% CI 62.5 - 76.5) for ICD codes and 51.6 (95% CI 43.9 - 57.8) for free text, and Llama scoring 64.5 (95% CI 54.6 - 73.7) and 43.9 (95% CI 38.0 - 50.3), respectively.

Across all models, performance was consistently higher for structured ICD codes than for free-text diagnoses, underscoring the inherent challenges of unstructured clinical narratives for language models in health care contexts.

Error analysis revealed distinct misclassification patterns across structured (325 ICD codes) and unstructured (435 free text) diagnoses. Table 3 compares the top two misclassification patterns for each model across both formats. For ICD codes, BioBERT primarily misclassified benign tumors as central nervous system (CNS) (6 cases), while other models struggled to differentiate between adjacent body regions and systems, such as Head and Neck cancers and Breast cancers. Specifically, GPT-3.5 misclassified benign tumors as CNS (13 cases) and Soft Tissue (3 cases). GPT-4o had similar struggles with benign

XSL•FO
RenderX

tumors misclassified as CNS (10 cases) and Soft Tissue (2 cases).

Table . Top two misclassification patterns for each model across ICD[a] code and free-text analysis.

Model	ICD code analysis			Free-text analysis		
	True category	Misclassified as	Count	True category	Misclassified as	Count
GPT-3.5						
	Benign	CNS[b]	13	Metastasis	CNS	14
	Benign	Soft tissue	3	Metastasis	Unknown	10
GPT-4o						
	Benign	CNS	10	Metastasis	Lung or thoracic	14
	Benign	Soft tissue	2	Unknown	Breast	9
Gemini						
	Skin	Head and neck	11	Metastasis	Lung or thoracic	25
	Benign	CNS	10	Gastrointestinal	Genitourinary	20
Llama						
	Breast	Gynecologic	8	Metastasis	CNS	12
	Hematologic	Head and neck	6	Unknown	Head and neck	10
BioBERT						
	Benign	CNS	6	Unknown	Metastasis	6
	Head and neck	Skin	2	Unknown	Lung or thoracic	5

[a]ICD: International Classification of Diseases.

[b]CNS: central nervous system.

In free-text analysis, all models struggled significantly with "Unknown" categorizations, with 6‐12 cases misclassified variously as Metastasis, CNS, Lung or Thoracic, or Head and Neck. For instance, GPT-3.5 misclassified Unknown as CNS (14 cases) and Metastasis as Unknown (10 cases). Similarly, GPT-4o misclassified Unknown as Breast (9 cases) and Metastasis as Lung or Thoracic (14 cases). Metastatic disease posed particular difficulties in free text, frequently miscategorized as CNS or Lung or Thoracic (5‐9 cases). For example, Gemini misclassified Metastasis as Lung or Thoracic (25 cases) and CNS (13 cases). This pattern suggests that the models face greater challenges in interpreting ambiguous or complex descriptions in free text compared to standardized ICD codes, as they often struggle to accurately identify Unknown or ambiguous diagnoses in the absence of a clear structure.

Discussion

Principal Findings

This study evaluated the performance of 4 LLMs and 1 specialized biomedical language model in categorizing cancer diagnoses from both structured ICD codes and free-text descriptions. The results revealed several valuable insights for clinical applications of language models.

BioBERT's superior performance on ICD codes (accuracy of 90.8%, weighted macro F_1-score of 84.2%) highlights the importance of domain-specific pretraining for structured medical data, consistent with recent studies in biomedical classification [12,13]. In free-text analysis, GPT-4o demonstrated performance comparable to BioBERT, achieving an accuracy of 81.8% and a weighted macro F_1-score of 82.2%, closely matching BioBERT's accuracy of 81.6% and weighted macro F_1-score of 84.2%. This suggests that while BioBERT holds a slight edge in weighted macro F_1-score, GPT-4o performs exceptionally well in free-text classification, showing that general-purpose LLMs like GPT-4o can effectively manage the complexity and variability of narrative clinical descriptions. The performance gap between the two models in free-text classification is relatively small, indicating that GPT-4o can perform nearly on par with BioBERT in unstructured clinical tasks. This is particularly noteworthy given that GPT-4o is a general-purpose model and was not specifically trained on biomedical corpora. Its strong performance indicates that modern general LLMs may be sufficiently robust for certain clinical NLP tasks, especially when domain-specific models are unavailable or when flexibility across different text types is needed.

Error analysis revealed significant challenges for language models in accurately categorizing benign tumors and metastasis. Benign tumors, while present in many diagnostic codes, often lack specific terminology indicating "benign," which makes it difficult for models to differentiate these cases. This limitation in the models' ability to accurately identify and classify benign diagnoses suggests the need for more specialized training that incorporates the nuances of medical coding and terminology, especially when explicit markers like "benign" are absent.

Metastasis presents an even greater challenge for accurate classification. In many cases, patients have multiple diagnosis

XSL•FO
RenderX

codes that could be classified under both cancer types and metastasis, depending on the body regions affected. For instance, metastasis may involve various organs or systems that are not explicitly labeled as metastatic in the diagnosis code. In this study, the expert team chose to treat metastasis as a distinct category, regardless of the body locations involved. This decision increased the complexity for the language models, which needed to establish thresholds to accurately identify and categorize metastasis, even when the diagnosis lacked explicit mention of its metastatic nature. As a result, distinguishing between primary cancer diagnoses and metastasis proved to be a particularly demanding task for the models, emphasizing the need for improved context understanding and refined classification thresholds to better manage ambiguous or overlapping medical descriptions.

In free-text analysis, distinguishing between appropriate Unknown classifications and specific cancer categories emerged as a significant challenge. Models often attempted to force-classify vague or incomplete clinical descriptions into specific cancer categories, rather than correctly assign them as Unknown. For instance, cases marked as Unknown by clinical experts due to insufficient information (like "right" or "pelvis" without context) were often misclassified by models into specific cancer types based on partial pattern matching. This tendency to overclassify ambiguous cases suggests that additional preprocessing steps may be needed to effectively identify and handle low-quality or incomplete data entries before classification.

Unlike structured ICD codes, free-text entries often include abbreviations, shorthand, and nonstandardized phrasing (eg, "b/1 GBM," "left RMT"), which are difficult to interpret without domain-specific knowledge. Many notes also lack explicit diagnostic terms, instead relying on symptomatic or anatomical references that require inference to determine the underlying diagnosis. Fragmented grammar and co-reference issues (eg, determining which condition is primary) further obscure the clinical meaning. These factors contribute to reduced model accuracy and highlight the need for enhanced preprocessing or confidence-based filtering of ambiguous inputs. Although current performance may be sufficient for administrative or research tasks, expert validation remains essential for high-stakes clinical use, particularly when interpreting complex or ambiguous free-text entries.

Given the observed misclassifications in high-risk categories such as Metastasis and Unknown, relying solely on automated outputs could pose clinical risks. To mitigate this, future implementations should incorporate confidence thresholds to flag uncertain predictions, rule-based validation checks to catch implausible outputs, and human-in-the-loop systems to review ambiguous or low-confidence cases. Such hybrid approaches would balance automation efficiency with the need for clinical reliability, especially when dealing with unstructured or incomplete documentation.

These findings have meaningful implications for real-world adoption. The high accuracy on structured ICD codes indicates that models like BioBERT and GPT-4o can support EHR automation and administrative tasks such as billing and documentation with minimal manual input. However, the lower performance on free-text inputs underscores the need for caution in clinical decision support, where unstructured data are common and precision is critical. A hybrid approach—automating routine cases while flagging ambiguous ones for expert review—may offer the most practical balance between efficiency and safety.

Our study has several limitations that may impact the generalizability of the findings. Because the dataset was drawn from a single radiation oncology department within one institution, the models were trained and evaluated on documentation patterns specific to that clinical environment. In real-world applications, model performance may vary across health care systems that use different EHR platforms, coding practices, clinical documentation styles, or language contexts. Additionally, patient populations can differ demographically and clinically, which may influence diagnostic terminology and disease representation. The variation in sample size across cancer types, especially rare diagnoses, could also skew performance metrics. Furthermore, our analysis was limited to English-language records from a specific geographic region, potentially overlooking linguistic and cultural differences in medical documentation. Future work should validate these models using data from multiple institutions and more diverse patient populations to assess their robustness across settings.

LLMs can reflect biases in their training data, leading to uneven performance across demographic groups or rare diagnoses. They may also generate clinically plausible but incorrect outputs, posing risks if used without oversight. To ensure safe and equitable use in health care, these models should be validated on diverse populations and implemented with human oversight to prevent overreliance on automation.

Conclusion

This study highlights both the promise and the challenges of using language models for automated cancer diagnosis classification. BioBERT and GPT-4o achieved strong performance, with BioBERT reaching 90.8% accuracy and a weighted macro F_1-score of 84.2% for ICD codes and GPT-4o achieving equivalent ICD accuracy (90.7%) with a slightly lower weighted macro F_1-score. In free-text classification, GPT-4o attained an accuracy of 81.8% and a weighted macro F_1-score of 82.2%, closely matching BioBERT's accuracy of 81.6% and weighted macro F_1-score of 84.2%. These results show considerable promise for clinical applications, particularly with structured data, while also demonstrating that general-purpose LLMs like GPT-4o can approach the performance of domain-specific models in unstructured tasks.

Nonetheless, significant challenges remain in free-text classification, especially for complex categories such as metastasis and ambiguous Unknown cases. These limitations underscore the need for enhanced preprocessing, confidence-based filtering, and human-in-the-loop validation to ensure safe clinical adoption. With further fine-tuning of domain-specific models like BioBERT, improvements in ICD coding systems, and hybrid approaches that combine automation with expert oversight, more robust and reliable tools can be developed for real-time prediction in health care workflows.

Future work should prioritize improving free-text classification, refining thresholds for complex diagnoses, and validating across diverse, multiinstitutional datasets to ensure generalizability and clinical robustness.

Acknowledgments

We thank the University of Tennessee IT team for their support with data access and infrastructure. This research was supported by a grant from the Tennessee Department of Health. Generative artificial intelligence tools (such as ChatGPT) were used to assist in language editing and formatting of the manuscript. All content was reviewed and verified by the authors for accuracy and integrity.

Data Availability

The data that support the findings of this study are available upon reasonable request from the corresponding author. The dataset is not publicly available due to institutional privacy policies. The code used for data preprocessing, model evaluation, and statistical analysis in this study is publicly available at [14].

Abstract

Background: For patients with cancer, the pathway to diagnosis will most often begin in general practice. In the absence of strong diagnostic features or in patients with nonspecific symptoms, delays in diagnosis can occur. Initial presentations and routine blood tests are important in determining whether a patient requires further investigation. Quality improvement interventions, including auditing tools and clinical decision support (CDS), have been developed for use in general practice to support this diagnostic process. We conducted a process evaluation of a pragmatic, cluster-randomized trial that evaluated the effectiveness of a new technology, Future Health Today (FHT), implemented in general practice to assist with the appropriate follow-up of patients at risk of undiagnosed cancer.

Objectives: This study aims to understand implementation gaps, explore differences between the general practices involved, provide context to the trial effectiveness outcomes, and understand the mechanisms behind the intervention successes and failures.

Methods: The trial intervention consisted of the FHT tool (with CDS, audit, recall, and quality improvement components), training and educational sessions, benchmarking reports, and ongoing practice support. The 21 general practices in the intervention arm of the trial were included in the process evaluation. Process data were collected using semistructured interviews, usability and educational session surveys, engagement with intervention components, and technical logs. The Medical Research Council's Framework for Developing and Evaluating Complex Interventions was used to analyze and interpret the data.

Results: The uptake of the supporting components of the intervention (training and education sessions, benchmarking reports) was low. Most practices only used the CDS component of the tool, facilitated by active delivery, with general practitioners reporting acceptability and ease of use. Complexity, time, and resources were reported as barriers to the use of the auditing tool. Access to a study coordinator and ongoing practice support facilitated the sustained involvement of practices in the trial, while contextual factors, such as the COVID-19 pandemic and staff turnover, impacted their level of participation. The relevance of the intervention varied between practices, with some practices reporting very low numbers of patients who were flagged for further investigation.

Conclusions: While some components of the intervention, such as the CDS tool, were considered to be acceptable and useful, this process evaluation highlighted barriers such as time and resources, practice differences, and considerations around the optimal amount of support needed when delivering the intervention. Addressing these in future studies may optimize the implementation process. Further work is needed to determine if a scaled-back approach, which meets the time and resource availability of a busy general practice, can effectively facilitate the implementation of CDS tools. Given the variation seen between practices, the use of the FHT cancer module may be better targeted to certain practices based on size, location, and patient demographics.

Introduction

Diagnosing cancer early can improve patient outcomes and quality of life [1,2]. But, in general practice, the timely detection of cancer can be challenging in the absence of strong diagnostic features, often resulting in prolonged diagnostic intervals [3-5]. In patients presenting to general practice with nonspecific symptoms, the use of routine blood tests can guide decision-making [6]. There is strong evidence that supports the diagnostic utility of abnormal blood tests (eg, iron-deficiency anemia and raised platelets) for multiple cancer types [7-9]. However, suboptimal follow-up and management of abnormal test results have been shown to contribute to delays in diagnosis [10].

Inadequate follow-up of abnormal test results may occur in the case of diagnostic errors, but is also influenced by the general practitioners' (GPs) experience and training; perceptions of cancer care and investigations; patient characteristics; and health system pressures [11,12]. For example, controversy and confusion about prostate-specific antigen (PSA) testing, coupled with changing guidelines and revised thresholds for what is abnormal, contribute to lower follow-up rates in men who have a raised PSA. Surprisingly, there are very few trials that look at modifying the practitioner- and practice-level barriers to following up abnormal results [11].

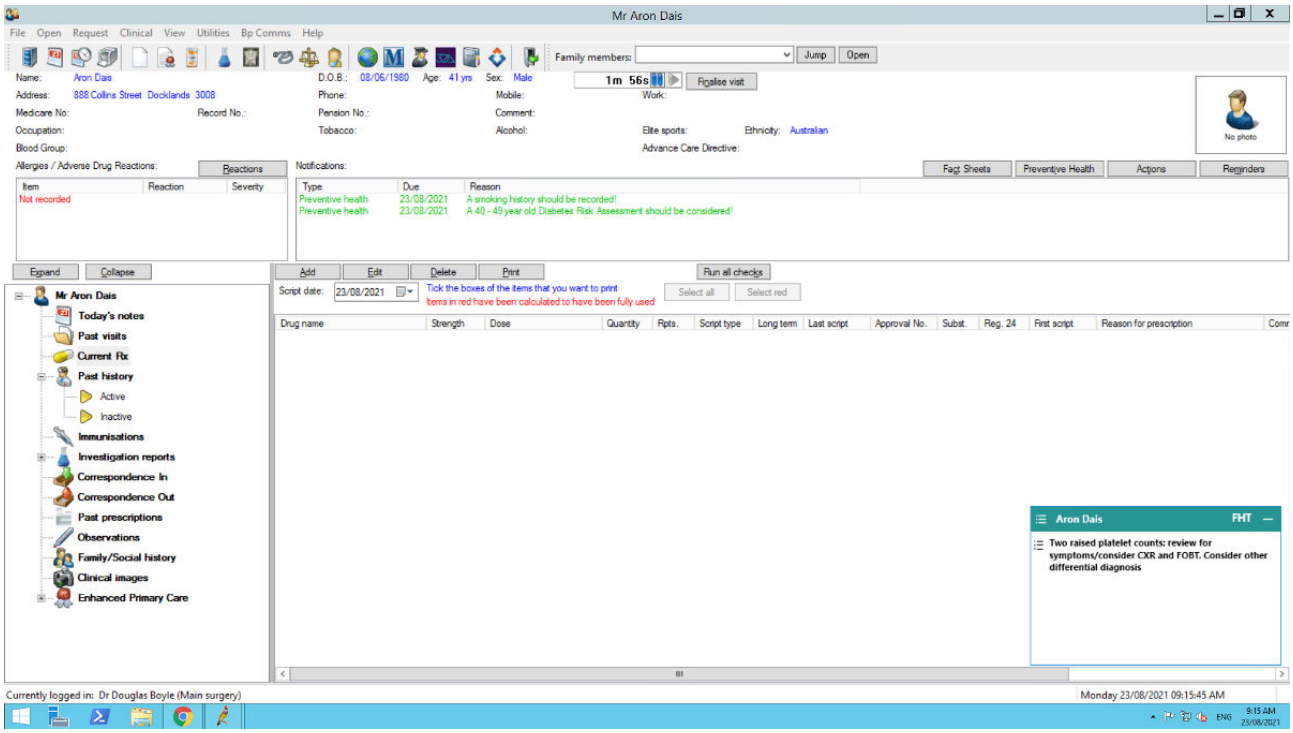
The general practice electronic medical record (EMR) allows for the integration of novel technologies, where algorithms apply epidemiological data on the underlying risks of undiagnosed cancer based on symptoms and test results to monitor and identify patients who may benefit from further investigation [13]. Clinical decision support (CDS) systems assist in clinical decision-making, where such tools are linked to patient data to produce patient-specific recommendations or prompts for the GP to consider [14,15]. Similarly, auditing tools that use patient information from the EMR enable practice population-level management and review and have the potential to capture patients who are at risk of being lost to follow-up [16,17]. Evidence suggests that tools that highlight patients for review, referral, or further investigation based on evidence-based guidelines can improve patient care, but many of these tools designed to support diagnosis in general practice are met with low uptake and implementation difficulties [18-20].

Complex interventions are used to assess the effectiveness and utility of such tools in general practice. Yet implementing complex interventions can be distinctly difficult, as they involve multiple interrelated components and there are often multiple levels where change is required [21]. Process evaluation can aid in the understanding of the factors that influence how or why a complex intervention succeeds or fails. This study presents the results of a process evaluation of a pragmatic trial, Future Health Today (FHT). This complex intervention consisted of a novel CDS and auditing software, education, quality improvement (QI), and practice support. The pragmatic trial evaluated whether the intervention, which flagged patients with an abnormal blood test that may be indicative of undiagnosed cancer (FHT cancer module), increased the proportion of patients receiving guideline-based care. By gaining process information, we aim to better understand the implementation gaps, explore differences between the general practices involved, understand the interactions between intervention components, and provide context to understand the effectiveness of the intervention.

Methods

Intervention Description and Study Population

The FHT study was a pragmatic cluster-randomized controlled trial that evaluated the effectiveness of a QI intervention [22]. Pragmatic trials, by definition, are trials that evaluate an intervention in everyday practice, with the aim of measuring the effectiveness of the intervention in routine clinical practice rather than under ideal conditions [23,24]. The implementation of the FHT software and the trial components (including implementation strategies) were applied and adapted to real-world conditions to understand and evaluate how the tool would be used in routine general practice.



The components of the complex intervention included the FHT software, training and educational sessions, benchmarking reports, and practice support. The trial was conducted between October 2021 and September 2022. Practices were randomly allocated to participate in either the intervention (follow-up of patients with abnormal blood test results associated with the risk of undiagnosed cancer) or the active control (which had access to a different FHT module). As the aim of this process evaluation was to explore the factors critical to the implementation of the cancer module, our study population comprises the 21 intervention arm practices only; results for the active control intervention will be reported separately. The study protocol has been published on the Australia and New Zealand Clinical Trial Registry (ACTRN12620000993998) [25].

FHT was integrated within the general practice EMR and consisted of a CDS tool, a web-based audit and feedback tool, and the capacity for general practices to monitor their QI activities [26]. Disease-specific modules were developed for use in FHT. The cancer module used patient information in the EMR (age, sex, previous cancer diagnosis) and results of abnormal tests associated with undiagnosed cancers. The FHT cancer module consisted of 3 central algorithms, designed to assist GPs by flagging patients with abnormal blood test results that are associated with an increased risk of undiagnosed cancer: markers of iron deficiency and anemia, raised PSA, and raised platelet count). The CDS component of the tool activates when the GP or general practice nurse (GPN) opens the patients' medical record, displaying a prompt on screen with guideline-concordant recommendations, such as the review of relevant symptoms or appropriate investigations (Figure 1).

XSL•FO
RenderX

There is also a web-based portal, containing an auditing tool; a QI monitoring tool; and access to resources, guidelines, education, and training, which can be accessed on any computer with FHT installed. Algorithms run each night, extracting data from the practice management software database (eg, Best Practice or Medical Director), processing the data locally by applying FHT algorithms (the data does not leave the practice), and categorizing the results. Examples of a CDS prompt and the audit tool are presented in Multimedia Appendix 1. Further details on the development of the tool and the cancer module explored in this study have been described elsewhere [27-29].

Figure 1. An example of the clinical decision support tool as it appears in the medical record. Simulated patient data are used in this image.

In the pragmatic trial, FHT was installed on general practice computers before study initiation. On the first day of the trial, practices were asked to create 3 cohorts of patients using the FHT auditing tool, one for each abnormal blood test (raised PSA, raised platelets, and markers of anemia). The cohorts included all patients identified by the FHT cancer module who had recommendations for guideline-based follow-up (as part of the trial, practices could then review the patient cohorts and determine if further follow-up was necessary). Cohorts were created again at the 6-month mark, using the audit tool, so that benchmarking information could be determined. After generating the cohorts, practices were invited to use FHT as they chose during the trial.

Implementation of the software was supported by a number of additional intervention components. This multifactorial implementation strategy was informed by the Reach, Effectiveness, Adoption, Implementation, and Maintenance framework, with strategies that were relevant and useful to general practice [30]. These components have previously been shown to increase reach; they are low intensity and high impact, with the purpose of limiting implementation workload while promoting continued engagement with the intervention [31,32]. Training on the use of FHT was offered regularly in the lead up to and in the first month of the trial, and then monthly thereafter. Each practice was assigned a study coordinator, who conducted the Zoom-based training sessions on how to use FHT, assisted with any technological queries, and facilitated requests for support throughout the trial. Practices had access to short training videos on YouTube and a range of short- and long-form written training guides. In addition, 6 Project ECHO (Extension for Community Healthcare Outcomes) [33] educational sessions were run on the topics of cancer diagnosis and QI, each consisting of a 10-minute didactic session, a 10-minute case discussion, followed by an open discussion for approximately 20 - 30 minutes. The ECHO sessions were delivered via a webinar, and general practice staff were invited to attend. Quarterly benchmarking reports were provided to practices to review their progress in the follow-up of patients who had been flagged by the tool, and to compare their progress to other practices in the trial. All practices were required to nominate a practice champion to lead the implementation of FHT in their practice and to be the primary point of contact with the study coordinator during the trial, managing the installation and technical queries, facilitating ongoing use of the tool, identifying staff for process evaluation interviews and to disseminating trial related information to the practice. The goal of the practice champion in this study was to mirror the pragmatic approach of the intervention (eg, they were asked to filter and disseminate information to the practice using an approach that best reflects their individual practice needs and current processes).

Ethical Considerations

The study was approved by the Faculty of Medicine, Dentistry and Health Sciences Human Ethics Sub-Committee at the University of Melbourne (ID:2056564). While practices consented on behalf of all practice staff to participate in the

XSL•FO
RenderX

wider trial, additional written consent was obtained for all interviews. Interview participants were compensated A $100 (US $64.83) for their time. Practice champions also consented separately and were compensated A $200 (US $129.66) for their role as practice champions. All participant data were deidentified and kept anonymous.

Data Collection

Data were collected via qualitative interviews, usability surveys, technical queries, engagement logs, and educational session surveys. For the semistructured interviews, all practice champions were contacted via phone and email to participate in an interview in the first and last months of the trial. The practice champion was most commonly a practice manager (PM) or GPN, but GPs occasionally took on this role during the trial (eg, due to staff changes). The semistructured interviews were conducted over the phone. The interviews were conducted by study researchers (SC, NL, and BH; see the following section on researcher characteristics). The duration of the interviews ranged between 15 and 42 minutes. The interview guides were developed using the Clinical Performance Feedback Intervention Theory framework [34] and were pilot-tested during earlier optimization work on the FHT cancer module [27]. The interviews explored installation, intervention delivery, implementation barriers and facilitators, goals, and usability (see Multimedia Appendix 2 for interview schedule). The interviews explored similar themes at each timepoint, although earlier interviews included questions around goals and intention, and the final interviews explored long-term implementation and sustainability. GPs and GPNs were also recruited for interviews in month 6 of the trial. These interviews have been reported separately [35], as the purpose of the clinical interviews was to explore the acceptability of the clinical recommendations and impact on clinical practice, rather than explore the implementation of the wider intervention.

Usability surveys were sent to practice champions in months 1 and 12 of the trial, with the request to distribute them to the rest of the practice. The survey was delivered via web using REDCap (Research Electronic Data Capture; Vanderbilt University) [36] and included 30 questions (multichoice or free text). This survey was anonymous but captured general demographic information about the user and the general practice in which they work. The survey then explored the use and experience with the intervention (eg, length of time using the tool, what components have been used, and feedback and engagement with the intervention components). The survey also included a System Usability Scale (SUS) a 5-point Likert scale that quantifies the perceived usability of FHT [37]. The usability survey was developed by the study implementation team and is available in full in Multimedia Appendix 3).

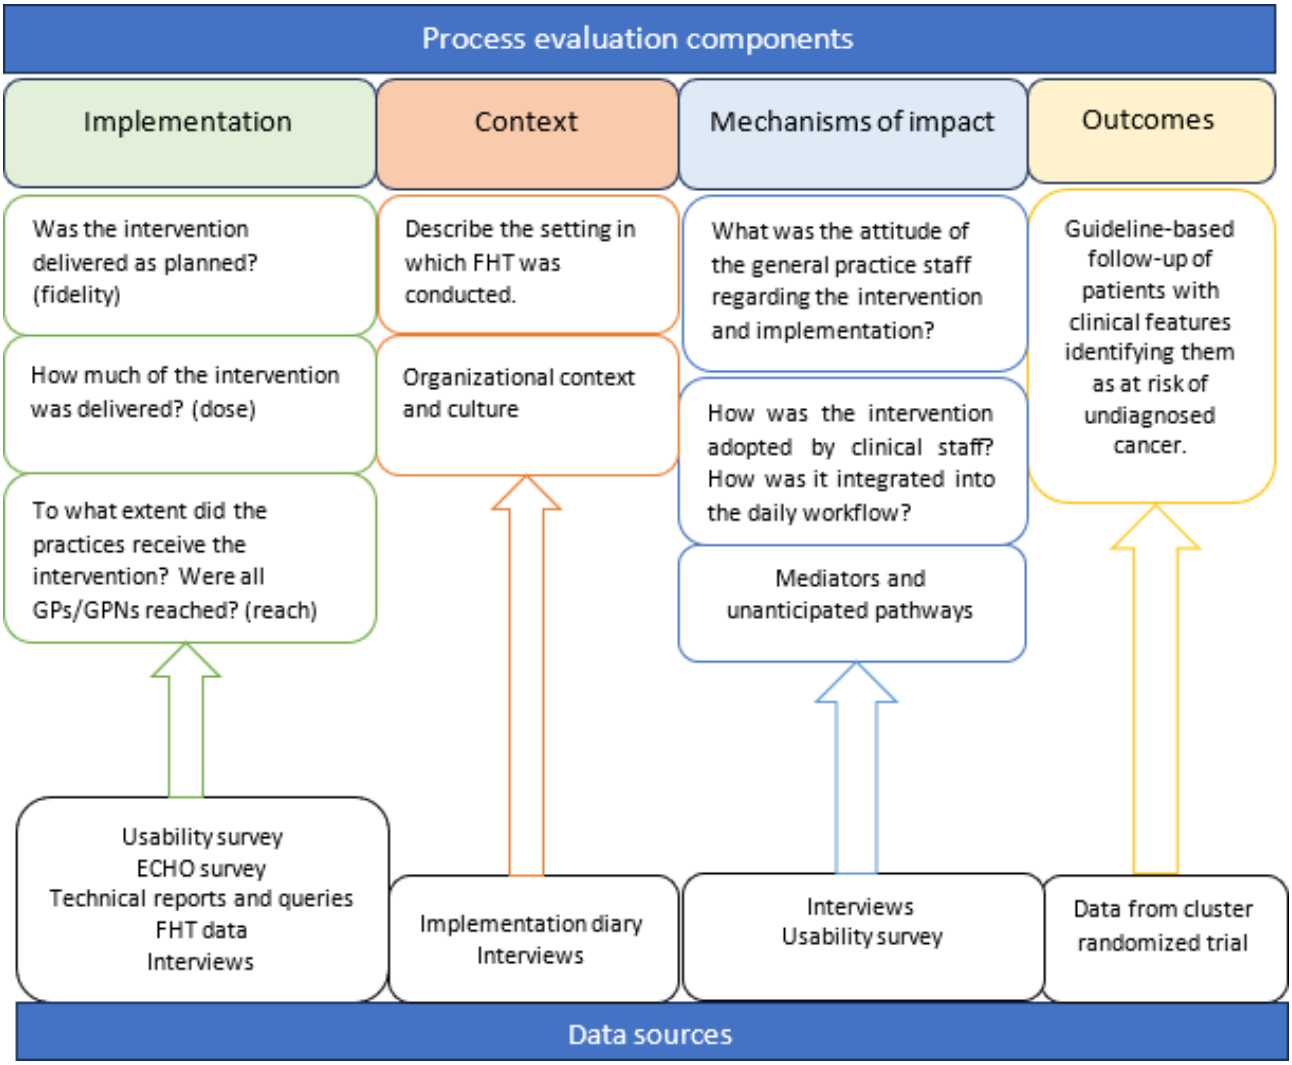
Postsession ECHO surveys were sent to all ECHO session participants via REDCap after each educational session and collected both demographic information and feedback on the specific learning outcomes of each webinar. The survey consisted of 23 multiple-choice or free-text questions. An example survey from one of the webinars is included in Multimedia Appendix 4.

Information on the number of installations in each practice, the number of individual users, and recommendation queries (submitted through the technology by the practice) was collected using the FHT technology. Technical reports, including any technical queries by the practice throughout the trial, were recorded by the study coordinator. All engagements between the practice and the study team (study coordinator and technical team), were recorded by the study coordinator and categorized by content (eg, technical queries, training, and administrative items). Implementation diaries were kept by study coordinators to record contextual information (eg, changes in COVID-19 pandemic guidelines, immunization rollout, and general practice initiatives) throughout the trial.

Researcher Characteristics

SC is a PhD candidate at the Department of General Practice and Primary Care, University of Melbourne. BH, a senior qualitative research fellow in the department is the implementation lead for the FHT trial. NL is a postdoctoral research fellow who was the study coordinator for the active control arm of the trial. All are female and experienced in qualitative research and conducting semistructured interviews. Some interview participants were known to the interviewer, given their position in delivering the intervention and supporting the implementation in practices throughout the trial.

Data Analysis



Recorded interviews were transcribed and imported into NVivo (version 12; Lumivero). Process evaluation data were analyzed independently (SC and BH), prior to trial effectiveness outcomes, so as not to bias the interpretation of the results. Each researcher independently conducted a structured, deductive content analysis of the interview transcripts to extract key themes in the data. The results of the content analysis were collated, and themes were presented to the research team. To promote trustworthiness, analytical codes and emerging concepts and categories were discussed at multiple points in the analysis. Positionality was discussed by the coding team, including how established relationships, biases, and experiences may influence their relationship to the study data, and reflexive notes were kept [38,39]. The interpretation of the key findings and discrepancies in interpretations was discussed with the wider team. The results of the evaluation were then mapped onto the UK Medical Research Council (MRC) framework [40,41].

While several frameworks are available to explore and evaluate the implementation of an intervention, the MRC framework was chosen as it is designed for evaluating complex interventions. It has previously been shown to be useful in evaluating the delivery of new technologies in complex environments and in instances of a multi-faceted implementation approach [42,43]. The framework includes overarching themes of context, implementation, and mechanisms of impact and provides a mechanism for understanding the implementation successes and failures (Figure 2) [40,41]. In the figure, the data sources from the trial are mapped onto the 4 process evaluation components as outlined by the MRC framework (implementation, context, mechanisms of impact, and outcomes). The figure outlines the core components and

XSL•FO
RenderX

questions underpinning each theme, and the process data used to answer these questions.

Figure 2. How the process evaluation data are mapped onto the Medical Research Council framework. ECHO: Extension for Community Healthcare Outcomes; FHT: Future Health Today; GP: general practitioner; GPN: general practice nurse.

Results

Overview

A total of 21 practices participated in the process evaluation. Characteristics of the participating practices are described in Table 1. Characteristics of the interview participants are outlined in Table 2. Participation in other components of the process evaluation (usability survey, ECHO surveys) and additional general practice details are outlined in Multimedia Appendix 5. In summary, 25 interviews were conducted with 19 practice champions in the first and last months of the trial. A total of 12 usability surveys were completed, and 13 post-ECHO session surveys. Usability survey responses included a mix of PMs (n=4), GPNs (n=4), and GPs (n=3), as well as one receptionist (n=1).

Results have been mapped onto the 3 themes of implementation, context, and mechanisms of impact.

Trial Results Summary

The results of the cluster randomized controlled trial did not demonstrate a significant improvement in follow-up in the intervention arm [22]. At 12 months, 76.2% (2820/3709) of patients with abnormal test results in the intervention arm had been followed up compared with 70% in the control arm, with an estimated difference of 2.6% (95% CI −2.8% to 7.9%). No significant differences were identified in the secondary analyses or in the time to follow-up of abnormal tests for patients flagged by the tool. The following results of the process evaluation provide some context for the null outcome of the trial and suggest areas for improvement in the development and

XSL•FO
RenderX

implementation of CDS and audit software for cancer diagnosis in general practice.

Implementation

There were 3 core themes on implementation: intervention delivery, installation, and general practice characteristics, each underpinned by different evaluation data sources. Intervention delivery was supported by data from engagement logs and educational session surveys, installation and general practice characteristics were supported by data from technical reports, and all 3 drew from qualitative interview data.

Intervention Delivery

The intervention consisted of multiple components: the FHT software components (CDS, an auditing tool, and QI monitoring) and the supporting trial components (educational ECHO sessions, zoom-based training sessions, benchmarking reports, and other web-based learning components that practices could opt-in to use). The uptake of the supporting elements of the trial was generally low, except for the initial formal training sessions. GPs, GPNs, and PMs from all intervention practices were invited to the Project ECHO sessions, yet attendance ranged from 2 to 9 people per session, a mix of GPs and GPNs. Three key barriers were assessed as driving the low uptake of these trial components. First, the supporting components of the intervention were promoted via phone calls, newsletters, and regular emails to the practice champion, so it is possible that the knowledge of each session may not have reached the whole practice, dependent on how the practice champion decided to distribute this information to the practice (eg, internal email systems). The second barrier is the time and resource cost associated with each component. For example, attendance at training sessions and ECHO sessions (1 h each), during or after work hours, was not feasible for many clinical staff. The final barrier relates to recognized need and usability, with many practices reporting that they could use the CDS tool and the cancer recommendations adequately, without the need for additional education or training.

> *It's quite straightforward and quite well explained so it didn't need anything extra particularly.* [GP, female, month 1]

Installation

The installation of the software was completed in the month prior to study initiation, with practices having access to a "practice" module on diabetes in the 2 weeks prior to study initiation so any technical issues could be addressed. The installation, which was done remotely and without much interruption to the practice, was reported to be a smooth process for most. For those who required additional assistance, the use of a study coordinator and technical support ensured PMs felt well-supported during this process.

> *I think what really has gone well is how it seamlessly was implemented. There was no - there's no interruption.* [PM, female, month 1]

Due to the pragmatic approach of the trial, practices determined how many workstations in their practice would have FHT installed at the start of the trial. A total of 14 practices had FHT installed on all clinical computers. Five practices had FHT installed on only one computer at trial initiation, and of these, 4 made the decision to add FHT to additional computers later in the trial. Implementation logs and technical reports indicate that 3 practices were offline for a short period of time (range: 2 - 6 wk), although this does not appear to have had a significant impact on the use of the system.

General Practice Characteristics

There was a large variation in the number of patients identified for follow-up across practices. Three inner-city practices, which had a younger and transient patient population, reported that the cancer module may not be useful in their clinic, given the low number of patients flagged by FHT. For example, in one practice, only 14 patients were flagged for follow-up during the entire 12-month trial period. While these practices acknowledged that the FHT cancer module was less useful for them, it did not deter them from continuing to use the tool after the trial, where they would have access to additional FHT modules (see Software Usability section).

> *Actually, it is cancer topic I don't think that it is very suitable for our clinic because our clinic – the majority of our patients are international students, and they are very young.* [PM, female, month 12]

Context

In exploring context, there were 2 prominent themes: the COVID-19 pandemic and staff turnover. Both themes were underpinned by engagement logs, implementation diaries, and qualitative interviews.

COVID-19

The FHT trial was conducted during the COVID-19 pandemic. In Victoria, restrictions were placed on how and when people could leave their homes, with Melbourne experiencing lockdowns for 262 days during the pandemic. There was a major shift in usual care, and many consultations were conducted via telehealth. During 2020, there was an 8% reduction in cancer-related diagnostic tests nationally, with greater reductions seen in Victoria [44]. The trial continued during a nationwide COVID-19 immunization rollout in primary care, and the burden on general practice was high. There were reports throughout the trial that practices could not devote as much time as they would have liked to FHT or to attend the ECHO sessions due to competing webinars related to COVID-19.

> *It's been a time of change, a lot of updates, a lot of new technology with telehealth. Yeah, there's been a lot going on because of COVID.* [PM, male, month 12]

Staff Turnover

Consequently, staff turnover was a common theme throughout the trial, and the resultant loss of information and increased resource pressure featured heavily in the month 12 interviews. A total of 9 practice champions left their practice during the trial, with 2 practices ending the trial with no replacement. Many interviewees talked about the magnitude of staff turnover during the pandemic and how it was a barrier to use and to keep up momentum in the study.

> *We lost two staff, and two doctors at the end of last year. Now we've got two doctors that we're training again. We started off from scratch again.* [GPN, female, month 12]

Mechanisms of Impact

We found 4 mechanisms associated with the delivery of the intervention: adoption and integration, training and support, software usability, and clinical recommendations. The sources of data varied within each theme. Technical reports, usability surveys, and interviews supported adoption and integration. Training and support were underpinned by engagement logs, education session surveys, and interviews. Software usability was supported by the usability survey, interviews, and engagement logs. The final theme of clinical recommendations was elucidated from technical reports (in particular, recommendation queries), which were further explored in the educational sessions and qualitative interviews.

Adoption and Integration

The majority of practices reported that they did not use the QI and audit and recall components of the tool, only the CDS, which was delivered at the point of care. The CDS was considered easy to use and quick to learn and was therefore easily integrated into the clinical workflow by matching the resources available in a busy general practice. However, the audit, recall, and QI components of the tool encountered a number of barriers. First, in comparison to the CDS tool, where recommendations are actively delivered to the GP, the audit and recall tool requires the user to visit a web page and log on to access this part of the tool. Second, there were additional layers of complexity and multiple steps involved in order to identify, review, and recall patients identified in the audit tool.

Training and Support

The level of engagement between the study coordinator and most participating practices was high, and the support provided by the research and technical team facilitated the continued involvement of practices in the study. No practices in the intervention arm withdrew during the study period.

> *The co-operation between the teams and myself was amazing. There were no issues whatsoever and they were always there to help … it was really good.* [PM, female, month 12]

Practice staff who attended training sessions or used the web-based resources found the training adequate enough to use the tool, and practice champions reported that they would be comfortable training other members of the practice who could not attend. However, in most interviews, especially with the GPs who did not attend the training sessions, it became evident that components of training on how to use FHT did not reach the entire practice. For example, many GPs were unaware of the patient deferral button (which allows GPs to pause recommendations for a patient for a specified period of time) or that there are patient resources available. The post-ECHO session surveys highlighted that the education and case discussion components of the ECHO sessions were useful to GPs and GPNs in managing more complex patient scenarios, but did not influence the way in which the tool was used.

Software Usability

Of the 12 usability survey responses, 11 (92%) would recommend FHT to others. As part of the usability survey, respondents filled in a SUS [37]. The results of the survey align with the separate qualitative results from the clinical interviews in that FHT is reported to be easy to use, simple, and intuitive [35]. The average SUS score from the respondents was 74 (out of 100), consistent with an above-average score (average score=68; score >70 is considered good).

Acceptance and perceived usefulness of the FHT software were indicated by the number of practices agreeing to continue using the FHT software posttrial. A total of 18 of the 21 practices opted to continue using the software after the trial ended (practices were offered a 3 mo extension), and 17 practices opted to continue using the tool into 2023‐24.

Clinical Recommendations

The software included a menu option to "report recommendation query" if the GP or GPN thought the recommendation was appearing in error or wanted further information. Five queries about the clinical recommendations in FHT, from 3 practices, were received during the trial. The most frequent recommendation query centered around the clinical recommendations for raised platelets. The risk of undiagnosed cancer increases at a platelet count threshold of 400×10^9/L, but different laboratories report an upper limit of either 400 or 450 $\times 10^9$/L; this caused some confusion among GPs if a patient was flagged with a count in the range of 400‐450x 10^9/L. This issue was addressed in training sessions and regular communications (monthly emails, newsletters), but the perceived error may have impacted some GPs' willingness to use the tool and their trust in the recommendations. Interestingly, there were no queries about the recommendations for raised PSA (the FHT recommendations were based on current Australian guidelines for PSA follow-up with a lower limit of 3ng/mL in men over 50, which contrasts with some laboratories that report a lower limit of the normal range of 4ng/mL). Established referral pathways and familiarity with the abnormal test as a cancer marker (raised platelet is a relatively new marker of cancer) may have been a contributing factor to this difference in response.

Discussion

Overview

In this study, we describe a comprehensive process evaluation exploring the delivery of a complex intervention as part of a pragmatic, randomized trial, where a module to support cancer diagnosis was implemented in general practice. The process evaluation describes implementation gaps and the mechanisms that drive implementation successes and failures in order to provide context to the outcomes from the trial [22].

Principal Findings

The FHT cancer module intervention did not demonstrate a significant improvement in the follow-up of abnormal test results in the patients flagged by the tool. While we hypothesize that the high-performing practices across both arms may have led

XSL•FO
RenderX

to a ceiling effect (ie, there was limited room for improvement given the high rates of follow-up in both arms), an absence of any intervention effect may in part be due to implementation barriers, primarily relating to practice characteristics and contextual factors. There was limited ability for some specific practices to engage with the tool when their patient population was not suited to the FHT module that was implemented. Given this variation in the relevance and usefulness between practices, the use of the FHT cancer module may be better targeted to certain practices based on size, location, and patient demographics.

Comparison to Prior Work

In comparison to interventions with only one component, complex interventions require more time and resources, and are, unsurprisingly, more difficult to implement [31,45]. We found that the uptake of the supportive components of the intervention was low, aside from some initial training on the software. It was also indicated in the interviews that the supporting components were not considered necessary to use the CDS. While the implementation of new software in general practice requires some training and support, the results of this process evaluation indicate that a scaled-back approach to implementation, one which aligns with the time and resources available to general practice, may have been sufficient for the CDS component of the tool [46]. However, given the null outcomes of the trial, the low uptake of the audit tool, and significant contextual factors (COVID-19 pandemic), more work is needed to determine the usefulness of each component, or combination of components, in supporting this type of change in practice.

Implementing new technologies in general practice is a complex and dynamic process, and despite the potential to improve patient outcomes, many tools have low uptake after implementation [47,48]. The trial consisted of a number of implementation strategies that aimed to optimize the uptake of FHT in routine care, and these methods were applied primarily at the professional level (eg, education or training strategies targeting health care professionals and identification of practice champions) [49]. We found that the use of a practice coordinator facilitated the continued involvement and engagement of practices throughout the trial, similar to previously reported successful implementation strategies used in complex evaluations delivered in general practice. One overview of reviews concluded that practice facilitators, who work with practices in areas such as QI, problem-solving, and education, are almost 3 times as likely to adopt evidence-based guidelines, and practice facilitation improved the adoption of guidelines associated with many chronic diseases [32]. But given the large amount of staff turnover, driven by the COVID-19 pandemic, identifying, maintaining, and replacing practice champions was difficult and resulted in a loss of information and a barrier to engagement for some practices.

Strengths and Limitations

This process evaluation was extensive, with a multi-modal approach to collecting process data, including interviews, surveys, technical and software data, engagement logs, and implementation diaries. Interviews and usability surveys were carried out at 2 time points during the trial, to address the dynamic nature of implementation barriers and facilitators and how perceptions of the tool can change over time. This substantive evaluation provides context to a complex intervention and the environment in which it was implemented.

There were, however, some limitations. While all practices were invited to take part or contribute to each component of the process evaluation, there were 3 practices who did not participate in an interview at any timepoint or complete any surveys. The opt-in method for the interviews and surveys meant that we may not have sufficiently captured the views of practices who were less engaged with the intervention. These 3 practices did contribute some data to the process evaluation, through software data, technical information, and engagement logs, which were captured from all practices involved in the trial.

The burden of the COVID-19 pandemic in general practice and the resultant impact on staffing was a core theme throughout the process evaluation and provided context when interpreting the trial results. A second limitation was that the pandemic also likely impacted the time, availability, and resources for general practice staff to participate in the interviews and contributed to the low response rate for the usability survey. To mitigate this, we provided numerous opportunities for users to engage in interviews and respond to surveys throughout the trial and promoted such activities through the continued engagement with each practice champion.

Finally, we had originally planned on including some additional software use statistics to complement the qualitative components of the intervention; however, incomplete data prohibited our ability to do so. Software use data would have allowed us to triangulate users' responses via interviews and surveys with their time using the software, including what parts of the tool they used and when. Future studies would benefit from including software statistics to cross-check the qualitative results.

Implications and Future Research

There are implications for both research and practice. While the FHT cancer module did not increase the proportion of patients followed up according to guidelines, the process evaluation highlighted factors around usability, which facilitated the adoption and integration of the CDS component of the tool. This, coupled with the acceptability findings from separate clinical interviews [35], and the willingness of the majority of practices to continue using the tool after the trial finished, indicates that different modules developed for use in FHT should be explored, as well as CDS tools for cancer diagnosis more broadly. There are also considerations for designing complex interventions that involve the use of a new technology. Given the low uptake of the supporting components of the tool, but indications of use and acceptability of the CDS component of the software, it is unclear whether a multifaceted implementation strategy is useful when implementing new CDS tools, especially if it has been carefully co-designed to meet the needs of users. Future work should be undertaken to determine if a scaled-back approach, which meets the time and resource availability of general practice, could be as effective in supporting the delivery of novel CDS tools.

XSL•FO
RenderX

Conclusions

This process evaluation highlights the implementation and process-related gaps that could be addressed in future studies that aim to implement diagnostic support tools for cancer in general practice. While some of the factors were context-specific (eg, driven by the COVID-19 pandemic), barriers such as time, resources, and practice variations, alongside considerations of design elements, could be built upon to optimize future CDS and QI programs.

Acknowledgments

We would like to thank the general practitioners, health care professionals, and consumers who provided input to the development of Future Health Today (FHT), piloted the tool in their practices, and participated in this trial. We are grateful to the consumer and general practice advisory groups who provided important insights into this trial. We would like to acknowledge the Primary Care Collaborative Cancer Clinical Trials Group (PC4) for their support on this project. Deidentified patient data from the Patron primary care data repository (extracted from consenting general practices), which has been created and is operated by the Department of General Practice and Primary Care, the University of Melbourne, were used to underpin trial feasibility, sample size calculations, and to evaluate the outcomes of the trial. The Paul Ramsay Foundation provided funding for staff costs related to the technical development of FHT and the Implementation and Evaluation team members. They have also provided funding for professional staff support and general practice and consumer advisory groups. The development of the cancer module of FHT was supported by the CanTest Collaborative (funded by Cancer Research UK C8640/A23385) of which JE is an Associate Director. JE is supported by an NHMRC Investigator grant (APP1195320). JMG is supported by a Victorian Cancer Agency Mid-Career Fellowship (MCRF21025).

Data Availability

Deidentified datasets analyzed during this study are available from the corresponding author on reasonable request.

Conflicts of Interest

Future Health Today has been developed and managed by the Department of General Practice and Primary Care, University of Melbourne, in collaboration with Western Health.

Abstract

Background: Despite its potential to predict and detect early cancer risks, genetic testing remains underused by the public. This study, guided by the health belief model (HBM), examined key factors influencing an individual's willingness to undergo genetic testing for cancer, with a particular focus on gender, caregiver status, and participation in online social support groups.

Objective: This study aimed to explore the factors that can influence the individual's decision to undergo preventative genetic testing for cancer so that more informed action can be taken to encourage the individuals to engage in preventative health behavior.

Methods: This study uses data collected from the 2020 Health Information National Trends Survey (HINTS 5 Cycle 4), which included 2947 respondents representing 199,510,996 US adults aged 18 years and older. Multivariable logistic regression and survey-weighted generalized linear models were applied to examine the relationship between cancer genetic testing and caregiver status, participation in online support groups, gender, and constructs associated with the HBM, while controlling for sociodemographic and health-related characteristics.

Results: Our findings show that women are more likely to undergo cancer genetic testing, with gender moderating the influence of perceived susceptibility (β=2.54, *P*=.03) and severity (β=0.94, *P*<.050) on testing decisions. In line with the HBM, perceived benefits (β=0.19, *P*=.03) and cues to action (β=2.86, *P*<.001) increase the likelihood of testing. Results also show that caregivers of patients with cancer (β=1.25, *P*=.04) and those actively participating in online health support groups (β=0.47, *P*=.04) are also more likely to engage in cancer genetic testing.

Conclusions: Cancer remains a significant health challenge in the United States, with 1.8 million new cases and 606,520 deaths annually. Early detection is vital for treatment success. This study investigates factors influencing the decision to undergo genetic testing for cancer. The examination of caregiver status and online support groups as influencing factors, along with the HBM, provided a significant theoretical contribution to the health care research domain. Results indicated that caregivers and men should be directly targeted with messaging on genetic cancer screening as a proactive health behavior. Additionally, online support groups can promote early detection and encourage participation in genetic testing. Future research should further explore implementing proactive outreach strategies to encourage wider adoption of genetic testing for cancer.

KEYWORDS

genetic testing; cancer; health belief model; caregiver status; online social support; gender differences

Introduction

Overview

Cancer remains one of the most urgent health challenges in the United States, with approximately 2 million new cases and 611,000 deaths projected to occur in the United States in 2024 [1]. These figures highlight the importance of early detection and timely intervention, which are critical for improving treatment outcomes and reducing cancer-related mortality [2]. Early detection, particularly through predictive methods, enables health care providers to identify cancers at earlier stages, where treatment options can significantly improve the chances of successful outcomes. Consequently, the development and widespread adoption of effective screening strategies have become paramount in the fight against cancer.

XSL•FO
RenderX

Among these strategies, genetic testing has emerged as a pivotal tool in cancer prevention and early detection [3]. By analyzing an individual's DNA, genetic testing can identify mutations that may predispose individuals to various forms of cancer [4]. This predictive capability empowers individuals with knowledge that allows them to take preventive actions or pursue early treatments. As medical science and technology continue to advance, the scope of genetic testing has expanded to detect a wide range of inherited disorders, making it an indispensable approach for reducing cancer risk [5,6].

The health belief model (HBM) offers a valuable framework to understand why individuals engage in preventive behaviors like genetic testing. The HBM suggests that individuals' health behaviors are shaped by their perceptions of susceptibility, severity, and the benefits of action [7]. This model has been widely applied to the study of various preventive health actions, including vaccinations for H1N1 [8] and COVID-19 [9], as well as screening for conditions like diabetes [10] and several types of cancer [11-14]. Alongside the HBM, three key factors—caregiver status, participation in online social support groups, and gender—are likely to influence preventive behaviors related to genetic testing.

Caregivers, who are often family members, gain a deeply personal and intimate understanding of cancer's devastating impact. Due to shared genetic ties and family history, these caregivers frequently face a higher risk of developing cancer themselves [15,16]. Their close connection to the disease makes them a critical demographic for studying behaviors related to genetic testing. Given their heightened risk and firsthand exposure to cancer, caregivers may be particularly motivated to pursue genetic testing as a preventive measure.

In addition to caregiver status, online social support groups have been shown to play a crucial role in promoting preventive behaviors. Hwang et al [17] demonstrated that participation in online peer support groups significantly increased motivation for colorectal cancer screening, reinforcing participants' belief in the effectiveness of early detection. Lastly, gender has a profound influence on preventive health actions. Research indicates that women tend to be more proactive in engaging in preventive health behaviors [18-20]. For instance, women with low social support are less likely to participate in breast cancer screening, further illustrating the interplay between social support and gender in health decision-making behaviors [21].

The remainder of this paper is organized as follows. First, we provide an overview of the literature on genetic testing and the HBM. Next, we develop hypotheses and propose our research model. We then outline the research methodology and present the results. Following this, we discuss the findings, exploring both theoretical and practical implications. Finally, we conclude with a summary of the key insights gained from this research and address its limitations.

Background

Advancements in identifying gene mutations have made genetic testing a crucial tool in reducing illness and death by enabling early detection and preventive measures [5]. Predictive genetic testing, which assesses an individual's risk of developing diseases like cancer, focuses on identifying genetic mutations linked to disease susceptibility [22]. However, challenges persist in diagnosing hereditary breast and ovarian cancers, particularly in terms of genetic literacy and interpreting test results [23]. Nelson et al [24] emphasize the critical role of genetic counseling in BRCA-related cancer testing, highlighting the importance of providing informed decision-making support to patients.

Prior research also suggests that people with a family history of cancer often overestimate their risk. Their decisions about genetic testing are often influenced more by their subjective perceptions of vulnerability than by objective data [25]. This cognitive bias can lead to increased anxiety. It may cause individuals to rush into testing without enough information or avoid testing out of fear of the results. Despite these misperceptions, genetic testing consistently offers significant benefits, regardless of the outcome. Whether the results confirm a genetic predisposition or provide reassurance, testing allows individuals to make informed health decisions, take preventive measures, and access appropriate counseling and support services [26]. This highlights the importance of education and counseling in helping individuals to more accurately interpret genetic risks and use the information to make effective health care choices.

Caregivers of patients with cancer often play a pivotal role in health care decision-making, including decisions about genetic testing [27]. As primary support figures, caregivers are frequently involved in gathering health-related information, navigating complex medical choices, and encouraging preventative behaviors. Social support groups, both in-person and online, have been shown to provide critical informational and emotional support during these processes [28]. With the rise of online communities, individuals considering genetic testing now have greater access to peer support and shared experiences. Silence [29] demonstrated that online cancer communities facilitate advice-seeking and information-sharing, creating a valuable space for individuals to navigate genetic testing options. Similarly, Ruco et al [30] found that online social interactions significantly increase participation in cancer screening, highlighting the potential of these platforms to influence health-related behaviors. Given their influence in health decisions and the growing prevalence of online support networks, understanding the combined impact of caregiver status and participation in online social support groups is essential for accurately capturing the social and behavioral drivers behind genetic testing decisions.

The HBM is frequently used to examine health behaviors by considering factors such as perceived susceptibility, severity, cues to action, benefits, barriers, and demographic variables [7]. Bunn et al [31] and Hartman [32] successfully applied the HBM to predict decisions about preventive screenings, like colon cancer screening and mammography. The HBM provides a robust framework for understanding and influencing health-related decision-making, particularly in the context of preventive interventions such as genetic testing.

XSL•FO
RenderX

Theoretical Model

Health Belief Model—Perceived Susceptibility

Perceived susceptibility is an individual's belief about their likelihood of experiencing a health condition and is a key driver of health-related behavior according to the HBM [33,34]. Research consistently demonstrates that higher perceived susceptibility significantly influences medical decisions. For instance, Champion and Skinner [35] found that women with greater perceived susceptibility to breast cancer were more likely to undergo mammography. Similarly, Irigoyen-Camacho et al [36] observed that older adults with heightened perceived susceptibility to COVID-19 engaged more in preventive behaviors. Meta-analyses further confirm the strong correlation between perceived susceptibility and health behavior change [37,38]. Thus, we hypothesize the following:

Hypothesis H1a: Perceived susceptibility positively influences an individual's decision to undergo genetic testing for cancer.

Further, the impact of perceived susceptibility varies by gender. Studies suggest that women generally perceive greater health risks and, therefore, are more likely to adopt health-promoting behaviors, such as regular screenings and healthier lifestyles [39]. For example, Lisha et al [40] found that women with similar levels of physical activity as men had lower alcohol consumption. Based on this, we hypothesize the following:

Hypothesis H1b: Gender moderates the relationship between perceived susceptibility and an individual's decision to undergo genetic testing for cancer.

Health Belief Model—Perceived Severity

Perceived severity refers to an individual's belief about the seriousness of contracting an illness [34]. According to the HBM, higher perceived severity increases motivation to engage in health-promoting behaviors [35]. Studies by Witte and Allen [41] and Brewer et al [37] show that individuals who perceive health threats as severe are more likely to adopt preventive measures, such as vaccination. Similarly, Irigoyen-Camacho et al [36] found that the perceived severity of COVID-19 significantly influenced compliance with stay-at-home guidelines. He et al [42] also reported that individuals with high perceived severity of colorectal cancer were more likely to undergo colonoscopy. These findings highlight the pivotal role of perceived severity in driving medical action. Thus, we hypothesize the following:

Hypothesis H2a: Perceived severity positively influences an individual's decision to undergo genetic testing for cancer.

Further, extant research found that women perceive risks higher and engage in more preventive health behaviors [43]. Women generally report higher levels of perceived severity regarding health issues compared to men, and this heightened perception is linked to greater engagement in preventive health behaviors [39]. Sattler et al [44] also demonstrated that women were more likely than men to perceive the severity of health threats such as COVID-19, which translated into a higher likelihood of adopting recommended health behaviors. Thus, we extend this notion and hypothesize the following:

Hypothesis H2b: Gender moderates the relationship between perceived severity and an individual's decision to undergo genetic testing for cancer.

Health Belief Model—Perceived Benefit

Perceived benefits refer to an individual's belief in the positive outcomes of a health action, and they play a crucial role in motivating behavior change [35]. For instance, individuals are more likely to engage in physical activity if they believe it will lead to significant health improvements [45]. Similarly, Chen et al [46] found that perceived benefits significantly impact decisions to get vaccinated. Chen et al [47] further confirmed the association between perceived benefits and preventive behaviors. Bosompra et al [48] found that perceived benefits significantly impacted decisions to undergo genetic testing for cancer susceptibility. Based on this, we hypothesize the following:

Hypothesis H3: Perceived benefits positively influence an individual's decision to undergo genetic testing for cancer.

Health Belief Model—Perceived Barrier

Perceived barriers refer to an individual's assessment of obstacles that hinder the adoption of health-related behaviors [34]. Research consistently shows that these barriers negatively impact medical decision-making. According to the HBM, barriers may include factors such as cost, time, inconvenience, and fear of adverse outcomes [35]. A systematic review by Al-Noumani et al [49] identifies perceived barriers as a key predictor of poor adherence to health behavior changes in chronic conditions. Similarly, studies demonstrate that perceived barriers influence compliance with COVID-19 preventive measures over time [50,51]. Building upon these findings, we hypothesize the following:

Hypothesis H4: Perceived barriers negatively influence an individual's decision to undergo genetic testing for cancer.

Health Belief Model—Cues to Action

Cues to action are stimuli that prompt individuals to engage in health-promoting behaviors and are crucial for motivating medical action [35]. In the HBM, cues can be internal, such as experiencing symptoms, or external, like advice from others or health campaigns. Carpenter [52] found that both internal cues, like symptoms, and external cues, such as media messages, significantly increase the likelihood of seeking medical care. Similarly, Glanz et al [53] showed that health communication campaigns effectively acted as external cues, leading to higher vaccination and screening rates. Based on this, we hypothesize the following:

Hypothesis H5: Cues to action positively influence an individual's decision to undergo genetic testing for cancer.

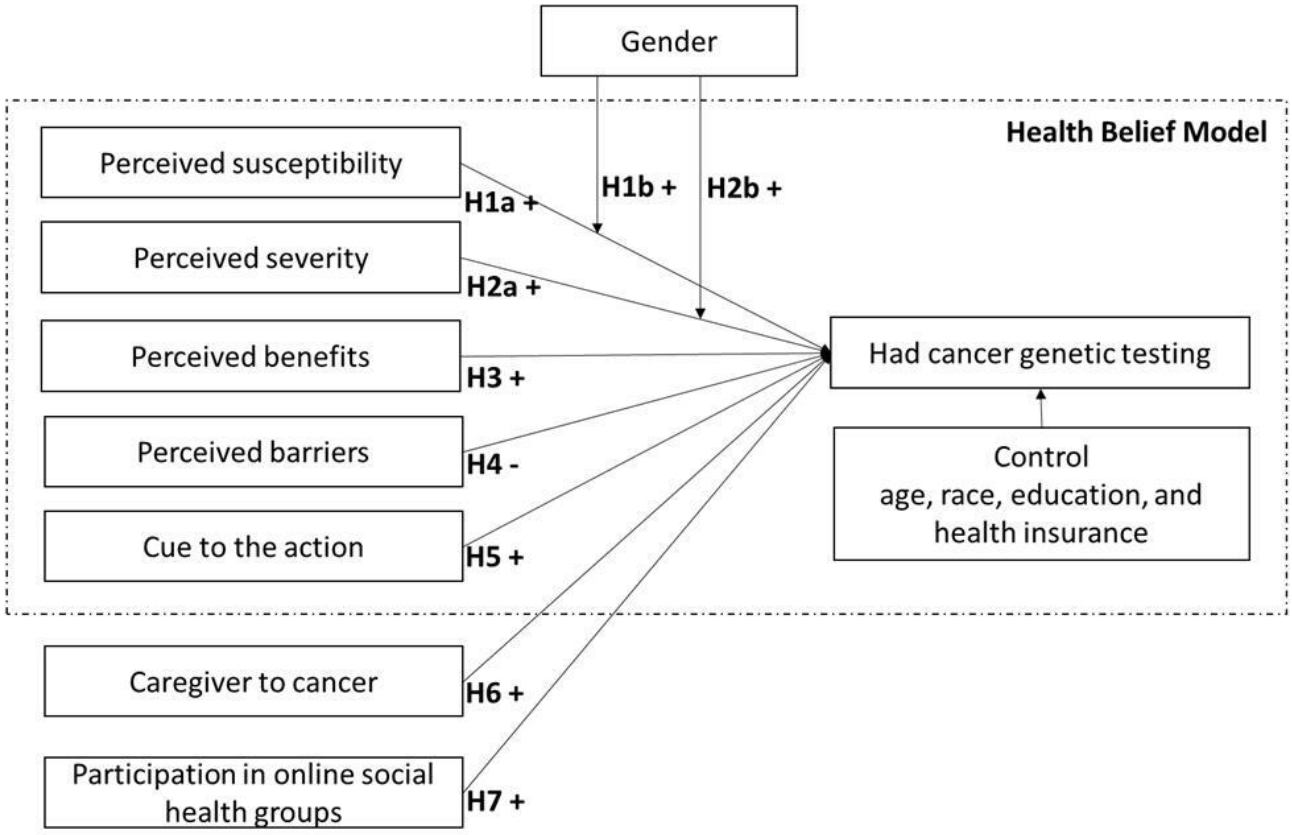
Caregiving

A caregiver provides care and support to someone with health-related needs due to chronic illness, disability, or aging [54]. When a family member is diagnosed with cancer, caregivers are deeply involved in diagnosis, treatment, and survivorship care [55]. During this time, they interact closely with health care providers, gather medical information, and

XSL•FO
RenderX

witness their loved one's experiences. The Center for Disease Control encourages caregivers to practice self-care and engage in preventive health care [56]. Research shows that spousal caregivers are more likely to undergo cancer screenings [57,58], with evidence of increased screening for stomach, breast, and cervical cancer among caregivers [59]. Additionally, caregivers are more likely to adopt health-promoting behaviors [60]. Extending this idea to genetic testing, we hypothesize the following:

Hypothesis H6: Caregiving positively influences an individual's decision to undergo genetic testing for cancer.



Online Social Support

Online social support groups provide a platform for individuals to share experiences and receive encouragement from others facing similar health challenges. This support fosters motivation and adherence to health goals. Participants often feel more committed to their health plans when they receive positive feedback and peer encouragement [61]. These groups also offer emotional support, reducing stress and anxiety, leading to better adherence to health-promoting behaviors and overall well-being [62]. Additionally, personalized advice from peers who have faced similar issues can be more practical and relevant than generic information, resulting in more effective health behavior changes [63]. A systematic review further supports the effectiveness of social media tools in delivering interventions for cancer prevention and management [64,65]. Based on these insights, we hypothesize the following:

Hypothesis H7: Participation in online health communities positively influences an individual's decision to undergo genetic testing for cancer.

Based on these hypotheses, our proposed research model is presented in Figure 1.

Figure 1. Research model.

Methods

Data

We used data from the 2020 National Cancer Institute Health Information National Trends Survey (HINTS 5 Cycle 4) survey, which is publicly available on the HINTS website [66]. Table 1 presents the correlations between the principal variables with survey weights. High correlations can indicate multicollinearity, but all correlations fall below the threshold of 0.5 [67], so multicollinearity was not an issue. The table also includes the means and SDs for the key variables.

XSL•FO
RenderX

Table . Correlation matrix.

	Mean	SD	PSUS[a]	PSEV[b]	PBEN[c]	CUES[d]	CC[e]	OSS[f]
PSUS	0.732	0.665	1.000					
PSEV	2.509	0.951	0.010	1.000				
PBEN	9.873	1.585	0.060	0.010	1.000			
CUES	0.438	0.704	0.160	−0.120	0.100	1.000		
CC	0.019	0.369	0.030	0.030	−0.090	0.020	1.000	
OSS	0.266	0.746	−0.020	0.040	0.060	0.040	0.010	1.000

[a]PSUS: Perceived susceptibility.

[b]PSEV: Perceived severity.

[c]PBEN: Perceived benefit.

[d]CUES: Cues to action.

[e]CC: Caregiving cancer.

[f]OSS: Online social support.

Measurements

The complete set of questionnaires for the dependent, independent, and control variables can be found in Multimedia Appendix 1. Although many variables are measured using multi-item scales, some are captured through single-item measures. The use of single-item measures is deemed appropriate when the question is straightforward and unambiguous, minimizing the risk of varied interpretation [68]. Moreover, single-item measures are widely recognized and commonly used within the health care domain [60,69,70], further supporting their validity in this study.

Outcome Variable: Cancer Genetic Testing

The main outcome variable "Had cancer genetic test" is a dichotomous variable and coded "1" for an individual who had a genetic test for cancer, otherwise "0." In our data, 142 respondents said they had cancer genetic testing; this represents 8,368,022 in the population when using survey weights. In total, 2805 respondents said they never had cancer genetic testing, which represents 191,142,974 in the population when using survey weights.

We effectively mitigated the potential concern of skewed outcome variables through the application of survey weights. Survey weights are designed to adjust for the complex survey design, including oversampling and nonresponse, ensuring that the results are representative of the target population. Studies have shown that when survey weights are appropriately applied, they can correct for biases introduced by skewed distributions in outcome variables, leading to more accurate and generalizable results [71].

Primary Independent Variables: Cancer Caregiver and Online Social Support

Caregiver cancer is coded as '1' if the individual is caring for or making medical decisions for someone with cancer, and '0' otherwise. Online social support is coded as '2' for individuals who both share health information on social networking sites and participate in an online forum or support group related to similar health or medical issues. If they engage in only one of these activities, it is coded as '1,' and if neither activity is present, it is coded as '0.'

Support Independent Variables: Health Belief Model

Perceived susceptibility is coded as "1" if first- or second-degree biological relatives had cancer, otherwise "0." Perceived severity ranges from "1" to "5" for respondents' general health, varying from "Excellent" to "Poor." Cues to action are coded as "1" if respondents have heard of cancer genetic testing, otherwise "0."

The perceived benefit was obtained by summing respondents' answers to 3 survey questions: How important is knowing a person's genetic information for preventing cancer? How important is knowing a person's genetic information for detecting cancer? and How important is knowing a person's genetic information for treating cancer. These questions have 4 options from "Not at all" to "Very." Several papers have pointed to income as a potential barrier to preventative health care [72,73]. Hence, we consider income as a proxy for perceived barrier, and it has 5 categories "1" to "5." Less than US $20,000 is coded as "1" while US $75,000 or more is coded as "5."

Moderating Variable: Gender

Females were coded as "1" and male as "0."

Control Variables

Race, education, marital status, insurance, and age were used as controls in the model. Whites were coded as "1" and non-Whites were coded as "0." Education of more than high school was coded "1" for individuals, otherwise "0." For married individuals, married was coded as "1", or else "0." Insured individuals were coded as "1" or else "0." We used the natural log of "Age" in our model as "Age" varies from 18 to 102 years.

Statistical Analysis

This study uses survey weights to report national estimates. We used survey-weighted generalized linear models to test the hypotheses in R using the "survey" package. We used HINTS-supplied survey weights using jackknife variance estimation techniques to account for the complex HINTS sampling design and to calculate nationally representative

XSL•FO
RenderX

estimates [74]. Since we used publicly available deidentified data, the Institutional Review Board review was exempted.

Common Method Variance

Data collected with a self-reported single survey may suffer from common method variance (CMV), which hampers the relationship between the variables [75]. To check if our data are suffering from CMV, we used the marker variable technique [76]. A marker variable is a variable that is theoretically unrelated to one or more of the principal variables measured in the study and typically should have a low correlation with the variables of interest.

The theoretically unrelated construct "UnderstandOnlineMedRec" (UOM) was used as a marker variable. The correlation between the marker variable UOM and other principal variables is very low, indicating that CMV is not a problem. The UOM for perceived susceptiblity was 0.03, that for perceived severity was 0.18, that for perceived benefit was −0.03, that for cues to action was −0.21, that for caregiving cancer was 0.02, and that for online social support was 0.02.

Ethical Considerations

The HINTS 5 survey, conducted with the general population, underwent expedited review and received approval from the Westat Institutional Review Board on March 28, 2016 (project no. 6048.14). In addition, on April 25, 2016, the National Institutes of Health Office of Human Subjects Research determined that the survey did not involve human subjects research, providing an exemption (exempt no. 13204) [77]. This analysis used deidentified, publicly available data from the HINTS, which did not constitute human subjects research as defined by 45 CFR 46.102 and, therefore, did not require IRB review. The original consent and IRB approval cover secondary analysis without the need for additional consent. No compensation was provided for participation.

Results

Study Population Characteristics

The data include 3865 civilian, noninstitutionalized US adults aged 18 or older. After filtering for valid responses to the question about genetic testing for high-risk cancer, our final sample consisted of 2947 respondents, representing 199,510,996 US adults. Descriptive statistics of the survey respondents are shown in Table 2 with survey weights applied.

The analysis did not identify a significant direct relationship between perceived susceptibility and the decision to undergo genetic testing (β=−0.70805, *P*=.36), leading to the rejection of hypothesis H1a. However, gender was found to be a significant moderator in this relationship. Specifically, women who perceive themselves as susceptible to cancer are significantly more likely to pursue genetic testing (β=2.53956, *P*=.03), providing support for hypothesis H1b.

Similarly, no significant direct association was observed between perceived severity and the decision to undergo genetic testing (β=−.58773, *P*=.13), leading to the rejection of hypothesis H2a. However, gender again played a moderating role in this relationship. Women were more likely than men to opt for genetic testing when they perceived cancer as a severe threat (β=.94366, *P*=.03), supporting hypothesis H2b.

Beyond gender effects, the findings indicate that individuals who perceive greater benefits from genetic testing are more inclined to undergo testing (β=.18903, *P*=.03), confirming hypothesis H3. The expected relationship between perceived barriers—represented by income in this study—and genetic testing decisions (hypothesis H4) was not supported (β=−1.11782,−0.17123, 0.44008, 0.05962, *P*>.05).

Cues to action emerged as a significant predictor of genetic testing decisions, with greater exposure to such cues being strongly associated with an increased likelihood of pursuing genetic testing (β=2.85722, *P*<.001), supporting hypothesis H5. Additionally, individuals who serve as caregivers for patients

XSL•FO
RenderX

with cancer were found to be significantly more likely to engage in genetic testing themselves (β=1.25257, *P*=.04), confirming hypothesis H6. Lastly, participation in online social health groups was positively associated with the likelihood of undergoing genetic testing (β=.47306, *P*=.04), supporting hypothesis H7.

Discussion

Summary of Findings

In line with previous research [78,79], our findings indicate that perceived susceptibility alone may not be enough to motivate individuals to undergo genetic testing. This suggests that additional cues to action or contextual influences may play a crucial role in shaping decision-making.

Moreover, the results show that perceived susceptibility has a stronger effect on genetic testing behavior among women compared to men. One possible explanation is that women may be more sensitive to health risks, particularly hereditary cancers such as breast and ovarian cancer, making them more likely to act on their perceived vulnerability.

This finding is consistent with existing literature [80,81], which suggests that while perceived severity is an important factor, it may not be a sufficient motivator for health-related behaviors without the presence of additional reinforcing elements.

The results also emphasize the importance of accounting for gender differences in health risk perceptions and decision-making. Women's stronger response to perceived severity may be attributed to their heightened awareness of specific cancer risks and a greater tendency to engage in proactive health behaviors.

Additionally, our findings reinforce a core principle of the HBM, which asserts that perceived benefits are a key driver of health-related actions.

Results further suggest that traditional barriers, such as cost, are being alleviated through evolving health care policies and financial assistance programs [82,83]. Measures such as subsidized testing, reduced out-of-pocket expenses, and insurance coverage for preventive screenings have helped minimize these obstacles [84].

Cues to action emerged as a significant predictor of genetic testing decisions. One explanation for this finding is the changing health care landscape, particularly in preventative care and personalized medicine. Many providers now recognize the value of genetic testing for early risk identification, prompting efforts to reduce financial and logistical barriers [85]. Major insurers increasingly cover preventative genetic testing, reducing costs for individuals [86]. Additionally, online support groups play a role by informing individuals about available financial assistance and providing emotional support, reducing psychological barriers like fear or anxiety about test results [87]. These developments suggest that the traditional "perceived barriers" construct in the HBM may not be relevant in the context of genetic cancer testing.

Another important result from the study is the role of caregiving in influencing decisions to undergo genetic testing. This finding underscores the role of online communities in promoting health-related behaviors by providing access to information, emotional support, and shared experiences. These groups act as cues to action by reducing uncertainty and raising awareness about the benefits of genetic testing, empowering individuals to make more informed health care decisions, especially in preventative care contexts.

Theoretical Contributions

Our study extends the prior body of research on HBM by examining factors that influence an individual's decision to undergo cancer genetic testing and incorporating variables that have not been widely explored in prior research. One of the key theoretical advancements of this study is the evidence supporting the moderating role of gender in the relationship between perceived susceptibility, perceived severity, and health behavior change. Our results demonstrate that women are significantly more likely to undergo genetic testing when they perceive higher susceptibility or severity of cancer, thus supporting the hypotheses related to gender moderation. Gender disparity in health decision-making behavior is rooted in cultural, psychological, or social factors that make women more responsive to health risks, particularly those related to cancer, such as breast and ovarian cancer. These findings align with prior research indicating that women are generally more responsive to health risks, particularly in the context of cancer (eg, breast and ovarian cancers), where early detection and preventive measures are critical [35,88]. This gender-specific behavior underscores the need for health interventions that are tailored to reflect differences in health perceptions and behaviors between men and women.

This study extends the HBM by incorporating caregiving as a variable that influences health behaviors. Our results indicate that individuals who are caregivers to patients with cancer are significantly more likely to engage in cancer genetic testing. Caregivers, who are often emotionally and practically involved in managing the health of others, are more attuned to genetic risks and motivated to take preventive action for their own health [89]. This finding suggests that future interventions could target caregivers specifically, providing them with information about the benefits of genetic testing and encouraging preventive health behaviors.

Furthermore, the study highlights the growing importance of digital communities, such as online social health groups, in shaping health behaviors. Our analysis shows that participation in these groups is positively associated with the likelihood of undergoing genetic testing. This finding is consistent with existing literature that points to the influence of social networks on health behavior change [90,91] and the growing importance of digital communities in shaping health behaviors. Online platforms can serve as a source of information, support, and motivation for individuals contemplating health-related decisions. In online platforms, individuals can share experiences, advice, and support, building virtual environments that encourage proactive health actions like genetic testing. As such, health practitioners and policy makers could leverage the power

XSL•FO
RenderX

of these digital communities to enhance awareness and promote the benefits of genetic testing and other preventive health measures.

Practical Implications

This study's findings have several practical implications for health care providers and public health campaigns. Our results support the importance of perceived benefits in the decision to get genetic testing. Efforts to promote cancer genetic testing should focus on clearly communicating the benefits of early detection, such as the ability to develop personalized cancer treatment plans using information from genetic testing. Early diagnosis significantly improves cancer outcomes, particularly when care is provided at the earliest possible stage [92]. Especially with cancer genetic tests, there is immense potential to facilitate early detection and personalized treatment strategies [93]. Our results also support the importance of cues to action in the decision to get genetic testing. Timely and effective communication can motivate individuals to take proactive steps in their health care journey. However, the success of these interventions depends on individuals' willingness to engage in preventive health behaviors. Public health officials can pursue changes to health care policy that will incentivize individuals to be proactive about their health and get genetic cancer screenings. Financial incentives have proven to be effective in encouraging individuals to get screenings [94]. Employers already reduce individual monthly insurance premiums by requiring employees to get regular health screenings [95]. Insurance providers can simply add free or reduced-cost genetic cancer screening in the included health care screenings, thus implicitly encouraging and supporting individuals to get screened.

The moderating role of gender highlights the need for improved public health campaigns directed towards men. The Center for Disease Control highlights that "men have higher rates of getting and dying from cancer than women" [96]. There is a lack of online social discourse on genetic testing, which may be the reason for lower male engagement with genetic testing [97]. To address this concern, there has been a notable increase in the number of public health campaigns encouraging men to get screening tests. Recent research has examined how to leverage social media to bring public awareness to the value of genetic testing for prostate cancer [98]. Further efforts in this area could focus on developing messaging on the benefits of early detection using gender-coded language to specifically target men. To improve online social discourse on cancer genetic testing [97], public health organizations can post informative messages on X (formerly Twitter) to encourage discussion of genetic testing, create and participate in regional Facebook groups and pages to develop a community of men interested in genetic testing, and share Facebook and YouTube videos to dispel concerns and address any misconceptions regarding genetic testing. Additionally, our research found the role of caregivers is particularly noteworthy. Our results indicate that caregivers are more likely to seek genetic testing, potentially due to their heightened awareness of cancer risk factors through their caregiving experience [98]. Health care providers should recognize caregivers as a key demographic for targeted interventions. By educating caregivers on the benefits of genetic testing, both for themselves and their families, health care professionals can increase the uptake of this preventive measure. Caregivers, often deeply involved in health care decisions, could also serve as advocates for genetic testing within their broader social networks, further amplifying the reach of these interventions.

In addition, the positive association between online social health group participation and genetic testing uptake suggests that digital platforms can be effective tools for health promotion. These platforms, where individuals can share experiences and seek advice, provide a valuable avenue for disseminating information about the benefits of genetic testing. Public health campaigns that leverage social media and online communities could encourage greater awareness and engagement with preventive health behaviors [99]. Engaging individuals in these groups may also help to reduce the stigma or fear surrounding genetic testing, ultimately facilitating behavior change.

Limitations and Future Research

Despite its contributions, this study is not without limitations. First, the research relied on secondary data, which constrained the analysis to available variables. The use of secondary data limits the flexibility to explore unmeasured constructs that may further elucidate the decision-making process surrounding genetic testing. Furthermore, we used the HINTS data that were collected in 2020, and hence, it may not fully capture the most recent trends and developments. Future research could consider incorporating primary data collection methods to include more contemporary variables and insights reflective of the current landscape.

Though our study examines the role of caregiving and participation in online support groups in influencing the genetic testing decision, it is important to acknowledge certain limitations that may reduce the potential positive impact of these factors. For instance, barriers such as limited digital literacy, unequal access to the Internet, and socioeconomic disparities can hinder individuals from fully benefiting from online health resources and support networks. These barriers may be particularly pronounced in underserved or marginalized populations, where individuals may lack the necessary tools or knowledge to engage in digital health activities effectively. Future research could address these limitations by exploring how cultural contexts, including beliefs, norms, and values, shape the genetic testing decision. Examining how different communities perceive genetic testing and their access to digital resources can provide more nuanced insights into reducing disparities and improving health outcomes across diverse populations.

Conclusions

This study explores the factors influencing the decisions to undergo cancer genetic testing in the US population. Our findings emphasize the significant roles of perceived benefits, cues to action, caregiving for patients with cancer, and participation in social health groups in motivating genetic testing. Additionally, gender moderates the relationship between genetic testing and both perceived susceptibility and severity of cancer risk. Given the hereditary nature of cancer, increasing

XSL•FO
RenderX

awareness of genetic testing benefits is essential for promoting preventive health behaviors.

The study contributes to both theory and practice. Theoretically, it extends the HBM by incorporating cancer-specific constructs and highlighting the role of information systems in health decision-making. Practically, it offers actionable insights on how tailored education and social support can foster proactive health behaviors, particularly among caregivers and social health communities. Targeted campaigns, especially within online support groups or aimed at men, can further promote early detection. Future research can explore these strategies to increase the adoption of genetic testing for cancer.

Abstract

Background: Skin cancers, including melanoma and keratinocyte cancers, are among the most common cancers worldwide, and their incidence is rising in most populations. Earlier detection of skin cancer leads to better outcomes for patients. Artificial intelligence (AI) technologies have been applied to skin cancer diagnosis, but many technologies lack clinical evidence and/or the appropriate regulatory approvals. There are few qualitative studies examining the views of relevant stakeholders or evidence about the implementation and positioning of AI technologies in the skin cancer diagnostic pathway.

Objective: This study aimed to understand the views of several stakeholder groups on the use of AI technologies to facilitate the early diagnosis of skin cancer, including patients, members of the public, general practitioners, primary care nurse practitioners, dermatologists, and AI researchers.

Methods: This was a qualitative, semistructured interview study with 29 stakeholders. Participants were purposively sampled based on age, sex, and geographical location. We conducted the interviews via Zoom between September 2022 and May 2023. Transcribed recordings were analyzed using thematic framework analysis. The framework for the Nonadoption, Abandonment, and Challenges to Scale-Up, Spread, and Sustainability was used to guide the analysis to help understand the complexity of implementing diagnostic technologies in clinical settings.

Results: Major themes were “the position of AI in the skin cancer diagnostic pathway” and “the aim of the AI technology”; cross-cutting themes included trust, usability and acceptability, generalizability, evaluation and regulation, implementation, and long-term use. There was no clear consensus on where AI should be placed along the skin cancer diagnostic pathway, but most participants saw the technology in the hands of either patients or primary care practitioners. Participants were concerned about the quality of the data used to develop and test AI technologies and the impact this could have on their accuracy in clinical use with patients from a range of demographics and the risk of missing skin cancers. Ease of use and not increasing the workload of already strained health care services were important considerations for participants. Health care professionals and AI researchers reported a lack of established methods of evaluating and regulating AI technologies.

Conclusions: This study is one of the first to examine the views of a wide range of stakeholders on the use of AI technologies to facilitate early diagnosis of skin cancer. The optimal approach and position in the diagnostic pathway for these technologies

XSL•FO
RenderX

have not yet been determined. AI technologies need to be developed and implemented carefully and thoughtfully, with attention paid to the quality and representativeness of the data used for development, to achieve their potential.

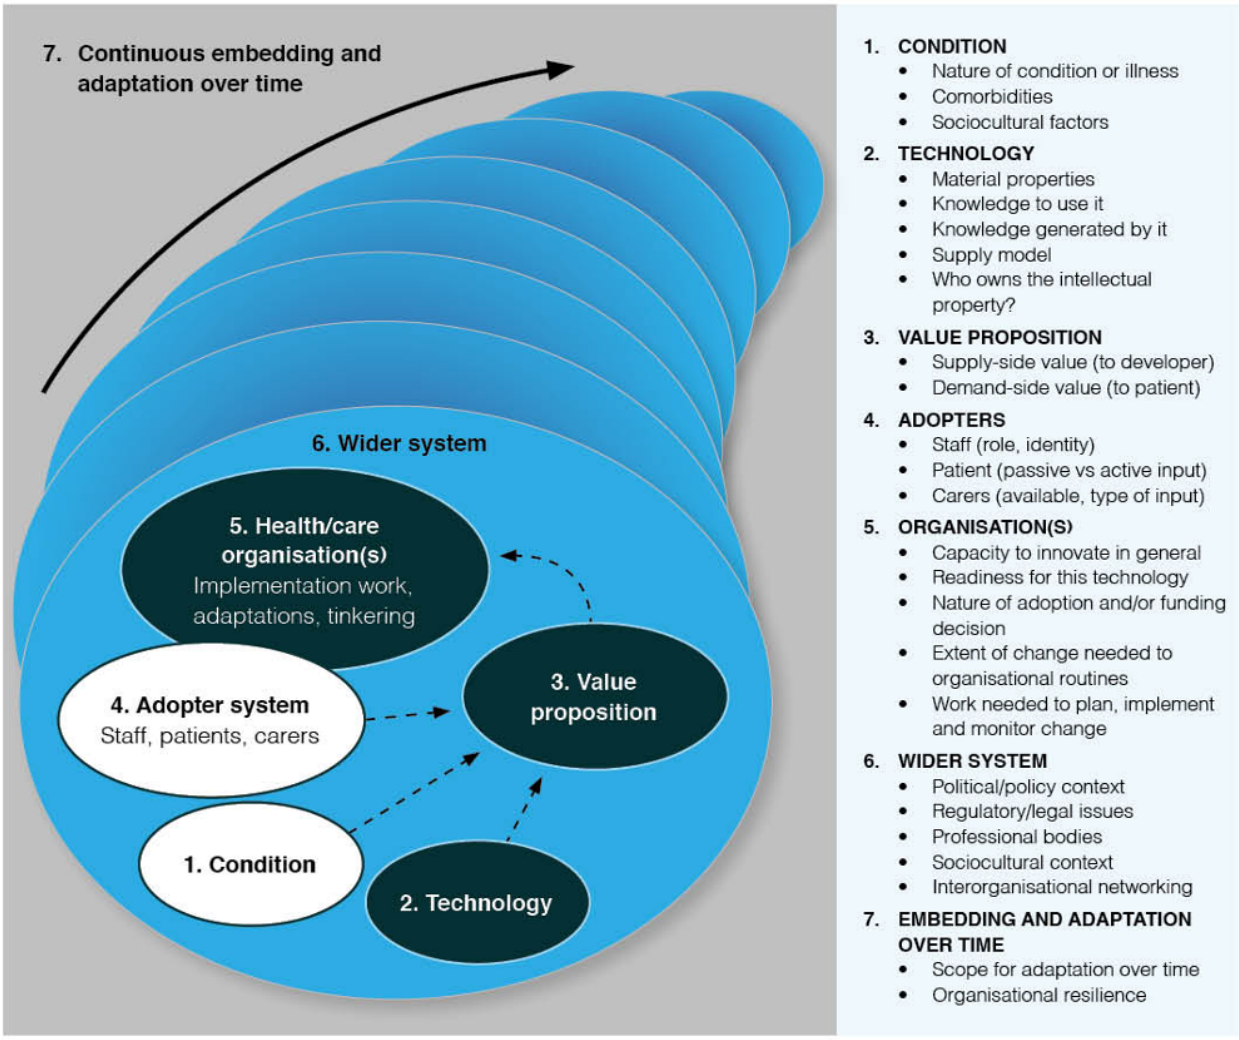
Introduction

Background



Skin cancers are among the most common cancers worldwide, with increasing incidence in most populations [1,2]. Melanoma is the most lethal skin cancer, but keratinocyte cancers (KCs), which include squamous cell carcinomas and basal cell carcinomas, comprise most skin cancers [1-3]. There were >200,000 skin cancer diagnoses in England in 2021, comprising 193,000 nonmelanoma skin cancers (which include KCs) and nearly 16,000 melanomas [4]. The World Health Organization estimates that 2 to 3 million nonmelanoma skin cancers and 132,000 melanomas occur globally each year [5]. Earlier diagnosis of skin cancers is associated with statistically significantly better outcomes [3]. In the United States, early detection of melanoma is associated with >99% five-year survival but falls to 74% when it has spread to lymph nodes and 35% when spread to distant organs [6].

There has been a substantial interest in applying artificial intelligence (AI) to the diagnosis of skin cancer through visual analysis of skin lesions, either through a smartphone app or uploading images of skin lesions. Many AI technologies have been designed for use by patients and a handful for use by clinicians as clinical decision aids [7,8]. Most of these technologies do not have the appropriate regulatory approvals in place to support their safety and efficacy when used in these settings [9], with limited evidence on their efficacy and accuracy from clinical trials or real-life clinical settings [7,8], although some evidence is emerging [10,11]. There is limited evidence on how users in clinical settings interact with AI technologies and how this might affect patient safety [12], and a lack of qualitative studies reporting public perspectives [13].

Implementation of a diagnostic technology in clinical settings is a complex process and prone to failure—a technology must pass through several stages of development before implementation is likely to be successful [14]. Several frameworks analyze factors around the implementation of new technologies. In this study we chose to use the Nonadoption, Abandonment, and Challenges to Scale-Up, Spread, and Sustainability (NASSS) framework [15] to help understand and interpret the data. This framework incorporates complexity principles and allows researchers to identify and explain the manifestations of complexity in technology-supported change projects (Figure 1) [15]. We believe that these attributes made it best suited to this study compared with other conceptual frameworks for implementation research.

XSL•FO

Figure 1. The Nonadoption, Abandonment, and Challenges to Scale-Up, Spread, and Sustainability (NASSS) framework [15].

Objectives

The aim of this study was to consult several stakeholder groups (ie, groups that may have views or concerns about the use of AI to help diagnose skin cancer in primary care) to provide in-depth understanding of barriers and facilitators to the implementation of AI technologies for the early diagnosis of skin cancers in primary care settings. Depending on how AI is implemented in the skin cancer diagnostic pathway, users of the technology could include members of the public, patients, general practitioners (GPs), primary care nurse practitioners (NPs), and dermatologists. Dermatologists also receive most referrals from primary care for suspected skin cancers. AI researchers working in both academic and commercial settings are the primary developers of AI technologies. The views of all these groups were important to understand.

Methods

Design

This was a qualitative study that was performed using semistructured interviews of stakeholders.

Recruitment and Sampling

Four groups were selected for the study: (1) members of the public, (2) patients previously diagnosed with skin cancer, (3) health care professionals (HCPs; including GPs, primary care NPs, and dermatologists), and (4) AI researchers from academic and commercial settings. Members of the public were approached via the Cambridge Biomedical Research Centre Patient and Public Involvement (PPI) group and “snowballing” invitations to their colleagues. Members of the public with a history of skin cancer were included in the patient group, with additional patients approached via Melanoma Focus (a UK melanoma charity that provides information, guidance, and support for patients, carers, and HCPs) [16]. GPs and primary care NPs were identified through the Primary Care Dermatology Society [17], with additional GPs approached via Sermo (medical market-research organization) [18]. Dermatologists were identified from the British Association of Dermatologists (BAD) [19] and through snowballing. AI researchers from academic settings were identified through contacts within academic institutions, and AI researchers from commercial settings were recruited via email from companies identified in 2 reviews [7,8]. In this paper, we use primary care practitioner (PCP) to denote any medical practitioner that works in a primary

XSL•FO
RenderX

care setting and might consult with a patient about a suspicious skin lesion, including GPs, family doctors, NPs, physician assistants, and paramedic practitioners. HCP is used when we refer to the views of wider HCPs, including secondary care HCPs. Staff who work in primary and community care and do not have clinical training and experience in the diagnosis of skin cancer but could potentially use an AI technology with patients with suspicious skin lesions are referred to as allied HCPs; a wide variety of professions could be included in this group, but it certainly includes practice nurses, health care assistants, clinical navigators, pharmacists, and podiatrists.

Participants were sampled to achieve a spread of age, sex, and geographical location within each participant group. Patients and the public were recruited to achieve a spread of ages >60 years and <60 years, reflecting the average age of skin cancer diagnosis. HCPs and AI researchers were recruited to achieve a spread of ages >45 years and <45 years, reflecting the midcareer point of these professions. Patients were sampled to include a range of prior history of skin cancer types. GPs were sampled to include a spread of roles (GP partner, salaried GP, locum GP, GP with extended role in dermatology). Participants were asked how supportive they were of using AI technologies to help diagnose skin cancer in primary care (using a Likert scale of strongly disapprove, disapprove, neutral, approve, and strongly approve). We aimed to recruit at least 1 participant in each group who disapproved and at least 1 who approved of the use of AI in this setting to obtain a range of perspectives.

Ethical Considerations

Ethics approval for this study was granted by the Cambridge Psychology Research Ethics Committee (PRE.2021.098). Participants gave informed written and verbal consent to take part in the interviews. Patient and public participants were invited to bring a friend or family member with them to take part in the study if they wished. All interviews were digitally recorded and transcribed verbatim by a professional transcription company. Transcripts were checked and anonymized before analysis. To facilitate recruitment, a £20 (US $25.24) Apple iTunes or Google Play voucher was offered to all participants.

Data Collection

An interview topic guide was developed with input from our PPI group to explore views on facilitators and barriers to the use of AI technologies to help diagnose skin cancer in primary care. All interviews were conducted by OTJ, who has a clinical background, with guidance from NC, a health services researcher with expertise in qualitative research. Interviews took place on the web using Zoom (Zoom Video Communications) at a time of the participants choosing between September 9, 2022, and May 25, 2023. Interview schedules for patients and members of the public and HCPs and AI researchers are available in Multimedia Appendix 2. Details on the interviews are reported in the COREQ (Consolidated Criteria for Reporting Qualitative Research; Multimedia Appendix 3) checklist. Interviews continued until we had a rich, multifaceted dataset. A reflexivity journal with field notes was kept and was discussed at regular meetings during the study.

Analysis

Interviews were analyzed inductively and deductively using thematic framework analysis [20]. Two researchers (OTJ and NC) repeatedly read the first 5 transcripts to become familiar with the data and generate initial codes. These initial codes were compared with the NASSS framework (Figure 1) [15] to generate a comprehensive list of codes. The remaining transcripts were then read and indexed using NVivo (version 14; Lumivero) [21], with codes modified or created as required where the data did not fit comfortably into the NASSS framework. Coding was completed by OTJ with a sample of transcripts (7/29, 24%) checked by NC. Codes were defined and discussed regularly in team meetings (OTJ, NC, and FMW), and coding files were saved throughout the process to maintain an audit trail of changes to the code tree. Data were charted into Microsoft Excel [22], and the characteristics, similarities, and differences between data were identified. Relationships and connections between categories were then mapped to generate the themes presented in the results. Themes were further refined with guidance from senior team members (FMW and SS [health psychologist]). Together this broad authorship group of clinical academics and behavioral scientists added rigor to data analysis and interpretation.

Results

Participants

A total of 29 interviews were conducted with members of the public (n=6, 21%), patients (n=5, 17%), HCPs (n=13, 45%), and AI researchers (n=5, 17%; Table 1). Participants were recruited via mailing lists and social media; therefore, the denominator is unknown.

[h]Educational qualification categories were taken from the UK National Census 2021. Definitions are available on the internet [23].

[i]Basal cell carcinoma (n=3), melanoma (n=1), and Merkel cell carcinoma (n=1).

The *Results* section is structured around the major themes and subthemes generated from the data. Major themes included the "position of AI in the skin cancer diagnostic pathway" and the "aim of the AI technology." There were several cross-cutting themes, including trust, acceptability, generalizability, evaluation, regulation, implementation, and long-term use (Figure 2). Participant quotations are identified by participant group, sex, and age.

Figure 2. Issues around the design and intended positioning of artificial intelligence (AI) technologies for the diagnosis of skin cancer that were identified from the data, and further cross-cutting themes identified. *Allied health care professionals that could use the technology include pharmacists, health care assistants, practice nurses, podiatrists, hairdressers, and potentially many more. UK NHS: UK National Health Service.

Position of AI in the Skin Cancer Diagnostic Pathway

AI Before the PCP

Patients and members of the public felt that giving patients access to AI technology would be more accurate than "random googling" and could help them to decide when to see a physician. However, they expressed concerns about using the AI technology without clinical input. The loss of the human touch in consultations worried them, including how the diagnosis would be communicated and whether patients would be able to get a PCP follow-up appointment to discuss the diagnosis and ask questions. Another concern was whether all patients would be able to effectively use the technology and the potential for it to exclude some groups of patients, including older people. Patients and the public discussed the risk of overuse of the technology by patients; they felt that implementing it in a practice nurse and allied HCP-led clinic would reduce the risk of overuse while also making it easier for patients to access skin lesion assessments.

All HCPs could envision AI technology being used by patients and thought there would be a high demand for this service. Some dermatologists felt this could be a useful approach, particularly for patients at high risk of skin cancer between dermatology clinic appointments; however, they were concerned about the potential for overuse and subsequent workload due to false positives that would inevitably occur. They thought patients might struggle to understand the risks, benefits, and the output of the AI technology and would find it difficult to take high-quality images needed for the AI to analyze. Some HCPs commented on the potential psychological benefits of AI technology, in particular reducing patient anxiety if the technology reduced the number of urgent suspected cancer referrals, although some HCPs felt that it could increase patient anxiety through increasing access to skin lesion checks. Dermatologists and NPs commented on how accurate AI technology could enable a wide variety of allied HCPs to use the technology to triage patients presenting with suspicious skin lesions, which may improve access and enable earlier detection of skin cancer. GPs reported both positive and negative views on the potential of positioning AI technologies in the role of triaging patient-submitted photographs before an appointment with a PCP.

AI researchers from academic backgrounds were broadly skeptical of patients having access to AI technology themselves, highlighting concerns about the diagnostic accuracy of the technology, the risk of false reassurance, and that patients would not necessarily understand the context of when it was safe to use. However, AI researchers from commercial backgrounds felt that, if the AI technology was accurate enough, positioning AI technologies with patients had the greatest potential for

XSL•FO
RenderX

impact. They highlighted various potential positive effects, including reducing the barriers to getting a skin lesion assessed, helping patients make better decisions about when they needed to see an HCP, and educating patients about skin cancer.

AI With the PCP

Patients commented that GP surgeries are accessible for most patients and so are an ideal place to locate the technology. They felt that if they were consulting about a potentially serious skin cancer (ie, melanoma), they would like to be able to speak to a PCP. Combining the clinical judgment of the PCP with the AI technology was generally viewed as being more powerful than the PCP alone and could be more beneficial for PCPs with less experience in skin cancer and reduce the variability in skin cancer triage in primary care. The public discussed whether PCPs would become reliant on the AI technology and lose their clinical judgment and even whether this was an issue if the AI diagnostic accuracy were better than the PCP's.

GPs largely wanted PCPs to have access to the AI technology and were concerned that the implementation of AI technology at other points in the diagnostic pathway could undermine their gatekeeping role. They believed that PCPs are well positioned to triage and monitor skin lesions over time and provide continuity of care and that it would be more efficient for the technology to be used to triage a lesion in a single consultation instead of needing a separate appointment to capture the image. NPs agreed that AI technology would be best placed with a PCP. One GP emphasized that the positioning of the technology in the diagnostic pathway is probably the most important factor in how impactful it will be.

Dermatologists expressed the opinion that something was needed to improve the accuracy of referrals to secondary care but were not sure implementing AI technology in primary care was the best approach. A broad educational program for PCPs was suggested as a better alternative. Whether AI technology is currently accurate enough to be used by PCPs was a concern, as well as the risk of deskilling PCPs in skin lesion recognition. Dermatologists did see benefits in situating AI technology with PCPs to help with rarer skin cancer recognition, to break bad news, and answer patient questions, and to give PCPs more confidence in diagnosing a lesion as benign and not referring on to secondary care.

Most AI researchers expressed strongly that a "human-in-the-loop" approach (ie, where a human clinician is always involved in decision-making alongside the AI) is needed. Potential benefits of this approach included increased safety, allowing for patient interactions, allowing the PCP to focus more on the patient, and increasing knowledge of PCPs. AI researchers also discussed that the decision to biopsy or refer a skin lesion involves many biopsychosocial and clinical factors outside of the appearance of the lesion, which cannot be measured or considered by the AI and thus needs input from a PCP.

AI After the PCP

Use of AI technology to triage referrals from primary care to secondary care in a teledermatology setting was only mentioned by 1 GP and 2 dermatologists. The dermatologists suggested AI technology could help triage obviously benign skin lesions, preventing them from being referred to a dermatology clinic.

Few participants commented on positioning an AI technology with dermatologists. Dermatologists believed that it could be a useful training tool, and in the future, if it were proven to be more accurate than dermatologists, then it could be implemented in dermatology clinics. One AI researcher agreed and discussed how AI technology could help improve dermatologists' consistency in diagnosis (Textbox 1).

XSL•FO
RenderX

Textbox 1. Positioning of artificial intelligence (AI) in the skin cancer diagnostic pathway.

AI before the primary care clinician

- So I think people first self-diagnose via Google a lot anyway so having something that's a little bit more accurate than self-diagnosis is probably helpful. [Patient 4; female, aged <60 years]
- I don't think it would be effective giving it directly to patients, least of all because they won't have the training and the right level of professional knowledge in being able to interact with digital innovations effectively. [Patient 1; male, aged <60 years]
- I would be a little bit concerned about it just being open-ended, because...the potential for over-use by some people and under-use by others would be quite large, I think. So, I think...a nurse-led clinic or something like that might be better. Or give people the option. [Member of the public 3; female, aged >60 years]
- I know from doing online and video consultations during COVID, what was quite evident is that patients have got varying skills in terms of how they use their mobile devices to show you their skin remotely and taking images, and the quality of those images. So I think you'd have to think very carefully about who is taking the image, what they understand about what the clarity of that image needs to be, and what devices they're being used on. Because that's going to affect your interpretation. So I would be hesitant to say as a matter of routine for it to be patient led. [NP1 (nurse practitioner 1); female, aged >45 years]
- And seeing this opportunity, for example, hairdressers, podiatrist, pharmacist, they get asked a lot about these things, about lesions. And from time to time you get referrals because they went to the hairdresser and they spotted a mole... it would be a good thing to implement in these areas, expand beyond the GPs. [Dermatologist 3; female, aged <45 years]
- I would really like to then streamline the process. So we have an ability within our practice that the patient doesn't need an appointment for asking about a mole of concern and they can send a photo. That photo would be reviewed by a clinician. It would be absolutely fantastic if that photo was also able to be reviewed by an AI process and advise whether there were concerning features on it or not. It would be useful if that photo could then be reviewed again six weeks later against a new photo to assess for changes. [GP5 (general practitioner 5); male, aged <45 years]
- Yeah, it (using the app) has especially low barrier to use it so it's way lower than going to a doctor or going to a dermatologist. It is really a first step into being more interested or more concerned about skin cancer. And I think it can help to raise awareness (of skin cancer) and inform people better. [AIR4 (AI researcher 4); male, aged >45 years]

AI with the primary care clinician

- I don't want to think that a doctor would see results on an app and still not think about it at all...But I think with time they might lose their skills. [Member of the public 6; female, aged <60 years]
- I'd love it in my hands. Anything that saves primary care queuing people up in dermatology...I think skin is difficult. And so my feeling is that human error will always exist and I guess if you've got something to support you in making the correct diagnosis in serious skin lesions, then it seems to me like a win-win and a sensible option. [GP2; male, aged >45 years]
- Most patients with a lesion will go straight to their GP. So I think definitely that's where it's going to be best placed and whether that's a specialist nurse within a GP setting or a GP, certainly within that primary care set up I think is most relevant. [NP1 (nurse practitioner 1); female, aged >45 years]
- I think selfishly, I'd be disappointed if I was told you don't need your dermatoscope anymore, because it's an area I'm really interested in and I'm really enjoying...because if it's automated and, therefore, you lose the skill set and you lose motivation around the topic. [NP3; male, aged <45 years]
- I would be worried about de-skilling our GPs by giving them a tool that tells them what to do. [Dermatologist 3; female, aged <45 years]
- The great thing would be if they were able to pick up those skin cancers that they haven't thought about, for example, amelanotic melanomas, or nodular melanomas, that they don't follow the typical a, b, c, d criteria. [Dermatologist 3; female, aged <45 years]
- If AI had a really, really good dataset of benign lesions, that would give a GP confidence to say 'no, that's benign, that doesn't need to be referred in' [Dermatologist 4; female, aged >45 years]
- They (dermatologists) are very experienced and they don't need a tool. But some of those tools might be needed for the people who refer patients, not to make any mistake at that stage for the early detection...So I can think of those two aspects, like speed and a better decision for the practitioner. I see really big opportunities in those kinds of things. [AIR2; male, aged <45 years]

AI after the primary care clinician

- So,...either a patient-generated image, but preferably taken in primary care on a high-quality camera and sent securely to dermatology for triage, then the AI helping with that triage process. [GP3; male, aged <45 years]
- In secondary care it would be really helpful, I think particularly for juniors starting out, to have a list of the differential, including the rarer things that could possibly be consistent with the appearances that the algorithm has identified. But giving you ranking of likelihood. [Dermatologist 2; female, aged >45 years]

XSL•FO
RenderX

Aim of the Technology

Education, Screening, or Diagnosis

Participants mainly discussed AI technology as a diagnostic tool; however, participants from all groups raised alternative uses. Patients discussed skin self-monitoring, including sequential monitoring of skin lesions over time, and patient education about the "red flags" of skin cancer. All groups discussed the potential to raise awareness and educate patients about skin cancer, including skin cancer prevention and how to perform skin self-monitoring.

GPs and NPs discussed the potential for AI technologies to educate PCPs and improve diagnostic skills. They suggested that a potent educational attribute would be if the AI technology could highlight visual features of skin cancer in images of skin lesions; AI researchers commented that these types of features have been developed. Dermatologists discussed the potential use of a patient-facing AI technology as a screening tool for high-risk populations.

Focus on Benign or Malignant Diagnoses

Patients and members of the public stated that the primary aim of the AI technology should be a very high accuracy to avoid missing skin cancers and giving false reassurance; to achieve this, the technology would need to have a high sensitivity. All HCP groups commented that aiming to diagnose benign skin lesions might be a safer approach with less risk of missing skin cancers. They proposed that focusing on diagnosing specific common benign skin lesions, such as seborrheic keratoses and dermatofibromas might reduce unnecessary referrals to secondary care.

Focus on Melanoma or All Skin Cancers

Patients were primarily concerned that any AI technology was accurate for melanoma. Some members of the public had experience of KCs in family or friends and felt AI technologies should also address KCs. GPs were primarily concerned about melanoma because it often affects younger patients and has higher mortality—they felt that AI technologies could be applied to other skin cancers in the longer term. Dermatologists and a NP commented that diagnosing all types of skin lesions, including all skin cancers, was important, especially for technologies that are designed to be used by patients or HCPs with less experience in diagnosing skin cancer. However, some dermatologists thought it could be difficult to train AI to diagnose KCs accurately, because patient history often has greater importance than for melanoma, and AI currently does not always incorporate this.

Threshold Between Malignant and Benign and Management of Borderline Lesions

All groups discussed the difficulty in setting a threshold between benign and malignant lesions for the AI technology, in essence how to translate the continuous risk score generated by the AI into a binary clinical decision of whether to refer a patient or biopsy a skin lesion. A 3-layer management strategy was suggested by several participants with further assessment of lesions that are close to the threshold, either through follow-up assessment in primary or secondary care or through sequential monitoring over time (similar to short-term sequential digital dermoscopy imaging models that already exist [24]). NPs and dermatologists reflected on how this issue demonstrates the complexity of clinical practice and that clear guidelines will be needed about what to do at each risk level (Textbox 2).

XSL•FO
RenderX

Textbox 2. Aim of the artificial intelligence (AI) technology.

Education, screening, or diagnosis

- I guess you always take a picture at a point in time and...say you noticed it change in a couple of months could you go back and say, it's changed from this to this, and almost keeping a progression record...I think that would be a really helpful feature. [Patient 4; female, aged <60 years]
- Give people recommendations of you should not go out unless you're wearing 50 SPF, we think you should not sunbathe between 12 and four, just because it's cloudy does not mean you're not going to burn...put a kid in a sun hat so they don't have sunstroke. [Member of the public 3; female, aged >60 years]
- I say to them (patients) there are mole apps that you can monitor, and that maybe it's not great in terms of getting a diagnosis, but they're more aware and they're keeping attention more to a particular lesion. And definitely it helps to diagnose cancer in the early state than what we saw years ago. [GP1 (general practitioner 1); female, aged <45 years]
- But the way I used AI was to try to train on some features in the image rather than giving me a diagnosis. For instance, to teach a deep learning algorithm to tell me whether that the borders are regular or irregular, 'cause that's something subjective sometimes between readers...So I used AI to reveal the features rather than giving the full diagnosis. [AIR2 (AI researcher 2); male, aged <45 years]
- So if you could develop one that was validated it might be useful for selected patients, maybe not the entire population but particularly high risk patients, maybe patients with lots of moles. [Dermatologist 2; female, aged >45 years]

Focus on benign or malignant diagnoses

- The first aim of the app needs to be to go and get it checked or not, or to go and get it biopsied or not. [Patient 4; female, aged <60 years]
- Just screening out the seborrheic keratosis, the pigmented dermatofibromas, the benign...if it could screen all of those out, which are the vast majority of the two-week-wait referrals that we see, that would be incredibly important for providing a better, more targeted service...plus potentially triaging things that are so unlikely to be a cancer that they don't need to be referred. So it kind of works both ways, early detection and reducing the massive numbers of 2-week-wait referrals that we get. [Dermatologist 2; female, aged >45 years]

Focus on melanoma or all skin cancers

- I think melanoma is the most important because I'd like to think that because your differential features for a squamous cell are quite obvious, that would be referred on anyway. I think it's melanoma and other pigmented lesion differentiation that's really tricky. So my thought would be more melanoma, and certainly that's what I've used it for. [NP1 (nurse practitioner 1); female, aged >45 years]
- People just think it's about diagnosing melanoma, where actually it's not. It's about recognising all skin lesions. You've got to diagnose benign lesions, and you've to diagnose malignant lesions, and it's not just melanomas, you've got BCCs, you've got SCCs, you've got AKs, and then you've got all the benign lesions. [Dermatologist 1; female, aged >45 years]

Threshold between malignant and benign—and management of borderline lesions

- I guess one approach you could take with marginal cases, you could say that we suggest you get re-tested in six months' time or something like that. So, you have a three-layer band. One you definitely need action, one you definitely don't, and then a middle level where you come back for a test after a bit. [Member of the public 3; female, aged >60 years]
- What I suggest would be good...if you're less than 70 per cent sure, it's an arbitrary...whatever number sure, then there is clinician involvement. So take a deeper dive into the history and that person then comes in and is looked at. [NP3; male, aged <45 years]
- So I think it would be really interesting, if when I looked at a lesion I gave the patient a percentage of how right I thought I was or even any diagnosis. I mean, I'd love that, that would be really cool to have that honesty. 'I think you've got a viral chest infection, I'm about 50-50, I'm going to hold off on the antibiotics, but here's some strict safety netting.' Yeah, I don't know whether I'd want to give the patient that information. [NP3 male, aged <45 years]
- So it would come back with a comment like 'this is 80% likely to be a melanoma, this is 20% likely to be a melanoma' and there would have to be some sort of understanding, some sort of cut off, what is the point at which a referral is merited...And I suppose that one of the dangers...where do you cast the net in terms of risk? [Dermatologist 4; female, aged >45 years]

Cross-Cutting Themes

Trust

Patients and members of the public often raised the issue of trust. The newness of the technology, the involvement of private companies and concerns about data privacy, and the diagnostic accuracy being <100% were all felt to be reasons for a lack of trust. However, there were also participants who thought patients would trust a consultation with a PCP more if it involved AI technology, even if it had made no difference to the assessment. GPs worried that patients could demand the AI technology be used in consultations and were concerned about the risk of false reassurance. NPs felt that patients fundamentally trust people more than machines. Dermatologists stated that there is not enough evidence that existing AI technologies are safe and accurate enough to be used in clinical practice and that it is difficult for patients to determine which patient-facing AI technologies they can trust.

AI researchers discussed that the "black box" nature of AI technologies should not be a barrier to trust, as we similarly do not understand the mechanism of action of many medications.

XSL•FO
RenderX

They felt that if clinicians recommended or adopted an AI technology, then patients would be more likely to trust it.

Ease of Use and Acceptability

Ease of use was a major concern for patients and members of the public; participants discussed that a technology that is easy to use enables patients to take high-quality images that are better suited for AI analysis and reduces the risk that patients will be unable to use the technology or use it incorrectly. Several members of the public raised the importance of enabling patients to choose how to consult, rather than mandating a consultation type that is inappropriate for them. GPs and NPs' primary concern was that it should be easy to integrate the AI technology with their current computer and Wi-Fi systems. Dermatologists and patients were concerned about whether the technology would facilitate taking high-quality images for the AI to analyze. AI researchers commented on how practical limitations of a technology can prevent it being used, even if it is potentially very beneficial; therefore, "real-world factors," such as cost, ease of use, and how well it fits into clinical workflows, need to be considered.

Accuracy and Generalizability

Accuracy was raised frequently by all groups and is linked to many of the subthemes. The primary concerns were the false negative rate and the risk of false reassurance and whether the diagnostic accuracy is generalizable to other clinical settings, using different camera technologies, and with other populations and demographics. AI researchers commented that currently AI technologies are often developed on small datasets, which are not representative of the general population and may contain errors and biases and hence, do not generalize well to be accurate in all sections of the population. Members of the public and HCPs were concerned this might mean AI technologies would be less accurate in melanin-rich skin or for rarer skin cancers.

AI researchers discussed how this situation might be improved with close collaboration between clinical and AI researchers and a focus on data quality in a "data-centric" approach. An AI researcher from a commercial background commented on the challenges in collecting a representative dataset for AI development and testing. There are fewer publicly available images of skin lesions in melanin-rich skin, and their app had significantly lower uptake among patients with melanin-rich skin.

Evaluation and Regulation

Patients felt that AI technologies should be evaluated by a mix of professionals before they can be adopted, including independent confirmation of diagnostic accuracy. Patients were concerned that AI technology would be adopted based on novelty and hype or because it is cheaper than clinicians' time when it may not be in the best interests of patients and their clinical care. HCPs felt that significant data from clinical trials would be needed to evaluate AI technologies but recognized that this might take time. AI researchers were concerned that we currently lack good measures to evaluate AI algorithms for use in clinical settings. They stated that the current practice of using simple diagnostic accuracy measures (eg, sensitivity and specificity) is not comprehensive enough to demonstrate the accuracy, benefits, and risks of AI technologies. AI researchers added that, while clinical studies, due diligence, and understanding biases and flaws in an AI system are all important aspects of evaluation, there are other factors, including business sustainability, that need to be considered before a decision on adoption can be made. Many groups commented on the need for health-economic evaluation as part of any evaluation program.

Patients and members of the public often disclosed that they did not understand regulatory processes. Some felt it was important that AI technologies had a Conformité Européene marking and were evaluated by a national body. HCPs were concerned about regulatory processes for AI technologies not being as robust as for medicines and treatments. GPs raised concerns about where the medicolegal responsibility for errors related to the use of AI technologies would lie. Dermatologists wanted the use case for AI technologies to be made clear and for the regulator to assess the technology based on this but acknowledged that regulating AI technologies is challenging. An AI researcher commented that regulatory processes for AI technologies are becoming more complex.

Implementation in the UK National Health Service

Members of the public and GPs discussed variation in National Health Service infrastructure in different regions of the United Kingdom, including wireless connectivity, and how this could make implementation difficult.

Most participant groups commented on the capacity of the health care system to implement a new technology where resources are strained. Current pressures may mean that PCPs have insufficient time to understand and implement a new technology. Some HCP participants highlighted that an AI technology with a low specificity might lead to a significant increase in referrals and worsen workload pressures. Conversely, some NPs and dermatologists commented that use of AI technology could help to reduce the number of referrals to secondary care. AI researchers hoped AI technologies could be used alongside PCPs and dermatologists to ease workload pressures.

All groups commented on the importance of professional bodies in the implementation of new technologies. Patients and HCPs felt that implementation would be greatly helped if professional bodies, such as the National Institute for Health and Care Excellence, National Health Service England, Integrated Care Boards, the BAD, or the Medicines and Health products Regulatory Agency, had recommended or evaluated it. GPs and NPs believed any decision to adopt and fund AI technology would need to come from a higher body rather than individual GP practices. AI researchers commented on the importance of the views of professional bodies for the adoption of AI technologies but also on the associated commercial challenges as these bodies vary internationally.

NPs and dermatologists highlighted the need for adequate training in how to use an AI technology as part of the implementation process and clear guidelines on how the AI technology should be used and interpreted.

XSL•FO
RenderX

Long-Term Use

The unique potential for AI technologies to continue learning after implementation and for diagnostic performance to improve over time was raised by different participant groups. GPs and patients assumed that this feature would be standard practice and that regular updates would sequentially improve the AI technologies performance as it learned from new data. Few participants commented on how this process could be regulated in practice.

A major concern of all groups was how to check that the AI technology was performing accurately. AI researchers were particularly worried about the potential for the performance of the AI technology to deteriorate over time, referred to as "drift in performance." They commented that this could occur because of a change in the way the AI technology is used, a change in the population (for example, using the technology in a population with lower skin cancer prevalence or different demographics compared to the development and testing datasets), a change in the hardware, or a change in the accuracy of the technology over time. All groups suggested "sanity checks" that could be used regularly to detect if an AI technology was not performing accurately. These "sanity checks" included expert systems monitoring image metrics over time, comparing the prediction of the new AI technology to the previous AI gold standard; a clinician reviewing all cases that the AI diagnoses as "likely skin cancer" or where AI has low confidence in the diagnosis; or limiting the use of AI technologies with a "human-in-the-loop" approach. AI researchers added that there needs to be an incentive for the makers of the AI technology to maintain and provide ongoing support long-term (Textbox 3).

XSL•FO
RenderX

Textbox 3. Cross-cutting themes.

Trust

- The fact that it hasn't been the norm within the health care setting, I think will make quite a lot of people feel uncomfortable. So the fact that it's just so up and coming and new will naturally spark a bit of anxiety in terms of people and they think about if it's safe, if it's got the same principles and standards in place in terms of care, safety, confidentiality et cetera. [Patient 1; male, aged <60 years]
- I think there is also a section of the population who are very suspicious of data not being used correctly. So, you would need to have some sort of reassurance about correct data use as well. [Member of the public 4; female, aged >60 years]
- I think people fundamentally put trust in people and we're still wary about putting trust in machines, or computers, because we've been fed sci fi for years that makes us worry, and also I do think that we still think we know best, even though the algorithms that will be in the computer will be absolute gold standard, and they won't be tired, hung over, jaded, they'll be right every time. [NP3 (nurse practitioner 3); male, aged <45 years]
- I think the concern at the moment is that there isn't enough evidence that any of these machines, or machine learning is up to speed to be able to make diagnoses without missing any skin cancer, and that includes rare skin cancers, skin cancers with rare presentations, or in different ethnicities. [Dermatologist 3; female, aged <45 years]
- Yeah. I'm just really unsure in how far, to be honest, machine learning can or will take over a medical setting, or should. The more I see and read, the more I'm getting also suspicious. [AIR3 (AI researcher 3); female, aged <45 years]
- I would question the premise that being a black box is actually a terrible thing or even a novel thing, because clinicians are black boxes. As far as I understand for most medicines we have no idea why they work, and we still use them because statistically it works. And as long as we regularly check that our models work statistically then who cares whether that's a chemical or a computational black box. Obviously, it's nicer if you can also present the clinician with some data that the clinician then can use to make further judgment calls. [AIR1; male, aged <45 years]
- As a field we're only beginning to scratch the surface of what that means, to trust technology. If say my physician tells me, this is a good way to understand more about your skin conditions, there's some element where I trust he or she as a professional and the information relayed is therefore accurate, and therefore that trust extends to the thing they had suggested. [AIR5; male, aged <45 years]

Ease of use and acceptability

- So, being accurate, being honest, easy to use, easy to understand. And easy for the GPs to use as well, the other health care professionals who've got to get the information through that as well, easy for them. Because they're going to have to look at whatever it's come up with and try and make some sense of that before they actually sit down in front of us. [Member of the public 1; female, aged >60 years]
- For me patient choice is so important—so both have a machine in the GP surgery for those who would prefer to do that and have an app for the people who are quite comfortable using those. [Member of the public 1; female, aged >60 years]
- I suppose if it was a lengthy process. So if there was dodgy Wi-Fi or it's hard to get your image or it's taking time to upload...I suppose it's just the practicalities and the ease of the software and hardware that you're using, those will be barriers, if it didn't work. [NP1; female, aged >45 years]
- How easy is it to take the photograph? I think that's really important. Because I get loads of referrals with photographs, but the photographs are completely useless, they're blurred and a complete waste of time. Somebody's ticked the box and said, sent a photograph, but they might as well not be there. [Dermatologist 1; female, aged >45 years]
- If you have a technology that's extremely beneficial for a certain disease but it's really expensive, it takes a really long time, and it's hard to use then no one will ever use it. So there's real world factors there. [AIR5; male, aged <45 years]

Accuracy and generalizability

- I think the key issue is generalisability, because algorithms are developed on a very small set which have very specific properties and there is biases. And then of course, they do not work on a wider range of other images from other scanners from other countries...this is a huge issue, the generalisability. You have all these algorithms that achieve higher numbers in one setting but it doesn't mean that they will work well on new data they have not seen. [AIR3; female, aged <45 years]
- They need to make sure that there is a proper diversity of people in there. Because AI is only ever going to be as good as what you use to train it. So I think they need to be particularly careful about diversity of skin color and capturing the wide variety that's needed. [Member of the public 13; female, aged >60 years]
- For us it's a kind of a chicken and egg problem. So, there's not a lot of data for darker skin available, so training on that...and especially proving the accuracy on dark skin it's almost impossible...We don't have the users, we don't get the data, we don't get the proof of how good we are on darker skin—so that definitely is a loop that we need to break at some point. [AIR4; male, aged >45 years]

Evaluation and regulation

- I have come across many issues because algorithms have been evaluated with measures that are actually not measuring what you would want or need in a clinical setting...So I actually think the most important thing right now would be to set up proper evaluation schemes and to think about how deep learning models should be or can be properly evaluated...The real question is, how do we evaluate them to make sure they will work in a medical clinical setting. [AIR3; female, aged <45 years]
-

XSL•FO
RenderX

So this is definitely a concern, not to send too many users into healthcare. The first concern's accuracy, we don't want to miss too many skin cancers, for sure, but the second concern is definitely also the health economic case. So, we can of course send a huge amount of people into healthcare. We find more skin cancer, we reach our goals of finding more skin cancer, that's fine. But we don't solve a real problem, we make it worse for the healthcare system as well. [AIR4; male, aged >45 years]

- I worry a little bit that if it's something that is a manageable cost it might be overused. It's a way to shift a number of patients who you might otherwise see...They're always on an efficiency drive, they're always under pressure to save money...I don't know whether, if the technology was affordable for GP surgeries, they would just think, oh great...we're short of doctors we can just process people through the hands-off routine...you stop thinking about it in clinical terms and you start thinking about it in financial terms. [Patient 2; female, aged <60 years]
- I think that's really important that it has CE marking; because I see a lot of apps and crap in the digital space that a lot of people are buying and spending money on and they're not evidence-based medicine. [Member of the public 2; female, aged <60 years]
- I know it (regulation) is fairly patchwork. Obviously, when it comes to medication and prescribing, there's fairly robust regulatory systems... When it comes to certain equipment, some patient devices it's a bit piecemeal. But I would be fairly reassured if the MHRA covered this equipment. [GP3; male, aged <45 years]
- I've been indoctrinated by the British Association of Dermatologists. And what they explained. They gave a position statement, I think it was a year or two ago, and we were've told these are medical devices and therefore they need to go through these medical regulatory agencies. I think before Brexit it obviously would have been Europe as well and now I think it's MHRA should be responsible for this. Which makes sense because obviously it's a very important thing for patients and for doctors, medicolegally as well. So it needs to work for its purpose, for what they say it's going to be doing. [Dermatologist 3; female, aged <45 years]
- And also where does it stand legally? If you come to me and you show me a mole and I do my AI thing and I say to you computer says no, and off you go and you keep doing the things that you do, and then two years later you come back to me with a large black blobule, sentinal lymph node biopsy positive...is that my fault? Is that the AI's fault? And if it's the AI's fault, who are you suing? [GP6; female, aged >45 years]

Implementation in the UK National Health Service (NHS)

- I think when you're an external looking in at the NHS it's just a monster beast to try and understand different parts of it...Overall I think integration of digitals is great, but it's not uniform, and also there are massive connectivity issues still in some areas...Some parts of the country are doing amazing things, and other parts are so backward. [Member of the public 2; female, aged <60 years]
- I'm just very much aware that the basics of general practice is under so much pressure that adding a new technology and complication is not everybody's first priority...I appreciate a lot of these new technologies can save time and resources in the long term, but certainly, if I'm thinking now of the start of a difficult winter, it's going to be a tough sell right now. [GP3; male, aged <45 years]
- One of the things I came across is that there was a shortage of dermatologists in general. This means that the practitioner is expected to see a lot of patients in the same day...the practitioner is a human, maybe some stress, or he had a bad day, he might not spot some feature in that image. So those (AI) tools can be something that fixes this gap if in that day he had a bad day and didn't notice some features. [AIR2; male, aged <45 years]
- So it's going to cost something to have this kind of level of equipment, but there's not an infinite amount of money in GP land, if they're spending on that then it's coming out of somewhere else, which might mean we won't have the money or equipment for something that may benefit patients. [NP2; female, aged <45 years]
- It's got to come with the support and the training along with it, it's not just about getting a new piece of kit...I think the important thing is that that cost incorporates training and a clear understanding of the device and what it's used for, and why, and how to use it. It's silly to give a piece of kit and then not have the support to know how to use it best. [NP1; female, aged >45 years]

Long-term use

- In some ways the accuracy would build as the technology was used. So the longer it's been in play the more you can depend on it probably...I assume that you don't just test the heck out of it and say it's fine now and then stop refining it. [Patient 2; female, aged <60 years]
- Let's say the model was trained in a way it works really well when you are taking dermatoscope photos, and it gives you a really good sense of the malignancy potential there and the studies support this. Then a patient sends you a photo...and this photo was taken using a smart phone with different kinds of lighting conditions, in a setting where it was actually never designed for use but that fact is not obvious to anyone who hasn't been thinking about this for a really long time. So with the best of intentions, I think you could still have a situation where the performance starts drifting away from how it was designed for use. [AIR5; male, aged <45 years]
- Maybe scanners will change...It is not clear that if an algorithm works well on the scanner of the last generation, even from the same company, (if) you get a new one that it would work on that as well...They (scanners) will not stay the same, but then we really should think about how do we integrate new modalities into the machine learning models, because it's not sustainable to develop something on a fixed dataset. [AIR3; female, aged <45 years]
- It should be tested before it gets to the GP surgery, and then it should be checked...at regular intervals, to make sure it's still working correctly. Because if you start falsely diagnosing people, that could be a complete waste of time. [Patient 3; female, aged >60 years]
- If we look at a top-level view across all AI it's really hard to summarise in a single sentence whether this will help or hurt. But if developed well, if used well I still do believe there's lots of great potential here. [AIR5; male, aged <45 years]

Discussion

Principal Findings

In this study, many of the discussions centered on 2 simple questions: who is going to use the AI technology, and what is it going to do? Most participants commented on positioning AI technology with patients or allied HCPs (before the PCP) or with the PCP as a decision support tool. Few participants proposed positioning the technology to triage referrals to secondary care or as a decision aid for dermatologists. Participants highlighted several overarching topics as important to them, including trust, acceptability, generalizability, evaluation, regulation, implementation, and long-term use.

The risk of false negatives resulting from an AI technology with poor sensitivity and missing skin cancers was a major concern for all participant groups. Missed skin cancers, especially melanoma, are likely to lead to late diagnosis and worse outcomes for patients [3,6]. One potential benefit of AI technology mentioned by all groups was the reduction in the workload of health care services, primarily through effective triage of patients that need to see PCPs or specialist clinicians. This could be the case if the AI technology has a good specificity with few false positive results. False positives are inevitable, but an AI technology with a low specificity could significantly increase the workload of health care services. This was a concern raised by HCPs, but few other participant groups commented on this risk. It has been suggested that overdiagnosis of melanoma is rising due to increased rates of skin examination, decreased thresholds for biopsying skin lesions, and for labeling morphological changes on histopathological examination as malignant [25]. Implementation of an AI technology with low specificity could increase both rates of skin examination and biopsy rates, both potentially contributing to overdiagnosis.

AI researchers were the most pragmatic, expressing concerns about the generalizability of many AI technologies and the relevance of current testing approaches in preparation for clinical implementation. They were concerned about the robustness of the datasets underlying AI technologies, including the representativeness of skin cancer prevalence and patient demographics in the datasets. They felt that, at the current time, these technologies need to be implemented with a human in the loop. Many HCPs were aware of the lack of evidence and potential risk to patients that has been publicly commented on by the BAD [9]. Patients and the public were aware of potential improvements in patient access, diagnostic accuracy, and reduced workload AI technologies could offer but were concerned about the risk of missing cancers and losing the opportunity for human interaction and to ask questions.

Complexity underpins most of the generated themes. Developing, evaluating, implementing, regulating, and maintaining AI technology in health care settings are all multifaceted, complex processes containing many opportunities for error, as laid out in the CanTest framework [14]. Therefore, it is unsurprising that so many diagnostic technologies fail at the implementation stage [26]. Several studies have discussed the complexity of implementing digital, AI, and machine learning (ML) interventions into health care settings; they recommended a whole-of-system approach with particular focus on how users interact with devices and user training [12,27].

Comparison With Existing Literature

The NASSS framework [15] was chosen to guide this study because it includes a wide range of domains that help capture the complexity of implementing health care interventions [28]. Most of the cross-cutting themes link closely to NASSS domains, specifically “knowledge to use the technology,” “demand-side value (to patient),” “adopters,” and “organizations.” There were several themes raised that did not fit into the NASSS framework (such as the potential for continued learning with AI technologies), as well as themes (such as trust and acceptability) that seemed to lose some of their breadth and nuance by being contained within the NASSS domains. We chose to code both inductively and deductively, which allowed us to better capture participants’ views and build knowledge about applying the NASSS framework to novel AI technologies.

A recent Swedish study used an AI-based melanoma decision support aid for clinicians as an example technology to generate discussions with participants about the implementation of decision aids. In keeping with their findings, many participants in our study discussed the issues of accuracy, safety, data security, liability, ease of use, and integration [29]. Our findings support those of a recent systematic review on the use of ML-based risk prediction models in health care settings [13] in which participants demonstrated largely positive views of AI technologies but identified many barriers. Echoing findings from several recent studies [30-33] we identified concerns about diagnostic accuracy, risk of patient harm, ease and speed of use, HCP overreliance on the technology, legal liability, data protections, data quality, impersonality, and positioning in the diagnostic pathway. In particular, we identified aspects of the consultation participants felt that AI technologies could not replicate, that is, the need for human interaction and clinical experience and judgment. Participants commented on the risk that AI technologies will not be effective in minority populations who are inadequately represented in training and testing datasets and may exclude populations with lower technological literacy, such as older people.

The wide variety in positioning and approach of existing AI technologies [7,8] indicates that the optimal position and approach have yet to be determined. Several participant groups highlighted that they wanted more evidence of the accuracy of technologies in real-life clinical use. This fits with recent reviews of AI technologies aimed at detecting skin cancer [7,8,33], although increasing evidence from clinical trials is emerging [10]. PCPs were keen to have an AI technology to support their diagnostic decision-making, in keeping with findings from a previous study [34]. AI researchers highlighted a growing body of research in AI technology development for health care settings, including the “human-in-the-loop” approach and the “data-centric AI movement” [12,35,36].

Regulation was a topic raised by several participant groups. The fast-moving pace of AI development makes regulation of AI technologies challenging: underregulation risks patient safety while overly zealous regulatory approaches could hinder AI

XSL•FO
RenderX

development pipelines and implementation [37,38]. AI has the unique potential to continue developing over time as it is exposed to more data. Regulatory bodies around the world are attempting to keep up with the rapid developments in AI technologies. In the United States, the Food and Drug Administration has proposed the 510k pathway, which facilitates the approval of software as a medical device if it is substantially based on a previously approved technology [39], and is developing an approach to an AI-ML workflow that would enable continued learning after implementation [40]. There are emerging national and international regulatory policies, including the European AI Act, the United States AI Bill of Rights, and the United Kingdom policy on AI [41-43].

Strengths and Limitations

To the authors' knowledge, this is the first study to report the views of a broad range of stakeholders about the use of AI technologies to facilitate the earlier diagnosis of skin cancer in primary care settings. We had good variation among interviewees in terms of background, age, sex, and geographical location. The study benefited from PPI at every stage, and a strong conceptual framework was used to develop the framing of the interview schedule and data coding.

Aiming to recruit a wide range of stakeholders was a conscious choice, as we felt this was important to achieve a breadth of opinions; the trade-off was that time and resources meant we were only able to include limited numbers in each participant group. The aim was to achieve breadth of opinion without necessarily achieving saturation. AI and clinical implementation are complex subjects, which meant that we were more likely to recruit participants with higher educational attainment and who are engaged with health care research or AI; both these aspects may have affected the balance of views we obtained. We only recruited 1 participant who reported that they disapproved of using AI technologies to help diagnose skin cancer. Skin cancer is more common in melanin-poor skin; however, a key limitation of current AI technologies is their lack of training and testing in populations with melanin-rich skin. We recruited limited numbers of participants with melanin-rich skin in this study, so participant views on this issue may be incomplete. In contrast to other participants, AI researchers were largely based outside the United Kingdom, reflecting the location of the majority of commercial companies developing these technologies. However, it meant their knowledge of United Kingdom clinical practice and diagnostic pathways was sometimes limited.

Implications for Clinical Practice, Research, Adoption, and Policy

Health care services are working under extreme pressures in primary and secondary care [44]. AI technologies aimed at diagnosis or triage of skin lesions could facilitate early diagnosis of skin cancer to improve outcomes for patients and potentially ease some of these pressures. However, before this can happen, research is required to prove their efficacy with real-world clinical populations and to address the questions that remain about the most effective positioning of the technologies in the diagnostic pathway and the optimal approach for their use. Diagnostic technologies that are used in populations that are different from those they were developed and tested in are prone to spectrum bias [45]. Better measures of clinical performance are required to inform these studies, which consider not only diagnostic accuracy but also provide a measure of generalizability and dataset quality [46].

Some of our findings can be used to further develop the NASSS framework, for example, to consider in more depth how users interact with an AI technology and the potential for continued development after implementation. When developing an AI technology aimed at the diagnosis or triage of skin cancer, developers need to consider carefully and be specific about the intended use, including where it will fit into the diagnostic pathway for skin cancer and the approach that it is going to take. Developers must also consider the quality and representativeness of the data they use to develop the AI.

The decision to adopt an AI technology is complex and multifaceted. Clear regulatory processes that consider unique features of AI technologies need to be established, including continued learning, to ensure AI technologies are safe and effective when used in clinical settings. Adopters should also consider what safety nets are in place to identify poor performance and reduce false negative results, such as expert systems and regular "sense checks."

Conclusions

AI technologies are being designed with a wide variety of approaches, and the optimal approach and position in the skin cancer diagnostic pathway for these technologies have not yet been determined. AI technologies have the potential to help detect and diagnose skin cancer, to improve patient experience and outcomes, and to reduce the workload of overstretched health care systems. However, we have identified important concerns surrounding trust, acceptability, usability, generalizability, evaluation, regulation, implementation, and long-term use. These technologies need to be developed carefully and thoughtfully to achieve their potential, guided by evidence-based approaches and appropriate implementation, taking into consideration long-term sustainability and safety.

Acknowledgments

The authors would like to thank our patient and public involvement and engagement group—Margaret Johnson, Jenny Hunt, Sylvia Bailey, and John Lancaster—who contributed to study development, recruitment strategies, study materials, and the interview schedule. The authors would also like to thank Professor Steve Morris, who contributed to the development of the study.

Abstract

Background: Decision aids improve patient and clinician decision-making but are underused and often restricted to clinical settings.

Objective: Given limited studies analyzing the feasibility of disseminating decision aids through social media, this study aimed to evaluate the acceptability, trust, and engagement of women with social media as a tool to deliver online decision aids for cancer treatment.

Methods: To prepare for potential dissemination of a breast cancer decision aid via social media, a cross-sectional survey in February 2023 was conducted via Prime Panels, an online market research platform, of women aged 35-75 years in the United States. Demographics, health, cancer information-seeking behaviors, social media use, trust in social media for health information, as well as the likelihood of viewing cancer-related health information and clicking on decision aids through social media, were assessed. Statistical analyses included descriptive statistics, correlations, and multivariable ordinal regression.

Results: Of 607 respondents, 397 (65.4%) had searched for cancer information, with 185 (46.6%) using the internet as their primary source. Facebook (Meta) was the most popular platform (511/607, 84.2%). Trust in social media for health information was higher among Black (14/72, 19.4%) and Asian respondents (7/27, 25.9%) than among White respondents (49/480, 10.2%; P=.003). Younger respondents aged 35-39 years (17/82, 20.7%) showed higher trust than those aged 70-79 years (12/70, 17.1%; P<.001). Trust in social media for health information was linked to a higher likelihood of viewing cancer information and accessing a decision aid online (P<.001). Participants who rated social media as “Trustworthy” (n=73) were more likely to view cancer information (61/73, 83.6%) and click on decision aids (61/73, 83.6%) than those who found it “Untrustworthy” (n=277; view: 133/277, 48.0%; click: 125/277, 45.1%). Engagement with social media positively correlated with viewing online cancer information (Spearman ρ=0.20, P<.001) and willingness to use decision aids (ρ=0.21, P<.001). Multivariable ordinal regression analyses confirmed that perception of social media’s trustworthiness is a significant predictor of engagement with decision aids (untrustworthy vs trustworthy β=–1.826, P<.001; neutral vs trustworthy β=–0.926, P=.007) and of viewing cancer information (untrustworthy vs trustworthy β=–1.680, P<.001, neutral vs trustworthy β=–0.581, P=.098), while age and employment status were not significant predictors.

XSL•FO
RenderX

Conclusions: This exploratory study suggests that social media platforms may increase access to health information and decision aids. No significant differences were observed between demographic variables and the use or trust in social media for health information. However, trust in social media emerged as a mediating factor between demographics and engagement with cancer information online. Before disseminating decision aids on social media, groups should identify existing trust and engagement patterns with different platforms within their target demographic.

Introduction

An estimated 2,001,140 new cancer cases are expected in 2024 [1]. Shared decision-making (SDM) describes a process between the clinician and patient to facilitate preference-sensitive choices [2]. Decision aids, which can support the SDM process, are evidence-based tools designed to provide patients with information, clarify their preferences, and prepare them to make a choice [3,4]. In this study, we explore the potential of social media as an avenue for engagement with decision-making tools.

SDM has been shown to be important for cancer decision-making, with multiple randomized controlled trials demonstrating that decision aids improve patient knowledge and the quality of decisions [3-11]. Unfortunately, decision aid use has been limited, and their dissemination has been largely confined to clinical settings. A 2010 study revealed that only 24% of clinicians working with patients with cancer used decision aids [12-18]. The focus on clinical settings as the singular forum for decision aid deployment is predicated on clinician buy-in and may restrict the use of decision aids to a select cohort of the population [12-19].

Social media offers a promising means for disseminating decision aids without relying on health care access. It may also provide a more extended and personalized modality for disseminating information [20]. With 81% of Americans using social media, a number that continues to grow, social media platforms present an underused opportunity to disseminate highly accessible decision-making tools [21]. Social media can help to overcome challenges associated with traditional clinical encounters (ie, time, workflow, etc) and can enhance the patient-clinician relationship by promoting empowerment, reducing communication barriers, and increasing knowledge about conditions and treatment options [14,22].

Numerous studies have highlighted the positive impact of web-based decision aids for women, particularly in the context of breast cancer, the leading cause of cancer among females [23]. Despite the potential benefits of social media for decision aid dissemination, it remains uncertain whether females will use cancer-related decision aids available through social media or other online channels. To address this gap, we examined factors influencing engagement with decision aids on social media and explored health information-seeking behaviors across various platforms. This study aimed to evaluate the feasibility, acceptability, trust, and engagement with social media as a tool to deliver online decision aids to women for cancer treatment. By focusing specifically on women, we aimed to address the unique health and decision-making needs of this population and provide insight for future research on breast cancer-related decision aids.

Methods

Survey Design

A cross-sectional survey was designed to assess the use and preferences for social media–advertised decision-making tools for cancer care. The survey involved several key areas of inquiry (Multimedia Appendix 1). Briefly, these areas included “Health-Related Information Behaviors” (5 questions) to assess participants’ behaviors in seeking and using health information; “Sources of Health Information” (3 questions), exploring individuals’ preferences and trust levels in various health information sources; “Social Media Use” (18 questions), examining patterns and motivations behind social media interactions, particularly concerning health information; and “Demographic Data” (10 questions), covering a wide range of personal and socioeconomic factors. Within the “Social Media Use” section, two items related to the main outcomes of the study were embedded, created by the study team, which asked participants to imagine themselves or a loved one deciding about cancer treatment and then assessing their likelihood of viewing cancer treatment information or clicking on a decision aid posted on social media. Other survey questions were adapted from items from the Health Information National Trends Survey [24]. Items assessing reasons to use social media included categories identified in the literature through the uses and gratifications theory and the social media engagement model [25-27].

The response formats varied according to the specific inquiry, including multiple-choice options, checkboxes for applicable answers, and Likert scales for assessing attitudes and opinions. Although all 39 questions could be answered, branching logic was used to tailor the survey based on participants’ responses (eg, only those reporting the use of specific social media platforms were asked follow-up questions about their motivations for use). The survey was designed to be completed within 5 to 10 minutes and included 2 attention-check questions. One single question, with the associated branching logic, was shown on the screen at a time. Participants were unable to skip questions (except for the questions asking the frequency of use and reason for use of social media platforms) and were notified, “Please answer this question” if attempted to skip. Participants were able to go back and change their answers if desired. The order of survey items, and answers, was fixed and not

XSL•FO
RenderX

randomized, as the survey design prioritized logical flow and ease of navigation for participants. This study is reported in a manner that is consistent with the specified Checklist for Reporting Results of Internet E-Surveys (CHERRIES) guidelines (Multimedia Appendix 2) [28].

Population Targeting and Survey Distribution

The survey was designed and hosted on the Qualtrics platform (Qualtrics, Provo) and distributed in February 2023 via Prime Panels, a component of Cloud Research [29]. Prime Panels uses a novel data collection method by aggregation of diverse opt-in market research panels into a comprehensive sampling platform, facilitating the recruitment of participants from existing commercial panel pools. This method supports demographic quotas and specific eligibility criteria, enhancing data representativeness, especially among hard-to-reach populations. Eligible participants were invited to participate through targeted email and dashboard invitations sent by the market research panels within the Prime Panels network, based on the demographic criteria specified for the study [30]. Participants were required to complete the survey in a single sitting, and no reminders were sent to those who did not finish it during that session. Due to the wide distribution on several platforms, response rates and the total number of invitations sent were not calculated by Prime Panels.

We aimed to gather a representative sample of United States females aged 35-75 years for this study, as this age range represents the peak period for breast cancer diagnosis. The study exclusively enrolled female participants to direct focus toward future research efforts related to breast cancer in women. Using 2022 US Census data, the population of females aged 35-75 years were inputted into the Qualtrics sample size calculator with a 99% CI and a 5% margin of error to determine the required sample size [31]. Based on these calculations, the survey targeted approximately 660 female participants, with an additional 15% included to account for potential exclusions due to poor response quality, bringing the total recruitment goal to 750 participants. Study specific eligibility criteria incorporated into the Prime Panels query included female participants aged 35 years or older with US IP addresses. Demographic quotas based on United States Census Bureau parameters were set as: 16% Hispanic, Latino, or Spanish origin; 78% White; 13% Black; 5% Asian; 2% American Indian or Alaskan Native; and 2% other races. Age quotas aimed for an equal distribution between the 35-55 years and 56-75 years age ranges to reflect the demographics of breast cancer survivors. To ensure survey security, Qualtrics options for “Bot Detection,” “RelevantID,” and “Prevent Indexing” were enabled.

Statistical Analyses

Data analysis was performed using Microsoft Excel and SPSS Statistics (version 28.0; IBM Corp). Graphs were constructed via R Statistical Software (version 4.1.2; R Core Team 2021). Descriptive statistics characterized the demographic characteristics, health-seeking behaviors, and social media engagement of the study population. Social media engagement was determined based on respondents’ selections of platforms they actively used, followed by survey questions that assessed the frequency of engagement with each platform. These questions categorized usage frequency into 4 levels: multiple times a day, once a day, at least 3 times a week, or less than 3 times a week. Numerical values ranging from 1 to 4 were assigned to these categories, with 1 indicating the least frequent usage and 4 the most frequent. An “Overall Social Media Engagement Score” was computed by aggregating these values across all platforms used by a respondent. Participants were classified into 4 groups based on their “Overall Social Media Engagement Score” to approximate quartiles for analysis. These groups were defined as follows: “Low Engagement” (scores of >0 and ≤3), “Moderate Engagement” (scores of >3 and ≤4), “Moderate-High Engagement” (scores of >4 and ≤8), and “High Engagement” (scores of >8 and ≤23).

To ensure data integrity, surveys were excluded based on the following criteria: completion times shorter than 3 minutes or longer than 20 minutes, flags from Qualtrics indicating duplicate responses, an Amazon Mechanical Turk fraud score above 50, or incorrect responses to two embedded control multiple-choice questions.

Analysis of Trustworthiness of Social Media

To evaluate associations between demographic factors and the perceived trustworthiness of social media as a reliable source of health information, chi-square, and Fisher’s exact tests were performed. To ensure that there were enough observations in each category for the statistical analysis to be reliable, the response categories “Trustworthy” and “Very Trustworthy” were merged into a single “Trustworthy” category, while “Untrustworthy” and “Very Untrustworthy” were combined into “Untrustworthy.”

Analysis of Social Media Engagement

In terms of the two questions assessing the likelihood of engaging with cancer treatment-related information seen on social media, responses were condensed from a 7-tier scale to 3 categories: “Unlikely” (1-3), “Neutral” (4), and “Likely” (5-7) to ensure a more balanced distribution of responses, as some of the original categories had very few observations. Spearman rank correlation coefficients were calculated to quantify the strength and direction of the association between the “Overall Social Media Engagement Score” and the tiered scores representing the likelihood of interacting with cancer-related information. For visual interpretation, the mean likelihood of respondents interacting with cancer-related information was calculated for each unique “Overall Social Media Engagement Score.” For all analyses, statistical significance was set at a P value of less than .05, using 2-tailed testing.

Analysis of Likelihood to View Cancer-Related Health Information or Click on Decision Aid

Nonparametric tests, specifically the Kruskal-Wallis and Mann-Whitney U tests, were used to evaluate the relationships between demographic characteristics, trust in social media, and the propensity to use decision aids or view cancer-related health information on these platforms. Variables that were found to be significantly related to the use of decision aids or viewing health information at $P \leq .10$ were then checked for multicollinearity via variance inflation factor (VIF) values <5 before inclusion in an ordinal regression model.

Ethical Considerations

This study was reviewed and received approval from the institutional review board at Ohio State University as exempt (protocol 2022E0836). Informed consent was obtained from all participants involved in the study. Participant data were collected anonymously, with no identifying information retained in the dataset. The original informed consent included provisions for the use of deidentified data for research purposes, as reviewed and approved by the institutional review board. Data were stored in a secure, password-protected database accessible only to study investigators. All participants were compensated by Prime Panels in the amount agreed to by the platform through which they entered the survey, which is unknown to study personnel.

Results

A total of 757 responses were initially recorded at the completion of distribution. Of these, 607 met inclusion criteria with a Qualtrics "Response Quality" of 99.0%. Participants completed the survey in a mean SD time of 5.5 (SD 2.6) minutes.

Respondent Demographics

All participants were female, aged 35-75 years (Table 1). Of the 607 respondents, most were non-Hispanic (556/607, 91.6%) and White (480/607, 79.1%). The most common education level was some college or an associate degree (201/607, 33.1%). The most common income range was US $20,000 to US $35,000 (119/607, 18.9%), with over half (327/607, 53.9%) earning less than US $50,000 annually.

Health-Seeking Behavior

In total, 551 out of 607 participants (90.8%) had sought health or medical information from various sources at some point (Table 2). Out of 551 respondents, the internet was the most common first source of health information (n=441/551, 80.0%), while 75 or 13.6% consulted a doctor or health care provider.

Question	Respondents (N=607), n (%)
Smartphone	497 (82.4)

[a]Participants were able to check all that apply.

Social Media Use and Engagement

In total, 80 out of 607 or 95.6% of respondents used social media. Of these, Facebook was the most popular platform, used by 511 or 84.2%, and was used primarily for social interactions by 338 out of 487 respondents (69.4%). YouTube (Alphabet Inc) and Instagram (Meta) were primarily used for entertainment (189 out of 251 or 75.3% and 110 out of 193 or 57.0%, respectively). 18.5%, or 112 out of 607 respondents, demonstrated a “Low Engagement” pattern regarding social media use.

Trustworthiness of Social Media

The majority of the 607 respondents found social media trustworthy (73/607, 12.0%) or neutral (257/607, 42.3%) for health information. Black or Asian race, younger age, and longer duration of US residency were associated with greater trust in social media. Among Black respondents, 14 out of 72 (19.4%) considered social media trustworthy, compared to 49 out of 480 (10.2%) of White respondents (P=.003). Asian respondents showed even higher trust levels, with 7 out of 27 (25.9%) rating social media as trustworthy. Younger individuals also reported greater trust, with 17 out of 82 (20.7%) of those aged 35-39 years trusting social media compared with 12 out of 70 (17.1%) among those aged 70-79 years (P<.001). In addition, respondents with longer US residency (more than 15 years) showed greater trust, with 272 out of 587 (46.3%) indicating trustworthiness in social media, compared with only 5 out of 20 (25.0%) of those with less than 15 years of residency (P=.004). In total, 277 respondents (45.6%) noted social media to be untrustworthy (Table 3).

Among social media platforms, the highest proportion of trustworthy users was noted among the 80 WhatsApp users (n=17, 21.3%), followed by 23 out of the 136 (16.9%) Twitter users. Amongst the 511 respondents who used Facebook, the most frequently used platform, 65 or 12.7% reported trust in social media for health information.

Use of Cancer Information or Decision Aids Through Social Media

Participants who considered social media "Trustworthy" (n=73) were more likely to view cancer information (n=61, 83.6%) or click on a decision aid through social media (n=61, 83.6%) than the 277 respondents who viewed social media as "Untrustworthy" (view: n=133, 48.0%; click: n=125, 45.1%) (Tables 4 and 5). Younger participants, particularly those aged 35-39 years were more likely to view cancer-related information through social media. Only 10 out of 57 (12.2%) in the 35-39 years age group rated their likelihood as "unlikely," compared with 54 out of 89 (32.7%) aged 60-69 years. Among respondents aged 35-39 years, 54 out of 82 (65.9%) were likely to click on the decision aid, while in the 60-69 years age group, 87 out of 165 (52.7%) indicated they were likely to click.

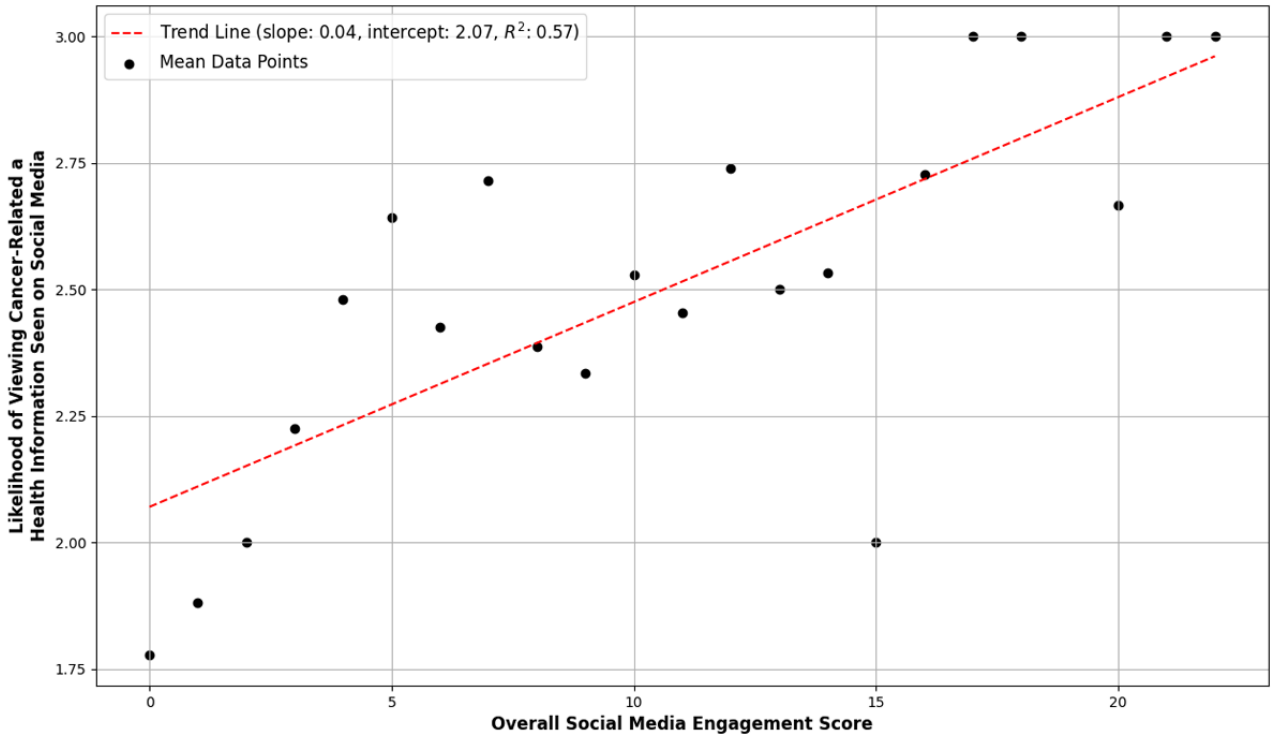
The "Overall Social Media Engagement Score" was associated with increased likelihood of viewing cancer treatment-related information (Spearman ρ=0.210, $P<.001$; Figure 1). For instance, among those with an engagement score of 1, only 10 out of 25 (40%) were likely to view cancer information, whereas among those with an engagement score of 8, 28 out of 44 (63.6%) were likely. In addition, the engagement score was also associated with accessing a decision aid on social media (Spearman ρ=0.203, $P<.001$; Figure 2). Among respondents with an engagement score of 1, only 8 out of 25 (32%) were likely to click on the decision aid, whereas for those with a score of 8, 25 out of 44 (56.8%) indicated they were likely.

XSL•FO
RenderX

Figure 1. Mean likelihood of viewing cancer-related health information seen on social media by "Overall Social Media Engagement Score.".



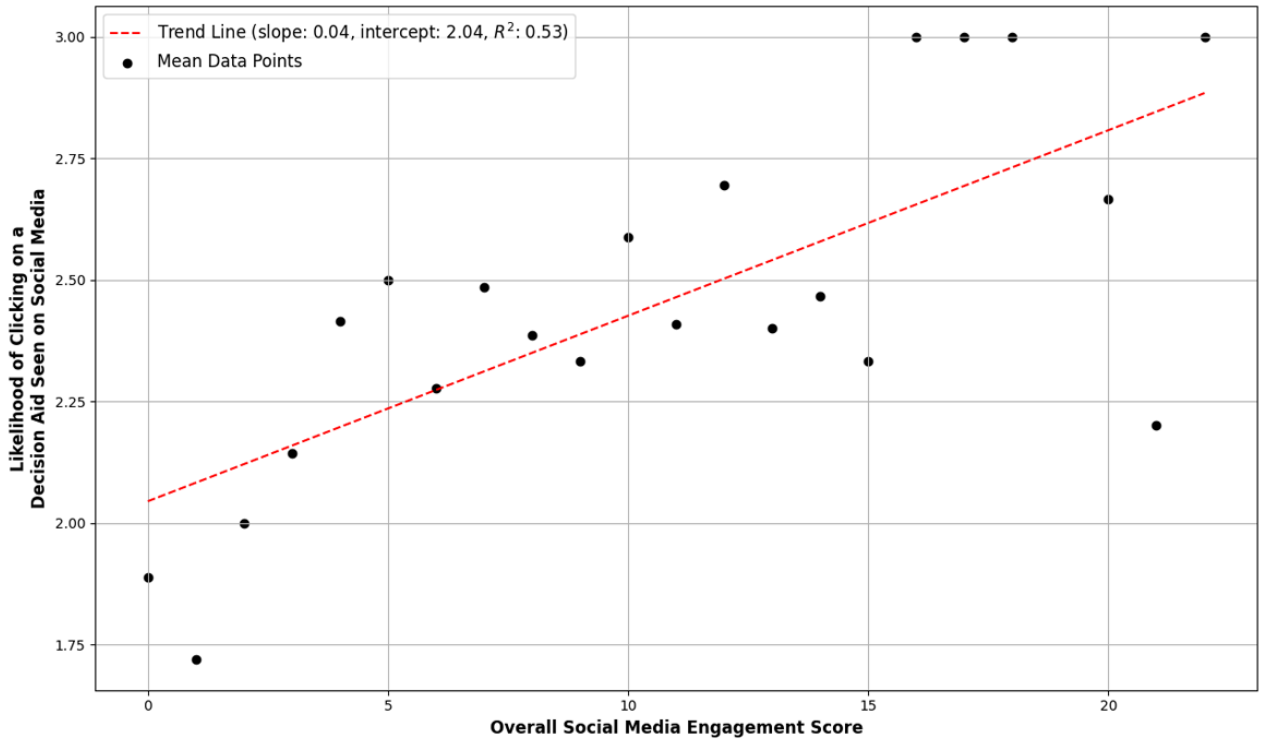


Figure 2. Mean likelihood of clicking on a decision aid seen on social media by "Overall Social Media Engagement Score.".

Age, employment, and perceptions of trustworthiness of social media were included as covariates in the ordinal regression models after significant multicollinearity was ruled out variance inflation factor (VIF≤1.2). The model fit for estimating the likelihood of clicking on decision aids was significant (χ^2_9=60.7, *P*<.001, Nagelkerke R^2=0.113). Respondent perception of the trustworthiness of social media for health information was a significant predictor. Compared with those who found social media trustworthy, respondents who considered social media "untrustworthy" (β=–1.826, Wald χ^2=29.14, *P*<.001) or "neutral" (β=–0.926, Wald χ^2=7.22, *P*<.007) were less likely to click. Age category (*P*=.59) and employment status (*P*=.29) were not significant predictors.

XSL•FO
RenderX

The model for viewing cancer-related health information was also significant (χ^2_9==70.4, P<.001, Nagelkerke R^2=0.133). Relative to those rating social media as trustworthy, those rating it as "untrustworthy" had significantly reduced odds of viewing cancer-related health information (β=–1.680, Wald χ^2=24.31, P<.001) while the reduction in likelihood of those rating it "neutral" did not reach statistical significance (β=–0.581, Wald χ^2=2.74, P=.10). Once again, age (P=.35) and employment status (P=.22) were not significant predictors.

Discussion

Principal Findings

The expanding role of social media in health information dissemination underscores a shift in public health communication. The internet is the most frequently reported source of information for individuals with cancer, especially among women, aligning with our findings [32]. To our knowledge, this is the first study to examine factors influencing engagement with decision aids and cancer-related information amongst women using social media platforms.

These study findings suggest that social media holds potential as a platform for the effective dissemination of cancer decision aids to women. Overall social media usage was high, with almost half of the respondents reporting moderate-high to high engagement. We found that about two-thirds of participants searched for cancer-related information, and nearly half of those used the internet to seek such information for themselves in the past year. Usage patterns varied across platforms: while Facebook emerged as the most used platform, WhatsApp was perceived as the most trustworthy source for health information among our respondents.

Most respondents expressed interest in engaging with cancer treatment information or clicking on a decision aid via social media. Higher frequency of social media use correlated with a higher likelihood of interacting with cancer-related content and decision aids online. In addition, trust in social media appears to be a mediating factor in the relationship between demographics and engagement with cancer information on social media. While younger participants and those who worked full time were more likely to view cancer-related information and click on a decision aid, this effect may be a function of their higher likelihood of trusting social media.

Comparison to Previous Work

Integrating two primary concepts of this study, trust in social media and the likelihood of engaging with health-related content, our findings suggest that individuals who perceive social media as a trustworthy source of health information are more likely to interact with cancer-related treatment information, regardless of their demographic. Numerous consumer studies have highlighted the importance of source credibility in engagement [33-35]. We recognize that trust is a multifaceted construct that is objectively hard to evaluate because it is influenced by factors including demographics, past experiences, and societal and cultural norms [36]. Future studies should focus efforts on better understanding their impact on health information engagement.

Recently, a study by Fridman et al [37] analyzed social media usage and trust in health information among patients with cancer and caregivers, focusing on demographic factors linked to social media use for medical decisions. They also found that a substantial proportion of patients with cancer and caregivers trust social media for health information. Factors associated with higher trust and engagement with social media tools included young age, Black race, and lower education levels. This is consistent with our findings that support trust as a motivating factor for engagement with social media in a medical decision-making context.

Our study was designed to identify trends and general usage patterns across several social media platforms. Facebook (Meta) was the most popular platform among our survey respondents, with 84.2% reporting usage, aligning with 2023 national data indicating that 69% of consumers use Facebook, making it the most used social media site [38]. This is consistent with findings from a recent study which found that Facebook was the most frequently used social media platform for health behavior interventions [39]. However, Facebook is not perceived as being as trustworthy as some of the other platforms. Given the relationship between perceptions of trustworthiness and the likelihood of a respondent using health decision aids on social media, popularity should not be the only factor guiding dissemination. The demographic profile of users also continues to evolve. For example, although less widely used overall, WhatsApp (Meta) is increasingly popular among Latino or Hispanic populations in the United States [40]. These trends highlight the importance of understanding variations in platform use amongst different cohorts when considering platform selection.

In addition, consideration of platforms that can deliver information in diverse formats (eg, text, video, photos, and polls) is important, as each platform's design and interaction style may be better suited for specific sub-audiences. Future research should focus on exploring platform-specific strategies for health information delivery, especially as new platforms emerge (eg, Bluesky [Bluesky PBLLC] and Threads [Meta]) and others become less frequent.

Moreover, the frequency of social media use has a significant impact on the likelihood of engaging with decision aids or accessing cancer-related health information. Frequent social media users may be more likely to perceive others on these platforms as having integrity and competence. They may also report stronger connections with and greater concern for other network users [41]. Frequency of social media use can significantly influence user interactions, such as clicking behavior [42]. However, our Spearman correlation analysis, which focused solely on frequency, accounted for only about 4% of the variance in viewing and clicking behaviors. This suggests that trust, along with other unmeasured factors, likely plays a critical role in these engagement dynamics.

Strengths and Limitations

This exploratory study provides insight into the use of decision aids for health information on social media and highlights the key role of trust. It is an important stepping stone for future research assessing online health behavior among female patients

XSL•FO
RenderX

in cancer. A key strength of our study is the large sample size (N=607) and the inclusion of a cohort that is fairly representative of United States female population demographics based on census data, enhancing the generalizability of our findings. In addition, by recruiting a female-only cohort, our study offers a more nuanced understanding of preferences and engagement patterns among women, which can inform the development of female-specific cancer decision aids tailored for social media.

As a cross-sectional survey-based study, this study was not designed to explore the many complex, nuanced factors associated with online use behavior. First, the survey, although informed by widely used and nationally developed surveys, was not pretested or pilot-tested for face validity. This lack of initial testing may have been associated with increased confusion among participants and could have influenced responses and overall participation in the survey. Relatedly, we were close but unable to meet the overall target population size of over 660 after the application of exclusion criteria. Second, as an internet-based survey, it was subject to selection bias. Participation required English proficiency, internet access, and the ability to navigate an online survey. While incorporating multilanguage options can be considered, facility and comfort with the internet would still be required. Third, we were unable to recruit a racially diverse population that would be matched with corresponding US census data. For instance, the proportion of Hispanic respondents was nearly half of the intended goal (7.9% vs 16%). However, there was more variation in age, education, and income distribution of respondents. Future efforts in larger populations should focus on targeting underrepresented demographics via other survey distribution platforms and recruitment strategies.

Fourth, regarding statistical analysis, although a multivariable regression was performed, our regression models only accounted for roughly 10%-15% of the likelihood of viewing health information or clicking on a decision aid seen on social media. Moreover, potential influences from unmeasured factors, such as medical conditions or personality traits, further complicated attempts to understand these complex dynamics [43,44].

Future Directions

This study offers an initial insight into factors influencing online health information and highlights the role of trust. Future research should explore the potential of social media for the delivery of online decision aids specifically designed for patients seeking cancer information. Our study points to the need for pilot testing health decision tools within the target demographic to help with tool optimization and reliability of findings. Trust is a nuanced concept, and efforts should focus on ways to better quantify and distinguish between trust in both social media platforms and online materials.

Once decision aids have been refined for their target population, continued efforts should consider strategies to promote adoption and optimize engagement. Partnering with reputable health organizations, featuring endorsements from trusted medical professionals, and using verified accounts for content delivery can all be considered. Examining platform-specific formats, such as interactive content on Facebook or visual aids on Instagram, could help increase diffusion. Presenting clear, evidence-based information in user-friendly, visually engaging formats (eg, infographics or explainer videos) may further increase credibility. Incorporating interactive features that allow users to connect with health care providers or support groups on social media could also render greater trust and engagement. Research on these trust-building strategies would offer valuable insight into optimizing social media as a reliable and accessible channel for health information dissemination.

Authors' Contributions

All authors read and approved the final manuscript. ARJ, GAL, GBS, CNL, and TMM conducted formal analysis. ARJ, GAL, and GBS handled visualization. ARJ, GAL, GBS, and MCP, TMM, CNL contributed writing- original draft. ARJ, GAL, GAS, MCP, and YR performed review and editing. YR, MCP, CNL, TMM, and BO handled methodology. MCP, CNL, TMM, and BO conducted to conceptualization. TMM, CNL and BO managed data curation.

Conflicts of Interest

Author MCP was a consultant for Epi-Q, Inc in 2023 and UCB Biopharma in 2024, on topics unrelated to this manuscript. All other authors reported no conflicts of interest.

Abstract

Background: Commonly used digital health technologies, such as electronic health record systems and patient portals as well as custom-built digital decision aids, have the potential to enhance person-centered shared decision-making (SDM) in cancer care. SDM is a 2-way exchange of information between at least a clinician and the patient and a shared commitment to make informed decisions. However, there is little evidence in the literature on how technologies are used for SDM or how best they can be designed and integrated into workflows and practice. This may be due to the nature of SDM, which is fundamentally human interactions and conversations that produce desired human outcomes. Therefore, technology must be nonintrusive while supporting the human decision-making process.

Objective: This study examined how digital technologies can help cancer care professionals improve SDM in oncology consultations.

Methods: Health care professionals who treat patients with cancer were invited to participate in online co-design focus group meetings. During these sessions, they shared their experiences using digital technologies for SDM and provided suggestions to improve their use of digital technologies. The session recordings were transcribed and then analyzed using qualitative thematic analysis. The 3-talk SDM model, which consists of 3 steps—team talk, option talk, and decision talk—was used as the guiding framework. This approach was chosen because the 3-talk SDM model has been adopted in Australia. The researchers walked the participants through the SDM model and discussed their routine clinical workflows.

Results: In total, 9 health care professionals with experience treating patients with cancer and using technologies participated in the study. Two focus groups and 2 interviews were conducted in 2024. Three themes and 7 subthemes were generated from the thematic analysis. The findings indicated that various digital technologies, such as electronic health record systems, mobile devices, and patient portals, are used by cancer care professionals to help improve patients' understanding of their disease and available care options. Digital technologies can both improve and undermine SDM. Current systems are generally not designed to support SDM. Key issues such as data integration and interoperability between systems negatively impact the ability of digital technologies to support SDM. Emerging technologies such as generative artificial intelligence were discussed as potential facilitators of SDM by automating information gathering and sharing with patients and between health professionals.

Conclusions: This research indicates that digital technologies have the potential to impact SDM in oncology consultations. However, this potential has not yet been fully realized, and significant modifications are required to optimize their usefulness in person-centered SDM. Although technology can facilitate information sharing and improve the efficiency of consultation workflows, it is only part of a complex human communication process that needs support from multiple sources, including the broader multidisciplinary cancer team.

Introduction

Background

Shared decision-making (SDM) is defined as a collaborative approach in which patients and health care providers work together to make medical decisions [1]. SDM emphasizes a cooperative relationship between the patient and the physician, characterized by a 2-way exchange of information and a shared commitment to making informed medical decisions [2]. During the SDM conversation, patients and clinicians share information, express preferences, participate in discussions to gain insights, negotiate conflicts, solve problems, and ultimately make decisions [3]. Through this approach, patients can play an active role in their care [4], while physicians gain a better understanding of the unique needs of each patient. Physicians can then make informed and collaborative recommendations that aim to improve patient health outcomes [5]. The use of SDM is particularly crucial in oncology consultations, as the results of treatments are often uncertain. This uncertainty makes treatment decisions complex for patients who often have to choose between aggressive disease management and maintaining their quality of life [6]. Therefore, SDM has been implemented in oncology consultations in several hospitals around the world, and perceptions of its use by cancer care specialists in hospitals have been studied [7-9]. Despite the integration of SDM into health policies and practice standards [10,11], the benefits of SDM are slow to materialize at the operational level [12], and a fragmented health care system can complicate the implementation of SDM.

Efforts have been made to integrate decision aids into electronic health record (EHR) systems used by oncologists [13]. Current EHRs used in oncology practices in hospitals may include functions to facilitate the scheduling of patient consultations and follow-ups, history taking, review of examination results, electronic medication management systems, and care planning [14,15]. However, existing EHRs often do not provide complete details about patients' health values and preferences [16]. This lack of patient details can cause clinicians to misunderstand patient preferences when patients experience cognitive difficulties or when their health conditions worsen too quickly to participate in SDM, which can have significant adverse consequences [16]. The introduction and integration of additional digital tools, such as cancer care dashboards, into EHRs that display patient treatment outcomes and other clinical measurements to monitor patient health status have been developed to increase the ability of both clinicians and patients to visualize results and aid decision-making [17] and to aid the stakeholders during SDM to improve cancer care delivery [18].

Research is ongoing to understand how digital health tools and EHRs can be combined in innovative ways to improve the SDM process [19]. In particular, we need to collect more detailed information to pinpoint where additional digital technology could be developed and used to help the SDM process in the delivery of cancer care. This paper examines how EHRs and other digital tools are used in practice to inform possible future improvements in applied digital technology to facilitate SDM in oncology consultations.

Objectives

Hence, the objective of this study was to explore how health care professionals use digital technology to support SDM in oncology consultations, understand the barriers to technology that support SDM in oncology consultations, and understand the opportunities for future technology to improve SDM in oncology consultations.

Methods

Study Design

This study design was informed by the 3-talk SDM model and the approach of previous studies to develop digital tools to support SDM [20]. The 3-talk model incorporates the principles of team-based collaboration throughout a multistage consultation process and is highly recognized in the health care sector. This model has 3 main components: team talk, option talk, and decision talk [21].

Therefore, to investigate the role of digital technology in SDM in oncology consultations and to achieve the study objectives, we applied the design thinking framework [22]. Design thinking is a creative approach that has been used effectively to address problems in the health care sector [23,24]. It helps to collect user insights to develop efficient products, services, and experiences [23]. Ideas are quickly prototyped and improved through continuous iterations [25]. This study design was chosen because it emphasizes collaboration with end users throughout the problem-solving process. We developed low-fidelity wireframe prototypes of EHRs. This technique was chosen to investigate the potential of EHRs to help oncologists and patients with cancer collaborate on decisions because it has been suggested to be effective in health care management and innovation [26]. Low-fidelity prototypes (Multimedia Appendix 1) were quickly created using affordable graphic software, allowing feedback to be gathered without consuming significant time and resources. We applied co-design and low-fidelity prototyping methods with study participants in focus groups and one-on-one interviews.

Participants and Settings

Health care professionals with opinions on the role of digital technologies in oncology consultations were invited to participate in this study. Specialists in medical and radiation oncology, as well as physicians in training programs, were included. Through existing university connections and local cancer networks, participants were purposefully recruited from 5 cancer care centers in Sydney, Australia. A researcher (TS)

XSL•FO
RenderX

initially contacted key potential participants who collaborated on previous research projects in oncology via email and introduced them to AY. AY then followed up on the communication by providing an information package about the research project and suggesting focus group schedules. The focus groups and interviews were scheduled on Microsoft Teams for remote videoconferencing, and the participants' attendance was recorded.

Data Collection

Guided by the core components of the SDM 3-talk model—team talk, option talk, and decision talk—a focus group and interview topic question guide were developed in advance to shape study inquiries in alignment with the SDM model. The researchers (AY, JK, AJ, and TS) iteratively developed the topic question guide. The topic guide was pretested by running pilot focus group sessions with researchers working on other health care projects within the department. Their feedback helped to refine the topic questions and focus group process. The final version of the topic question guide is shown in Multimedia Appendix 1. The topic questions were used to ask participants about their experience with how technology is used to support SDM within each component of the 3-talk SDM model, particularly if they used the 3 SDM core components in their usual medical practice. The focus groups and interviews were semistructured and guided by the topic questions. The low-fidelity prototypes were presented to participants after discussing the application of technology in their practice, and feedback was sought on the usefulness of the concepts included in the prototype design. The prototypes also served as a trigger for further discussion.

Each focus group and interview concluded by summarizing and reflecting on the discussion and confirming the accuracy of the researcher's understanding of the information provided by the participants while they were still present. This final concluding step was necessary because scheduling busy, working health care professionals providing cancer care to patients for study reviews is difficult.

All interviews and focus groups were recorded in video and audio formats. They took place online between April and May 2024. Author AY led all the focus groups and interviews.

Data Analysis

Three researchers (AY, AJ, and TS) analyzed the qualitative data collected using the reflexive thematic analysis as a framework by Braun and Clarke [27-30]. This method guided the initial coding process applied to the focus group meetings and interview recording transcripts, which were deidentified and anonymized. The researchers first read through the transcripts to fully understand the data. They then proceeded with line-by-line coding, collaboratively compiling and discussing the codes. After completing the coding, the codes were inductively arranged into themes and subthemes. Researcher AY created a codebook, and the researchers engaged in multiple discussions to agree on the identified themes and subthemes. The codebook was tested on 1 transcript. Iterative discussions and consensus resulted in a refinement of the codebook. The final codebook was then used to code the remaining focus groups and interview transcripts. Then, AY used the codebook to code the content of each remaining transcript. Columns in an Excel (Microsoft Corporation) sheet were created to represent different themes and subthemes. AY analyzed the content of each transcript line by line and coded the text. The coded chunks of text were extracted and added to the Excel table according to their alignment with the themes. As new knowledge was found, the codes were refined accordingly. Afterward, AJ reviewed, modified, and confirmed the recategorization of the codes. Eventually, AY finalized the recorded data in the Excel sheet.

Ethical Considerations

The Human Research Ethics Committee of the University of Sydney approved this study (project number: 2023/790). All participants provided written informed consent. Data collected were anonymized and deidentified, and the research data were stored in the university's secure computer systems. All the participants provided their time and information freely without receiving financial compensation.

Positionality of the Research Team

Our research team (TS, JK, and AJ) has extensive experience conducting research on the implementation of digital technologies in health care organizations in Australia from an academic point of view. On the other hand, author AY is a practicing professional with experience in developing and implementing computer software in hospital settings for clinicians. We believe that digital technologies can improve health care. Thus, we are driven to implement the latest innovations in health care.

Results

Participants

The study involved 9 participants who participated in different co-design focus groups and interview sessions. One focus group was attended by 5 (56%) participants; another focus group was attended by 2 (22%) participants. Two interviews were conducted one-on-one. Each session lasted between 30 and 60 minutes. The participant demographics are presented in Table 1.

XSL•FO
RenderX

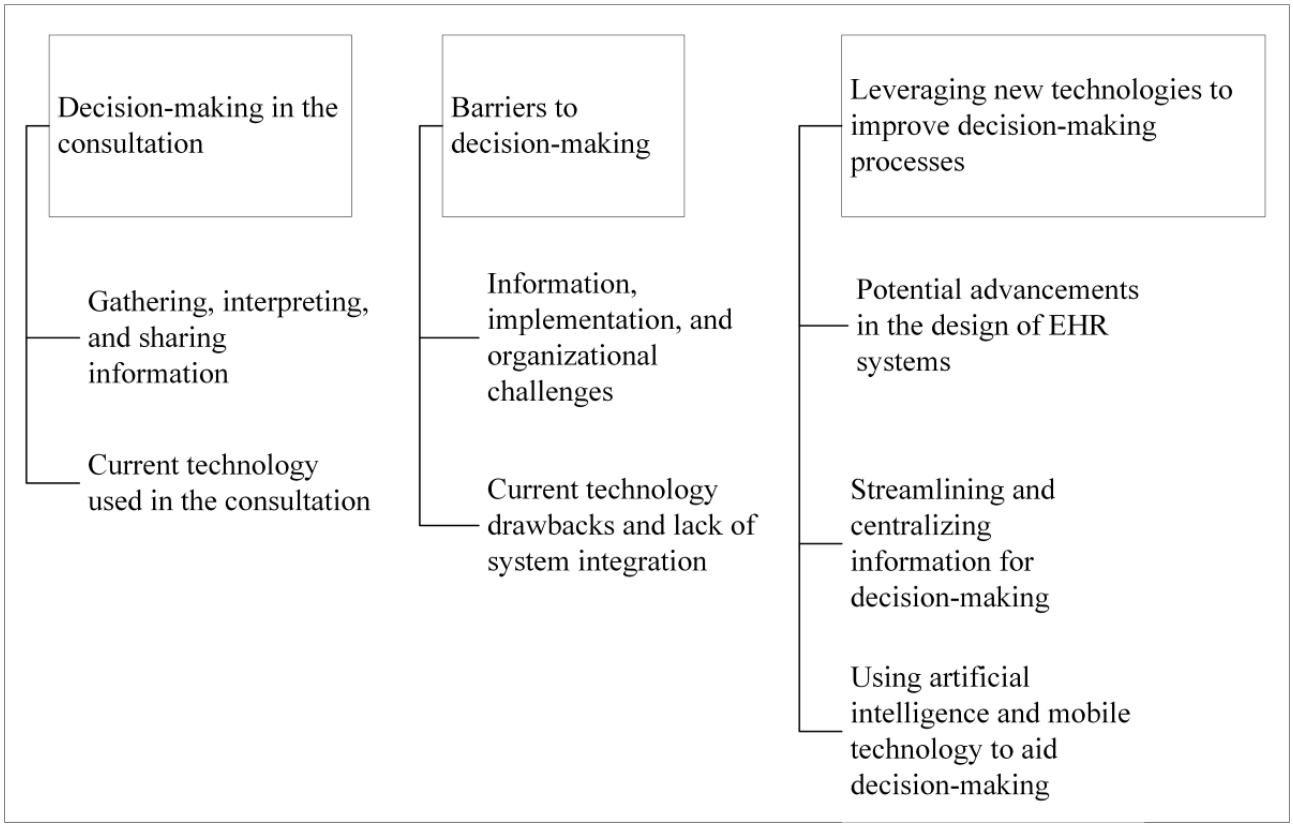

Table 1. Individual participant characteristics.

Participant ID	Session ID	Cancer Care Center ID	Sex	Cancer care stream	Level of experience
P1	A	C1	Female	Breast and lung	Radiation oncologist (consultant)
P2	B	C1	Male	Breast and lung	Radiation oncologist (consultant)
P3	B	C1	Male	Breast and lung	Radiation oncology registrar (in training program)
P4	B	C2	Male	Prostate	Radiation oncology registrar (in training program)
P5	B	C2	Female	Prostate	Radiation oncologist (consultant)
P6	B	C2	Female	Prostate	Radiation oncology registrar (in training program)
P7	C	C3	Male	Lung and head and neck	Medical oncologist (senior consultant and hospital executive)
P8	C	C4	Male	Perioperative	Anesthetic registrar (in training program)
P9	D	C5	Female	Lung	Respiratory specialist (consultant)

Overview of Themes and Subthemes

Three themes and 7 subthemes were generated from the thematic analysis. The three themes are (1) decision-making in the consultation, (2) barriers to decision-making, and (3) leveraging new technologies to improve decision-making processes (Figure 1).

Figure 1. Overview of themes and subthemes. EHR: electronic health record.

Theme 1: Decision-Making in the Consultation

Overview

Participants discussed their decision-making process during consultations and how they felt their clinical workflow aligned with the 3-talk SDM model while being prompted by the wireframe prototypes. The participants appreciated the 3-talk SDM model for breaking the clinical decision-making process into 3 core components:

> *...in general,...this is quite similar to what my approach is in the clinic.* [Participant P4 B C2]
>
> *...it's interesting, and I appreciate this model...breaks it into three pieces.* [Participant P7 C C3]
>
> *...I like team, option, and decision...I hadn't heard of it, but it's exactly how I structure my consultation.* [Participant P9 D C5]

XSL•FO
RenderX

On the basis of their experience, participants highlighted that they did not differentiate between the option talk and the decision talk components:

> *I...in the real world, don't differentiate between option talk and decision talk. So, option talk and decision talk, for me, is the same process. So, as I'm discussing options...I don't sit there and say here are all the options. Now, let's stop and have a discussion about the decision. I blend those two conversations together.* [Participant P7 C C3]

Participants described how they collect information by talking to their patients directly rather than having them fill out responses to a list of questions in advance:

> *I'm actively, kind of, discussing what would be involved in making a decision to go down this pathway. What further information would be needed? So, the implication for digital technology is that it's the same technology I use while discussing options. I don't sort of stop and say now, here's another one I prepared earlier. And let's talk about it this way.* [Participant P7 C C3]

Some participants were concerned about patient privacy:

> *...in the waiting room, I'm not sure...I don't know that I can see an easy way to get personalized digital information in the waiting room, in a safe way. I think that...needs some human and clinical inputs...it could be like a nurse coordinator, someone like that could meet with the patient before going to the consultation. So, there's all those sorts of very personalized differences.* [Participant P9 D C5]

Another important step, in their view, is that the participants noted that they plan activities before patients visit for their consultations:

> *So firstly,...these patients would have been discussed by the multidisciplinary team before they saw me with the surgeons and medical oncologists,...and we would have a plan of action from the MDT.* [Participant P1 A C1]

After the multidisciplinary team planning discussions, the participants described how they would discuss the situation with the patient and involve other professionals in the patient model of care:

> *So, we've looked at performance status, frailty, and pulmonary function. We identified things that are needed. We discussed that at the consultation and asked the care coordinator to link up.* [Participant P1 A C1]

The subthemes of decision-making in consultation include gathering, interpreting, and sharing information through digital and analogue communications.

Subtheme 1.1: Gathering, Interpreting, and Sharing Information

Participants said that decision-making often occurred in multidisciplinary team meetings without input from the patient:

> *...some of our decisions or, you know, consensus, optimal decisions are also influenced by our MDT meetings...in most MDT meetings, the patient is not there....we think we are arriving at a decision that can be communicated to patients, but often, it actually doesn't align with their preferences.* [Participant P5 B C2]

When reflecting on the decision-making component of consultations, participants noted that patient wants and expectations at the point of care they were at were shaped by their previous experiences along the way. Participants remarked that some patients may be ready to decide after meeting with the physician, while others may be hearing about their condition for the first time and feel overwhelmed. The participants know that this approach takes longer. Yet, they prefer having the ability to understand the patient's wishes better:

> *...there's a huge variation in what patients want at this point and what they expect, and it also probably is not independent of what specialty you're in and how they've gotten to you. So, you know, for me, by the time a patient's gotten to me, they may well have been through two or three specialists already. They've got...cancer and, so sometimes, they're already primed. They're ready to make a decision. Other times, it's the exact opposite, and this is the first time they've heard they might have cancer.* [Participant P7 C C3]

> *I use the time when I'm talking to patients, collecting...information to kind of just get to know the person...it takes longer than if they fill in a list of questions in advance and I'm just looking down the list...I'm building a relationship. If I look at a screen...that's not the same as asking those questions and, kind of, building a rapport with a patient.* [Participant P7 C C3]

Different approaches were described for different patient situations and desires for information. Participants said that some patients want to know their treatment plan, while others seek detailed explanations of the decision-making process. The preference for the type of clinical workflow in consultations can also depend on the physician's training, work style, and personality:

> *They've got no idea what's going on....it's the opposite conversation, where they absolutely need to go away and think about it....and I think the things you do to help them in those situations are somewhat different. The first one, those people often already have the information they need. The second one, they absolutely don't.* [Participant P7 C C3]

Several important points related to patient care were covered in the participants' discussions. Participants highlighted the challenges of bringing bad news to patients, the need for better participation of patients in decision-making, and the importance of documentation following decisions:

> *I see them at the start...usually, the person who sees them earlier then has to break the bad news, and then...all the referrals afterward...that's where things*

XSL•FO
RenderX

> *fall apart a little bit...they'll get discussed in MDT...but sometimes that's a little bit delayed. Sometimes, the patient doesn't always get the right information. The right time is the other problem.* [Participant P8 C C4]

The reliability of clinical information sources was raised. It is crucial to always refer to a trusted source of information:

> *...and look, the very important thing in clinical medicine is you go to the primary source for the information; you never make, you should never make a significant clinical decision based on anything but firsthand information.* [Participant P9 D C5]

The value of having care coordinators share the patient care to address patient needs and support them throughout their treatment journey was emphasized:

> *...the need for a care coordinator to triage the patient's care needs, ...it's helpful to have the prostate care nurse who can talk to patients about the radiation therapy and the surgery...they [the patients] get time to make the decision about what they want. We refer them to the men's health physiotherapist as well.* [Participant P6 B C2]

Understanding the specific concerns of the patient is key. It is important to begin the decision-making process with the patient's desired outcome and then work out the appropriate care pathway:

> *...you need to work out the patient's goals first...then work backward from that... "Well, I think it isn't that…" "I definitely don't want radiotherapy" or "I definitely do want radiotherapy because my sister had it. It was good."…you might not get the decision if the patient is still sort of weighing things up...the decision is going to be informed by the goals. It's coming back to the quality of life versus the quantity of life.* [Participant P1 A C1]

The information gathering step is followed by reviewing the patient's results and interpreting the situation before the patient arrives for their visit. One participant described this step as follows:

> *...what I'm talking about is more around interpreting patient results...like the pre-three-talk process...is having the information available...when I prepare for the clinic, I like to have an opportunity to read everything in the pile, and everything is there...that I'm not chasing stuff. So, I'll usually look at my clinic two days ahead of time and make...notes in chronological order to try and figure out firstly whether there is any missing information. Umm…then ensuring that it's adequately documented in a way that is more meaningful to me.* [Participant P2 B C1]

After interpreting the available information step, the participants discussed how they communicated the medical information to patients. They like the way visual aids, as suggested in the wireframe prototypes, help them to clarify and make information more understandable, improving patient understanding and facilitating informed decision-making through effective communication:

> *I find, you know, drawing diagrams and having pictorial, sort of, explanations of things help...I think it breaks through language barriers and understanding of things. Anyway, I'm scrolling through the images and going through the results with the patient, pointing things out, simplifying things, maybe drawing...handwritten...document...to help explain things.* [Participant P4 B C2]

Information and knowledge sharing was discussed in addition to visual aids. Participants mentioned that they often explained results using prognostic calculators that can assess life expectancy, especially in older patients. One participant explained how they discuss different options with patients to help them make treatment decisions:

> *...in some lung cancer patients where there are some poor prognostic factors, and even though they've got technically localized disease that could be curable, you might be a bit worried whether this patient can get through six weeks of umm daily treatment. So, sometimes, we do discuss more palliative options...You give the options; you discuss the harms and benefits of options...but I don't...use the EMR [electronic medical record] apart from the imaging information....I do use...e-prognosis calculators to calculate life expectancy, particularly in older persons.* [Participant P1 A C1]

The participants also discussed the idea of summarizing the consultation decisions:

> *...you know, I appreciate that we don't do it today, but you could imagine a summarized transcript of the consultation generated.* [Participant P7 C C3]

Subtheme 1.2: Current Technology Used in the Consultation

Some participants explained that they do not use digital technology extensively in their consultation workflows. Digital technology is only sometimes used to show patients their medical images or to show images of medications. Videos have been used, but the participants found them too slow. They currently do not have interactive digital tools, but the technology would be useful for discussing treatment options:

> *...in terms of the team talk, how do I use digital technology at this point...mostly show people images, ...I show a lot of scans and X-rays. I usually find the videos are a bit slow for the consultation,...the patients get bored.* [Participant P9 D C5]

Decision aids were discussed. Tools to help predict outcomes of cancer treatments are available on the web for physicians to calculate patients' life expectancy and survival rates. Participants described how they use the decision aids in practice:

> *...I use a predictive tool...I will plug the patient numbers in and print them out for the patient. ...we often use it before we see the patient...in medical oncology, there's one for adjuvant systemic therapy...*

XSL•FO
RenderX

> *" ...without adjuvant chemotherapy, this is your 5 or 10-year survival or recurrence, and with...it's..." they'll show the magnitude of benefit. Then, the patient can decide.* [Participant P1 A C1]

Information sharing was emphasized. Participants described how they provide patients with information about advocacy and treatment protocols and search the internet for basic information, such as images, models, or videos. They share the information they find with patients to educate them. These web-based resources are then used to explain treatment procedures and complex equipment operations, saving them time and effort. The patients are then expected to be able to access and review the same web-based information that they have been introduced to and recommended when at home:

> *...radiation therapy is a technology that most people don't know anything about, ...they get confused....the value of images, models, or video to actually just show what a radiation linear accelerator machine is...you don't have to draw a picture of it. You don't have to waste time taking somebody around to look at the machine...trusted website resources.* [Participant P5 B C2]

> *I found myself doing a lot of...very basic Google images search...the information can be so basic...I think we get lost in explaining things.* [Participant P3 B C1]

Theme 2: Barriers to Decision-Making

Two subthemes were identified under the barriers to decision-making theme. The first subtheme, "information, implementation, organizational challenges," focuses on the participants' perceived challenges regarding access to and the quality of information. The second subtheme, "current technology drawbacks and lack of system integration," deals with the participants' difficulties related to the limitations of the EHRs and the lack of information integration.

Subtheme 2.1: Information, Implementation, and Organizational Challenges

Participants pointed out challenges such as experiencing difficulties when communicating with patients from different cultures and non–English-speaking patients in communities. They also mentioned challenges with patients' lack of health literacy:

> *...meeting patients of non-English backgrounds and cultural and health literacy issues; uh, very significant, and that's very hard together in a very quick clinical environment.* [Participant P2 B C1]

The involvement of the family and interpreters was also raised as a challenging area due to the time needed to understand the needs and priorities of the individuals:

> *...family care as support, and...the interpreter as well, ...can be part of the communication process, which can either assist or umm or slow down dramatically the process...It's hard to think of a solution because it takes time to talk to people and find out what's important to them.* [Participant P5 B C2]

Gathering precise patient information during visits, as patients often forget details, was expressed as a difficulty. Participants noted the need to improve communication methods and understand each patient's needs:

> *There are even times when a patient has had a test done, and it's not until they're, literally, sitting in the clinic room before me, and I go, where did you have this done? Sometimes, I have to ask them three questions to clarify...Umm, it's a common assumption of the patients as well. "Don't you have this information?" And the answer is often no, I don't.* [Participant P6 B C2]

Verifying the accuracy of the information patients provide can be time-consuming, as one participant pointed out the following:

> *...patients come in...and say, oh yes, I had a scan. ...you spent 5 minutes searching all the providers...then you Google where they live and what radiology practice is in their town, and then you find out they did have a scan, but it was an MRI of their ankle. It wasn't actually their chest, but they don't remember.* [Participant P9 D C5]

Subtheme 2.2: Current Technology Drawbacks and Lack of System Integration

Manual processing of information and uploading data into the EHRs is problematic for physicians, especially under time pressure:

> *At the moment, when we upload imaging, it's not the actual images themselves,...to, just, get the image in, I take a screenshot and paste it into a document in the EMR, or I am literally, highlighting and copying the text from the report and pasting it in,...when you are time-pressured, that's just how you get it done.* [Participant P6 B C2]

Obtaining and merging data from various sources presents additional challenges to physicians. Especially the lack of integration among older information systems for data sharing was considered a drawback. This situation caused difficulties in accessing different systems for decision-making tasks:

> *...needing multiple passwords in multiple different information systems or not having access to all the patient results. ...unfortunately, most hospitals, including ours, rely so much on a technology called fax.* [Participant P2 B C1]

The participants said the systems could not provide integrated results even when patients had medical tests conducted in public hospitals:

> *There are already difficulties in accessing scans and results...done even in other public hospitals...patients have blood tests done by multiple providers. Imaging from multiple different providers.* [Participant P6 B C2]

Besides the lack of system integration, 1 participant pointed out that their hospital does not have full access to the facilities of EHRs:

XSL•FO
RenderX

> *I sit in a hospital that does not use an EMR or has a partial EMR. So, the medical notes don't go, for the most part into an EMR, it does in the oncology clinics, but that's not where I work anymore. So, we mostly write on paper in the private clinic. I use my own digital interface and I'm always zooming around to different portals, external radiology, different pathology providers, et cetera.* [Participant P9 D C5]

Poor wireless digital communication network connectivity was also mentioned as another drawback:

> *...it's again getting onto another website, potentially getting password...Terrible Wi-Fi in most cancer centers...I think that is a big barrier.* [Participant P5 B C2]

Theme 3: Leveraging New Technologies to Improve Decision-Making Processes

The theme "leveraging new technologies to improve decision-making processes" encompasses the following subthemes: (1) participants' interest in implementing potential improvements to advance the design of EHR systems; (2) making data more accessible and understandable by streamlining, centralizing, and communicating information for collaborative decision-making; and (3) helping to share evidence data and decisions with patients' care team members outside consultations, as well as analyzing patients' data using artificial intelligence (AI) and mobile technologies.

Subtheme 3.1: Potential Advancements in the Design of EHR Systems

Participants expressed their interest in improving the design of the EHRs. They highlighted the need for improved access to laboratory diagnostic test results and recommended automatically providing reliable medical information from different systems:

> *...if there was some magic like a digital resource that could do all of that detection for me and link me to multiple different providers and go to clinical labs...and pull it all in, I would love it...If it was as good as me, it would be transformative. But you'd have to really be sure and be able to trust it...and then...the reliability of information.* [Participant P9 D C5]

There is interest in decision-making tools to help patients make treatment decisions. Participants said they do not need additional electronic devices to replace what they already have. They want decision-making tools to help patients choose their preferred treatments according to their desires and goals, especially when treatment options are risky:

> *...some, sort of decision tool may help in those situations where radiotherapy is high risk or trying to help people decide about quality versus the longevity of life or some sort of tool where you...answer to some questions..."quality of life is more important to me or length of life is more important" ...it would be good to have a tool where you can...help guide the patients to...their priorities...and...help the decision-making...I don't want any extra devices. I'd do it on the computer and then, maybe, print it out for the patient rather than an iPad type stuff.* [Participant P1 A C1]

Subtheme 3.2: Streamlining and Centralizing Information for Decision-Making

Centralizing and systematically organizing medical information to make it more accessible and easier to interpret is important to some participants. These participants were interested and emphasized that providing the right information to the physician at the point of care would help:

> *...one thing I found very helpful is the centralization of information. ...things like scans, test results from clinics or centers outside of the...health system...something that aggregates that information into...something to sort of centralized or funnel information to us...having patient information presented in a way where...making things more centralized, it would be helpful to us.* [Participant P3 B C1]

Other participants stressed the importance of obtaining comprehensive patient information before the consultation:

> *...I guess what I'm talking about is more around interpreting patient results, which is almost...preempted to the whole three-talk process, really...is having the information available.* [Participant P5 B C2]

The introduction of a patient portal for sharing information with patients is seen as a benefit. This would enhance physicians' ability to maintain communication with patients outside of consultations as they consider treatment options:

> *...if there's a patient portal, they can log in and see things, that could be nice. ...if I could say to them... "I've put all these in...I've put in the options...when you go home, you can log into your patient portal..." I could even imagine they could post some questions.* [Participant P9 D C5]

Subtheme 3.3: Using AI and Mobile Technologies to Aid Decision-Making

The potential use of generative AI was discussed to streamline medical documentation and improve patient care. Participants suggested using basic AI to generate patient reports that can be shared with medical colleagues:

> *...information can be more easily extractable...we use very basic artificial intelligence in our practice where we can generate a patient report, for example, where we pull information from different parts of...and combine it with text that we put in the record and that then goes to the general practitioner. So, I can do a treatment summary on a radiotherapy patient in about a minute, and I only have to type a line or two, and yet, a complex report goes back to the general practitioner, and we do that in medical oncology as well.* [Participant P2 B C1]

XSL•FO
RenderX

However, one other participant disliked the idea of using AI for report writing:

> *Wouldn't use it. I write better than generative AI. I think the kind of language that generative AI produces is boring and opaque, and I'm better than that. So, I wouldn't do it yet.* [Participant P9 D C5]

Discussion

Key Findings

This research examined how health care professionals in Sydney use digital technology to support SDM during oncology consultations. It sought to understand the difficulties they encounter when using technology for SDM and explore potential developments of new technologies that could improve the implementation of SDM in clinical oncology settings. First, the findings of this study emphasize the critical need for oncologists to consolidate health information from patients with cancer to facilitate SDM in oncology consultations. The results also highlight a significant misalignment between the current operations of existing EHRs and the clinical practice workflow in oncology clinics to help clinicians follow the SDM process. Second, the study draws attention to the challenges of access to information due to outdated technologies and communication barriers due to language and the lack of knowledge of the patient about health. Nevertheless, the study participants were interested in developing new technologies that could streamline access to health information and automate administrative processes, thus supporting SDM and ultimately improving the delivery of cancer care.

Current Use of Technology to Support SDM in Oncology Consultations

The study participants stressed the importance of consolidating medical information to improve decision-making in oncology consultations. Studies in similar data-driven cancer care management reinforce these findings of the investigation [31]. Similar to other studies on cancer care, participants in this research study have emphasized the critical role that information and data play in driving SDM processes and improving health service outcomes [18]. As digital technologies transform the health care sector, cancer care is also being transformed [32].

Discussions between health care professionals during the study addressed the 3 key components of the SDM model: team talk, option talk, and decision talk [21]. The prototyped EHRs used to investigate the feasibility of supporting SDM with EHRs demonstrated that some components of the SDM model of care, such as option talk, could be implemented to match established oncology consultation practices and workflows where patients and oncologists usually discuss treatment options. However, the phase sequence of the SDM model did not fit fully into the typical consultation procedures or workflow patterns of the study participants. The health care professionals who participated in this study appreciated the SDM model but stated that, in their routine clinical practice, they frequently combined option and decision discussions. This means that EHRs must be flexible to support cancer care workflows to accommodate the iterative nature of the oncology decision-making process.

Study participants highlighted the importance of direct patient communication to foster relationships and ensure complete information collection before choosing treatments or health care options. Previous research in this area has also emphasized the importance of the relationship and communication between oncologists and patients beyond consultation visits in cancer care management [33]. Several study participants have pointed out that a key to the successful implementation of SDM is the integration of digital systems and EHRs, ensuring accessibility to digital information when needed at the correct point of care for the right patient. However, some participants have also stated that they do not use their digital systems or EHRs extensively to support patient discussions. They may use only part of the system to show diagnostic images to share information with the patient. Other participants use EHRs only to look up patient results or document consultations.

Future Use of Technology to Support SDM in Oncology Consultations

Cancer treatment is based on data, involves multiple disciplines, is a lifelong process, and is increasingly dependent on the smooth digital exchange of clinical information [34]. In this study, the participants identified several key obstacles to SDM in their clinical oncology settings related to access to information, implementation, organization, and limitations of current technology, specifically EHRs. In addition, the participants mentioned communication challenges due to language barriers, emotions, comprehension, low health literacy, participation of patients, difficulties in accessing and integrating patient data, lack of information that often leads to poor data quality and inefficient processes, time pressure, and lack of privacy. Similar barriers have been reported by Steenbergen et al [35]. The participants informed the research about the absence of integrated systems and their continued dependence on outdated technologies in their clinical settings, which hinders information exchange between cancer care facilities. Furthermore, during the investigation, some health care professionals who participated in the study described that their hospitals do not have comprehensive EHRs, leading to a greater dependence on paper records and personal digital interfaces. Researchers in Canadian health systems have also reported on clinician experiences with outdated, ineffective, or inefficient technologies that do not fit their clinical workflows [36]. Therefore, the implementation of better information and communication technologies could eliminate some technological barriers and improve the overall efficiency of cancer care provided by oncologists.

During the study, health care professionals said that they use the information from the EHRs to help in their decision-making process to treat cancer. They focused on integrating digital resources to improve efficiency and support patient care. However, integrating quality health data remains challenging due to the lack of guaranteed interoperability, even between EHRs from the same vendor, as reported in a previous study in the United States [37], although the requirement to improve interoperability among digital health systems was legislated in the United States in 2016 [38], and the Fast Healthcare Interoperability Resources specifications were approved by the Health Level 7 International in August 2019 [39]. In June 2024,

XSL•FO
RenderX

the Canadian government introduced Bill C-72, which requires health IT systems to be interoperable [40]. Therefore, the stated goal of the health care professionals, which is to be able to securely access all the health information of their patients in integrated EHRs, is expected to be achieved in Canada in the future [40]. Therefore, future EHRs in the North American health care systems, designed to make health care information more accessible and transparent to patients and the health care team [41], are expected to be available to provide oncologists with critical cancer care data needed to support the SDM process in oncology consultations.

Furthermore, the study participants were interested in the potential benefits of an integrated web-based portal driven by clinical information designed to simplify access to data from private laboratory tests and automate various clinical documentation processes, such as generating interclinician letters and managing patient diagnostic test results. Petrovskaya et al [42] performed an evaluation of web-based patient portals and emphasized the elements that the study participants seek to help improve patient participation in SDM. The researchers stated that the patient portal is connected to the EHRs of health organizations, providing patients with functionalities such as secure and convenient access to medication lists and the ability to arrange and verify appointment availability and communicate with their health care team securely through SMS text messaging, in addition to access to their laboratory test results [42]. However, in a recent patient portal implementation initiative, Grewal et al [43] found that there are technical challenges in enrolling patients to use the patient portal, but involving nurses in the patient education and enrollment process is a promising approach and reinforces the value of multidisciplinary methods in improving patient care.

During the study, the participants explored the concept of a patient web-based portal that can consolidate health information from multidisciplinary treatment journeys. They emphasized the need for sophistication and proper allocation of resources. The participants envision a web-based portal where patients can access information about care options, ask questions, and review details such as their therapeutic plans and preferences. They believe that this would lead to more streamlined communication, better decision-making, and automation that uses AI capabilities. They perceive that AI innovations could help reduce the double handling of information and miscommunication, as well as prevent patients from falling through the cracks in their care. However, trust in AI systems and the data provided emerged as a significant concern among some participants. In an article on digital transformation in cancer care, Papachristou et al [32] emphasized that ensuring the safety, accuracy, and ethical application of data-driven interventions requires building trust among health care professionals, patients, family members, caregivers, and other stakeholders. Nevertheless, integrating AI into the cancer management workflow has been shown to transform individual treatment planning by accurately predicting responses of patients with cancer to different therapies [44].

Efforts to improve EHRs for better cancer care management are ongoing around the world. Two international workshops focused on technology in cancer care management were held in 2019 and 2020 in Europe [31] and one in 2022 in the United States [38]. These workshops addressed SDM processes, data integration and management, analytics, EHRs, and AI-based clinical decision-making [31,38]. While significant progress has been made in implementing EHRs in public hospitals in Sydney for cancer care [15,45], the full potential of EHRs to consistently improve cancer care quality and patient outcomes has not yet been fully realized [38,45]. Similar to the challenges that the participants of this study encounter with poor EHR usability, lack of fitness with clinical workflows, fragmented data sources, and large amounts of data, researchers from other health care jurisdictions have also described similar experiences [31]. The participants suggested that in addition to using technologies, nurses and other health care professionals could also assist in patient engagement. These additional clinical resources have skills, such as patient education and effective communication, crucial to facilitating patient participation in SDM during clinical oncology consultations and can help improve patient outcomes [46]. The effectiveness of SDM is maximized when health care professionals have experience, strong relationships with patients, and sufficient time for treatment discussions [35]. As reported by Steenbergen et al [35], the exchange of knowledge and the efficient flow of health information between clinicians and patients are essential to facilitate SDM in oncology. Consequently, technological opportunities are tailored to support human interactions [31,38].

Barriers to the effective digitalization of information in oncology have been identified. However, continuous innovations and technological improvements have helped minimize the effects of several major barriers. Technological innovations such as Health Level 7 Fast Healthcare Interoperability Resources [47], the Minimal Common Oncology Data Elements [48], and the Systematized Nomenclature of Medicine–Clinical Terms [49] when combined with legislation, such as the Connected Care for Canadians Act in Canada, make better access to health information possible. Therefore, digital health data in oncology can be shared across health care organizations in a more standardized way that all stakeholders can understand.

Conversely, although AI technologies have been introduced in oncology over numerous decades, a persistent distrust exists toward the suggested technology. The level of trust in AI systems influences the acceptance of these technologies. Therefore, frameworks and guidelines have been suggested to tackle the issues related to the reliability of AI-powered health care systems, such as the FUTURE-AI framework, which defines 6 requirements for trustworthy AI [50]. Accepting AI systems in health care depends on ethical principles, trust dynamics, and rigorous evaluation processes [51].

Tools and protocols are available globally to support SDM in oncology consultations. For example, in the United States, tools include Watson for Oncology [52] and the Adjuvant! Platform [53]. In Australia, EVIQ chemotherapy protocols are available nationally [54,55]. In the United Kingdom, the PREDICT tool aids in breast cancer treatment decisions [56]. In Canada, standards for SDM tools have been developed and are often used as a reference by international researchers [57-59]. Despite multiple trials, the integration of these tools and protocols into practice remains nonroutine, and several programs, such as IBM

XSL•FO
RenderX

Watson for Oncology, have failed to meet expectations [60]. These examples illustrate the ongoing challenges.

In summary, various oncology specialists and health care professionals perceive the usefulness of technology in supporting SDM in oncology consultations differently. A senior medical oncologist preferred face-to-face conversations with patients. In contrast, an anesthetic registrar preferred a high level of computerization and welcomed the possibilities of driving health care delivery with data. Other specialists, especially radiation oncologists, did not see the need to use technology extensively when helping patients make treatment decisions, as their oncology specialization typically involves only one treatment modality. However, they do want technology to accurately and promptly share information provided by other health care professionals. However, young health care professionals are ready to adopt more digitalized medical practices. Most health care professionals recognized the value of technology in supporting access to information for consumers, thereby facilitating informed decision-making.

Limitations and Future Research

The first limitation of the study was that only 9 health care professionals were available to participate in the co-design sessions. The second limitation was that no surgeon was identified to potentially participate in the co-design sessions. It is difficult for practicing physicians to allocate time for research projects and to attend co-design sessions when they are already working overtime and long hours providing patient care. Therefore, physicians who participated in the study may not have fully represented the larger oncology practice community. Only their views and practices on SDM were collected. The third limitation was that oncology consultation involves patients, other oncology specialists, and other health care providers. However, they were not invited to participate in this study due to time constraints. Patients and other health care providers may have provided different perspectives on their experience with SDM and the use of digital technology.

A larger group of oncology specialists, including surgeons, would have represented the larger oncology community and provided more generalized views. Furthermore, patients who have had oncological consultations would have provided their views on decision-making processes, particularly SDM. To mitigate the limitations of this study and obtain more generalizable results, our approach should be replicated in future studies with a larger and more diverse group of cancer health care professionals. This diversity would include many specialty dimensions, including surgeons and other health systems specialists. Furthermore, similar future studies should include patients who have experienced oncology consultations.

Conclusions

The findings of this study indicate that digital health technologies can assist in SDM in oncology consultations. This includes providing concise and consolidated information to support decision-making, tools such as multimedia resources to support patient understanding of cancer and treatments, and patient access to information and data outside of the consultation through tools such as patient portals. Emerging technologies, such as generative AI, may assist SDM by consolidating and personalizing information.

Nevertheless, care needs to be taken to ensure that technology does not erode the development of rapport and trust between a clinician and patient. Although EHRs and other systems are continually improving, there are substantial barriers to realizing the potential of technology to improve SDM, including the lack of data integration between systems and integration of new tools and resources into clinical workflows. However, continuous technological innovations and government efforts through new legislations are eliminating some of the digital system integration and data interoperability difficulties.

In conclusion, the study shows that digital technology can facilitate the exchange of information between independent health care organizations and individual health care providers, thus increasing the efficiency of oncology consultation workflows. However, technology is only part of the support needed for the complex human communication process in oncology. Oncology consultation services need support from a multidisciplinary cancer team, which includes other health care professionals and the patient's family. Health care professionals, such as nurses, must educate and prepare patients for consultations. Allied health professionals are often needed to help with language difficulties. Only through an ecosystem that is fully integrated, interoperable, and seamlessly fits in with the human and social interactions of numerous stakeholders involved in the care of a patient with cancer can the goals of the person-centered model of care be achieved through the implementation of SDM in cancer care.

Acknowledgments

The authors thank the participants who generously shared their experiences to support this research study.

Abstract

Background: The growing importance of real-world data (RWD) as a source of evidence for drug effects has led to increased interest in clinical research utilizing secondary use data from electronic medical record systems. Although immune checkpoint inhibitors and targeted therapies have advanced lung cancer treatment, managing complications such as interstitial lung disease (ILD) remains challenging. Early detection and prevention of ILD are crucial for improving patient prognosis and quality of life; however, predictive biomarkers have yet to be established. Therefore, methods to identify ILD risk factors and enable early detection using RWD are needed.

Objective: This exploratory study aimed to identify associated factors and prodromal symptoms of ILD onset using clinical data stored in a hospital information system.

Methods: Clinical data of patients diagnosed with stage IV lung cancer between November 2011 and December 2018 were extracted from the hospital information system of the National Cancer Center Hospital in Japan. A total of 3 patient groups were defined: the ILD Set, based on laboratory test results and radiological records; the ILD-GC Set, which added glucocorticoid treatment to the ILD Set; and the No ILD Set, for patients without ILD. The primary endpoint was the frequency of Japanese words extracted from electronic medical records, specifically from notes in the Problem-Oriented System/Subjective, Objective, Assessment and Plan format. Noun frequencies were compared between the ILD or ILD-GC Sets and the No ILD Set. Free-text data were processed using morphological analysis, and terms were categorized using the Patient Disease Expression Dictionary or the World Health Organization Drug Dictionary. Key terms were extracted from physician and nurse records based on the descending order of ranking differences to identify associated factors and prodromal symptoms.

Results: The analysis included 674 cases (105 in the ILD Set [including 12 in the ILD-GC Set] and 569 in the No ILD Set). Baseline characteristics showed no apparent differences across groups. In the 30 days prior to ILD onset, notable differences in word frequencies per 1000 notes between the ILD-GC Set and No ILD Set were observed in the following term categories: respiratory symptoms (eg, breathlessness, shortness of breath, oxygen), ranging from 170.59 to 46.51; pain or analgesics (eg, Lyrica [pregabalin], soreness, precordial pain, opioids), ranging from 462.88 to 45.16; and appetite-related terms (eg, inappetence, food intake, queasiness, Novamin [prochlorperazine]), ranging from 102.23 to 51.90.

Conclusions: Terms related to respiratory symptoms, pain or analgesics, and appetite were identified as associated factors for ILD onset in patients with stage IV lung cancer using RWD from acute care institutions for malignant tumors. These findings may support the early detection of ILD and underscore the potential of RWD to generate real-world evidence that informs drug discovery and pharmaceutical development.

Introduction

Since the late 2010s, pharmaceutical regulatory authorities, such as the US Food and Drug Administration and European Medicines Agency, have referred to medical data routinely collected in health care institutions and a variety of sources as real-world data (RWD) [1,2]. They began to examine the usefulness of RWD as a source of evidence for various drug effects. In recent years, the importance of conducting clinical research to obtain new insights by reusing diagnostic information stored in hospital information systems, primarily electronic medical record (EMR) systems, as a source of data has increased [3]. EMR data can be broadly categorized into structured and unstructured formats. Unstructured data include electronic health records, free-text narratives, and test reports (eg, radiation reports), which often contain key clinical details such as patient symptoms, treatment intent, and symptom outcomes. Information on the effectiveness and safety of cancer treatments is typically embedded in these unstructured data sources. However, the unstructured nature of these records presents challenges for the immediate and accurate extraction of relevant information. Natural language processing techniques offer potential for extracting symptom-related data from unstructured EHR free-text narratives [4]. Furthermore, integrating structured and unstructured data (eg, medical records and radiological reports) may enhance the evaluation of safety information and aid in identifying initial symptoms or other critical clinical information [5].

Lung cancer is reported to have the highest incidence and mortality among various cancer types worldwide [6]. The treatment strategy for lung cancer depends on the histological subtype, stage, and oncogenic driver mutations or alterations; systematic treatment (ie, medication) is recommended for advanced or metastatic lung cancer [7-12]; its efficacy has been improved by immune checkpoint inhibitors [13-18], and personalized medicine for lung cancer has advanced with the advent of targeted therapies for driver mutations and companion diagnostics [19-25] in the past decade. However, these treatments have been reported to induce interstitial lung disease (ILD) as a toxic effect in 1.6% - 5% patients [26,27]. ILD not only makes it difficult to continue treatment but also results in respiratory failure or death, especially in patients with pulmonary fibrosis [28]. Hence, establishing risk factors and prodromal symptoms is crucial. Patient selection or early intervention can help prevent the worsening of ILD, thereby contributing to improved patient prognosis and quality of life. Although Krebs von den Lungen-6 (KL-6) [29] and surfactant protein D (SP-D) [30] are important diagnostic biomarkers of ILD, there is no established biomarker for predicting ILD onset [31,32]. Additionally, conducting diagnostic examinations, such as blood tests or diagnostic modalities like computed tomography, frequently for the sole purpose of ILD risk assessment is not reasonable in terms of cost-effectiveness or radiation exposure. Age, preexisting lung disease, preexisting ILD, idiopathic pulmonary fibrosis, smoking, drug dosage, and poor performance status have been reported as risk factors for drug-induced ILD in systematic reviews [33]; however, time-dependent risk factors have not been sufficiently investigated. Another study has reported the initiation of clinical trials to construct onset-prediction models using wearable devices [34]; nevertheless, a solid model has not yet been established. Thus, a novel time-dependent approach is warranted for information on ILD onset, and extracting symptoms from free-text narratives of electronic health records [4] can provide insights into ILD development in real-world settings; to the best of our knowledge, such an approach has not been previously reported. Therefore, we conducted an exploratory study using the EMR in a hospital information system to identify associated factors and prodromal symptoms of ILD onset, mainly focusing on the preceding period of ILD development.

Methods

Study Design

This was an exploratory observational study that used anonymized medical records from the National Cancer Center Hospital in Japan for secondary use. Patients diagnosed with stage IV lung cancer between November 2011 and December 2018 who provided comprehensive informed consent regarding registration in the biobank [35] were eligible for the study. We excluded patients who were enrolled in clinical trials between November 2011 and December 2019, those who had a disease that fewer than 10 patients had in the anonymized database, and those who explicitly refused to participate in the study after being informed about the study's details and their option to opt-out (Textbox 1).

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria and definition of patient sets.

Inclusion criteria

Diagnosis of Stage IV lung cancer from November 2011 to December 2018 (to enable a 1-year follow-up period before the end of the extraction period)

Comprehensive informed consent for the biobank

Exclusion criteria

Enrollment in clinical trials from November 2011 to December 2019

Disease that fewer than 10 patients had in the anonymized database

Patients explicitly refused to participate in the study based on the contents of the study disclosed for opt-out

Patient set definition

Common algorithm

ICD10 code of C34 (malignant neoplasm of bronchus and lung)

Exclude patients with any of the following documentation within 30 days from the first visit

Abnormal laboratory test result (KL-6>500 U mL^{-1} or surfactant protein D [SP-D]>110 ng mL^{-1}

Interstitial lung disease (ILD)-related documentation (diagnosis of ILD or ILD-related irregular findings in radiation reports)

ILD Set

Patients with any of the following documentation after 30 days from the first visit.

Abnormal laboratory test result (KL-6>500 U mL^{-1} or SP-D>110 ng mL^{-1})

ILD-related documentation (diagnosis of ILD or ILD-related irregular findings in radiation reports)

ILD With the Glucocorticoid Treatment Set

Patients with all of the following documentation:

All of the following documentation within 7 days

Abnormal laboratory test result (KL-6>500 U mL^{-1} or SP-D>110 ng mL^{-1})

ILD-related documentation (diagnosis of ILD or ILD-related irregular findings in radiation reports)

Glucocorticoid therapy (including steroid pulse therapy) within 7 days after the ILD onset

No ILD Set

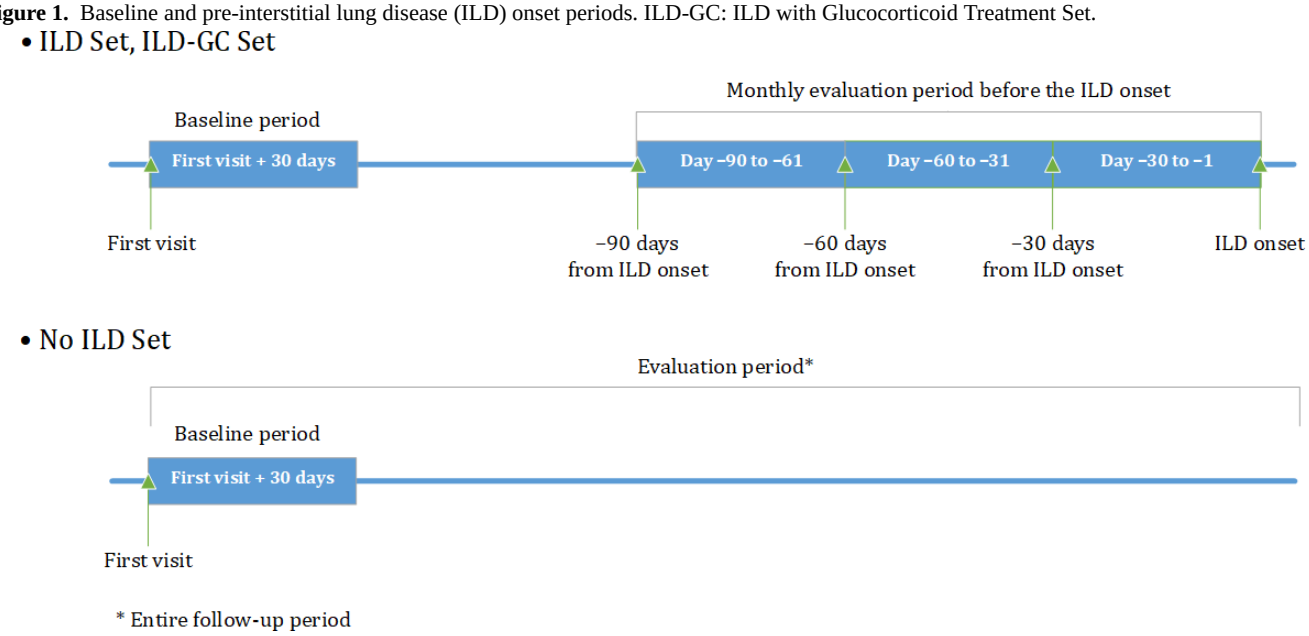
Patients without any of the following documentation:

Abnormal laboratory test result (KL-6>500 U mL^{-1} or SP-D>110 ng mL^{-1})

ILD-related documentation (diagnosis of ILD or ILD-related irregular findings in radiation reports)

Data Collection

Patients diagnosed with stage IV lung cancer until December 2018 who provided comprehensive informed consent for biobank participation were included. Data from November 2011 to December 2019 were extracted. Algorithms to identify the ILDs based on the radiation reports and laboratory test results were used because identification using only recorded disease names may result in the misidentification of diagnosis and its development date (eg, it may include ILD initially developed in former hospitals or differences between the development date and the diagnosis date). ICD-10 code C34 was used to identify patients with lung cancer. The ILD Set, ILD with Glucocorticoid Treatment Set (ILD-GC Set), and No ILD Set were defined using the following algorithms. Patients with documentation of an abnormal laboratory test result or ILD-related documentation in the radiation reports within 30 days of the first visit were excluded from each analysis set because the duration was insufficient to evaluate early symptoms. The ILD Set was defined as patients with an abnormal laboratory test result (KL-6>500 U mL^{-1} or SP-D>110 ng mL^{-1}), or ILD-related documentation (diagnosis of ILD or ILD-related abnormal findings) in the radiation reports 30 days after the first visit. To focus on patients who reliably developed ILDs, the ILD-GC Set was defined as patients with an abnormal laboratory test result and ILD-related documentation in the radiation reports within 7 days and who received a glucocorticoid therapy (including steroid pulse therapy) within 7 days after the onset of ILD. Glucocorticoid therapies used as supportive care for anticancer therapy were excluded from the analysis. The No ILD Set was defined as patients without an abnormal laboratory test result or ILD-related documentation in the radiation reports. The ILD onset date was defined as the earliest date of documented abnormal laboratory test results or ILD-related documentation in the radiation reports in the ILD Set, and the earliest date of documented abnormal laboratory test results and ILD-related documentation in the radiation reports within 7



XSL•FO
RenderX

days in the ILD-GC Set. ILD-related findings were documented as follows: interstitial pneumonia, traction bronchiectasis, reticular abnormalities, diffuse involvement, and ground-glass opacity [36].

Outcome Measures

The primary endpoint was the frequency of words in the medical charts in Japanese. Word frequencies were calculated by writers (physicians or nurses), time windows, and patient sets. Only nouns from notes in the Problem, Subjective, Objective, or Assessment sections of the Problem-Oriented System/Subjective, Objective, Assessment, and Plan format were included in the frequency calculation (the Plan section was not used). The difference in word frequencies between the ILD, ILD-GC, and No ILD Sets was calculated to evaluate the distinctive words seen in patients who developed ILD. Age, sex, height, and weight were collected as baseline characteristics. To evaluate the potential detection ability and presentation timing of irregular values for ILD, temporal trends of laboratory test results (white blood cell count, platelet count, neutrophil count or percent, hemoglobin, alanine transaminase, aspartate transaminase, serum bilirubin, gamma-glutamyl transferase, serum creatinine, free thyroxine, thyrotropin, KL-6, SP-D, and C-reactive protein [CRP] levels) were evaluated using time windows. The laboratory results closest to ILD onset or the date of the first visit were used as representative values. To investigate drugs potentially associated with ILD induction, the temporal administration status of anticancer medications was described using time windows before ILD onset. The time windows were divided into 2 categories: baseline (background information from the first visit date to 30 d after) and monthly intervals before the onset of ILD (days –1 to –30, –31 to –60, and –61 to –90). These intervals were based on the typical 3 - to 4-week cycle of lung cancer regimens. The frequency of words in the No ILD Set was calculated during the entire follow-up period as a control that reflected the trend, regardless of specific periods, after the first visit date (Figure 1).

Figure 1. Baseline and pre-interstitial lung disease (ILD) onset periods. ILD-GC: ILD with Glucocorticoid Treatment Set.

Data Processing

The EMR database from the National Cancer Center, Japan, including information on medical charts, radiation reports, medications, and laboratory test results, was anonymized before analyses by using rule-based processing with regular expressions. These anonymization techniques were applied to mask patient identifiers, names, facility information, addresses, and phone numbers, following methodologies described previously [37,38]. Because data were generated from a single hospital, there was no linkage. Because there is insufficient research on associated factors and prodromal symptoms of ILD onset, we began by analyzing traditional word frequencies to understand the actual situation.

No large language models (LLMs) were used in this study. While LLMs have recently been utilized for the extraction of data, such as that on cancer progression events from EMR [39], to our knowledge, there are no established models suitable for the task aligned with this study's objective of exploring a wide range of undefined prodromal symptoms and risk factors for ILD. Furthermore, traditional word-frequency analysis is based on the direct tabulation of word occurrences, providing transparency in the derivation process and allowing for an intuitive interpretation of results. Because Japanese is an unsegmented language (ie, words are not separated with spaces or other letters in sentences), free text from medical charts was processed using the morphological analysis method to extract words related to symptoms or treatments. This natural language processing approach produces segmented words from non-space-delimited sentences, which was performed using a Japanese morphological analysis tool, Mecab (version 0.966 [32 bit]; Taku Kudo) [40]. ComeJisyo (version Utf8-3) [41], a Japanese practical medical terminology dictionary, was specified as the user dictionary for Mecab to enable the extraction of words with consideration for medical information. Nouns from the output results of Mecab's morphological analysis were treated as target words for aggregation. Words with no medical meaning or interpretation (eg, symbols, numbers, or units) were

XSL•FO
RenderX

excluded. As sentences in past notes were copied and reused repeatedly, the same descriptions in the same patient's past notes were excluded by sentence unit to analyze only newly added descriptions.

The words with a larger difference in frequency in the ILD or ILD-GC Set were classified into term categories in a post hoc manner to facilitate interpretation, to correct for fluctuations in descriptions, and to organize words with the same meaning or background. The words related to symptoms were classified with reference to the Patient Expression Dictionary [42] and clinical perspective. The words related to medicine for the same treatment purpose were classified with reference to the standardized drug groupings in the WHO Drug Dictionary [43]. The categories of pain-related and analgesic medications were defined as N02 and M02 of the ATC classifications in the WHO Drug Dictionary, respectively. At least 1 author implemented the classification of words into the categories, and other authors reviewed and confirmed its validity. This classification work was conducted entirely in Japanese and subsequently translated into English. For the English translation of symptoms, we utilized Medical Dictionary for Regulatory Activities (MedDRA) version 27.1, a medical terminology dictionary developed by the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use [44]. For pharmaceutical product names (brand names), we employed the English names as documented in the package inserts, while generic drug names were directly translated into their English equivalents.

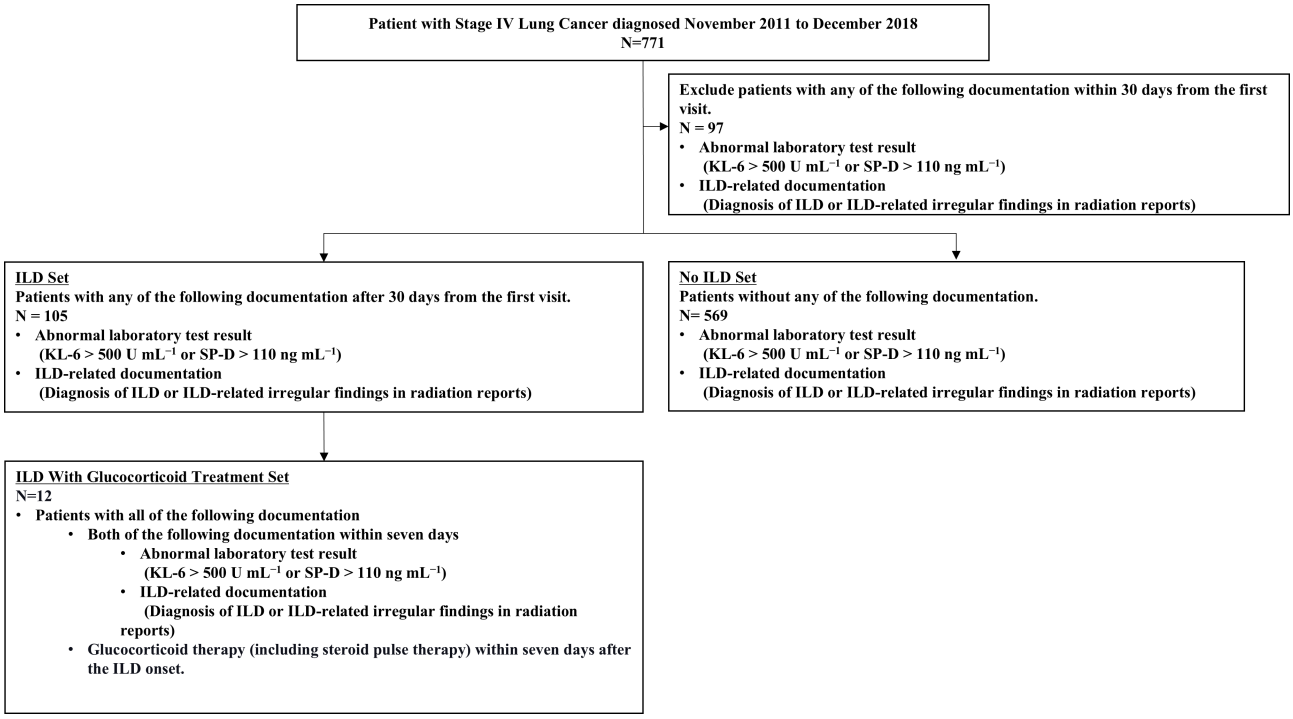
Ethical Considerations

This study was conducted in accordance with the Ethical Guidelines for Medical and Health Research Involving Human Subjects [45,46]. This study was approved by the ethics committee registered with the Ministry of Health, Labour and Welfare (Registration No. 11000489). The approval of the ethical committee covered this secondary analysis study without the requirement for additional consent [1]. The opportunity to opt out was provided to patients, along with publicly disclosed information about the research implementation, in accordance with guidelines. This approach was taken as this study did not involve invasive procedures or interventions and used only information, including the results of examinations that already existed prior to the preparation of the research protocol. The disclosed information included the significance, purpose, and methodology of the research; the name of the research institution; and contact information for inquiries and complaints. This study utilized anonymized medical records from the National Cancer Center Hospital, and patient anonymity and confidentiality were strictly maintained. No compensation was provided, as this study was a secondary analysis utilizing existing data. The data are not publicly available, and approvals are required to access the EHR database.

Statistical Analysis

As this exploratory study used an existing database for secondary use, sample size calculations based on formal statistical tests were not implemented. We included all registered patients who met the eligibility criteria in the existing database. Word frequencies were calculated as the total appearance per 1000 notes. The difference in frequency in the ILD or ILD-GC Sets compared to the No ILD Set was described (the specific calculation formula is presented in Supplementary Material 1 in Multimedia Appendix 1).

Descriptive analyses of continuous variables were performed using the mean, median, standard deviation, minimum, 25th percentile, 75th percentile, and maximum. Imputation methods for missing values were not implemented. The results of laboratory tests were aggregated without missing data. Word frequencies were counted if the word existed in the notes. All statistical analyses were performed using Python (version 3.7.6; Python Software Foundation) or R (version 3.6.1; R Foundation for Statistical Computing).



Results

Participants

Between November 2011 and December 2018, 771 patients were diagnosed with stage IV lung cancer and met the inclusion criteria. Of these, 97 patients had abnormal laboratory test results or ILD-related documentation in the radiation reports within 30 days of their first visit and were excluded from the analysis set. The ILD, ILD-GC, and No ILD Sets included 105, 12, and 569 patients, respectively (Figure 2).

XSL•FO
RenderX

Figure 2. Flow diagram of analysis sets. ILD: interstitial lung disease; KL-6: Krebs von den Lungen-6; SP-D: surfactant protein D.

Descriptive Data Analysis

Baseline Characteristics

There were no apparent differences between the ILD, ILD-GC, and No ILD Sets. The mean age (SD) was 62.8 (11.7), 66.6 (7.4), and 65.2 (12.3) years, respectively. The proportions of male patients were as follows: 60.0% (63/105) in the ILD Set, 66.7% (8/12) in the ILD-GC Set, and 61.2% (348/569) in the No ILD Set (Table 1).

Table . Baseline characteristics of the patients.

Characteristic	ILD Set (N=105)	ILD-GC Set[a] (N=12)	No ILD[b] Set (N=569)
Age, years, mean (SD)	62.8 (11.7)	66.6 (7.4)	65.2 (12.3)
Sex, n (%)			
Male	63 (60.0)	8 (66.7)	348 (61.2)
Female	42 (40.0)	4 (33.3)	221 (38.8)
Height, cm, mean (SD)	161.8 (8.0)	162.1 (9.0)	162.1 (11.8)
Weight, kg, mean (SD)	55.7 (14.4)	55.7 (23.7)	55.1 (11.6)

[a]ILD-GC Set: ILD With Glucocorticoid Treatment Set.

[b]ILD: interstitial lung disease.

Frequency of Words in the Medical Charts in Japanese

To understand the trend of symptoms recorded before ILD onset, we focused on words with higher word frequencies in the ILD and ILD-GC Sets compared to non-ILD cases immediately before ILD onset (days –30 to –1). Words recorded for only 1 patient were excluded as they might have been used specifically for the patient. Descriptions related to units or alphanumeric characters without a clear medical significance were also excluded.

Tables 2 and 3 summarize the top 50 words with the highest word frequencies by physicians and nurses, respectively, in the ILD-GC Set immediately before ILD onset (days –30 to –1). Words with negative frequency values appear less frequently in the ILD-GC Set or ILD Set than in the No-ILD Set. The words were classified into term categories to facilitate interpretation (Table 4).

XSL•FO
RenderX

Among the words with increased word frequencies by physicians in the ILD-GC Set immediately before ILD onset (days –30 to –1), those related to symptoms or medication names were Lyrica (product name of pregabalin), Pain, Sleepiness, Breathlessness, Soreness, Anxiety, NRS, Anemia, Oxycodone, Delirium, Bleeding, Skin eruption, Ache, O_2, and OxyContin (product name of oxycodone).

Among the words with increased word frequencies by nurses in the ILD-GC Set immediately before ILD onset (days –30 to –1), those related to symptoms or medication names were Pain, OxyContin (product name of oxycodone), NRS, Oxinorm (product name of oxycodone), Opioid, Breathlessness, Inappetence, Soreness, Anxiety, Novamin (product name of prochlorperazine), Shortness of breath, OxyContin-increased, Pain-precordial, Feeling queasy, Oxycodone, O_2, and Food-intake.

In the ILD Set, similar to the ILD-GC Set, words related to symptoms or medication names with increased word frequencies by physicians immediately before ILD onset (days −30 to −1) were as follows: O_2, Lyrica (product name of pregabalin), Pain, Sleepiness, Breathlessness, Soreness, NRS, Anemia, Oxycodone, and Delirium. Other words related to symptoms or medication names with increased word frequencies included Fever, BP, RT, Tenderness, Opso (product name of morphine), ERCP, Stomatitis, Metastasis, and Exacerbation (Table S1 in Multimedia Appendix 1).

In the ILD Set, similar to that in the ILD-GC Set, words related to symptoms or medication names with increased word frequencies by nurses immediately before ILD onset (days -30 to -1) were OxyContin (product name of oxycodone), NRS, Opioid, Breathlessness, Soreness, Novamin (product name of prochlorperazine), Shortness of breath, and Oxycodone. Other words related to symptoms or medication names with increased word frequencies were Stomatitis, Fever, Sleepiness, Edema, Pneumonia, Right precordial, Dizziness/Vertigo, and Dyspnea (Table S2 in Multimedia Appendix 1).

In the ILD-GC Set, for words related to symptoms or medication names that showed increased word frequencies by physicians immediately before ILD onset (days –30 to –1), the number of patients with these words documented increased (Table S3 in Multimedia Appendix 1). Similarly, for words related to symptoms or medication names that showed increased word frequencies by nurses immediately before ILD onset (days –30 to −1), the number of patients with these words documented increased (Table S4 in Multimedia Appendix 1). As with the ILD-GC Set, in the ILD Set, words related to symptoms or medication names that showed increased word frequencies by physicians or nurses immediately before ILD onset (days –30 to −1) also showed an increase in the number of patients with these words documented (Tables S5 and S6 in Multimedia Appendix 1). A corresponding table of terms used in the Japanese medical charts and their English translations is presented as Table S7 in Multimedia Appendix 1.

Term Categories and Their Constituent Words

We focused on the top 50 words with higher word frequencies by physicians or nurses in the ILD-GC Set compared to the non-ILD Set during the period immediately preceding ILD onset (days –1 to –30) (Table 4).

Temporal Trends in the Laboratory Test Results

Trends in CRP, KL-6, and SP-D levels, which are known to be particularly elevated with the onset of ILD, are shown in Table 5. No other clinical laboratory tests showed explicit changes before ILD onset.

In both ILD-GC and ILD Sets, the mean CRP values increased toward the date of ILD onset. However, in the ILD Set, the median remained at 0.9 from days −30 to −1, confirming that the CRP levels did not clearly increase in more than half of the patients. In contrast, in the ILD-GC Set, the median increased to 8.2 from days −30 to −1.

[a]ILD: interstitial lung disease.

[b]ILD-GC Set: ILD with Glucocorticoid Treatment Set.

[c]Monthly periods before the onset of ILD.

[d]CRP: C-reactive protein.

[e]Number of patients who had a laboratory test result.

[f]—: not applicable.

[g]KL-6: Krebs von den Lungen-6.

[h]SP-D: surfactant protein D.

KL-6 and SP-D

For both KL-6 and SP-D, only a few cases had test values measured consistently from days −90 to −61, −60 to −31, and −30 to −1, making it difficult to observe trends in the population. The aggregated values alone did not show any particular upward trend.

Administration Status of Anticancer Medications

The administration status of the anticancer medications is presented in Table 6. The period until ILD onset was divided into 30-day intervals, and the anticancer medications administered during each period were categorized by their mechanism of action and aggregated. If the same patient received different categories of anticancer medications during the same period, each category was counted as 1 case. If multiple anticancer medications were used concurrently within the same category, they were counted as 1 case.

None	47 (44.8)	33 (31.4)	32 (30.5)	5 (41.7)	4 (33.3)	3 (25)

[a]ILD: interstitial lung disease.

[b]ILD-GC Set: ILD with Glucocorticoid Treatment Set.

[c]Monthly periods before the onset of ILD.

[d]Programmed cell death protein 1 inhibitors: pembrolizumab and nivolumab.

[e]Programmed death-ligand 1 inhibitors: atezolizumab.

[f]Epidermal growth factor receptor tyrosine kinase inhibitors: afatinib, osimertinib, gefitinib, and erlotinib.

[g]Anaplastic lymphoma kinase tyrosine kinase inhibitors: ceritinib, crizotinib, lorlatinib, and alectinib.

[h]Vascular endothelial growth factor inhibitors: bevacizumab.

[i]Cytotoxic agents: gemcitabine, amrubicin, docetaxel, paclitaxel, cisplatin, pemetrexed, irinotecan, carboplatin, and etoposide.

In the ILD-GC Set, the categories of anticancer medications administered from 30 days before to the day before ILD onset were as follows: programmed cell death protein 1 (PD-1) inhibitors (3 cases), epidermal growth factor receptor tyrosine kinase inhibitors (EGFR-TKIs) (2 cases), anaplastic lymphoma kinase tyrosine kinase inhibitors (ALK-TKIs) (1 case), and cytotoxic agents (4 cases). In total, 3 patients did not receive any anticancer medications. On the other hand, in the ILD Set, these categories were as follows: PD-1 inhibitors (8 cases), programmed death-ligand 1 inhibitors (1 case), EGFR-TKIs (21 cases), ALK-TKIs (8 cases), vascular endothelial growth factor inhibitors (4 cases), and cytotoxic agents (34 cases). A total of 32 patients did not receive any anticancer medications.

Discussion

Principal Results

We explored the associated factors and early symptoms of ILD using articles, records, and various examination reports stored in the hospital information system of a specialized hospital for acute care and treatment of malignant tumors. We used algorithms to identify patient sets of ILD development and the treatment status based on radiation reports and laboratory test results because identification using only recorded disease names may result in the misidentification of diagnosis and its development date. In the ILD Set, the CRP levels increased; however, in the ILD-GC Set, the CRP levels showed a more pronounced increase as the time window approached the onset of ILD, suggesting that the onset of ILD was more accurately captured. Furthermore, the overall incidence in the population was consistent with that observed in typical clinical settings. Hence, we mainly focused on the ILD-GC set, which is also important in severity.

Based on these results, we identified words with differences in word frequencies between the ILD-GC and No ILD Sets. As the words used varied depending on the writers (physicians or nurses), we organized words with the same meaning or background into terms before making comparisons. In the ILD-GC Set, within the time window immediately before the ILD onset date (days −1 to −30), there was a tendency for higher word frequencies of terms related to respiratory symptoms (Breathlessness, Shortness of breath, O_2), Pain or Analgesics (Soreness, Ache, Pain, Pain-precordial, NRS, Lyrica [product name of pregabalin], Opioid, Oxinorm [product name of oxycodone], OxyContin [product name of oxycodone], OxyContin-increased, Oxycodone), and appetite (Inappetence, Food-intake, Feeling-queasy, Novamin [product name of prochlorperazine]).

The values of KL-6 and SP-D did not show abnormal levels (KL-6>500 U mL^{-1}, SP-D>110 ng mL^{-1}) or an increasing trend in the time window immediately before the ILD onset date (days –1 to −30). This can be interpreted to be caused by the same cut-off that was used for the abnormal values used in the patient-set identification algorithm by ILD development and treatment status. Hence, there was no impact on the diagnostic utility of KL-6 and SP-D. Additionally, there were many missing values in the test results, making it difficult to evaluate their trend. These missing values could be attributed to the fact that these tests were only performed when physicians suspected ILD and were not conducted in the absence of such suspicion. Some of the patients used anticancer drugs before the ILD onset date (days −1 to −30). PD-1 inhibitors, EGFR-TKIs, and ALK-TKIs

XSL•FO
RenderX

are anticancer drugs that can cause ILD, which is consistent with previous reports [26,27]. In the ILD-GC Set, no words related to anticancer drug administration were identified among those with an increasing trend in the time window immediately before the ILD onset date (days −1 to −30). Words such as "reduction" and "discontinuation" were observed to have increased frequencies in physician documentation immediately before the ILD onset (d −30 to −1). Words such as "increase" and "administration" showed increased frequency in nursing documentation. However, owing to variations in anticancer drugs administered to different patients and insufficient sample size, it was not possible to identify definitive trends.

Comparison With Prior Work

The word with the largest difference in the word frequency in the physicians' notes was the brand name of pregabalin (Lyrica). Systematic reviews of pregabalin do not explicitly indicate a risk of ILD [47]. In contrast, an analysis using a spontaneous reporting database in Japan [48] reported a high odds ratio for interstitial pneumonia. Ethnic differences exist in the occurrence of drug-induced ILD; for example, gefitinib-induced ILD has a relatively high incidence in Japanese patients [49]. Although the absolute number of adverse events associated with pregabalin is small, there may be ethnic differences, making it easier to detect pregabalin as a risk factor than in other regions. Therefore, pregabalin may be considered a candidate risk factor for ILD. In hospitals, indirect factors for ILD onset can be discovered by examining the factors that lead to pregabalin use. Other neuropathic pain medications, such as mirogabalin, were not included in the analyzed data; therefore, they were not evaluated.

Poor performance status (PS) is known as a risk factor for interstitial pneumonia [50,51]. In our study, the PS score itself was not available from the dataset, and thus, we could not directly verify the relationship between the ILD onset and the poor PS score before the onset of ILD. On the other hand, the difference in word ratio for words included in respiratory symptom-related terms immediately before the onset date (days −1 to −30) was 170.59-46.51 in the physicians' notes (170.59-46.51 more occurrences per 1000 articles compared to non-ILD cases) and 130.25-52.71 in the nurses' notes.

Furthermore, among the words included in the pain- or analgesic-related terms, the difference in word ratio immediately before the onset date (days −1 to −30) was 209.76-45.16 in the physicians' notes and 462.88-53.06 in the nurses' notes. The group of terms associated with poor PS and palliative care consultation suggests local or systemic progression of lung cancer, which can be interpreted as approaching the end-of-life stage and considered consistent with the general clinical course.

There are reports that 72% - 83% of patients who actually received palliative care had a PS score of 2 or higher [52,53]. One reason for the lack of difference in the word frequency of PS itself may be that PS is an evaluation item, and the current word extraction method may not have been able to evaluate the actual score recording. Although PS is commonly used in clinical trials, respiratory symptom-related and pain- or analgesic-related terms indicate more specific patient conditions. We believe that future research can establish these as reliable risk factors for ILD, which can be useful for the prediction and early diagnosis of ILD in patients with stage IV lung cancer. Although respiratory symptoms and cancer pain change during the course of treatment, these symptoms are considered associated factors.

In the ILD-GC Set, respiratory symptom−related and appetite-related terms were more frequent immediately before the ILD onset date (days −1 to −30) compared to the No ILD Set, suggesting them as potential prodromal symptoms. Although respiratory symptom−related terms can be the initial symptoms of ILD, they may also indicate the disease progression of lung cancer itself. Rather than prodromal symptoms, they were considered associated factors.

Appetite-related words were documented more frequently by nurses. These were also considered more appropriate as risk factors rather than prodromal symptoms, as they likely reflect the deterioration of respiratory conditions or the side effects of anticancer drugs.

Delirium is known to be associated with the worsening of symptoms in patients living with cancer [54] or with the administration of anticancer drugs [55]. It can be considered an associated factor candidate, as it occurs more frequently in the period immediately preceding the ILD onset date (days −1 to −30) than in the No ILD Set. Moreover, sleepiness is thought to be a side effect of opioid administration (such as oxycodone and OxyContin) for cancer pain [56], and it indicates worsening of symptoms in patients with cancer. These can also be considered associated factors.

Although skin eruptions can be considered side effects of anticancer drugs [57], no words related to skin abnormalities other than "skin eruption," such as rashes or skin, appeared. The fact that a rash appears alone suggests that there is no clear trend in skin abnormalities, and it may be a prodromal symptom or risk factor for ILD. However, there are limitations in its interpretation.

Both anemia and bleeding are known symptoms in patients with cancer [58,59] or side effects of anticancer drugs [59,60]. These words also represent the worsening of symptoms in patients with cancer. Since they are more frequent in the period immediately before ILD onset (days −1 to −30) compared to the No ILD Set, they can be considered associated factors.

Words such as "relief," "decrease," and "worsening" that supplement symptoms were not considered standalone words because they are used in combination with symptoms. "Residual" and "reduction" are considered to be words related to anticancer drug administration; however, they were excluded from consideration as standalone words because they could potentially be used in other contexts as well.

In this study, we were able to identify the risk factors for ILD onset, including a history of pregabalin use, respiratory symptom-related terms, and pain- or analgesic-related terms. On the other hand, we found that other terms (such as those that only express trends, eg, "relief," "decrease," or "worsening," or those that only describe states, eg, "residual" or "reduction," which are difficult to interpret as clear events on their own) did not reveal any noteworthy words. We suggest that there is a

XSL•FO
RenderX

possibility of finding certain trends within free descriptions in EMRs, free-text narratives, and test result reports.

For words related to symptoms or medication names that showed increased word frequencies immediately before ILD onset (d −30 to −1) in either the ILD-GC Set or ILD Set, we confirmed an increase in the number of patients with these words documented, similar to the increase in word frequencies. Thus, the increased word frequency was not dependent on individual patients but rather the documentation rates of these words increased across multiple patients. This indicates that the words identified in this study may be candidates for prodromal symptoms or risk factors for ILD.

In this study, we analyzed free text from medical records using morphological analysis with Mecab and ComeJisyo. Because there is insufficient research on associated factors and prodromal symptoms of ILD onset, we began by analyzing traditional word frequencies to understand the actual situation. Although we identified words that had higher frequencies in the periods preceding ILD onset, we could not consider them with contextual interpretation. To resolve these limitations, we believe that in future studies, advanced LLMs could be a useful option for analyzing specific descriptions prior to onset with contextual interpretation.

Limitations

This study used the medical records from a single institution. Moreover, information on precise diagnoses of ILD was not available, and patients with a history of ILD or concurrent ILD at the time of initial consultation were possibly included. However, our algorithms to identify patient sets of ILD seem to mitigate misidentification from the tendency of CRP levels to elevate in periods near the onset of ILD, especially in the ILD-GC Set. Furthermore, there may have been cases in which ILD developed after discharge; however, we were unable to conduct a verification that included such occurrences.

The evaluation was conducted based on the difference in frequencies of word occurrence in this study. This indicator was not based on previous studies but was devised and applied to identify symptoms or treatments. It should be noted that this indicator cannot truly determine whether symptoms actually occurred prior to ILD onset. Because this indicator is simply based on written records, we believe that it is useful for identifying words that appear with a specific frequency in populations or periods of interest. Further research is needed to determine the actual sensitivity of this approach. Moreover, negation words for events often follow nouns and verbs in Japanese sentences; thus, the terms may be extracted even from entries confirming the absence of symptoms. Thus, this is not the result of interpreting the context per se, even if the impact of the words routinely written from the standard rule for medical records or templates is mitigated by using the difference in word frequency. This study examined the possibility of extracting words that contribute to the prediction of ILD onset without contextual interpretation. Furthermore, the difference in frequency based on the term categories was not implemented owing to the difficulty of the comprehensive classification of the large amount of free text with medical concepts; nonetheless, the differences were observed at the word unit. Lastly, this study was not a confirmatory study with hypothesis testing but instead was an exploratory study. The interpretations from this study should be validated in further studies.

Conclusions

In summary, we were able to identify respiratory symptom-related, pain- or analgesic-related, and appetite-related terms as associated factors for ILD using RWD from medical institutions providing acute treatment for malignant tumors. These results may be useful for the early detection of ILD in patients with stage IV lung cancer. We identified the potential of utilizing RWD to generate real-world evidence and its application in drug discovery and pharmaceutical development. The approach presented in this study suggests the possibility of identifying specific disease and risk factors leading to disease onset in a well-defined patient population.

Abstract

Background: Health care system–wide outcomes from routine treatment with erlotinib and gefitinib are incompletely understood.

Objective: The aim of the study is to describe the effectiveness of erlotinib and gefitinib during the first decade of their routine use for treating advanced epidermal growth factor receptor (*EGFR*) mutation-positive nonsquamous non–small cell lung cancer in the entire cohort of patients treated in Aotearoa New Zealand.

Methods: Patients were identified, and data collated from national pharmaceutical dispensing, cancer registration, and mortality registration electronic databases by deterministic data linkage using National Health Index numbers. Time-to-treatment discontinuation and overall survival were measured from the date of first dispensing of erlotinib or gefitinib and analyzed by Kaplan-Meier curves. Associations of treatment outcomes with baseline factors were evaluated using univariable and multivariable Cox regressions.

Results: Overall, 752 patients were included who started treatment with erlotinib (n=418) or gefitinib (n=334) before October 2020. Median time-to-treatment discontinuation was 11.6 (95% CI 10.8 - 12.4) months, and median overall survival was 20.1 (95% CI 18.1 - 21.6) months. Shorter time-to-treatment discontinuation was independently associated with high socioeconomic deprivation (hazard ratio [HR] 1.3, 95% CI 1.1 - 1.5 compared to the New Zealand Index of Deprivation 1 - 4 group), *EGFR* L858R mutations (HR 1.3, 95% CI 1.1 - 1.6 compared to exon 19 deletion), and distant disease at cancer diagnosis (HR 1.4, 95%

XSL•FO
RenderX

CI 1.2 - 1.7 compared to localized or regional disease). The same factors were independently associated with shorter overall survival. Outcome estimates and predictors remained unchanged in sensitivity analyses.

Conclusions: Outcomes from routine treatment with erlotinib and gefitinib in New Zealand patients with advanced *EGFR*-mutant nonsquamous non–small cell lung cancer are comparable with those reported in randomized trials and other health care system–wide retrospective cohort studies. Socioeconomic status, *EGFR* mutation subtype, and disease extent at cancer diagnosis were independent predictors of treatment outcomes in that setting.

KEYWORDS

non–small cell lung cancer; mutations; epidemiology; target therapy; retrospective cohort study

Introduction

Lung cancer is the most common cause of cancer death in the world today [1]. Most clinical presentations of lung cancer are nonsquamous non–small cell lung cancer (NSCLC) [2]. Epidermal growth factor receptor (*EGFR*)–mutant nonsquamous NSCLC was the first type of lung cancer identified with an oncogenic driver that could be directly targeted by drug treatment [3-5].

The treatment of advanced *EGFR*-mutant nonsquamous NSCLC has evolved rapidly following the results of randomized controlled trials demonstrating improved progression-free survival. Initial randomized controlled trials established the superiority of first-generation *EGFR* kinase inhibitors, erlotinib and gefitinib, over platinum-doublet chemotherapy [6-10]. Subsequent randomized controlled trials established the superiority of second- and third-generation *EGFR* kinase inhibitors, including afatinib, dacomitinib, osimertinib, aumolertinib, and lazertinib, over those first-generation inhibitors [11-15]. Other randomized controlled trials compared erlotinib or gefitinib given alone or in combination with bevacizumab, ramucirumab, or chemotherapy [16-20]. In the 15 aforementioned randomized controlled trials, a total of 2257 patients with advanced *EGFR*-mutant nonsquamous NSCLC were allocated erlotinib or gefitinib monotherapy in control or experimental treatment arms. In those erlotinib or gefitinib monotherapy treatment arms, median progression-free survival ranged from 8.0 to 13.3 months. These clinical trial data provide a point of reference against which real-world studies of outcomes from treatment with erlotinib or gefitinib can be compared.

To fully understand outcomes from treatment with erlotinib and gefitinib in the setting of routine care, large-scale observational studies are required in addition to the extensive data already available from randomized controlled trials. Randomized controlled trials may have overestimated the benefits [21], and underestimated the harms [22], associated with the routine use of erlotinib and gefitinib. Compared to participants in randomized controlled trials, patients presenting for routine treatment with erlotinib or gefitinib are older, are of non-Asian ethnicity, have more comorbidities, have poorer performance status, and more often have brain metastasis. Randomized controlled trials have not evaluated many factors potentially impacting treatment outcomes, such as socioeconomic status. To improve their generalizability and avoid bias, observational studies of real-world outcomes from treatment with erlotinib and gefitinib could include all patients treated within a whole health care system or nation rather than being limited to those from 1 or a few institutions. To aid comparisons to clinical trial data, those observational studies could evaluate progression-free survival or proxies of progression-free survival rather than just overall survival, which is strongly influenced by factors other than treatment with erlotinib or gefitinib.

Only since 2019 have large-scale nationwide or health care system–wide studies reported real-world outcomes from routine treatment with erlotinib and gefitinib in patients with advanced *EGFR*-mutant NSCLC from Canada [23], the United States [24], Taiwan [25,26], Poland [27], Finland [28], and the Netherlands [29,30]. Among those aforementioned studies, 5 studies [24-28] reported progression-free survival or proxies of progression-free survival, such as time-to-treatment failure. In those 5 studies, median progression-free survival or its proxy ranged from 9.7 to 13.1 months. These observational data provide a point of reference against which other real-world studies of outcomes from treatment with erlotinib or gefitinib can be compared.

Starting in 2010, erlotinib and gefitinib were introduced into routine use in Aotearoa New Zealand for treating advanced lung cancer. The overall *EGFR* mutation positivity among patients with nonsquamous NSCLC who were tested was 22.5% in New Zealand [31]. To date, the effectiveness of erlotinib and gefitinib in the general population of New Zealand patients with lung cancer has not been described. With this background, this study aimed to describe the effectiveness of erlotinib and gefitinib during the first decade of their routine use for the treatment of advanced *EGFR*-mutant nonsquamous NSCLC in the entire cohort of patients treated in New Zealand. The study also aimed to evaluate associations between baseline factors and the effectiveness of erlotinib and gefitinib in this real-world setting.

Methods

Study Design and Participants

This was a nationwide, population-based, observational, data-linkage, retrospective cohort study that analyzed routinely collected health and administrative electronic data. The study group was a whole-of-population sample comprising a single group of patients. Patients were eligible for inclusion if they (1) were diagnosed with *EGFR*-mutant lung cancer, (2) dispensed erlotinib or gefitinib first before October 1, 2020, and (3) followed thereafter until death or for at least 1 year. Patients were excluded from the study if they had (1) erlotinib dispensed before January 1, 2014, or gefitinib dispensed before August 1, 2012, when positive *EGFR* mutation test results became mandatory for state-subsidized treatment; (2) no notification of a diagnosis of nonsquamous NSCLC in the New Zealand Cancer Registry; or (3) an unactionable or unknown *EGFR* mutation subtype.

Setting

From 2010 to 2020, New Zealand had a resident population ranging from approximately 4.3 to 5.1 million people, comprising predominately New Zealand European (70%), Māori (17%), Asian (15%), and Pacific people (8%) [32] (the total percent is greater than 100 because some people have more than 1 self-reported ethnicity). New Zealand residents were eligible for state-funded health care, including state-subsidized prescription medicines. Starting in 2010, the *EGFR* kinase inhibitor drugs erlotinib and gefitinib were introduced into routine clinical use in New Zealand for lung cancer treatment [33]. From October 1, 2010, to December 31, 2013, erlotinib was state-funded as a second-line treatment for advanced NSCLC, initially without any requirement for *EGFR* mutation testing. From August 1, 2012, gefitinib was state-funded as a first-line treatment for advanced *EGFR*-mutant NSCLC in New Zealand. On May 1, 2013, the National Health Committee of the New Zealand Ministry of Health issued recommendations for *EGFR* mutation testing in New Zealand, including testing of all patients with nonsquamous NSCLC at diagnosis irrespective of stage as part of standard pathology processes. From January 1, 2014, state funding for erlotinib was restricted to treating advanced *EGFR*-mutant NSCLC in New Zealand. During the first decade of routine use of erlotinib and gefitinib for lung cancer treatment in New Zealand, from 2010 to 2020, no other *EGFR* kinase inhibitor drugs were state-funded for use in New Zealand. During the period of study, treatment with erlotinib or gefitinib was provided by 10 public hospitals, and *EGFR* mutation testing was provided by 3 pathology laboratories in New Zealand.

Ethical Considerations

Ethics approval for this study was obtained from the New Zealand Government Ministry of Health Northern B Health and Disability Ethics Committee (reference 13/NTB/165/AM02). As the research retrospectively analyzed routinely collected data and did not involve direct contact with patients, the participants were not able or required to give informed consent by the ethics committee or governance groups who approved the study. The study used the identifiable data, which were password-protected, stored on the secured University of Auckland managed drive, and only accessible to the research team. The study was registered (ACTRN12615000998549). A study protocol and results of a validation substudy have been published [34].

Data Sources

Patients were identified, and data collated from national electronic pharmaceutical dispensing (Pharmaceutical Information Database [PHARMs]), cancer registration (New Zealand Cancer Registry), and mortality registration (National Mortality Collection) databases. Individual-level data on eligible cohort patients were compiled from these national electronic health databases by deterministic data linkage using each patient's unique National Health Index number. Additional data on eligible cohort patients were sourced from regional laboratory test data repositories, databases, and clinical records to determine the *EGFR* mutation status. A validation substudy demonstrated the feasibility and validity of using these national electronic health databases as the main source of data for this study [34].

Outcomes

The primary effectiveness outcome for this analysis was time-to-treatment discontinuation. Prescribing guidelines [35,36] recommend continuing daily treatment with erlotinib or gefitinib until disease progression, as long as treatment is safe and tolerable. In an analysis of randomized clinical trials submitted to the Food and Drug Administration, time-to-treatment discontinuation correlated well (r=0.91) with progression-free survival for patients with advanced *EGFR*-mutant NSCLC treated with *EGFR* kinase inhibitor drugs [37]. Time-to-treatment discontinuation is also less affected by subsequent cancer treatments and other factors that impact overall survival. Time-to-treatment discontinuation thereby reflects the duration of benefit from treatment with erlotinib or gefitinib. Time-to-treatment discontinuation was defined as the duration between the dates of the first dispensing and the last treatment with erlotinib or gefitinib. The date of last treatment with erlotinib or gefitinib was calculated by adding the number of days erlotinib or gefitinib dispensed for at the last dispensing to the date of the last dispensing, except when death occurred before the calculated date of last treatment, in which case the date of last treatment was the date of death. The secondary effectiveness outcome for this analysis was overall survival, defined as the duration between the date of first dispensing of erlotinib or gefitinib and death from any cause. A validation substudy had demonstrated the feasibility and validity of these methodologies for determining the outcomes of this study [34].

Variables

Baseline variables used for patient characterization included age, sex, ethnicity, geographical region of residence, smoking status, performance status, diagnosis year, NSCLC morphology, basis of NSCLC diagnosis, disease extent at cancer diagnosis, socioeconomic deprivation, rurality, comorbidity, choice of erlotinib or gefitinib for initial treatment, and *EGFR* mutation subtype. Socioeconomic deprivation was determined by mapping domicile codes recorded in the New Zealand Cancer Registry

XSL•FO
RenderX

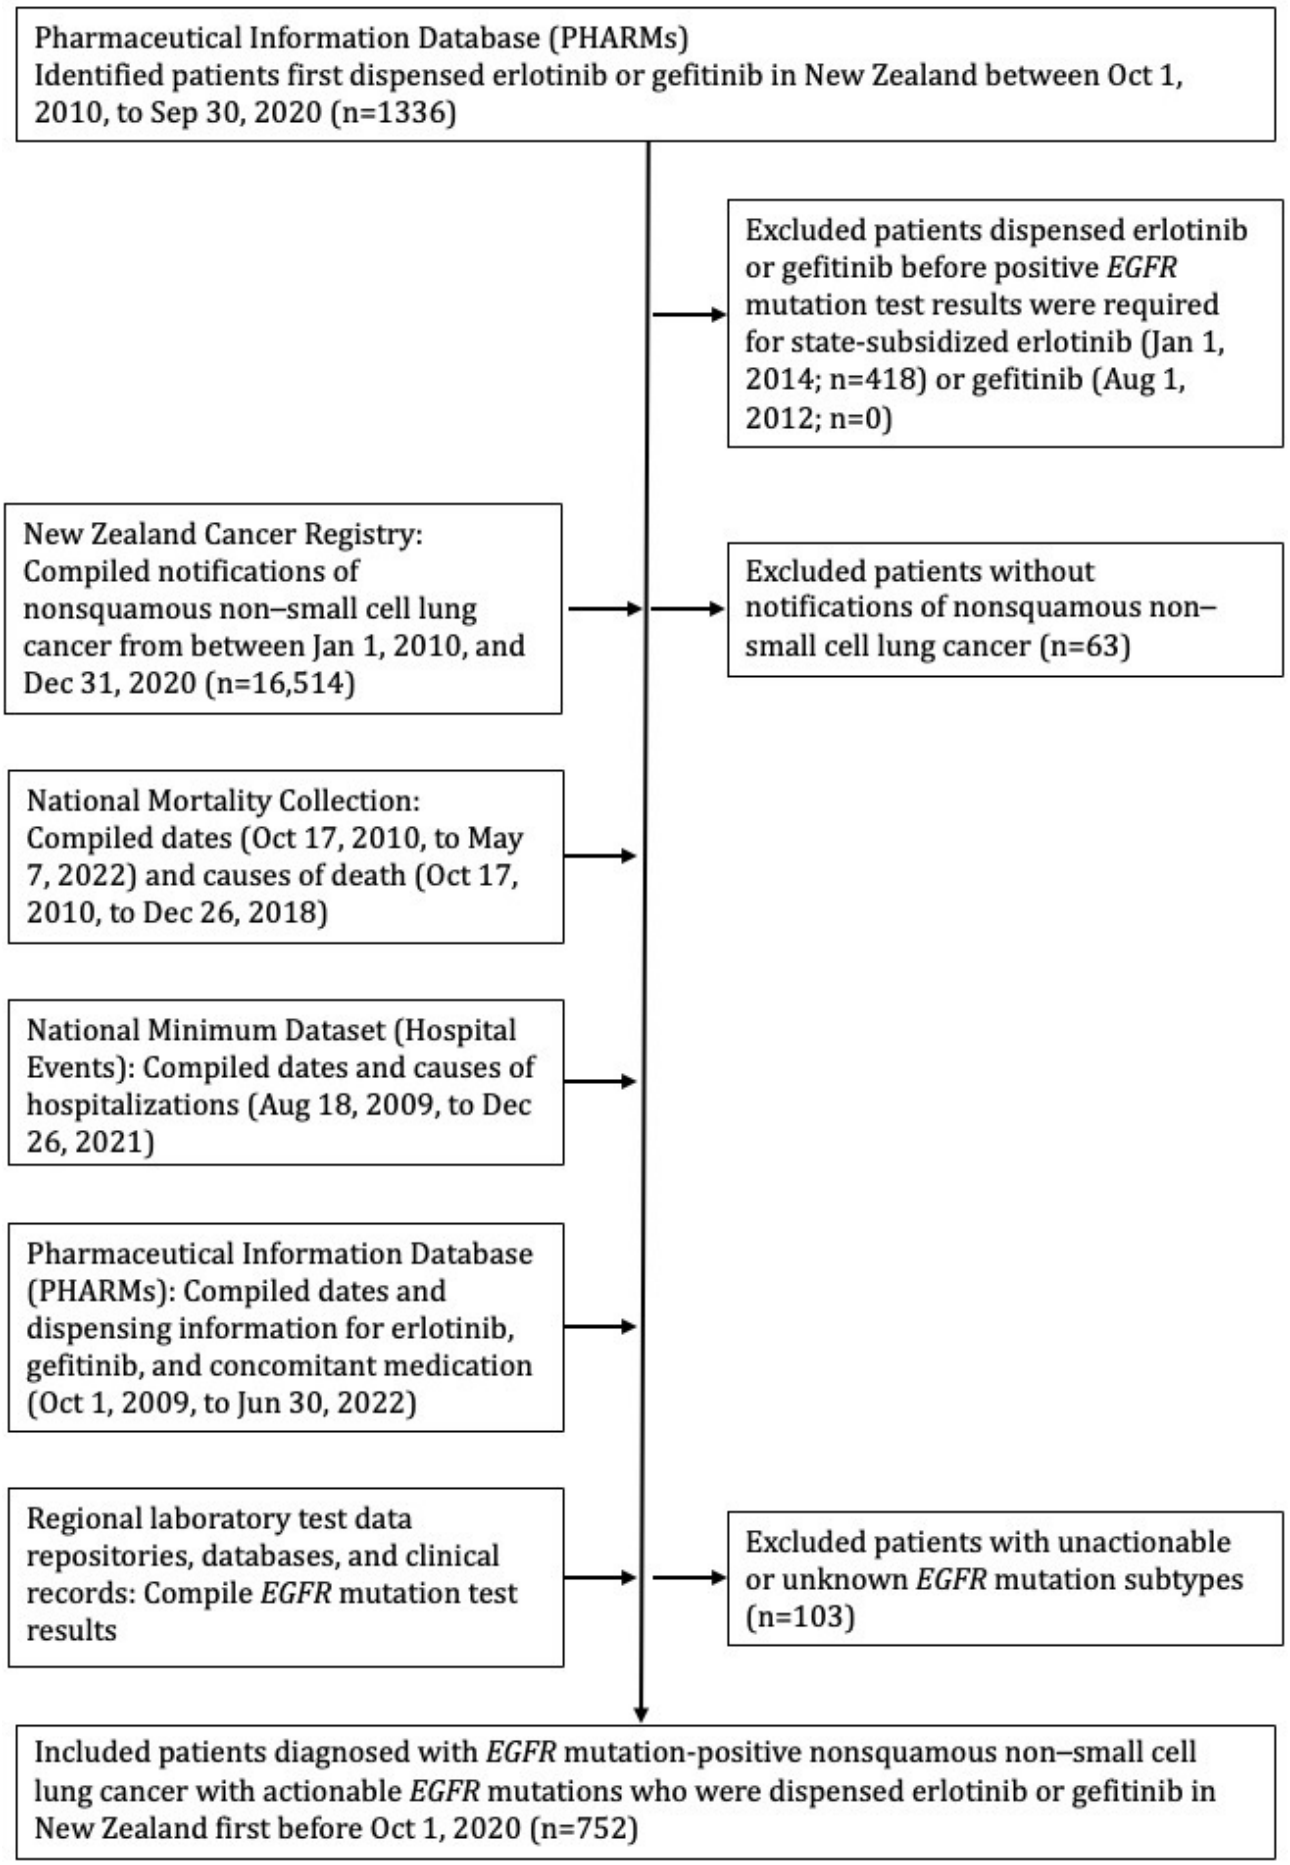
to the 2006 New Zealand Index of Deprivation and was categorized into deciles with 1 being the least deprived and 10 being the most deprived [38]. Rurality was determined using the same domicile codes applied to Statistics New Zealand's Urban/Rural profile [39]. Comorbidity was assessed using a validated pharmacy-based comorbidity index for patients with cancer [40], modified for this study as previously described [34]. Ethnicity was classified into Asian, Māori, New Zealand European, or Pacific, and prioritized ethnicity was used if a registration listed multiple ethnicities (patients with more than 1 recorded ethnicity were allocated to a single ethnic group in order of priority: Māori, Pacific, Asian, and New Zealand European) [41]. *EGFR* mutation variants were classified according to the system of Koopman et al [42] into the following categories: (1) exon 19 deletion, (2) L858R, (3) uncommon actionable variant, (4) exon 20 insertion, and (5) nonactionable or unknown variant. Since *EGFR* mutation variant categories (4) and (5) were unactionable with erlotinib or gefitinib, patients with those variants were excluded from this study. A validation substudy had demonstrated the feasibility and validity of the methodologies used for determining the variables used for this study [34].

Literature Search

For comparing the results from this study to those from randomized controlled trials and other retrospective observational studies, a literature search was undertaken using a combination of the following MeSH terms: "carcinoma, non-small-cell lung," "ErbB receptors," "erlotinib hydrochloride," "gefitinib," "protein kinase inhibitors," and "mutation." Observational studies were included in this comparison if they were nationwide or health care system–wide studies and reported progression-free survival, or a proxy of progression-free survival, measured from the commencement of treatment with erlotinib or gefitinib [24-28]. Institution-based studies [43] and those not reporting progression-free survival or a proxy of progression-free survival [23,29,30] were excluded from these comparisons.

Statistical Analysis

Descriptive statistics were used to analyze the demographic profile and baseline characteristics of the retrospective cohort. Time-to-treatment discontinuation and overall survival were analyzed by Kaplan-Meier curves, and survival differences between subgroups were assessed using log-rank tests. Patients with no known dates of last treatment or death were censored at the date of last follow-up of dispensing (June 30, 2022) or survival (May 7, 2022), respectively. To assess the robustness of estimates of time-to-treatment discontinuation and overall survival, sensitivity analyses were carried out in an expanded study cohort (n=885) that included patients with no registration of nonsquamous NSCLC and those with unknown or nonactionable *EGFR* mutation subtypes, except those with exon 20 insertions. Associations between baseline factors and time-to-treatment discontinuation or overall survival were evaluated by univariable and multivariable Cox regression models to compute hazard ratios and their 95% CIs and *P* values. Baseline factors selected for univariable and multivariable analyses included age, sex, disease morphology, disease extent, *EGFR* mutation subtype, and initial choice of *EGFR* kinase inhibitor drug, which had been identified as independent predictors of outcomes in previous studies [44,45], and ethnicity, comorbidity, socioeconomic deprivation, and residential status (urban vs or rural, and region), which had not been previously evaluated in the New Zealand patient population. There were complete data for all those factors for all 752 cohort patients. Smoking and Eastern Cooperative Oncology Group performance status were excluded from the univariable and multivariable analyses due to high levels of missing data (>50%). Missing extent of disease at cancer diagnosis and ethnicity data were included in univariable and multivariable analyses by adding an unknown category for each of these variables comprising <20% and <1% of patients, respectively. Otherwise, data were complete for all other factors for all 752 patients. Factors were selected for multivariable analyses if they had statistically significant associations with the outcome of interest on univariable analysis. To assess the robustness of the findings of multivariable analyses, sensitivity analyses were carried out using less stringent criteria for factor inclusion. Differences were considered statistically significant when *P* values were less than .05. Data analyses were performed using Stata (version 16; StataCorp LLC).



Results

The assembly of the retrospective cohort and compilation of study data from national electronic health databases was carried out as shown in Figure 1. From the PHARMs, 1336 patients were identified who had been dispensed erlotinib or gefitinib first between October 1, 2010, and September 30, 2020. A total of 418 of those patients were excluded because they were first dispensed erlotinib or gefitinib before positive *EGFR* mutation test results became mandatory for access to state-subsidized erlotinib or gefitinib in New Zealand, leaving 918 potentially eligible patients. From the New Zealand Cancer Registry, 16,516 patients were identified with notifications of nonsquamous NSCLC diagnoses made between January 1, 2010, and December 30, 2020. Of the 918 potentially eligible patients, 63 did not have notifications of diagnoses of nonsquamous NSCLC recorded in the New Zealand Cancer Registry and were excluded, leaving 855 potentially eligible patients. Dates and causes of death and hospitalizations and full dispensing information for erlotinib, gefitinib, and concomitant medications were compiled on those patients from the National Mortality Collection, National Minimum Dataset (Hospital Events), and PHARMs, respectively. *EGFR* mutation test results, smoking status, and Eastern Cooperative Oncology Group performance status were then compiled from regional laboratory test data repositories, databases, and clinical records. Of 855 potentially eligible patients, 103 patients had unactionable or unknown *EGFR* mutation variants, including 33 patients with *EGFR* exon 20 insertions, and were excluded. Finally, 752 patients remained, who had been diagnosed with *EGFR*-mutant nonsquamous NSCLC with actionable *EGFR* mutation variants, and had started treatment with erlotinib or gefitinib prior to October 2020 for inclusion in this study.

The baseline characteristics of the retrospective 752 patient cohorts are shown in Table 1. Their mean age was 67 (SD 12) years, and 67% (n=504) were female. About one-quarter were Asian, half New Zealand European, one-quarter Pacific or Māori, and 1.1% (n=8) had other or unknown ethnicity. Most had adenocarcinoma and *EGFR* exon 19 deletions or L858R mutations. The extent of disease at cancer diagnosis was available for only 604 (80.3%) patients, most of whom had distant disease at cancer diagnosis. Smoking status was available for only 301 (40.1%) patients, most of whom were nonsmokers. Performance status was available for only 273 (36.6%) patients, most of whom had limited performance status.

At the date of the last dispensing follow-up (June 30, 2022), treatment with erlotinib and gefitinib had been discontinued in 724 (96.3%) patients and was continuing in 28 (3.7%) patients. Treatment was discontinued prior to death in 618 patients and at the time of death in 103 patients. Median time-to-treatment discontinuation was 11.6 (95% CI 10.8-12.4) months. The 1-, 2-, and 5-year rates of treatment continuation were 47.3% (95% CI 34.7%-50.9%), 17.4% (95% CI 14%-20.2%), and 3.4% (95% CI 2.2%-5.1%), respectively. Sensitivity analysis in an expanded study cohort (n=885) gave similar results for median time-to-treatment discontinuation (11.1, 95% CI 10.1-11.8 months). Univariable analysis (Table 2) showed that shorter time-to-treatment discontinuation was associated with socioeconomic deprivation, *EGFR* L858R mutations, distant disease at cancer diagnosis, and adenocarcinoma morphology. The initial choice of *EGFR* kinase inhibitor (erlotinib or gefitinib), age, sex, ethnicity, geographical region, year of diagnosis, basis of diagnosis, rurality, and comorbidity were not associated with time-to-treatment discontinuation on univariable analysis. Multivariable analysis showed that shorter time-to-treatment discontinuation was independently associated with socioeconomic deprivation, *EGFR* L858R mutations, and distant disease at cancer diagnosis (Table 2). Sensitivity analyses using less stringent criteria for factor inclusion identified the same independent predictors of time-to-treatment discontinuation (Table S3 in Multimedia Appendix 1).

At the date of last survival follow-up (May 7, 2022), 614 (81.6%) patients had died, and 138 (18.4%) patients were alive. Median overall survival was 20.1 (95% CI 18.1-21.6) months. The 1-, 2-, and 5-year overall survival rates were 69.2% (95% CI 65.8%-72.4%), 43% (95% CI 37.4%-43.5%), and 13.9% (95% CI 11.2%-17%), respectively. Sensitivity analysis in an expanded study cohort (n=885) gave similar results for median overall survival (19.4, 95% CI 17.8-21.2 months). Univariable analysis (Table 3) showed shorter overall survival in association with socioeconomic deprivation, *EGFR* L858R mutations, distant disease at cancer diagnosis, initial choice of *EGFR* kinase inhibitor of gefitinib (vsversus erlotinib), age >65 years, non-Asian ethnicity, residence outside the Northern or Midlands regions, and adenocarcinoma morphology. Sex, diagnosis year, basis of diagnosis, rurality, and comorbidity were not associated with overall survival on univariable analysis. Multivariable analysis showed that shorter overall survival was independently associated with socioeconomic deprivation, *EGFR* L858R mutations, distant disease at cancer diagnosis, and non-Asian or non-Pacific ethnicities (Table 3). Sensitivity analyses using less stringent criteria for factor inclusion identified the same independent predictors of overall survival (Table S4 in Multimedia Appendix 1).

For the purpose of comparison of the results from this study to the existing literature, our literature search identified 15 randomized controlled trials and 5 nationwide or health care system–wide retrospective observational studies. These randomized controlled trials showed that the median progression-free survival for erlotinib and gefitinib monotherapy treatment arms ranged from 8.0 to 13.3 months (Table S1 in Multimedia Appendix 1). The retrospective observational studies showed that the median progression-free survival, or its proxy, ranged from 9.7 to 13.1 months, and the median overall survival ranged from 17.5 to 23.9 months (Table S2 in Multimedia Appendix 1). Our study reports the results following the RECORD (Reporting of Studies Conducted Using Observational Routinely-Collected Health Data) statement checklist (Table S5 in Multimedia Appendix 1).

Discussion

Principal Findings and Comparison to Prior Work

The outcomes from treatment with erlotinib and gefitinib in this study of 752 patients with advanced *EGFR*-mutant nonsquamous NSCLC, treated between 2010 and 2020 in New Zealand, corresponded with those reported in randomized controlled trials and in other large-scale health care system–wide retrospective cohort analyses. The median time-to-treatment discontinuation of 11.6 months found in this study paralleled the median progression-free survival values reported for erlotinib and gefitinib monotherapy treatment arms of 15 randomized controlled trials [6-20], which ranged from 8.0 to 13.3 months (Table S1 in Multimedia Appendix 1). It also paralleled the median progression-free survival values, or its proxy, reported in other nationwide or health care system–wide observational studies of similar patient groups from elsewhere [24-28] (range of median progression-free survival or proxy 9.7 to 13.1 months; Table S2 in Multimedia Appendix 1). The median overall survival of 20.1 months found in this study was also within the range reported in other nationwide or health care system–wide observational studies of similar patient groups [24-28] (range of median overall survival 17.5 to 23.9 months; Table S2 in Multimedia Appendix 1). In this way, this retrospective study has confirmed that the therapeutic benefits expected from erlotinib and gefitinib had been conveyed into the setting of routine care in New Zealand.

EGFR mutation subtype was an independent predictor of outcomes from treatment with erlotinib and gefitinib in this study. Study patients were stratified according to whether their tumors had exon 19 deletions (56%), L858R mutations (34%), or other actionable *EGFR* mutations (10%). Compared to those with exon 19 deletions, study patients with L858R mutations had 30% and 50% increased risks of treatment discontinuation and death, respectively, after commencing treatment with erlotinib or gefitinib. This finding is consistent with those of previous studies exploring outcomes from erlotinib or gefitinib in similar patient groups [45]. *EGFR* mutation subtype may have impacted upon treatment outcomes in this study via the higher pharmacological potency of erlotinib and gefitinib for inhibiting exon 19 deletion *EGFR* oncoproteins compared to those associated with L858R or other *EGFR* mutations [46,47].

Socioeconomic deprivation was an independent predictor of outcomes from treatment with erlotinib and gefitinib in this study. Study patients were stratified into groups with low (41%), intermediate (29%), or high socioeconomic deprivation (30%) based on their residential area. Compared to the study patients from high socioeconomic areas, those from low socioeconomic areas had 30% and 50%, and those from intermediate socioeconomic areas had 20% and 30%, increased risks of treatment discontinuation and death, respectively, after commencing treatment with erlotinib or gefitinib. People from low socioeconomic areas are known to have poorer outcomes from lung cancer due to more limited access to screening and diagnostic services that lead to delayed diagnoses and more advanced disease at presentation [48]. However, few previous studies have evaluated the impacts of socioeconomic deprivation on outcomes from treatment with erlotinib, gefitinib, or other systemic anticancer therapies in patients with *EGFR*-mutant or

XSL•FO
RenderX

other forms of advanced lung cancer. A pooled analysis of SWOG Cancer Research Network clinical trials showed significant associations between socioeconomic deprivation and lower progression-free survival, including in a subgroup of 1307 patients with stage IV NSCLC treated with various platinum-based chemotherapy regimens in randomized clinical trials [49]. Socioeconomic deprivation may have impacted treatment outcomes in this study by limiting access to health care during treatment with erlotinib and gefitinib, directly via other yet to be defined mechanisms or indirectly through correlated predictive factors not accounted for in the multivariable analyses, such as smoking and performance status. Future studies should more closely evaluate the impacts of socioeconomic deprivation on outcomes from the treatment of advanced lung cancer.

Disease extent at cancer diagnosis was an independent predictor of outcomes of treatment with erlotinib and gefitinib in this study. Study patients were stratified according to whether they had localized or regional (18%), distant (62%), or unknown extent of disease (20%) at the time of notification of their diagnosis of nonsquamous NSCLC to the New Zealand Cancer Registry. Compared to those with localized or regional disease extent, study patients with distant disease at diagnosis had 40% and 80% increased risks of treatment discontinuation and death, respectively, after commencing treatment with erlotinib or gefitinib. This finding was consistent with previous studies demonstrating the negative impacts of distant metastasis on outcomes from treatment with erlotinib and gefitinib in similar patient groups [44].

Ethnicity was an independent predictor of overall survival, but not of time-to-treatment discontinuation, in this study. Study patients were categorized as Asian (25%), Māori (10%), New Zealand European (52%), Pacific (12%), or unknown or other ethnicity (1%). Time-to-treatment discontinuation was unchanged among these different ethnic groups when compared to New Zealand European group. However, the risk of death was reduced by 20% and 30%, respectively, in the Pacific and Asian groups but unchanged in the other groups compared to New Zealand European. Overall survival may have been impacted by ethnicity in this study independently of the effectiveness of treatment with erlotinib or gefitinib. Ethnicity may have impacted overall survival indirectly through correlated factors, such as smoking status, that vary between ethnic groups and influence the risk of death [50].

Strengths and Limitations

The strengths of this study include its large population-based sample, internal validity, national generalizability, and unique patient cohort. Only 4 similar analyses [25-28] have included all patients treated in an entire country as far as we are aware. Limitations of the study include those inherent in retrospective study designs or in the use of routinely collected data. The variables available for analysis were limited to those collected routinely during pharmaceutical dispensing and cancer and mortality registration. Some important variables were unavailable or incomplete, such as smoking status, performance status, and clinical stage of disease at the time of commencing treatment with erlotinib and gefitinib, and therefore could not be included in the multivariable analysis. Socioeconomic deprivation was determined by residential area rather than at an individual level, which may have introduced bias. The study did not evaluate the impact of treatments other than erlotinib and gefitinib, which may have influenced overall survival. Safety outcomes were not included in this analysis but will be the subject of subsequent reports.

Conclusions

Outcomes from treatment with erlotinib and gefitinib in this New Zealand cohort of patients with advanced *EGFR*-mutant nonsquamous NSCLC were comparable to those reported in randomized controlled trials and other large-scale health care system–wide retrospective cohort studies. This nationwide study thereby demonstrated that the therapeutic benefits expected from erlotinib and gefitinib had been achieved in the setting of routine care in New Zealand. In that setting, socioeconomic status, *EGFR* mutation subtype, and disease extent at cancer diagnosis were independent predictors of treatment outcomes.

Acknowledgments

The authors thank the patients and their families for contributing to this study. This study has been funded by the Health Research Council of New Zealand project (grant 19-450).

Data Availability

The datasets generated and analyzed during this study are not publicly available due to patient information being identifiable but are available from the corresponding author on reasonable request. For ethics queries, please contact the Health and Disability Ethics Committees at hdecs@health.govt.nz.

Authors' Contributions

PSA, JB, GL, LC, MA, BL, SD, DH, STT, ME, PH, and MJM were involved in conceptualization and funding acquisition. PSA and MJM were involved in validation, writing original draft, and visualization. GL, LC, ME, BL, SD, DH, BM, EB, JW, RL, MA, and MJM were involved in data curation and supervision. JB, GL, and PH were involved in supervision. PSA, STT, and ME were involved in formal analysis and methodology. All authors reviewed and edited the manuscript.

Abstract

Background: Although the use of telehealth has declined since the pandemic, it remains a popular mode of care delivery across the cancer care continuum. Understanding telehealth in the context of cancer care is essential, as its benefits and challenges may differ among diverse population groups and geographic areas.

Objective: This study aimed to examine patterns of telehealth utilization across the cancer care continuum and to identify factors associated with the receipt of telehealth in a large patient population. This study also aimed to assess the telehealth's impact on key health care delivery outcomes.

Methods: We used an annualized retrospective cohort design using patient data from the Johns Hopkins Health System (JHHS), a large regional academic health center in Maryland. The study analyzed electronic health record (EHR) data covering the period from January 1, 2019, to December 31, 2023. Chronic conditions were defined through the Johns Hopkins Adjusted Clinical Groups (ACG) System, which identifies comorbidities based on the International Classification of Diseases, Tenth Revision, Clinical Modification, codes in the electronic health record. In addition, we used publicly available geospatial data (eg, internet connectivity, rural–urban commuting area) to assess telehealth receipt associations. Statistical modeling, including generalized estimating equations, was used to evaluate variations in telehealth utilization and outcomes.

Results: A total of 124,974 adult patients receiving cancer-related care at Johns Hopkins Health System were identified during the study period. Telehealth users were significantly older (52.2% aged ≥65 years, 19,942 patients) compared to nonusers (48.7%, 42,209 patients). In addition, these users were more likely to be male (45.4%, 17,365 patients vs 40.2%, 34,839 patients) and to identify as White (70.8%, 27,071 patients vs 64.7%, 56,122 patients). Telehealth users also had a higher prevalence of comorbidities, with 61.5% (23,503 patients) reporting 3 or more chronic conditions compared to 38.0% (33,000 patients) among nonusers. A positive correlation was noted between rural–urban commuting area codes and telehealth service utilization ($\rho=0.36$; $P<0.05$), indicating higher usage in more rural areas. Conversely, average maximum download and upload speeds showed an inverse relationship with telehealth utilization ($\rho=-0.22$; $P<0.05$; and $\rho=-0.34$; $P<0.05$, respectively). Adjusted analyses indicated that concurrent telehealth use was associated with reduced odds of emergency department visits (0.916, 95% CI 0.884-0.948) and hospitalizations (0.830, 95% CI 0.799-0.863), acknowledging the potential influence of residual confounding.

Conclusions: Telehealth has emerged as a crucial mode of care delivery for patients with complex conditions such as cancer. Understanding usage patterns and factors influencing telehealth across the cancer care continuum, including geographic barriers, is vital to optimizing its implementation and ensuring health care systems meet the diverse needs of patients with cancer in a value-based care environment.

Introduction

Background

The COVID-19 pandemic disrupted cancer care delivery, exacerbated existing disparities in cancer care, and may have a long-term detrimental impact on cancer mortality [1-4]. The pandemic also catalyzed the delivery of telehealth, a digitally supported, remote health care tool that has been available for decades but had limited adoption before the pandemic [5,6]. Although receipt of telehealth has declined since the beginning of the pandemic, telehealth remains a popular care delivery channel and continues to exceed prepandemic utilization levels [7,8]. In the postpandemic era, across the cancer care continuum, the successful integration of telehealth with traditional in-person care processes has critical implications for the provision of care for patients with different cancer-related acute and chronic conditions.

In recent years, a growing body of evidence has demonstrated the benefit of telehealth for multidisciplinary care across the cancer care continuum [9-14]. However, differences in the receipt of telehealth are documented among patient subpopulations, indicating significantly lower receipt among historically underserved populations and differential access across clinical settings [15,16]. For telehealth to be effective as a permanent stand-alone substitute or in combination with in-person cancer care, research is needed to identify the extent to which telehealth is an optimal mode of cancer care delivery for different clinical settings and patients with cancer [4]. This is especially important in cancer care, given the range of care settings, including medical, surgical, and radiation oncology, and for survivorship care, which may occur in nonspecialized settings, such as primary care. Specifically, research is needed on possible current differences in receipt of telehealth-based cancer care and the association of telehealth with outcomes such as health care utilization [17]. Thus, a greater understanding of telehealth is vital, especially because the benefits and barriers of telehealth, as with other digital health tools, may vary across different population groups [18,19].

Objectives

Given the need to better understand telehealth in cancer care and associated outcomes, this study implemented a retrospective analysis to examine patterns of telehealth utilization across the cancer care continuum among patients with cancer in a large referral health care system in Maryland. It also examined factors associated with the receipt of telehealth and the association of telehealth with health care outcomes.

Methods

Design and Setting

In a retrospective study, we used the Johns Hopkins Health System (JHHS) Corporation's EPIC-based electronic health record (EHR) data between January 1, 2019, and December 31, 2023, and developed five 1-year cohorts [20]. We identified patients aged ≥18 years, receiving cancer-related care at JHHS, who had 1 or more encounters with the JHHS Cancer Center or a provider specializing in oncology during the study period [20]. This approach enabled us to include a diverse range of patients across the cancer care continuum, from those actively undergoing treatment to cancer survivors. Importantly, our population definition did not depend on the presence of a cancer diagnosis code, allowing us to exclude individuals whose records might reflect such codes for reasons unrelated to current cancer care, such as routine screening tests, historical diagnoses lacking clinical relevance, or instances where patients received care outside of JHHS, which could result in incomplete or missing records and limit the reliability of assessment. Our resulting denominator of 124,974 adult patients had identifiable cancer-related care with JHHS. Of the selected sample, 81,327 (65.1%) had at least one valid 5-digit ZIP code tabulation area (ZCTA) of residence in Maryland during our observation period, and the remaining 43,647 (34.9%) had an out-of-state ZCTA (surrounding states or far away), but we did not exclude any patients based on residency.

Ethical Considerations

The institutional review board (IRB00424877) of the Johns Hopkins School of Medicine reviewed and approved this study as exempt. The board approved the EHR data extraction for the secondary analysis of deidentified data. The data were deidentified, and the patients did not receive any compensation.

Variable Definitions

We defined the receipt of telehealth services as an encounter associated with specific Current Procedural Terminology and Healthcare Common Procedure Coding System codes, Current Procedural Terminology modifiers *GT or 95*, Centers for Medicare and Medicaid Services place of service code *02*, or recorded encounter type as *video* or *phone* [21]. A full accounting of our telehealth definition appears in supplemental materials (Table S1 in Multimedia Appendix 1). We further specified whether a telehealth encounter was linked to cancer-related care by flagging cases where it was linked to encounters with an oncology specialist or a department that was part of the JHHS Cancer Center.

We identified several covariates of interest at the patient and ZCTA levels. Overall, we assessed care utilization and comorbidity using the Adjusted Clinical Groups System (ACG) published by Johns Hopkins University [22]. The ACG system identified patient age, sex, presence of any social needs, counts of chronic conditions, medications, total medication gaps, and care utilization for multiple points of care (eg, all-cause hospitalization, emergency department (ED) visits, outpatient encounters identified in each 1-year cohort of the study population). The ACG system used expanded diagnostic clusters (EDCs) from *International Classification of Diseases, Tenth Revision, Clinical Modification* (ICD-10-CM) codes documented in the EHR, including encounter diagnoses, problem lists, and clinical documentation. This validated methodology flagged patients with multiple comorbidities based on relevant diagnoses. Medication counts reflected the number of unique prescriptions recorded in the EHR, including all actively prescribed or renewed medications during the study period. We aggregated binary encounter-level flags for whether a patient required language interpretation services at any point during the observation period.

XSL•FO
RenderX

The 'comorbidity' package of the R programming language flagged validated ICD-10-CM codes for cancer and metastatic cancer from the Charlson comorbidity index (CCI) [23]. In addition, the ACG system further subdivided ICD-10-CM codes by EDCs, which generally specifies a body system of neoplasms and other malignancies. However, it is important to note that patients were not required to have a cancer diagnosis confirmed through ICD-10 coding, per the JHHS EHR. We justify this through the observation that the EHR data, compared to administrative claims records, are typically found to be less complete in diagnostic information, including cancers, and the possibility of excluding individuals without ICD-10 coding but with cancer-related care may result in biasing these findings [24].

We obtained counts of cable internet service providers (ISPs) and maximum available download and upload speeds in Gbps from the 2019 report of the Federal Communications Commission's Connect2Health system and translated them to ZCTA geographies by converting and aggregating values using the 'zipcodeR' library of the R programming language [23,25]. We obtained counts of COVID-19 cases between March 2020 and February 2022, as reported by the Maryland Department of Health, through the State of Maryland Open Data Portal [26-28]. We calculated the Area Deprivation Index (ADI) by pulling related variables from the US Census API at the ZCTA level, for the year 2020, using a methodology elaborated on by the original authors [29-32]. Finally, the US Department of Agriculture publishes decennial categories for the category of the rural–urban commuting area (RUCA) at the ZCTA level, but only the 2010 Census release was available at the time of these analyses. The RUCA primary categories were ordinal, ranging from 1 to 10 in order of increasing rurality [21]. We treated the primary categories as continuous values for these analyses to simplify the interpretation of linear effects in predictive modeling. We attached ZCTA-level features of ISPs, maximum available speeds, the cumulative count, and prevalence of COVID-19 cases for the 2 years following the start of the pandemic, national-ranked ADI, and the primary RUCA to match patient records.

Statistical Tests

We used a combination of statistical modeling and null hypothesis tests to assess patterns of telehealth utilization and its association with health care outcomes (ie, hospitalization, ED visitation, and elevated resource utilization). Thus, we performed multiple comparisons between those receiving or not having received cancer-related telehealth services between 2019 and 2023 and evaluated for significant effects at any point during the observation period using χ^2 tests of independence. We assessed both demographic and clinical characteristics, including comorbidities, care utilization, and cancer type (defined by the EDC malignancy groups). We set the alpha level for patient-level significance testing at .001 to reduce the frequency of spurious findings due to sample size.

We cross-tabulated the geospatial characteristics by quartile of telehealth utilization at the ZCTA level, allowing for missingness wherever our sample did not have a valid ZCTA of residence listed. We suppressed areas with fewer than 11 patients for privacy. The quartiles contained an equal number of ZCTAs of residence and were categorized from the Maryland ZCTA containing the lowest proportion of residents observed to have cancer-related telehealth services at JHHS (quartile 1) to the highest number (quartile 4). The out-of-state ZCTA (surrounding states or far away) was all put together in a separate group. This category also included patients missing the ZCTA information. Visual inspection of trends permitted a general assessment of whether geospatial characteristics were associated with telehealth utilization in aggregate and were confirmed by Spearman ρ for significance testing and using only valid geographies. We set the α level for ZCTA-level hypothesis tests at .05.

We used patient-year aggregated observations in the modeling of concurrent year cancer-related telehealth utilization and for assessing its association with health care outcomes of hospitalization, ED visitation, and elevated resource utilization (ie, ACG system Resource Utilization Band [RUB] of 4 or 5 categories). RUB represents expected future utilization based on current morbidities. It is presented in the following categories: (1) healthy users, (2) low resource utilization, (3) moderate resource utilization, (4) high resource utilization, and (5) very high resource utilization [22].

We fitted a generalized estimating equation model with an exchangeable correlation structure for patient identifiers, given the repeated nature of observations across years of data. We evaluated the model for performance and variable effects as part of an analysis to assess the factors associated with receiving cancer-related telehealth services. The model consisted of patient age, sex, need for interpreter services, presence of any social need, counts of chronic conditions, medications, total medication gaps, outpatient visits count, a binary flag for each EDC associated with malignancies or neoplasms, and all ZCTA-level geospatial features. The model would help to assess the association of different types of cancer (defined by the EDC variables) with the outcome of interest. We fitted another model consisting of the same features as the first model, with a CCI-defined cancer diagnosis instead of the binary flag for the EDC groups. This model would help to assess how the high-level information regarding the severity of cancer (defined through the CCI variable) would impact the use of cancer-related telehealth services.

We performed a similar set of analyses to assess the telehealth association with health care outcomes (ie, hospitalization, ED visitation, and elevated resource utilization). In addition to the factors listed earlier, this set of models included a flag for whether the patient received cancer-related telehealth services.

We converted the effects of coefficients to odds ratios with 95% CIs to detect significant effects. We completed all models and plots using the R programming language (version 4.0.2). We compared the model performances on area under the receiver operating characteristic curve and area under the precision-recall curve, a measure of success of prediction when the classes are very imbalanced, along with point-estimated positive predictive value (PPV) and sensitivity.

Results

Patient Characteristics

Table 1 presents the high-level characteristics of the study cohort. The proportion of patients not receiving and receiving cancer-related telehealth services during the observation period was split 69.4% to 30.6% (86,732 vs 38,242 patients). Patients receiving cancer-related telehealth were significantly older on average (19,942, 52.2% vs 42,209, 48.7% for patients aged ≥65 years, P<.001) and more often male (17,365, 45.4% vs 34,839, 40.2%). They were significantly more likely to identify as White race (27,071, 70.8% vs 56,122, 64.7%), have 3 or more chronic conditions (23,503, 61.5% vs 33,000, 38.0%), take 3 or more medications (37,104, 97.0% vs 73,623, 84.9%), have hospitalizations (16,096, 42.1% vs 21,834, 25.2%), and ED visits (8644, 22.6% vs 15,590, 18.0%). Patients with cancer-related telehealth care were also much more likely to be identified as having high resource utilization (22,695, 59.3% vs 30,464, 35.1%; Table S2 in Multimedia Appendix 1 presents patient characteristics of the study cohort by quartiles of telehealth utilization at the ZCTA level).

Patterns of Telehealth Utilization

Table 1 presents the high-level characteristics of the study cohort. The proportion of patients not receiving and receiving cancer-related telehealth services during the observation period was split 69.4% to 30.6% (86,732 vs 38,242 patients). Patients receiving cancer-related telehealth were significantly older on average (19,942, 52.2% vs 42,209, 48.7% for patients aged ≥65 years, P<.001) and more often male (17,365, 45.4% vs 34,839, 40.2%). They were significantly more likely to identify as Caucasian race (27,071, 70.8% vs 56,122, 64.7%), have 3 or more chronic conditions (23,503, 61.5% vs 33,000, 38.0%), take 3 or more medications (37,104, 97.0% vs 73,623, 84.9%), have hospitalizations (16,096, 42.1% vs 21,834, 25.2%), and ED visits (8644, 22.6% vs 15,590, 18.0%). Patients with cancer-related telehealth care were also much more likely to be identified as having high resource utilization (22,695, 59.3% vs 30,464, 35.1%; Table S2 in Multimedia Appendix 1 presents patient characteristics of the study cohort by quartiles of telehealth utilization at the ZCTA level).

[a]Patients could receive cancer-related telehealth services at any point during the observation period.

[b]Statistically significant with *P*<.001.

[c]These clinical measures are derived from the Johns Hopkins Adjusted Clinical Groups System Version 12.0. The Resource Utilization Band represents expected future utilization based on current morbidities. It is presented in the following categories: (1) healthy users, (2) low resource utilization, (3) moderate resource utilization, (4) high resource utilization, and (5) very high resource utilization.

[d]Low- and high-impact neoplasm groups do not capture severity for all cancers. Rather, they include cancers that are not specified in other expanded diagnostic cluster groups. For example, the expanded diagnostic cluster groups do not include head and neck cancer malignancies, so cancers for those sites would be mapped to low- and high-impact neoplasm groups.

Table 1 also illustrates malignancies by EDC with respect to telehealth utilization. Our significance testing identified a greater proportion of telehealth patients for each EDC group, with the smallest significant finding for ovarian cancers (χ^2=19.1, *P*<.001). We observed the highest differences in rate for low-impact neoplasms among those with no telehealth versus telehealth use (10,994, 12.7% vs 10,805, 28.3%, respectively), high-impact neoplasms (12,356, 14.2% vs 13,877, 36.3%, respectively), lung cancers (3157, 3.6% vs 3143, 8.2%, respectively), and pancreatic cancer (2463, 2.8% vs 2397, 6.3%, respectively), and each was associated with more than twice the rate among those with cancer-related telehealth encounters.

We broke the Maryland ZCTAs into quartiles for the proportion of residents observed to have cancer-related telehealth services at JHHS. When split into quartiles, the ZCTA covered by the JHHS in this analysis included 325 (69.4%) of the 468 Maryland ZCTA codes, mostly reflective of the central and capital regions of the state. Patients arrived at JHHS points of care from everywhere in the state (Figure S1 in Multimedia Appendix 1).

The number of patients with any telehealth use increased from 17,687 (56.5%) in quartile 1 to 16,244 (58.9%) in quartile 2, 9924 (59.4%) in quartile 3, and 3527 (61.4%) in quartile 4. The number of patients with any cancer-related telehealth use increased from 8352 (26.7%) in quartile 1 to 8788 (31.9%) in quartile 2, 6126 (36.7%) in quartile 3, and 2545 (44.3%) in quartile 4. We put together the out-of-state ZCTA (surrounding states or far away) in a separate group. This category also included patients missing the ZCTA information. There were a total of 110 ZCTA codes in this category. Of 543 patients in this category, 331 (61.0%) received any telehealth services, and 237 (43.6%) received any cancer-related telehealth services. Most notably, patients in this category resided in Washington, DC, a heavily populated metropolitan area.

Table 2 presents the characteristics of the patient's place of residence by ZCTA quartiles. Some of the most notable findings were that with increasing telehealth utilization in the aggregate, the primary RUCA code shifted from core metropolitan areas (code 1) to metropolitan noncore (codes 2 - 3) and micropolitan, small town, or rural (codes 4 - 10).

Table . Characteristics of the patient's place of residence at 5-digit ZIP code tabulation area by quartiles of telehealth utilization.[a]

Characteristics of patient's place of residence	Maryland ZCTA[b]				Other ZCTA
	Quartile 1	Quartile 2	Quartile 3	Quartile 4	
Total population, 2020	1,918,616	1,773,007	1,587,433	624,630	81,304
ZCTA codes (n)	82	81	81	81	110
Patients in the sample (n)	31,295	27,580	16,711	5741	543
Socioeconomic characteristics of area, mean (SD)					
Average National Rank ADI[c]	21.1 (21.3)	15.7 (14.3)	15.8 (10.5)	17.8 (14.8)	34.4 (29.3)
Primary RUCA[d] of area, n (%)					
Metropolitan—core	63 (76.8)	59 (72.8)	51 (63)	28 (34.6)	21 (19.1)
Metropolitan—noncore	17 (20.7)	20 (24.7)	22 (27.2)	35 (43.2)	62 (56.4)
Micropolitan	0 (0)	1 (1.2)	4 (4.9)	7 (8.6)	13 (11.8)
Small town, rural	2 (2.4)	1 (1.2)	4 (4.9)	11 (13.6)	14 (12.7)
COVID-19 prevalence in area, mean (SD)					
Cumulative per 100,000 residences (through February 2022)	17,097.2 (5169.2)	15,404.1 (3439.4)	16,140.0 (3730.4)	15,042.6 (4112.1)	17,448.5 (11,077.7)
Internet connectivity in area, mean (SD)					
Count of cable ISPs[e] per ZCTA	2.5 (0.8)	2.5 (0.8)	2.4 (0.8)	2.3 (0.9)	1.7 (0.7)
Max cable download speed in Mbps	988.7 (9.4)	983.7 (82.8)	991.0 (6.0)	956.4 (162.1)	892.0 (244.4)
Max cable upload speed in Mbps	828.4 (226.8)	834.4 (249.6)	752.0 (335.1)	529.3 (441.8)	364.0 (425.7)

[a]Areas where the sample count is <11 patients are removed from the sample. The quartiles contain an equal number of ZIP codes and are categorized from the ZIP codes in Maryland containing the lowest proportion of residents observed to have cancer-related telehealth services at Johns Hopkins Health System (Q1) to the highest number (Q4). The out-of-state ZIP codes (surrounding states or far away) are all put together in a separate group. This category also includes patients missing the ZIP code information.

[b]ZCTA: 5-digit ZIP Code Tabulation Area.

[c]ADI: Area Deprivation Index (the higher the number, the greater socioeconomic challenges).

[d]RUCA: Rural–Urban Commuting Area.

[e]ISP: internet service provider.

The RUCA code was positively and significantly associated with the percentage of the sample using cancer-related telehealth services (ρ=0.36; P<.05). Moreover, the average maximum of available download and upload speeds dropped as well (ρ=−0.22; P<.05; and ρ=−0.34, P<.05, respectively), signifying an inverse relationship between telehealth utilization and internet speeds, but not the number of cable ISPs (ρ=−0.09). Telehealth utilization had no significant aggregate association with nationally ranked ADI (ρ=0.01) but did for COVID-19 prevalence (ρ=0.36, P<.05; Figure S2 in Multimedia Appendix 1 provides detailed information on reported correlations).

Table 3 presents odds ratios and 95% CIs for the model containing the EDC-derived markers assessing the concurrent-year cancer-related telehealth utilization. After controlling for other factors, cancer-related telehealth usage was high among males (1.062, 1.032:1.093), those with chronic conditions (1.034, 1.03:1.039), higher number of medications (1.036, 1.035:1.037), and outpatient care utilization (1.026, 1.026:1.027). Moreover, it was higher among those living in more rural areas (ie, higher primary RUCA, 1.117, 1.1:1.134), areas with higher COVID-19 prevalence (1.001, 0.999:1.004), and higher maximum cable internet download speed (1.717,

XSL•FO
RenderX

1.292:2.282). In assessing the cancer type and severity, the model found the strongest significant associations between greater cancer-related telehealth usage with malignant neoplasms of the prostate and pancreas (1.953, 1.87:2.04 and 1.82, 1.731:1.913, respectively), as well as low- and high-impact malignant neoplasms (1.712, 1.662:1.764 and 1.701, 1.654:1.749, respectively).

[a]The odds ratio (95% CIs) is presented for each variable included in the model and for the concurrent year outcome. The model includes a binary flag for each expanded diagnostic cluster (EDC) associated with malignancies or neoplasms to assess the association of different types of cancer (defined by the EDC variables) with the outcome of interest.

[b]These clinical measures are derived from the Johns Hopkins Adjusted Clinical Group System version 12.0.

[c]Low- and high-impact neoplasm groups do not capture severity for all cancers. Rather, they include cancers that are not specified in other EDC groups.

XSL•FO
RenderX

For example, the EDC groups do not include head and neck cancer malignancies, so cancers for those sites would be mapped to low and high-impact neoplasm groups.

[d]ADI: Area Deprivation Index.

[e]The Rural-Urban Commuting Area (RUCA) primary categories are ordinal, ranging from 1 to 10 in order of increasing rurality. We treat the primary categories as continuous values for these analyses to simplify the interpretation of linear effects in predictive modeling.

[f]Cumulative prevalence per 100,000 residences through February 2022.

[g]ISP: internet service provider.

[h]ZCTA: 5-digit ZIP Code Tabulation Area.

Association of Telehealth With Health Care Outcomes

Table 4 presents odds ratios and 95% CIs for the model containing the EDC-derived markers assessing the concurrent-year health care outcomes. Concurrent year receipt of cancer-related telehealth services was significantly associated with reductions in odds of ED utilization (0.913, 0.882:0.946) and hospitalization (0.78, 0.75:0.811). Despite these findings, overall concurrent year resource utilization was still high among those receiving cancer-related telehealth (1.148, 1.113:1.185), even after controlling for chronic conditions (2.224, 2.205:2.242), medications (1.102, 1.1:1.104), outpatient care utilization (1.022, 1.021:1.023), and social needs and need for an interpreter (1.811, 1.714:1.914 and 1.526, 1.405:1.657, respectively). In assessing the cancer type and severity, the model found a significant association between high-impact malignancies with greater hospitalization (2.033, 1.954 - 2.116), but not ED utilization (0.908, 0.873:0.944) and elevated RUB (0.915, 0.884 - 0.947). Several individual EDC malignancies had lower ED and inpatient care utilization but higher RUB. These included skin neoplasms (1.132, 1.062 - 1.207), breast cancer (1.274, 1.220 - 1.334), ovarian cancer (1.249, 1.124 - 1.388), pancreatic cancer (1.070, 1.001 - 1.144), and leukemia (1.404, 1.300 - 1.517).

Hospitalization[c]	0.747
Elevated (4-5) Resource Utilization Band[c, d]	0.826
Sensitivity	
Cancer-related telehealth utilization[a]	0.142
ED visit[c]	0.049
Hospitalization[c]	0.610
Elevated (4-5) Resource Utilization Band[c, d]	0.721

[a]The model consists of patient age, sex, need for interpreter services, presence of any social need, counts of chronic conditions, medications, total medication gaps, outpatient visits count, a binary flag for each associated with malignancies or neoplasms, and all 5-digit ZIP Code Tabulation Area–level geospatial features.

[b]ED: emergency department.

[c]The model consists of patient age, sex, need for interpreter services, presence of any social need, counts of chronic conditions, medications, total medication gaps, outpatient visits count, a binary flag for each expanded diagnostic cluster associated with malignancies or neoplasms, a flag for whether the patient received cancer-related telehealth services and all 5-digit ZIP Code Tabulation Area–level geospatial features.

[d]Resource Utilization Band is derived from the Johns Hopkins Adjusted Clinical Group System version 12.0. and represents expected future utilization based on current morbidities. It is presented in the following categories: (1) healthy users, (2) low resource utilization, (3) moderate resource utilization, (4) high resource utilization, and (5) very high resource utilization.

Discussion

General Findings

In this study, we examined the patterns of telehealth utilization across the cancer care continuum and the factors associated with the receipt of telehealth. Our findings showed that in our large academic medical center, the receipt of cancer-related telehealth care varied by sociodemographic characteristics, type of cancer, and health care resource utilization level among our patient cohort.

Telehealth seems particularly well-suited for cancer care delivery. During cancer care, patients and caregivers may face unique challenges such as the need for more frequent visits than required for other health conditions [33]. Moreover, challenges with transportation, high cost of care, and restricted access to providers can serve to limit utilization of in-person medical, psychological, and supportive care among patients with cancer, especially those with complex comorbidities or social needs [34-36]. Telehealth can reduce the burden of traveling to multiple visits within a short period or traveling when a patient with cancer is experiencing side effects from treatment.

Furthermore, in the oncology care context, telehealth has been shown to reduce wait times, expedite cancer diagnosis and treatment (compared to in-person visits), improve symptom management and comfort, reduce health care utilization, and increase patient satisfaction [37-39]. The implementation of telehealth strategies has also helped to address gaps in

XSL•FO
RenderX

cancer-related care associated with geographic access that could otherwise result in differences in the cost of care and cancer-related outcomes [40]. Thus, across the cancer care continuum, telehealth has been an important mode of care delivery, especially in ambulatory care settings and in locations where in-person access is limited due to social conditions or economic challenges [41-46].

Comparison With Other Studies

Our adjusted analyses found that patients who received cancer-related telehealth were significantly more likely to be younger and male. Current evidence shows that the receipt of telehealth (overall and among cancer survivors) is significantly lower in patients who are members of racial minorities, older, rural-dwelling, and socioeconomically challenged, compared to those who are Whites, younger, urban-dwelling, and wealthier [7,18]. In addition, national population-based studies report greater receipt of telehealth among younger individuals and females [7,8,47]. This divergence in gender use rates captured by our study may reflect differences in the reasons for cancer-related telehealth use versus telehealth that is unrelated to cancer care (eg, a very large percentage of national telehealth being used for behavioral health).

Our adjusted analyses found that patients who received cancer-related telehealth were significantly more likely to be younger and male. Current evidence shows that the receipt of telehealth (overall and among cancer survivors) is significantly lower in patients who are members of racial minorities, older, rural-dwelling, and socioeconomically challenged, compared to those who are Caucasians, younger, urban-dwelling, and wealthier [7,18]. In addition, national population-based studies report greater receipt of telehealth among younger individuals and females [7,8,47]. This divergence in gender use rates captured by our study may reflect differences in the reasons for cancer-related telehealth use versus telehealth that is unrelated to cancer care (eg, a very large percentage of national telehealth being used for behavioral health).

Also in our study, patients with at least one social need received fewer cancer-related telehealth services compared to those with no social needs. This finding may indicate that socioeconomic challenges can impact patients' access to any care, including that provided through telehealth. Other studies have identified sociodemographic differences associated with age, sex, race/ethnicity, and health insurance type in receipt of video-based telehealth (compared with phone-only telehealth) [7,48-50]. Research that identifies potential contributors to different patterns of telehealth utilization in cancer care and the association between cancer-related telehealth utilization and health care outcomes can inform cancer management strategies [8]. Understanding correlates of receipt of telehealth among individuals diagnosed with cancer who are receiving care across the cancer care continuum and in different clinical settings (eg, at a cancer center or a primary care clinic) can help identify gaps in care.

In our study, patients with a higher number of chronic conditions, medications, and outpatient visits were more likely to receive cancer-related telehealth. This is concordant with previous general population research that found greater receipt of telehealth among individuals with more comorbidities [8]. These findings may indicate a preference (or need) for telehealth among patients with more comorbidities and complex conditions, given the utility of telehealth in reducing some access barriers. Also, patients with high-impact neoplasms, prostate, and pancreatic cancer had higher rates of cancer-related telehealth use than other types of cancer. These findings further suggest that telehealth may be particularly well-suited for patients with certain types of more serious cancer care needs. However, the findings that patients with low-impact neoplasms were also more likely to receive cancer-related telehealth may indicate that patients with less complex health needs may seek types of care that are more suitable for telecare or that these patients prefer fewer in-person interactions with health care. Additional research to understand patient preferences for telehealth among people with cancer is needed.

Analyses examining quartiles of cancer-related telehealth use and the correlation matrix for geospatial characteristics revealed informative findings. Consistent with prior research [7,18], our study found a positive association between cancer-related telehealth use and rural areas of residence, with the percentage of the sample using telehealth increasing with the rurality of where they lived. This finding was confirmed in the adjusted analyses. In addition, the adjusted analyses showed higher cancer-related telehealth use among those living in areas with higher COVID-19 prevalence and higher access to the internet (as measured by maximum available internet download speed). These findings may indicate the effectiveness of telehealth in overcoming geographic access challenges (eg, associated with distance and limited transportation) among patients with cancer living in rural areas [51] or when public health emergencies such as a pandemic emerge. Strategies that maximize, or otherwise support, telehealth availability in rural areas are warranted.

Our findings suggested that after adjustment, concurrent receipt of cancer-related telehealth was associated with lower odds of ED utilization and hospitalization. This is concordant with several other studies (both overall and within the cancer context) that likewise report associations between telehealth and reductions in ED utilization or hospitalization [52-55]. A scoping review of telehealth during the COVID-19 pandemic concluded that telehealth could reduce hospital admission rates [56]. In a surgical oncology study, postoperative receipt of telehealth reduced ED visits and 30-day readmissions [55]. It appears that the use of timely digital care decreases ED visits and hospital admissions, which can reduce cancer care costs, improve quality of care, and potentially protect patients with cancer, who are susceptible to infections. A population-based study found that among patients with cancer, ED visits increased from an estimated 3.7 million in 2012 to 6.2 million in 2019, with more than half of these visits identified as potentially preventable [57]. Combined with the overall effectiveness of telehealth in reducing the time and travel costs of patients with cancer, continued use of telehealth in cancer care may have a significant impact on cancer care costs and cancer-related financial toxicity [58].

Our findings related to hospitalization and severity/disease complexity were somewhat paradoxical. High-impact

XSL•FO
RenderX

malignancies were associated with greater rates of hospitalization, but patients with cancer with higher overall comorbidities (across all conditions as measured by our ACG-RUB measure) were not more likely to be hospitalized. This finding may be due to higher in-hospital death rates among high-impact malignancies. Also, certain EDCs representing ICD-10 codes falling within selected malignancy categories (eg, skin neoplasms, breast cancer, ovarian cancer, pancreatic cancer, and leukemia) did not consistently reach levels of significance for each outcome, but several were significant and had the same pattern as cancer-related telehealth: lower ED and inpatient care utilization and higher elevated RUB. Lower ED visits and hospitalizations may reflect high survivability. However, in the case of pancreatic cancer or leukemia, it may reflect a higher use of palliative care. Further research in this and other settings on this topic is warranted.

In terms of the model performance, the inclusion of individual EDC diagnosis clusters specifying malignancy type in the place of CCI-defined cancer diagnosis appeared to have substantially improved both PPV and sensitivity for cancer-related telehealth utilization and hospitalization and PPV for ED visitation. In addition, area under the precision-recall curve was improved with this approach, suggesting better precision-recall across much of the response distribution (Tables S3-S5 in Multimedia Appendix 1 provide details of models, including the CCI-defined cancer diagnosis).

Study Limitations

Our analysis relied on a binary measure of telehealth exposure (received or not) due to limitations in the EHR dataset, which did not uniformly capture telehealth modality (eg, phone vs video), frequency, or clinical purpose. While these granular data could deepen insights into how telehealth encounters affect outcomes such as ED visits and hospitalizations, they were unavailable for inclusion. Future research should aim to incorporate such measures to optimize telehealth delivery and better inform tailored interventions.

In addition, the endpoints used to assess telehealth's association with health care outcomes were limited. Other clinically relevant measures, such as laboratory test use and medication adjustments, or hybrid models integrating telehealth and in-person care, could offer more comprehensive insights into its effects on outcomes.

The reliance on EHR data may have affected the identification of telehealth services due to potential coding inaccuracies. Furthermore, this study focused on patients within a single large academic health system, which may not fully represent broader cancer populations. JHHS's specialized programs, advanced technological infrastructure, and patient demographics—such as higher proportions of insured or resource-accessible patients—limit external generalizability. Patients in other settings, such as rural clinics or community hospitals, may have distinct experiences and patterns of telehealth use. Future research across diverse health care systems is needed to ensure findings are applicable to more varied populations, particularly in rural and underserved areas.

The COVID-19 pandemic accelerated telehealth adoption, addressing barriers such as long travel distances, workforce shortages, and limited health care facilities. However, sustaining these access levels beyond the pandemic is uncertain due to challenges such as broadband availability, financial constraints, and evolving policies. Telehealth must be carefully optimized to address infrastructure gaps and ensure equitable access across rural and urban areas.

The use of dated RUCA codes and ZCTA-level internet speed data introduces limitations in assessing connectivity and geographic classifications, as changes in infrastructure over the last decade may not be adequately captured. These outdated measures could misclassify areas and underestimate connectivity, affecting conclusions about disparities in telehealth access.

Finally, the retrospective design inherently limits causal inferences, as unmeasured variables, such as disease severity, referral patterns, and insurance coverage, may introduce residual confounding. Telehealth encounters might have been selectively offered to patients with less severe conditions or used as a precursor to in-person services, complicating causal interpretation. Prospective studies and randomized trials are needed to better understand the directional relationships between telehealth use and clinical outcomes.

Despite these limitations, our findings provide valuable insights into patterns of telehealth use in cancer care and highlight opportunities for targeted engagement in digital health. Telehealth has emerged as a key tool for improving access to specialized care, increasing efficiency, and enhancing convenience, particularly for patients navigating complex treatments or survivorship. Addressing disparities tied to socioeconomic factors, digital literacy, and geographic location will be crucial to ensuring telehealth delivers equitable care while reducing the burden on patients and caregivers throughout the cancer care continuum [7,16-18,48-50,59].

Abstract

Background: National Cancer Institute–designated cancer centers (NCI-CCs) throughout the United States are mandated to translate state-of-the-art cancer research to communities and enhance clinical care for patients within their catchment areas. NCI-CCs play a vital role in national cancer initiatives focused on optimizing cancer care via personalized medicine in which improved risk assessment, screening, and genetic testing are foundational. In this era of targeted personalized care, although genetics has been incorporated into cancer centers, it is unknown how these innovations are being communicated to the public and communities served on cancer center websites. There is particularly limited knowledge surrounding how NCI-CCs publicly communicate their efforts to integrate patient-reported experiences with genomics to fulfill their overall mission and reduce the cancer burden in their catchment areas.

Objective: The objective of this study was to evaluate how NCI-CCs publicly share information on their websites related to cancer center programming and activities to measure and incorporate patients' experiences with the use of genetics to guide cancer care.

Methods: For all NCI-CCs providing clinical care (N=65), we conducted a review of publicly available and published information and assessed five domains relevant to patients' experiences with genomic medicine: whether NCI-CCs (1) provided genetic testing, (2) directly expressed a goal of delivering personalized care, (3) provided pharmacogenomic testing, (4) assessed patient-reported experience measures with genomic medicine (including patient-reported outcomes [PROs] and other patient experience measures [OPEMs]), and (5) indicated an established infrastructure or set of resources to evaluate patient experience. We conducted a content analysis of the publicly available websites of NCI-CCs using the validated directed approach to content analysis. We quantified the results of our content analysis using count measures based on a binary (yes or no) coding scheme.

Results: While almost all the NCI-CCs (64/65, 98%) discussed providing personalized care and performing genetic testing on their websites, we found that 58% (38/65) indicated online that they assessed PROs or other patient experience measures with genomic medicine. Fewer centers (25/65, 38%) discussed on their websites having a mechanism for evaluating patients' experiences with genomic medicine that captured broader types of information beyond PROs, such as measures of patient education or care team communication. Finally, approximately 1 in 3 NCI-CCs (23/65, 35%) indicated having an established infrastructure with departmental resources dedicated to monitoring patients' experiences. These centers reflecting a built-in infrastructure were 8% to 12% more likely to publicly communicate targeted activities to assess patients' experiences with genomic medicine.

Conclusions: With the burgeoning use of genomics in research and clinical care, comprehensive evaluation and incorporation of measures of patients' experiences with genomic medicine present a key opportunity to enhance cancer care at NCI-CCs.

Introduction

The National Cancer Institute's Cancer Centers Program

Established by the National Cancer Act in 1971, the National Cancer Institute's (NCI) Cancer Centers Program has worked for over 50 years to support and unify cancer research efforts and clinical care across institutes nationwide [1]. Achieving the status of an NCI-designated comprehensive cancer center (NCI-CC) is the crowning achievement for US cancer-focused research centers and hospitals. As NCI-CCs, these centers shape the future of cancer care through supporting the translation of laboratory discoveries to clinic, community-focused programming, and developing advancements in the prevention, diagnosis, and treatment of cancer for their catchment areas [2,3].

NCI-CCs play a vital role in national cancer initiatives focused on optimizing cancer care via personalized medicine in which improved risk assessment, screening, and genetic testing are foundational [4,5]. Personalized medicine is a burgeoning field focused on providing patient-specific treatment by considering unique factors that can impact individuals' health, most principally their genetic makeup [6,7]. Personalized medicine in oncology includes several types of care, including genetic testing (1) for germline mutations related to inherited susceptibility to cancer, (2) for somatic mutations providing tumor characterization, and (3) for pharmacogenomics (PGx) profiles that predict responses to medications (eg, potential efficacy and side effects).

Patient-Provider Communication Regarding Genetic Testing

Efforts to understand the human genome in the last 30 years have changed the way in which we look at and treat cancer [8-10]. Despite these advancements and best practice recommendations, genetic testing is only performed for a fraction of eligible patients. In an observational study of the prevalence of germline genetic testing following a cancer diagnosis, only 6.8% of patients diagnosed between 2013 and 2019 underwent germline genetic testing [11]. While up to 15% of cancer cases are attributable to inherited mutations, over 70% of patients with a breast or ovarian cancer diagnosis reported not being advised on any genetic testing by their providers [12]. Moreover, these germline genetic testing rates are lower among Asian, Black, and Hispanic patients in comparison to non-Hispanic White patients with comparable cancers [12-16]. In a systematic review and meta-analysis of patients with ovarian cancer, 40% of White patients completed genetic testing, whereas only 26% and 14% of Black and Asian patients, respectively, underwent such testing following a diagnosis [17].

Among patients newly diagnosed with breast cancer and high risk of genetic mutations, the number 1 reason cited for not receiving germline genetic testing was not expense or lack of interest but rather the lack of a physician's recommendation for testing [13]. Similarly, health care professionals identify themselves as the responsible party for identifying individuals who would benefit from genetic testing and disclosing the results to patients. Despite this recognition, communication barriers between providers and patients regarding genetic testing and results continue to contribute to low uptake among eligible patients [1,18,19].

To ensure that all patients are able to fully benefit from genetic advancements in cancer care, we need to address communication regarding genetic testing for both cancer screening and treatment at cancer centers. While many national and international organizations have published guidelines for genetic testing to address this testing gap, effective communication and outreach regarding cancer genetic testing remains an active area of study and development [8]. Even in cases where patients have received testing, they often cite misunderstanding the risk implications of such testing for them and the utility of results to their family members [20].

Patients' Experiences With Genetic Testing

One established way to address these communication gaps and understand the underlying cause for testing disparities is to evaluate and understand patients' experiences within the health care system. The National Academy of Medicine identifies a shortage of patient experience evaluations as a contributing factor to the quality of personalized patient care [21]. Supporting patient experience is fundamental to improving health care across many domains through improving patient engagement, transparency, and patient-provider communication [22]. Previous studies have addressed the implementation of such genetic testing to guide treatment and physicians' perspectives on its utility, yet they often fall short of considering patient experiences. However, when patient experience evaluation is incorporated in cancer care, patients and their families benefit from a better understanding and risk communication regarding their genetic test results [23-25]. Understanding patient perspectives and the accessibility of genetic testing in cancer care is a key part of equitably implementing precision oncology care [26,27].

Evaluating patient engagement and communication in the delivery of personalized medicine requires measurable responses and feedback from the patients themselves. Patient-reported experience measures (PREMs), such as patient satisfaction scales and knowledge assessments, are vital to providing comprehensive patient-centered care [28,29]. We define PREMs to include all measures that encapsulate a patient's experience with the health care system in line with the US Agency for Healthcare Research and Quality [28]. PREMs have been associated with clinically-relevant differences in patient understanding, trends in emergency room visits, and patterns of overall survival [30-33]. A subset of PREMs, patient-reported outcomes (PROs), includes measures such as quality of life assessments and symptom reporting in oncology practice to facilitate communication between physicians and patients regarding clinical care [34,35]. Moreover, other patient experience measures (OPEMs) can capture alternative aspects important to personalizing care, such as the way in which patients view their illness and interact with their care team.

At the individual level, PREMs can facilitate patient-provider communication and improve symptom management, and on a public and administrative level, PREMs can inform the

XSL•FO
RenderX

implementation of burgeoning genetic technologies into equitable cancer care [31,36]. As leaders, and in alignment with NCI priorities, NCI-CCs' incorporation of PREMs into patient care and research efforts, especially alongside the implementation of genomic medicine, may facilitate improving care quality and addressing cancer health disparities.

Outside of the examination room, the internet, and specifically patient-facing information on cancer center websites, serves as a valuable resource for patients to become informed about their cancer care and the resources available to them that they can pursue or advocate for [37]. In these cases, online information is crucial to communication with patients and health education beyond the limited time frame of the health encounter. Cancer center websites can bolster communication efforts with the community, provide information transparency, and promote resources to patients [38]. It is important that these websites disseminate information about genetic testing resources available to their catchment area and their efforts to incorporate patients' experiences. Furthermore, cancer center websites may reflect certain priorities and efforts with regard to genetic testing programs, such as expanding screening for hereditary risk, personalized medicine, and patient outreach. Few studies have evaluated the content of the information that cancer centers directly communicate to the public [39,40], and none of these studies has specifically addressed patients' experiences with genomic medicine. One study evaluated cancer center websites for information about a novel oncology intervention [39], whereas another assessed the content of cancer center public advertising [40]. Limited research exists on the efforts of NCI-CCs to incorporate patient experience with genomic medicine implementation, let alone their public communication of these efforts. Therefore, to further characterize the integration and accessibility of PREMs and genetic testing within NCI-CCs, we reviewed publicly available content to determine their communication about PREMs in their patient care and research efforts related to the implementation of genomic medicine.

Methods

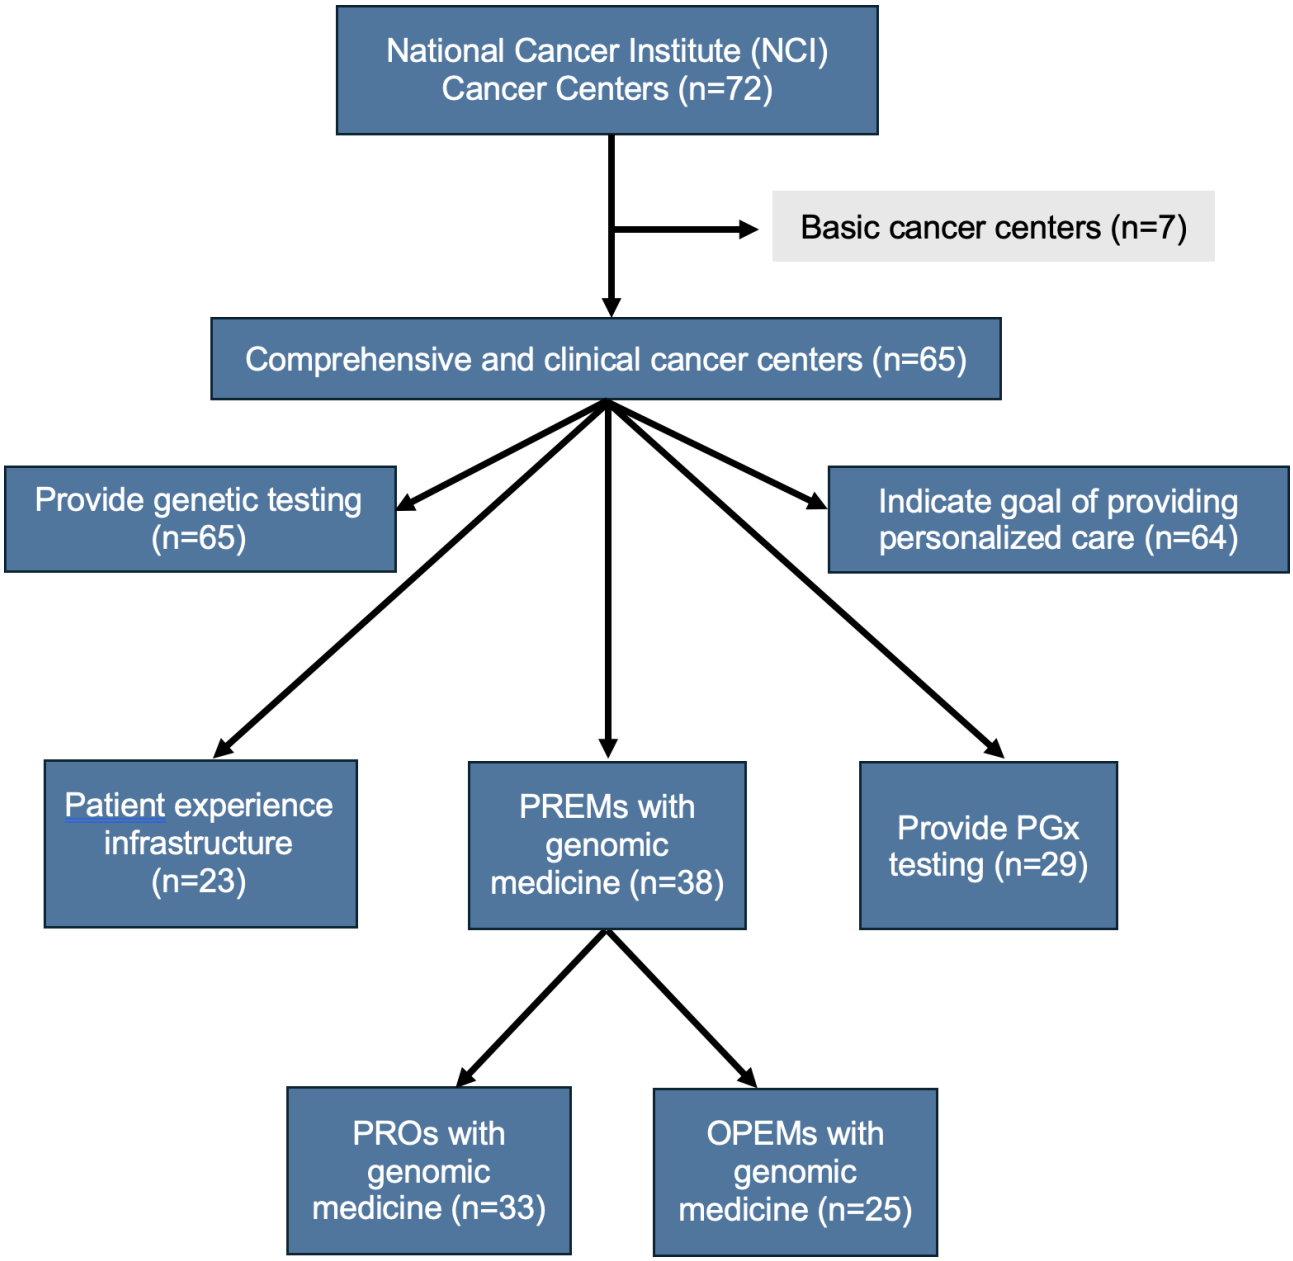
Study Inclusion Criteria

A list of 72 US NCI-CCs was originally compiled from the National Institutes of Health NCI's list of designated cancer centers in October 2023 [41]. The NCI Cancer Centers Program encompasses 3 subdesignations: basic cancer centers, clinical cancer centers, and comprehensive cancer centers [3]. To be evaluated, the centers had to provide direct clinical care; therefore, of the 72 NCI-CCs, 7 basic laboratory cancer centers were excluded from our content analysis, leaving 65 evaluable centers.

Content Analysis

The websites of these centers are critical access points for the public, communicating the centers' goals and accomplishments along with providing a digital footprint of their community-serving and research activities [42,43]. Thus, we conducted a content analysis of the publicly available websites of NCI-CCs using the validated directed approach to content analysis previously described in the literature [44]. The findings of our content analysis were quantified using count measures based on a binary (yes or no) coding scheme. When a specific content element as outlined by our domain criteria was discovered on a cancer center website, its presence was recorded using "yes" in the study database. To arrive at a quantitative count measure, at least one "yes" in a domain would correspond to counting that cancer center as publicly communicating about that particular domain.

Website Review Process and Variable Coding



Each website assessment started with the NCI-CC website home page [41], which directs the user through designated links to each specific cancer center's website. Once navigated to the specific cancer center's website, the reviewer first assessed that website's directory (eg, main tabs or prominent links to web pages within the site that referenced domain criteria). Second, the reviewer systematically followed the links of all matches to domain criteria to their resulting web pages; this included a systematic review of the website's directory as well as searches based on a specified term list on the main website's internal search bar. Following these procedures, when the reviewer observed domain criteria, the presence of that specific content element was recorded in the study database using a binary indicator ("yes" for present or "no" for absent). At least one instance in which that domain criterion was discussed was required for recording that the NCI-CC publicly communicated regarding that specific domain on their website.

Domain Criteria for Data Collection

Before the start of the evaluation of each center's website, the 2 reviewers established definitions and criteria across five domains: whether NCI-CCs (1) provided genetic testing, (2) directly expressed a goal of delivering personalized care, (3) provided PGx testing, (4) assessed PREMs with genomic medicine (including PROs and OPEMs), and (5) indicated an established infrastructure or set of resources to evaluate patient experience (Figure 1). For each domain, we determined a set of phrases and terms to search for within each cancer center site to compile relevant results, which we further evaluated for specific content. All percentages reported in the tables reflect the proportion of all NCI-CCs (N=65) observed to publicly communicate content regarding each domain on their websites.

XSL•FO
RenderX

Figure 1. Flow diagram illustrating the criteria for the selection of cancer centers for content analysis and the domains on which National Cancer Institute–designated comprehensive cancer center websites were evaluated. OPEM: other patient experience measure; PGx: pharmacogenomics; PREM: patient-reported experience measure; PRO: patient-reported outcome.

To assess the first domain of whether genetic testing of any kind was mentioned or provided by the cancer center, we searched for generic terms including "genetic test," "genetic counseling," and "genomic medicine." To mark each center as "yes" with respect to providing genetic testing, there had to be at least one instance in which genetic testing was made available to patients within their catchment area (eg, germline genetic testing was provided for hereditary cancer risk screening). Furthermore, with regard to the second domain of whether they described a goal of delivering personalized medicine, the relevant search terms included "precision medicine" and "personalized medicine" along with broader terms such as "personalized" and "individualized." To classify centers as expressing this goal (and mark them as "yes"), they had to use the aforementioned terms in the context of personalized care being a center-wide mission and not be solely reflective of an individual provider or entity within the center.

For our third domain, we investigated whether centers publicly referenced PGx testing as a part of their research, clinical activities, or programs. We defined PGx broadly to ensure inclusion of germline genetic testing that is used to guide medication prescribing. In the cancer context, PGx testing can be used in reference to a range of biomarker testing to select the targeted cancer therapy most appropriate for a patient's tumor type [45,46]. Through targeted search phrases such as "personalized medicine" and "pharmacogenomics," we identified centers that described the use of PGx testing to optimize patient drug therapies, inclusive of chemotherapy regimens, adjuvant therapies, and other supportive medications for oncology patients. We did not wish to include only tumor-specific somatic mutations as a form of PGx in this domain. Although tumor profiling is more common in pathology analysis and has been widely adopted [13], the consistent use of germline PGx to identify hereditary risk, improve drug

XSL•FO
RenderX

efficacy, or reduce treatment toxicity is still an emerging area of personalized medicine and is indicative of NCI-CCs' work to incorporate new innovative genetic technologies [47].

For the fourth domain, the inclusion of PREMs with genomic medicine opportunities was evaluated. To be marked as "yes" for this domain, the centers had to demonstrate the incorporation of at least one PREM concurrent with the use of genetic testing in either clinical practice or a clinical trial context. Following our assessment of the presence of genomic programs in the first domain, we identified the presence of PREMs in coordination with these programs and efforts at the NCI-CCs as indicated through clinical study design, clinical outcome data, or published patient results that explicitly mentioned collection of patient feedback. We further differentiated within this domain by classifying PREMs as either PROs or OPEMs with genomic medicine. PROs included any direct patient-reported measures used or collected in clinical care (eg, quality of life or mood tracking). OPEMs included any type of patient feedback beyond that used in direct clinical care, such as the impact of genomic medicine on their life, preferences for information delivery, their understanding of results, or risk communication with their care team.

Incorporating consideration of patient experiences in cancer care can improve cancer care and the accessibility of new technologies such as genetic testing [21]. For the fifth and final domain, we evaluated whether NCI-CCs had a previously established built infrastructure or dedicated resources specific to incorporating patient experiences into cancer care delivery. The presence of such infrastructure was initially identified from reviewing the results obtained using search phrases including "patient experience" and "patient engagement" before content review. Resources identified that we considered as a "yes" could include an office or department dedicated specifically to patient experiences [48,49], systematic surveying of patient experiences, a patient experience board, and other center-wide efforts concerning patient experiences. We recognize that this fifth domain is inclusive of very different types of resources that may potentially create variation in their impacts on centers in terms of accountability.

To ensure the accuracy of our determinations, the primary reviewer checked each website for these domains in 2 separate rounds, and the second reviewer checked to ensure the accuracy of the determinations. Both reviewers met regularly to discuss and resolve any discrepancies within the determinations. All results for these determinations were stored in a database and evaluated for quality control. Figure 1 shows the raw results for the presence of resources and communication among these domains.

Finally, we stratified NCI-CCs based on whether they indicated the presence of patient experience infrastructure (fifth domain) to assess the impact of having this established set of resources on public communication about the other domains of personalized medicine and patient experience measures of interest described previously. We recognize that, as the first analysis of its kind related to genomic medicine, our approach for stratification may be broad, yet it establishes a foundation upon which future analyses can build to provide more granular characterizations of patient infrastructure resources to further evaluate their possible influence on cancer centers.

Ethical Considerations

All data were aggregated and publicly available; thus, no ethics approval, exemption, or deidentification process was needed.

Results

Content analysis revealed that all 65 NCI-CCs evaluated indicated that they provided genetic testing of some sort to guide cancer care, and all cancer centers except 1 (64/65, 98%) explicitly indicated a center-wide goal of providing personalized care to their patients (Figure 1). In some cases, NCI-CCs had dedicated genetic counseling departments or even online eligibility screeners for patients interested in genetic testing, whereas others solely described the availability of genetic testing to patients through a clinical trial. However, slightly less than half (29/65, 45%) of the NCI-CCs discussed PGx testing in some form within their core resources, molecular tumor boards, or research activities (Table 1).

Table . Number and percentage of National Cancer Institute–designated comprehensive cancer centers (NCI-CCs) that described activities related to genomic medicine (N=65).

Activities related to genomic medicine	NCI-CCs, n (%)
Describing personalized care	64 (98)
Assessing PROs[a] with genomic medicine	33 (51)
Assessing OPEMs[b] with genomic medicine	25 (38)
Providing PGx[c] testing	29 (45)
Indicating patient experience infrastructure	23 (35)

[a]PRO: patient-reported outcome.

[b]OPEM: other patient experience measure.

[c]PGx: pharmacogenomics.

Overall, we found that most of the NCI-CC websites (38/65, 58%) indicated the use of PREMs with genomic medicine, whether through incorporating PROs in clinical care or evaluating OPEMs. Among NCI-CCs using PREMs in some capacity, assessing PROs with genomic medicine was the most common, with approximately half (33/65, 51%) of all centers

XSL•FO
RenderX

indicating that they assessed factors such as quality of life or symptom monitoring for patients receiving genomic-guided cancer care (Table 1). OPEMs with genomic medicine, representing broader aspects of patient experience beyond direct clinical care, such as evaluations of patient education and communication feedback, were described by 38% (25/65) of the NCI-CCs (Table 1).

In our stratified evaluation of whether the NCI-CCs had a previously established patient experience infrastructure, we found that approximately 1 in 3 NCI-CCs (23/65, 35%) indicated on their websites having dedicated center resources for evaluating and incorporating patient experience (Table 2). Furthermore, our content analysis showed that the presence of an established patient experience infrastructure was directly related to increased rates of the other measures relevant to personalized medicine and PREMs with genomic medicine (Table 2). For example, 57% (13/23) of the cancer centers with patient experience infrastructure demonstrated the assessment of PROs with genomic medicine compared to 48% (20/42) of the centers that did not indicate the same dedicated resources. Centers that communicated having dedicated resources to incorporate patient experience were also 7% more likely to assess OPEMs (10/23, 43% with dedicated resources vs 15/42, 36% without). Moreover, over half (12/23, 52%) of the centers that demonstrated having an established infrastructure provided PGx testing, yet only 40% (17/42) of those without this infrastructure provided the same opportunity for PGx-guided care.

Table . Number and percentage of National Cancer Institute–designated comprehensive cancer centers (NCI-CCs) that communicated about specific activities related to genomic medicine stratified by the presence of an established infrastructure and dedicated resources for incorporating patient experience.

Activities related to genomic medicine	NCI-CCs without patient experience infrastructure (n=42), n (%)	NCI-CCs with patient experience infrastructure (n=23), n (%)
Assessing PROs[a] with genomic medicine	20 (48)	13 (57)
Assessing OPEMs[b] with genomic medicine	15 (36)	10 (43)
Providing PGx[c] testing	17 (40)	12 (52)

[a]PRO: patient-reported outcome.

[b]OPEM: other patient experience measure.

[c]PGx: pharmacogenomics.

Discussion

Principal Findings

In this study, we evaluated the publicly available online content presented by NCI-CCs communicating their efforts to incorporate patient experience with genomic medicine. Our content analysis revealed that all the NCI-CCs discussed incorporating genetic testing in some form or another. In addition, we found a high prevalence of statements emphasizing commitment to personalized care throughout the NCI-CCs' websites. Our content analysis revealed variation between NCI-CCs in the type and content of information publicly communicated relevant to such personalized cancer care, particularly as it related to the incorporation of patient experience measures into cancer center programs. Finally, we discovered that cancer centers that had invested in building an established infrastructure focused on monitoring patient experience were more likely to provide information and describe the breadth of their activities to enhance patient-centered care.

Given the importance of genetic testing to providing personalized cancer care, we expected to see prominent levels of cancer center communication regarding these mission-driven priority areas. In spite of an expressed commitment to these areas of care, only about half of the nation's cancer centers indicated the incorporation of patient experience measures with genomic medicine. Even fewer centers communicated about their evaluation of patient experiences with receiving genetic testing beyond the PROs typically accompanying clinical care. Less attention to OPEMs created gaps in knowledge related to patient views, preferences, and values regarding the use of genetics to guide cancer care across the continuum. Both PROs and OPEMs illuminate aspects of the patient experience that could contribute to disparities in cancer health outcomes [14,15]. Comprehensive integration of the patient perspective improves quality of care and facilitates centers' efforts to accomplish their goal of providing patient-centered care [27]. Understanding and incorporating the patient experience into health care delivery is an established method of improving appropriately tailored implementation of genetic testing into the care received by a diverse patient population and their families [21,23,50].

Our stratified evaluation showed that those centers with a previously established infrastructure for integrating patient experience were more likely to communicate targeted activities to assess patient experience with genomic medicine. On the basis of our findings, the NCI-CCs that made investments in a patient experience infrastructure, such as an office dedicated to patient experience or patient advisory boards, communicated a wider range of activities to leverage patient experience and promote more equitable access to genomic medicine. NCI-CCs with such an established infrastructure were also more likely to communicate about the use of PGx testing to guide medication selection. Concerted efforts by NCI-CCs to disseminate information about the incorporation of patient experience may be one critical step toward augmenting public knowledge about the use of genetics in cancer care. As implementation and widespread use of these emerging genomic technologies increases, establishing such resources to amplify the patient voice may help enhance the accessibility of information to underserved and underrepresented populations

XSL•FO
RenderX

in these NCI-CC catchment areas [51], for example, serving as a key conduit regarding eligibility for clinical trials incorporating genetic susceptibility, which often lack diversity [52-54].

The NCI emphasizes the long-term commitment to community outreach and engagement (COE) that is required to have a profound impact on the cancer burden of a center's catchment area, and consequently, their primary metric in evaluating the strength of COE is the scope, quality, and impact of the center's COE activities on the burden of cancer in the center's stated catchment area [2]. Our study results suggest ample opportunities for cancer centers to leverage their websites to foster a more bidirectional sharing of information between cancer centers and the patients of their catchment areas. Key recommendations for centers to improve patient engagement and communication focus on building on the foundations of each center's COE efforts, which are strategically tailored for their catchment area. The evolution of COE has enhanced its integration throughout cancer center programs and leadership activities [55]. While some NCI-CCs may be well-resourced enough to establish separate offices or departments dedicated to patient experience, others may augment collaborations with COE on public communication about patients' experiences with personalized cancer care, whether through online sources such as the website or through the multilevel partnerships that promote innovation that cancer centers' COE efforts are uniquely positioned to develop. In addition, even well-resourced NCI-CCs could improve the efficiency of their investments in incorporating patients' experiences with personalized cancer care through engagement with COE.

This study has some limitations. Our evaluations of the NCI-CCs' resources and communication on these issues were limited to their publicly available websites and did not account for other forms of communication including news articles, direct patient-provider communications, or materials distributed in person to patients. Furthermore, NCI-CCs' varying resources may impact whether they have a dedicated infrastructure for enhanced communications or for enhancing patients' experiences. Centers with comparatively more resources to support such a dedicated infrastructure may have a greater ability to allocate more resources to communicating effectively with patients (eg, public relations teams and website support services). Previous research has shown that, in NCI-CCs across the United States, catchment areas are extremely diverse in size, composition, cancer incidence, and mortality rates [56]. Catchment areas reflect the geographic area where centers focus their research, outreach, and engagement efforts to reduce cancer burden. However, despite these differences across the populations served, Cancer Center Support Grant funding varies widely across these centers serving catchment areas with varying intensity of needs. Thus, resource inequity may impact website quality due to having to choose where to allocate limited resources. A center with comparatively fewer resources might need to direct them toward sustaining offerings versus enhancing their website. In that case, a center's website may be misleading as to the full scope of their actual offerings to enhance patient care. Nevertheless, NCI-CCs' websites often serve as the first and most prominent public representation of a center to interested patients, reflecting their ongoing efforts and directly communicating center priorities.

Second, this study's approach as a content analysis of cancer center websites did not confirm (1) efforts or activities to incorporate patient experience measurement into cancer center activities, (2) genetic data collection, or (3) the implementation of genetics into clinical care. However, outside of the patient-provider interaction, public information on cancer center websites serves as a valuable resource for patients in cancer center catchment areas to become informed about their cancer care and the resources available to them that they can pursue or advocate for [37]. In these cases, online information is crucial to expanding communication with patients and opportunities for health education beyond the limited time frame of the health encounter. Cancer center websites can bolster communication efforts with the community, provide information transparency, and promote resources to patients [38]. Future work will assess in more detail the variation in implementation strategies that cancer centers pursue regarding incorporating the patient perspective into personalized cancer care.

Conclusions

As leaders in cancer care, NCI-CCs are poised to promote accessibility of information about advancements in genomic medicine being implemented into clinical care. Our findings show that, while genetic testing may be available, many NCI-CCs do not indicate currently monitoring patients' experiences with genomically guided cancer care. It is particularly important to determine how many NCI-CCs report providing personalized care and assessing PROs via their public websites to provide a greater understanding of the scope of future opportunities for improved communication with patients in their catchment areas about patient-centered care within federally-funded centers with responsibilities for cancer care delivery innovation. To our knowledge, this is the first study to evaluate cancer centers' communication with the public about incorporating patient experience, engagement, and communication regarding genomic medicine. Moreover, to our knowledge, the NCI neither publishes for public consumption nor provides any explicit guidelines specifically tailored for genomic medicine. Lack of public communication on a critical tool for personalizing care presents a key area for improvement in the communication efforts of NCI-CCs. Systematic efforts to incorporate patient experience could serve as one mechanism for cancer center outreach to the diverse patient populations they serve, as well as act as another step toward achieving their stated goals of providing high-quality, personalized cancer care.

Abstract

Background: In contemporary health care, patient-centered care has emerged as a pivotal paradigm shift that redefines the traditional physician-centric model. Particularly in the context of cancer care, marked by its intricate nature and emotional impact, there is a pressing requirement to rethink how health care is delivered. In this context, comprehensive cancer care networks (CCCNs) provide a new means of structuring and delivering quality cancer care, recognizing each patient's unique preferences and needs.

Objective: This study aimed to establish a consistent definition and framework for patient centeredness in CCCNs, facilitating the integration of a patient-centered approach to enhance care quality.

Methods: We conducted an umbrella review focusing on generic and oncology-specific dimensions of patient centeredness to establish the definition and framework. The data were analyzed and synthesized using an inductive category development approach, which guided the derivation of dimensions for the framework. The review was complemented by a survey of 23 key stakeholders within CCCNs and a focus group with patient representatives. This process involved iterative group discussions to achieve consensus on the framework and definition.

Results: The study presents a robust definition and framework of patient centeredness tailored to CCCNs, validated by an initial agreement rate of 96% among survey respondents. Patient centeredness in a CCCN is defined as a philosophy of care prioritizing the physical, emotional, and social needs and personal values of patients with cancer at every step of the patient pathway. In patient-centered CCCNs, patients are empowered and engaged in becoming active partners in health care in relation to their individual preferences and capabilities, with the goal of providing personalized, high-quality, holistic care with the best possible outcomes. The framework comprises 8 primary dimensions: empowering patients, engaging and involving patients, treating the patient as a unique person, enhancing the therapeutic relationship, enhancing a patient-centered culture, providing holistic care,

XSL•FO
RenderX

recognizing and supporting the health care professional as a person, and coordinating care. Each dimension is supported by specific subdimensions and actionable patient-centered activities that facilitate practical implementation.

Conclusions: The results provide a comprehensive perspective on the complex elements that compose patient-centered care within CCCNs in Europe. This contributes to a better understanding and application of patient centeredness in cancer care and possibly other contexts. The results presented in this paper promise to support cancer care networks and other health care contexts in creating a patient-centered environment where patients feel genuinely heard, valued, and actively engaged in their care decisions.

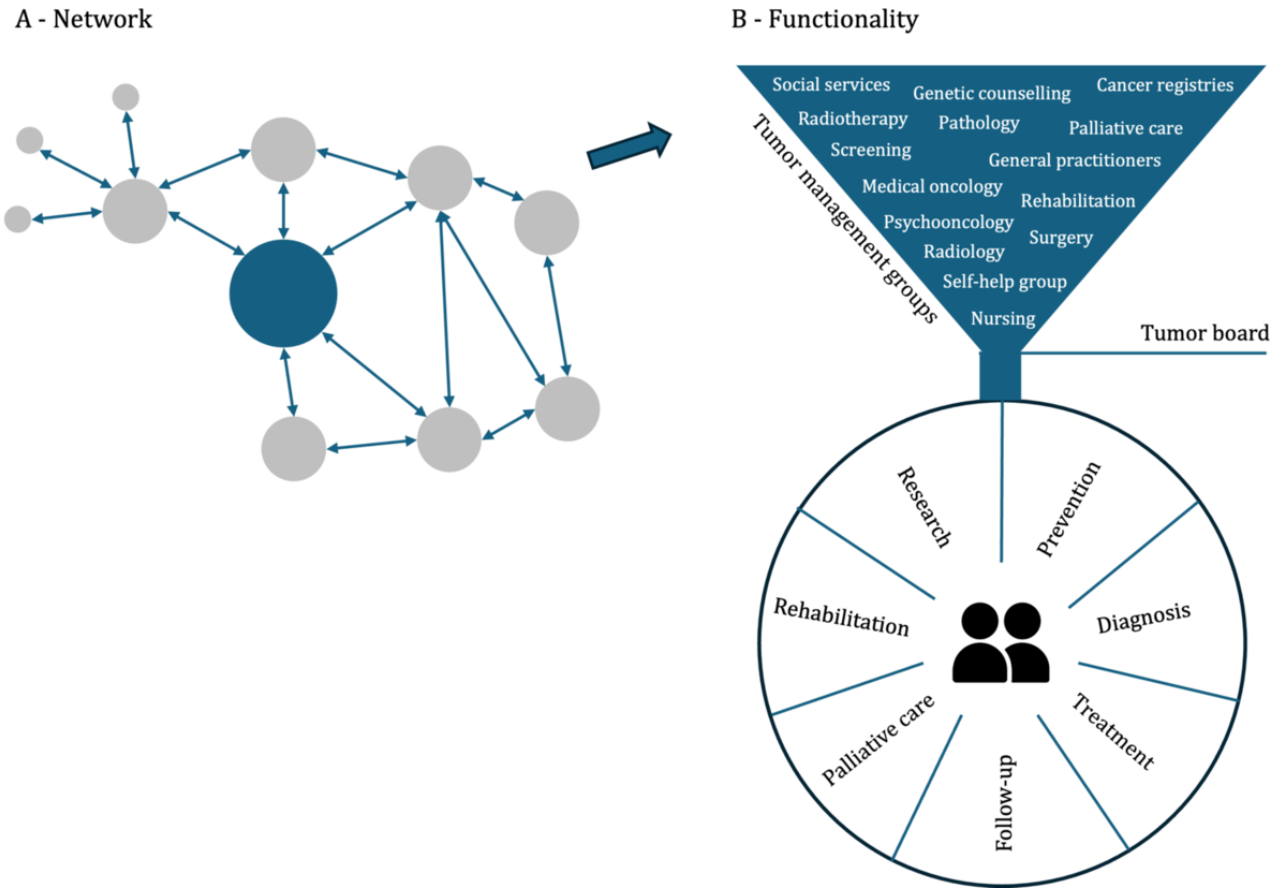
Introduction

Background

In the realm of contemporary health care, the concept of patient-centered care has emerged as a pivotal paradigm shift that redefines the traditional physician-centric model [1]. Patient-centered care implies empowering and engaging patients as active partners in their health care and ensuring their distinct preferences and needs are addressed [2]. The concept has been associated with multiple improved patient outcomes, encompassing higher patient satisfaction, increased patient safety, and better adherence to treatment plans while simultaneously reducing health care expenses. In addition, the focus on patient centeredness corresponds with ethical ideals such as respect for people, beneficence, and autonomy [3-5].

Patient Centeredness in Cancer Care



Particularly in the context of cancer management, a domain characterized by its intricate nature and emotional, financial, and physical impact, there is a pressing requirement to rethink how health care is delivered by placing patients at the heart of their care [6,7]. This becomes particularly evident when considering current statistics. For instance, 30% to 55% of patients with advanced cancer have an unfulfilled information need [8]. Similarly, 10% to 24% of patients with newly diagnosed cancer report unfulfilled information needs. During the treatment phase, this unmet information need is reported by up to 97% of patients [9,10]. Further statistics show that >20% of patients do not feel sufficiently incorporated into decision-making processes, and >25% do not understand answers to their questions. These statistics are illustrative of the insufficient integration of patient centeredness in health care, thus clearly falling short in meeting the needs and preferences of patients.

Comprehensive Cancer Care Networks

The evolving understanding of cancer as a complex illness has prompted a reorientation in how cancer care is structured, giving rise to comprehensive cancer care networks (CCCNs). These networks encompass various units across different institutions, covering the entire spectrum of a patient's pathway through cancer—from diagnosis to treatment, follow-up, supportive and palliative care, and rehabilitation. These units are represented as dots in Figure 1 [11].

XSL•FO
RenderX

Figure 1. Key elements defining a comprehensive cancer care network (image based on CanCon Guide).

The tumor management groups within the CCCN are interprofessional, multidisciplinary, and tumor specific. The collaborative goal of the network is to deliver all-encompassing cancer care, focusing on enhancing outcomes and promoting consistent, high-quality care [11]. Hereby, it has been recognized that a patient-centered approach, as a cornerstone of modern, high-quality care, is indispensable [1]. Therefore, by recognizing the uniqueness of each patient's situation, preferences, and needs, CCCNs seek to transition to a more personalized and tailored approach to cancer care [11].

Aims

To support the shift toward a more personalized and tailored approach in cancer care, this paper aims to advance the concept of patient-centered care in CCCNs by proposing a definition, a comprehensive framework, and actionable strategies. Such a definition and framework can serve as a foundational platform for effective communication, research, and discussion. Furthermore, while existing models have defined general elements of patient-centered care [10] and identified barriers [12], there is a lack of practical guidance for CCCNs to enhance patient centeredness in their care practices.

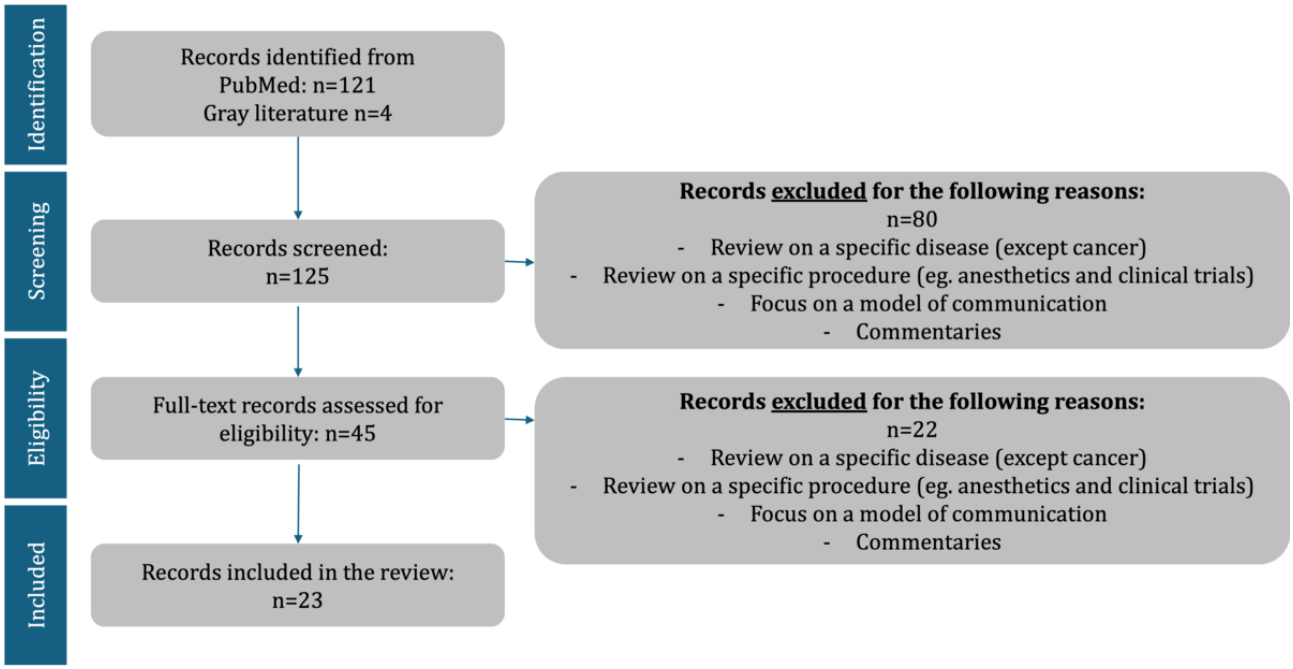
Methods

To develop a definition, framework, and actionable strategies for patient centeredness within CCCNs, an umbrella review, a survey with CCCN stakeholders, and 2 focus groups with patient representatives were conducted. The subsequent section will display how these methodologies were integrated and harmonized.

Umbrella Review

The umbrella review, that is, a review compiling evidence from multiple systematic reviews [13], was performed in accordance with the framework proposed by Brocke et al [14]. The review aligns with the specifications of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement. The PRISMA checklist is provided in Multimedia Appendix 1 [15]. The objective of the review was to provide an overview of the generic and oncology-specific dimensions of patient centeredness, including any actionable patient-centered activities that may already be derived from literature, to enhance patient centeredness in practice. An umbrella review was chosen to provide a comprehensive overview of the concept of patient centeredness while still accounting for the large number of publications on the topic. The following search string was used in a PubMed query: (patient centered*[Title] OR person centered*[Title] OR patient centred*[Title] OR person centred*[Title]) AND (defin*[Title] OR concept*[Title] OR framework[Title] OR model[Title] OR element*[Title]).

Hereby, the terms patient- and person-centered care were used interchangeably. Although slight conceptual differences are described in some sources [16], they are more commonly described as synonyms [2,17]. Filters used to narrow down the search included English or German language. Furthermore, due to the nature of an umbrella review, only reviews, systematic



XSL•FO
RenderX

reviews, and metareviews were included in the search. No restrictions were made concerning the date of publication.

The search intentionally included studies beyond oncology, given that general research on patient centeredness is likely applicable to oncology as well. Restricting the search would have overlooked valuable literature. To ensure relevance and validity specific to oncology, we conducted the survey and focus groups with stakeholders from the cancer field.

The initial search of the databank identified 121 records. In addition, a search of gray literature using Google and Google Scholar with the term “patient centeredness” combined with those used in the PubMed query yielded 4 more sources, which were included. After a 2-stage screening process by 2 independent researchers (EH and PR), 23 records were included in the final set of publications (Figure 2 [15]).

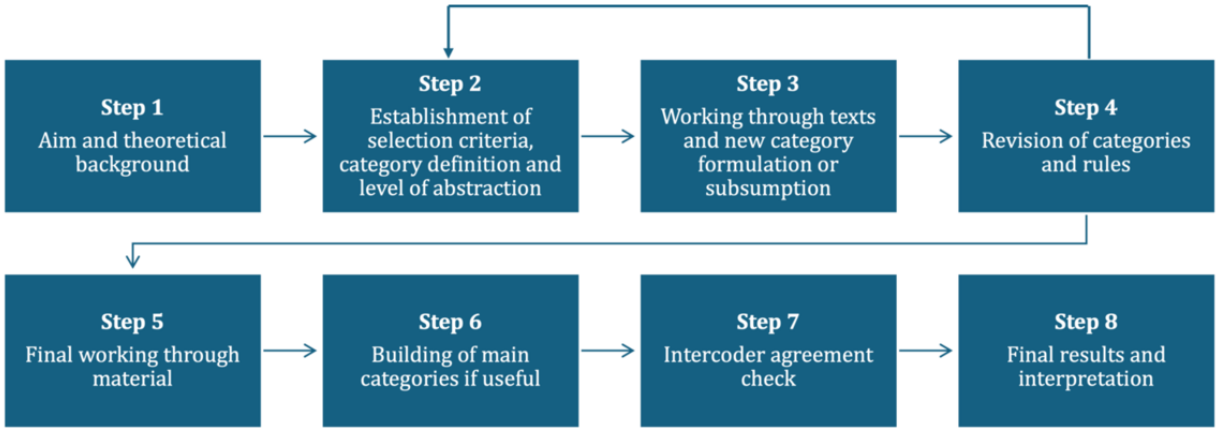


Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the literature selection process.

We decided to refrain from searching further databases, as a saturation point was reached where no new dimensions of patient centeredness were identified by adding further reviews to the set of included articles. Articles were chosen for inclusion in the study if their main emphasis was on defining or investigating the concept of patient centeredness, whether in a general health care context or specifically within the field of oncology. Articles were excluded if they concentrated solely on patient centeredness related to other specific diseases outside of oncology. This approach aimed to ensure that the study remained aligned with its focus on oncology while allowing a broader exploration of patient centeredness as a concept. Furthermore, articles were included if they focused on patient centeredness in a network of health care providers. Articles that solely focused on a particular disease (except cancer), specific medical procedures (such as patient centeredness during sedation or clinical trials), communication models, or commentaries on existing articles were excluded. A list of the 23 included records, including their publication year, country, and focus, can be found in Multimedia Appendix 2 [10,17-38].

To extract information from the articles, an inductive category formation approach was used following the guidelines proposed by Mayring [39]. The steps displayed in Figure 3 [39] were performed.

Figure 3. Inductive category formation approach based on the methodology by Mayring [39].

XSL•FO
RenderX

The aim of the inductive category development was to identify dimensions relating to patient centeredness. To define initial categories and levels of abstraction, we used the overview of patient-centeredness dimensions by Langberg et al [18] as our foundation. This model is the most recent and comprehensive available, effectively integrating and expanding upon earlier frameworks such as that of Mead and Bower [19]. The study by Langberg et al [18] was selected not only for its up-to-date synthesis of insights but also because it remains generic enough to encompass a broad range of applications without concentrating on a specific stakeholder. Consequently, the following five dimensions proposed by Langberg et al [18] served as the starting point for our umbrella review: (1) biopsychological, (2) patient as a person, (3) sharing power and responsibility, (4) therapeutic alliance, and (5) coordinated care. As described by Mayring [39], this was a deductive element in the process, and further categories (ie, dimensions) were then inductively added if the material that was worked through could not be sorted into one of the existing categories.

The inductive category development was performed by 1 of the reviewers (EH) and constantly reviewed through group discussions with 2 further independent researchers (PR and HS). In case of dissenting views, consensus was reached through majority or through consultation of further researchers. This was an ongoing process used to revise and refine the categories and rules (step 4). Consequently, changes to the existing categories of Langberg et al [18] were made, as refined dimensions could be identified. For instance, “sharing power and responsibility” was differentiated into 2 categories: “engaging and involving patients” and “empowering patients.” After several rounds of revision, 8 categories were identified.

In this manner, the findings from the umbrella review, encompassing both generic and oncology-specific dimensions, were methodically used to establish a first draft framework of patient centeredness within CCCNs consisting of 8 main dimensions and associated subdimensions. The framework and its dimensions were also used as a basis to formulate a first approach to a definition for patient centeredness in CCCNs.

Furthermore, in each subdimension, actionable activities that could already be retrieved from the literature were recorded in a Microsoft Excel document. These patient-centered activities were collected to support the implementation of the dimensions in practice.

Survey With Key Stakeholders in CCCNs

Subsequently, the proposed definition and framework of patient centeredness within a CCCN were transposed into a survey (Multimedia Appendix 3). The survey aimed to revise the results obtained in the umbrella review to make them more practice-oriented and applicable to the CCCN context. The reporting of the survey aligns with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist for reporting results of e-surveys [40].

The survey was developed using LimeSurvey, a robust online tool that has demonstrated reliability and efficacy across various projects. To enhance the survey’s clarity, a preliminary test was conducted with 3 stakeholders, resulting in minor refinements to the wording. In addition, the platform’s inbuilt consistency check was used and did not identify any errors. The survey procedure did not require further approvals.

The survey was distributed among key stakeholders of CCCNs across various European countries. These stakeholders were identified based on their involvement in the CraNE Joint Action (European Network of Comprehensive Cancer Centers), facilitating the identification of 77 potential recipients with relevant experience in CCCNs. Key stakeholders are health care providers, such as oncologists who offer direct patient care, and managers of health care organizations responsible for the administration and coordination of services. Methodologists, such as medical guideline developers, play a crucial role as key stakeholders by setting care standards and ensuring that CCCNs operate based on the latest evidence-based practices. Representatives from national authorities and both international and national health organizations are also integral stakeholders, as they provide essential regulatory oversight and are involved in shaping policies that impact CCCNs. Including patient representatives ensures that the patient voice and perspective are central to the care process, addressing their needs and preferences effectively. In addition, researchers contribute their expertise by integrating scientific advancements and innovative approaches into cancer care. Together, these key stakeholders represent the comprehensive spectrum of expertise and experience required to deliver holistic and effective care in CCCNs.

The survey was disseminated through email, which included a hyperlink to access the online questionnaire. Participants were informed that the estimated time required for completion of the survey was approximately 20 to 30 minutes. Participants had the option to review their responses by using the back button throughout the survey. No incentives were provided for completing the survey.

Participants were asked to provide insight on the following subjects:

- Their level of agreement or disagreement with the proposed definition and framework of patient centeredness within a CCCN (5-point Likert scale).
- Recommendations for modifications to the suggested description and framework of patient centeredness within a CCCN (open text).
- What actionable and concrete patient-centered activities are currently being undertaken or could potentially be undertaken within CCCNs to enhance each of the 8 dimensions (open text).
- The extent to which patient-centered care is currently reflected in the operational practices of CCCNs concerning each specific dimension (5-point Likert scale). This topic was not confined to the particular CCCN where the participant works; instead, it encompassed their perspective on all CCCNs in general.

The survey consisted of 33 questions, organized into 10 groups, with each group displayed on a separate page. During the 3 weeks that the survey was available online, 34 potential participants visited the first survey page, and 23 complete responses were collected. This corresponds to a response rate

XSL•FO
RenderX

of 30%. It was not possible for participants to make duplicate entries. Table 1 illustrates the specific stakeholder groups of a CCCN that participated in the survey.

Table 1. Stakeholder groups of survey respondents (N=23).

Stakeholder group	Respondents, n (%)
Health care provision	8 (35)
Cancer organization	4 (17)
Public health institute	4 (17)
Network management and certification	2 (9)
Research	2 (9)
Cancer patient organization	1 (4)
Ministry of health	1 (4)
Other	1 (4)

The results obtained from the survey, especially qualitative feedback from open-text questions, prompted adjustments to the proposed definition and framework of patient centeredness. Participants' input informed these changes, ensuring the definition and framework remained relevant and practical for CCCNs. This iterative process underscores the importance of stakeholder engagement in refining patient-centered care models. Furthermore, the list of actionable patient-centered activities in the respective subdimensions could be expanded significantly.

Focus Group With Patient Representatives

A focus group with 3 patient representatives, selected from the patient representative board of the medical university in Dresden, was performed. They were chosen because each representative had first-hand experience with cancer and possessed >3 years of experience serving on the board of representatives. Furthermore, these individuals served as contact people and spokespeople within the cancer care network in Dresden, providing guidance and advice to patients with cancer and fellow representatives. Thereby they offer a comprehensive understanding of the patient perspective across the entire care spectrum.

The focus group was facilitated in the following manner: in August 2023, a preparatory 1-hour kick-off meeting took place. The purpose of this session was to introduce the study's goals, methodology, and initial findings. Following this, the patient representatives were requested to individually contemplate the preliminary results, express their thoughts, and contribute additional instances of patient-centered activities. These examples could either be ones they had personally encountered during their care or ones they would have desired within the specific context.

In October 2023, the focus group was conducted with the same 3 patient representatives. This approach should not be confused with a group interview, where the researcher directs questions, guides the discussion, or interacts individually with participants. Instead, in a focus group discussion, researchers act as moderators, facilitating group discussions among participants [41]. After a short introduction, each theme was discussed separately, and the results of the individual contemplations of each patient representative were discussed together. Commonly agreed-upon aspects were added to definitions of themes and specified in the list of patient-centered activities.

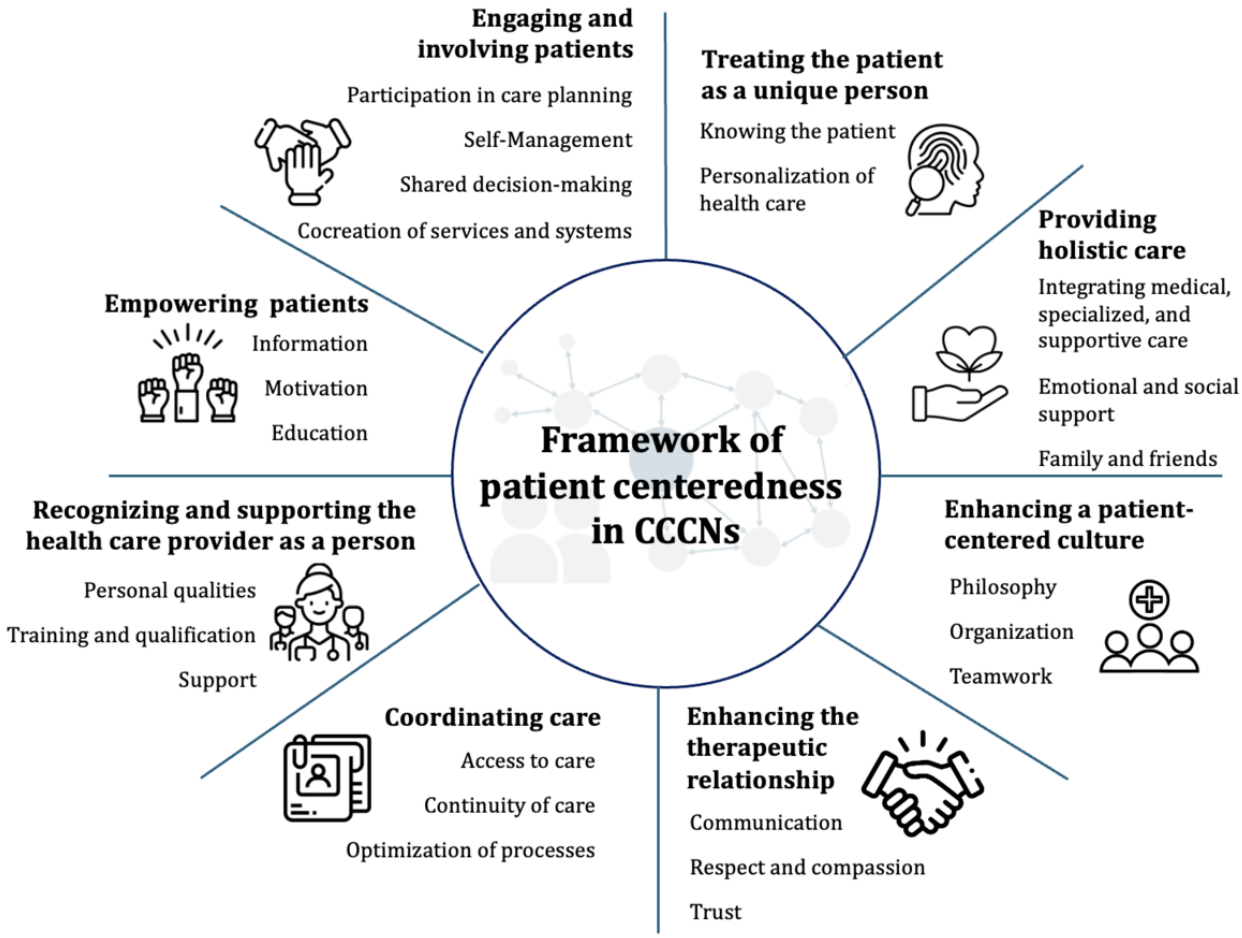
Ethical Considerations

Participants in both the survey and focus group were informed about the study's purpose and methodologies. By proceeding with the survey or participating in the focus group, they provided their consent to partake in the research. All collected data were aggregated to maintain participant anonymity and confidentiality. Participants of the focus group received a compensation of €90 (US $104) per hour for their involvement, acknowledging their time and contribution to the research. No incentives were provided for survey completion. The study received a retrospective ethical exemption (dated April 29, 2025) from the ethics board of the Technische Universität Dresden.

Positionality Statement

Our research team comprises a diverse group of individuals with varied backgrounds and roles within the health care ecosystem. Some of us are researchers affiliated with universities, with expertise in health care management and business informatics. We bring an academic perspective that values evidence-based approaches and systematic analysis to understand complex health care systems. Others in our team are practitioners directly involved in cancer care or work within cancer organizations, contributing valuable on-the-ground insights from daily interactions with patients and health care systems. Our collective experiences and professional backgrounds inevitably shape our approach to this research, infusing it with both theoretical rigor and practical relevance, as we strive to enhance patient-centered care.

Results



Overview

Informed by the umbrella review and survey findings, the subsequent framework (Figure 4) for patient centeredness in a CCCN was established. It consists of 8 main dimensions, each with 2 to 4 subdimensions. The framework is primarily applicable within a European context because, while the literature includes diverse perspectives from outside Europe, the survey itself was conducted exclusively with European

XSL•FO
RenderX

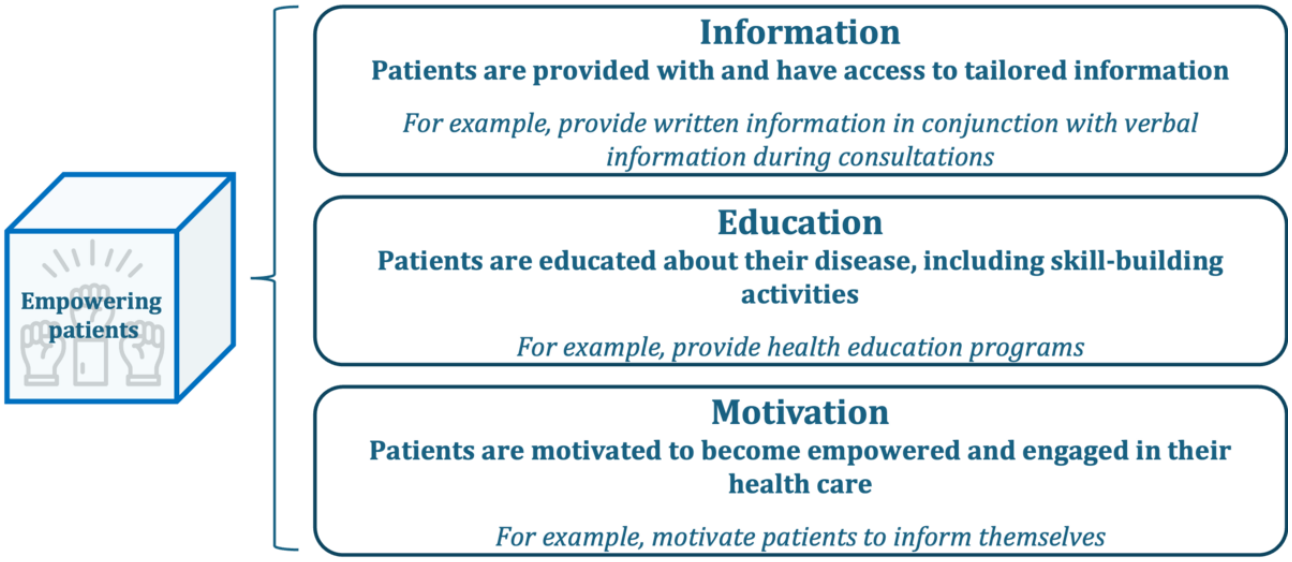
participants. The dimensions do not have a specific order or hierarchy. Dimensions are interconnected, so a higher degree of implementation in one dimension can facilitate an easier implementation in another. For instance, if patients in a CCCN are already largely empowered, it will be easier to foster their engagement. A patient-centered culture will support the formation of a therapeutic alliance.

Figure 4. Framework of patient centeredness in comprehensive cancer care networks (CCCNs; icons created by Freepik, Kliwir art, and Samber The Labs from flaticon).

Out of all survey participants, 96% (22/23) of the participants either "agreed" or "strongly agreed" (on a 5-point Likert scale) with the initial framework of patient centeredness in a CCCN, which was developed based on the umbrella review results. Feedback from the survey guided revisions to the framework. Particularly, the input from the participant who did not agree with the framework prompted us to add a new subdimension, "cocreation of services and systems," under the existing dimension of "engaging and involving patients." This subdimension underscores the significance of involving patients in the design and improvement of health care services and systems, thereby enhancing their patient centeredness.

While the focus group with patient representatives did not result in any changes to the framework itself, adjustments were made to dimension descriptions, and additional examples of patient-centered activities were incorporated. Especially regarding patient-centered activities, patient representatives contributed unique insights and real-life examples from a patient standpoint that had not been integrated before. These modifications, prompted by the focus group discussions, are indicated in Multimedia Appendix 4 [10,17-38].

In the following subsections, the individual dimension and subdimensions of the framework for patient centeredness in CCCNs will be described, including exemplary patient-centered activities that have the potential to facilitate the practical implementation of patient centeredness in each subdimension. It is important to note that certain activities may be relevant to multiple dimensions, and there are clear synergies and overlaps between the different dimensions. Therefore, a primary allocation has been made to assign activities to specific subdimensions based on their primary focus. As the list of potential activities is very extensive, only examples will be provided in the following, while the complete list can be retrieved in Multimedia Appendix 4. In addition, the data gathered from the survey regarding the current state of implementation of patient-centered care within the operational practices of CCCNs are discussed individually for each dimension, referred to as the "status quo."



Empowering Patients

Patient empowerment refers to the process of enhancing patients' knowledge, skills, and self-awareness while also fostering their confidence to actively participate in care [2].

XSL•FO
RenderX

Three subdimensions, displayed in Figure 5, were formed: information, education, and motivation.

Figure 5. Subdimensions and examples of patient-centered activities in the dimension "empowering patients.".

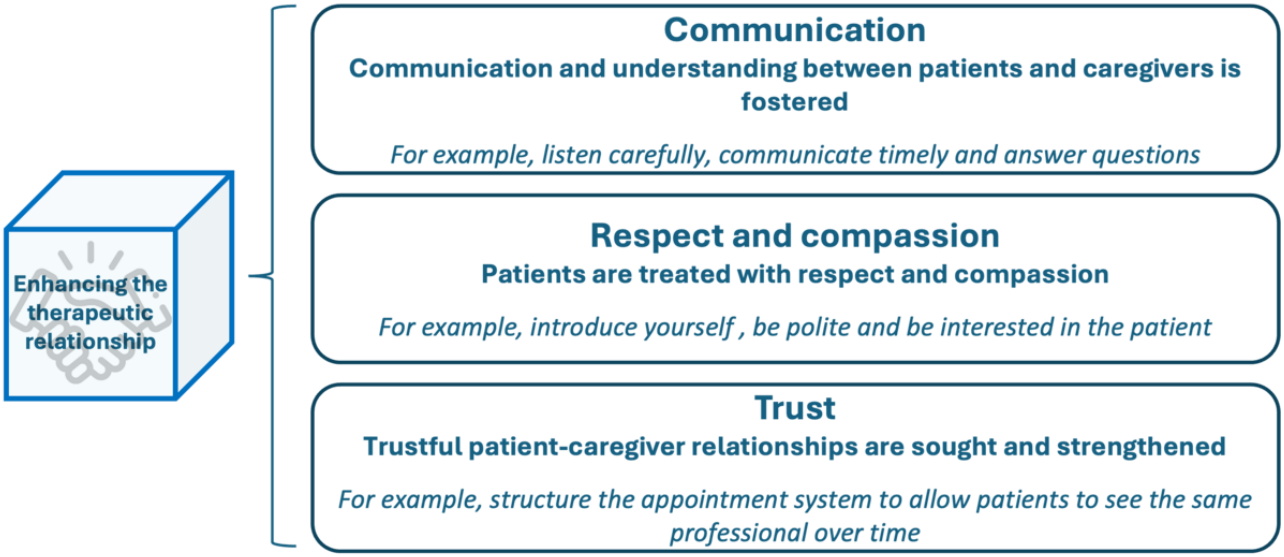
Information refers to patients being provided with and having access to tailored information. Exemplary patient-centered activities found in the literature include ensuring access to care plans and health care records [20,21]; providing patients with access to audio recordings or written summaries of clinical consultations [21]; and making an information and support center available and easily accessible for staff, patients, family members, and health care professionals [22]. Examples of further activities that emerged through the survey include allocating sufficient time during consultations, establishing an informative website, and ensuring patients understand the provided information. An approach, such as the teach-back method [42], could be used for this purpose. The second subdimension focuses on patient education. Exemplary patient-centered activities found through the review process include providing health education and management programs [10,20,21,23-31], using waiting rooms and other public spaces for opportune health education [20,25], and ensuring access to patient advocacy and advisory services [10,20]. An additional activity from the survey is providing discussion groups for patients. Finally, the last subdimension emphasizes the importance of patient motivation. Hereby, health care providers can actively seek to motivate patients to engage in and take control of their health care [27]. Within the survey, respondents described the status quo of the dimension "empowering patient" as follows: 17% (4/23) to a little extent, 61% (14/23) to some extent, 13% (3/23) to a large extent, and 9% (2/23) to a considerable extent.

Engaging and Involving Patients

The dimension "engaging and involving patients" refers to the active role of patients in health care, either independently through self-management activities or in collaboration with health care professionals through shared decision-making and care planning [2]. Figure 6 displays the 4 formed subcategories: self-management, participation in care planning, shared decision-making, and cocreation of services and systems.

XSL•FO
RenderX

Figure 6. Subdimensions and examples of patient-centered activities in the "engaging and involving patients" dimension.



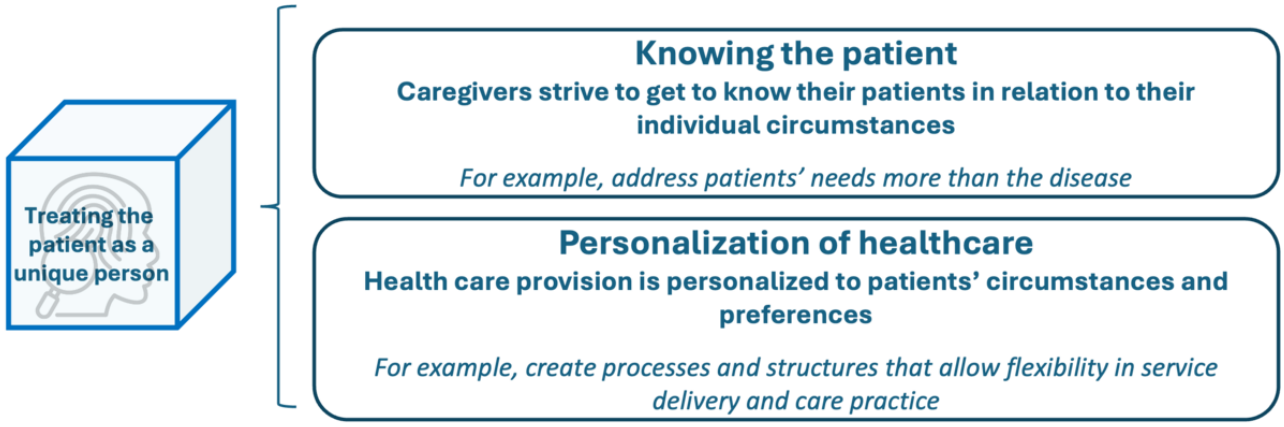
Self-management involves recognizing and actively supporting the patient's ability and responsibility to manage their disease. An exemplary patient-centered activity within this subdimension is the provision of self-management tools [20,21,23,25,32,33]. An example of this, which was described in the survey, is a patient passport, which patients can use to record their cancer pathway. Further patient-centered activities in this subdimension include self-management training programs [20,21,23,25,32,33] and providing patients with navigation assistance [10,32]. Examples of additional activities outlined in the survey encompass supporting the self-management of pain and initiating specific patient engagement programs, such as self-initiated follow-ups for patients. The subsequent subdimension describes patients' participation in care planning. Hereby, patients' personal preferences and capabilities for participation must always be considered. Patient-centered activities described both in the literature and the survey consist of setting common goals with patients [20], encouraging patients to ask questions [23], co-designing and discussing care plans [20,27], and providing opportunities for integrating patient needs [25,31]. Within the third subdimension, shared decision-making, patients and health care professionals engage in a collaborative process aimed at reaching the optimal choices for patients' well-being. Exemplary patient-centered activities in this subdimension encompass offering a clinical decision support system [28,32], providing decision-making tools [21,30,34,35], and exchanging clinical and experimental knowledge [36]. Another example from the survey is training patients in communication and negotiation skills. The fourth subdimension concerns the cocreation of services and systems, focusing on the organizational level. It is considered an essential aspect of patient centeredness because a service or system can arguably only achieve true patient centeredness if patients are involved in its design and implementation. Patients need to be provided with opportunities to participate in shaping and improving health care services and systems actively. The survey revealed various activities that illustrate this concept, for instance, (1) jointly developing patient information and patient pathways; (2) involving patients, their affiliated organizations, and support groups in the planning and coordination of services; and (3) engaging patients in strategic planning, guideline formulation, and policy development. Hereby, as in other dimensions, it is essential to allocate economic resources to carry out these activities. Within the survey, respondents described the status quo of the dimension "engaging and involving patients" as follows: 17% (4/23) to a little extent, 57% (13/23) to some extent, 17% (4/23) to a large extent, and 9% (2/23) to a very large extent.

Enhancing the Therapeutic Relationship

The dimension "enhancing the therapeutic relationship" underscores the significant importance placed on the relationship between health care professionals and patients [18-20]. Three distinct subcategories have been identified: clinician-patient communication, respectful and compassionate care, and a trusting relationship, which are displayed in Figure 7.

XSL•FO
RenderX

Figure 7. Subdimensions and examples of patient-centered activities in the "enhancing the therapeutic relationship" dimension.



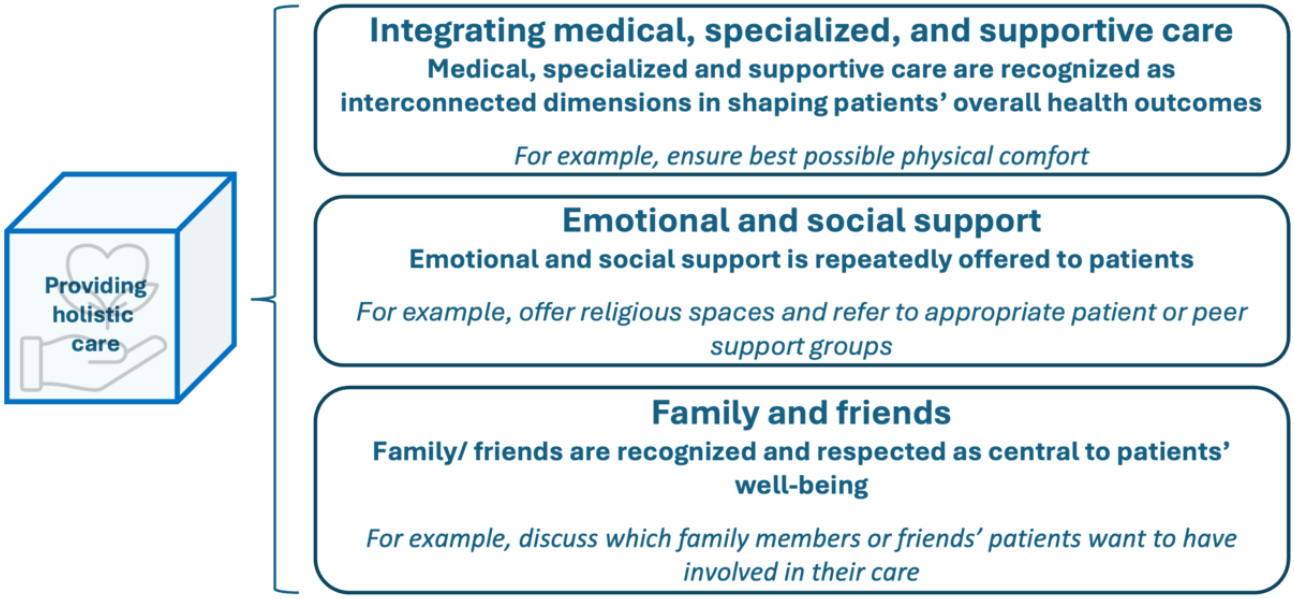
Within the realm of physician-patient communication, efforts are directed toward nurturing comprehension between the parties involved. Patient-centered activities pertinent to this subdimension encompass active listening [20,23-26,32,36], engaging in timely communication [10], using nonverbal cues [23], and dedicating sufficient time [23,28]. An additional activity assembled from the survey involves implementing concise, straightforward, and effective communication and counseling protocols. To foster respectful and compassionate care, the literature highlights patient-centered activities, such as being empathic [32], warm, friendly, and approachable [10,34]; demonstrating genuine interest in the patient [23]; using polite introductions [34]; and treating the patient with dignity and respect [10,30,34,36]. The final subdimension pertains to the pursuit and reinforcement of a trusting relationship between the patient and the health care professional. Patient-centered health care professional activities identified in the literature encompass the virtues of sincerity, truthfulness, and professionalism [10,23,25,32,34,36]; safeguarding the patient's privacy [10,23,34]; and ensuring a designated primary point of contact for the patient [23,26]. Further activities brought to light through the survey involve structuring the appointment system to facilitate continuity of care with the same health care professional over time and establishing mechanisms for direct patient-professional interaction, for example, by implementing platforms or tools that enable secure communication between patients and health care professionals, such as telemedicine or patient portals. Within the survey, respondents described the status quo of the dimension "enhancing the therapeutic relationship" as follows: 22% (5/23) to a little extent, 30% (7/23) to some extent, 39% (9/23) to a large extent, and 9% (2/23) to a very large extent.

Treating the Patient as a Unique Person

Treating the patient as a unique person entails acknowledging the patient's distinctive needs, preferences, values, feelings, beliefs, concerns, ideas, and expectations. An effort is made to get to know the patient, and care is personalized, respectively to the obtained knowledge [18,19,25]. Two subcategories, displayed in Figure 8, were formed: knowing the patient and personalization of health care.

Figure 8. Subdimensions and examples of patient-centered activities in the dimension "treating the patient as a unique person.".

Knowing the patient entails health care professionals making concerted efforts to comprehend their patients within the context of their specific situations. Noteworthy patient-centric activities within this dimension, as found in existing literature, encompass continually reassessing a patient's objectives vis-à-vis their ongoing care plan [26], prioritizing patient needs beyond their



XSL•FO
RenderX

medical condition [35], and identifying common ground based on patient preferences [30,32]. In addition, the survey yielded further examples of activities, including conducting comprehensive needs assessments to uncover patients' priorities and giving physicians time to prepare before consultations. The second subdimension describes how health care provision is personalized to patients' circumstances and preferences. Patient-centered activities outlined in the literature entail leveraging the knowledge of the patient as an individual to facilitate effective interactions [23,32], cultivating collaborations with community organizations [20,43], enabling home-based care possibilities [37], and creating an individualized care plan [26]. Within the survey, respondents described the status quo of the dimension "treating the patient as a unique person" as follows: 4% (1/23) to no extent, 17% (4/23) to a little extent, 35% (8/23) to some extent, 35% (8/23) to a large extent, and 9% (223) to a very large extent.

Providing Holistic Care

Providing holistic care emphasizes the vital role of addressing not only the physical requirements of patients but also their emotional, social, and spiritual needs [18,19,31,38]. The dimension is further divided into 3 subdimensions, as displayed in Figure 9: integrating medical, specialized and supportive care, emotional and social support, and family and friends.

Figure 9. Subdimensions and examples of patient-centered activities in the dimension "providing holistic care.".

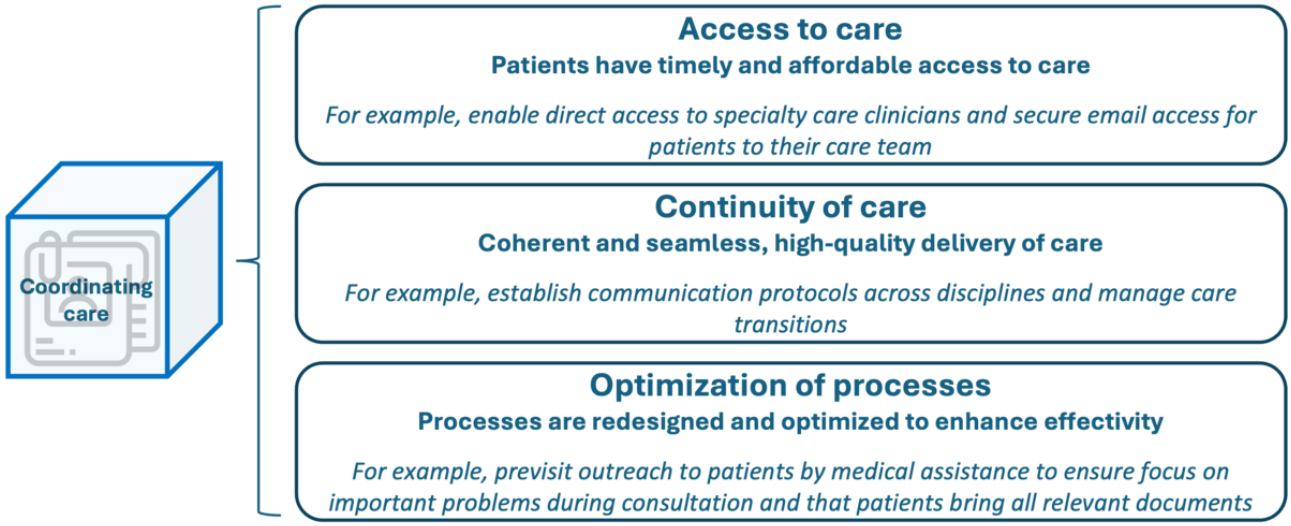
Medical, specialized, and supportive care are recognized as interconnected dimensions in shaping patients' overall health outcomes. Hereby, specialized care plays a crucial role in tailoring interventions and treatments to specific medical conditions, ensuring precision and effectiveness in addressing the unique health care needs of individual patients. Furthermore, supportive care is recognized as an integral part of care provision. Patient-centered activities sourced from the literature encompass initiatives such as identifying patients who could benefit from early palliative care [33,37], facilitating the continuity of everyday routines and self-identity [17], ensuring optimal physical comfort [33], and specifically addressing the needs of survivors (eg, fear of recurrence) [35]. Examples of other activities mentioned in the survey include providing access to auxiliary disciplines or guidance on supportive care possibilities. The second subdimension, focused on emotional and social support, underscores the provision of emotional and social assistance. Literature highlights measures such as cultivating a supportive and accommodating environment [20,21,32,36], allocating resources for self-help programs [21], offering spaces for religious practices [20,32], and providing emotional support while being empathetically present [28,31,32]. The survey also draws attention to the importance of access to psycho-oncology services. The third subdimension, family and friends, acknowledges the central role of these individuals in patients' well-being. Notable patient-centered activities delineated in the literature include ensuring the availability of spiritual care support for families [34], addressing the needs of family members and friends [17], and encouraging the participation of family and friends in consultations [33]. As publicized in the survey, an additional patient-centered activity involves establishing an appropriate and flexible visiting policy. Within the survey, respondents described the status quo of the dimension "providing holistic care" as follows: 9% (2/23) to no extent, 13% (3/23) to a little extent, 39% (9/23) to some extent, 35% (8/23) to a large extent, and 4% (1/23) to a very large extent.

Recognizing and Supporting the Health Care Provider as a Person

"Recognizing and supporting the health care provider as a person" emphasizes the significance of acknowledging the pivotal role of health care professionals; the unique challenges they face; and the need to provide multifaceted support, including emotional, informational, and instrumental assistance [18-20]. The concept delineates 3 distinct subdimensions: personal qualities, training and qualification, and support, which are displayed in Figure 10.

XSL•FO
RenderX

Figure 10. Subdimensions and examples of patient-centered activities in the dimension "recognizing and supporting the health care provider as a person.".



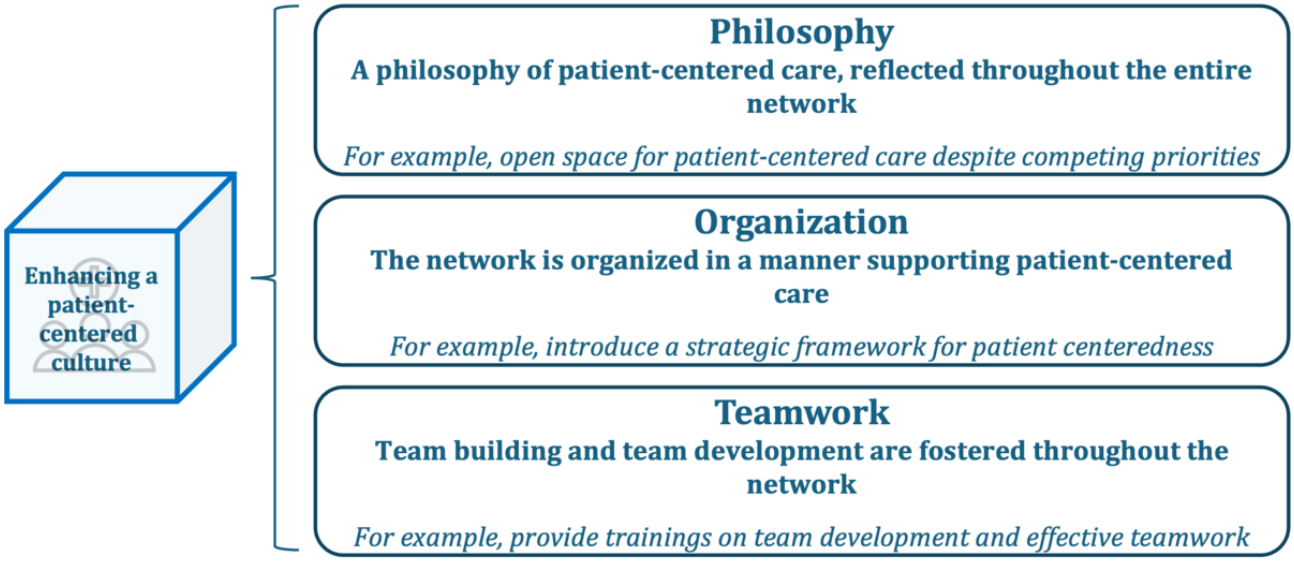
In the first subdimension, the health care professional embodies personal qualities essential for patient-centered care. The literature underscores traits such as commitment to their job [28], dedication to quality [21], fostering respect and nonjudgmental behavior [25], exhibiting self-reflective behavior [23,28,31], demonstrating empathy and compassion [23,31], and adhering to principles of honesty [31]. The second subdimension emphasizes the continuous training and qualification of health care personnel. Exemplary activities found in the literature include ensuring a well-rounded skill mix [28]; promoting lifelong learning [21]; offering opportunities for continuous professional development [21,25,28,30,34]; advocating evidence-based practice [21]; and providing training in patient centeredness, effective communication, and self-care [21,22,32,34]. The third subdimension pertains to supporting health care professionals to enable them to carry out their daily tasks effectively. Activities deemed patient centered, both within the literature and gleaned from the survey, involve delivering sustained support to health care professionals throughout the care process, ensuring financial stability, providing psychological assistance, implementing incentive packages based on performance, offering recreational programs, and fostering a balance between work and personal life [21,34]. Within the survey, respondents described the status quo of the dimension "recognizing and supporting the health care professional as a person" as follows: 9% (2/23) to no extent, 35% (8/23) to a little extent, 35% (8/23) to some extent, 17% (4/23) to a large extent, and 4% (1/23) to a very large extent.

Coordinating Care

Coordinating care highlights the need to structure care processes, promote access, and ensure the continuity of care [18,20]. This concept unfolds into 3 subdimensions, as displayed in Figure 11: access to care, continuity of care, and optimization of processes.

Figure 11. Subdimensions and examples of patient-centered activities in the dimension "coordinating care.".

In the access to care subdimension, the emphasis is on timely and affordable care provision. Notable patient-centered activities within this subdimension, as documented in the literature, encompass enabling secure email access between patients and



XSL•FO
RenderX

clinicians [32], providing direct access to specialty care clinicians [32], implementing suitable appointment scheduling [21,32,33], and ensuring care affordability [20,32]. The survey further highlighted an additional activity: ensuring universal access to both primary and secondary care. The second subdimension, dedicated to continuity of care, revolves around delivering coherent, uninterrupted, high-quality care. Patient-centered activities highlighted in the literature include establishing interprofessional leadership teams [21], using patient pathways [32], conducting posttreatment follow-ups [10,29], and guaranteeing the seamless flow of information [20,32,37]. In addition, the survey revealed further activities, such as involving and supporting the primary family caregiver, instituting a nurse navigator, and defining wait times for diagnosis. Hereby, achieving a delicate balance between standardizing high-quality care and permitting adequate flexibility and individualization becomes essential. The third subdimension, optimization of processes, focuses on refining processes to enhance effectiveness. Patient-centered initiatives sourced from the literature encompass developing discharge and referral protocols [21], ensuring efficient workflow [30,32], minimizing clinical wait times [32], fostering continuous quality improvement [26], appointing case managers or oncology nurses with case management duties for patients with cancer [29], and implementing transparent and understandable service protocols to improve patient flow [21]. Within the survey, respondents described the status quo of the dimension "coordinating care" as follows: 13% (3/23) to a little extent, 39% (9/23) to some extent, 35% (8/23) to a large extent, and 13% (3/23) to a very large extent.

Enhancing a Patient-Centered Culture

Enhancing a patient-centered culture underscores the imperative of a profound cultural shift, where patient centeredness becomes deeply ingrained in the foundational philosophy and organizational structure of the health care network [20,24,25]. This dimension, displayed in Figure 12, is segmented into 3 subdimensions: philosophy, organization, and teamwork.

Figure 12. Subdimensions and examples of patient-centered activities in the dimension "enhancing a patient-centered culture.".

In the philosophy subdimension, patient-centered care permeates the entire network. Patient-centered activities documented in the literature within this subdimension encompass positioning patient-centered care as a major priority in the CCCN, fostering a culture of reflective practice [21], and embracing corporate responsibility for equality and diversity [34]. This implies that all stakeholders, for instance, medical staff and management, value the concept of patient centeredness and promote the conceptual framework. Additional patient-centered activities surfaced from the survey, including positioning patient-centered care as a primary priority within the CCCN, instilling trust and respect as core values of the CCCN, and establishing a patient charter. The second subdimension, organization, revolves around structuring the network to support patient-centered care. This encompasses patient-centered activities outlined in the literature, such as establishing services that promote a patient-centered culture [20,24,28,34]. This could, for instance, include interpretation, language, or information services. Further activities found in the literature include introducing a strategic framework for patient centeredness [28] and implementing change management aimed at anchoring patient-centered care in the everyday culture of the network [28]. Teamwork, including team building and development, is the final subdimension in the dimension "enhancing a patient-centered culture." Exemplary patient-centered activities found in the literature include establishing and strengthening a multidisciplinary and interprofessional patient care team [21,26,29], encouraging teamwork and team building [20,28], and ensuring a strong team leadership committed to a patient-centered culture [17,24,34]. Within the survey, respondents described the status quo of the dimension "enhancing a patient-centered culture" as follows: 9% (2/23) to no extent, 13% (3/23) to a little extent, 65% (15/23) to some extent, 4% (1/23) to a large extent, and 9% (2/23) to a very large extent.

Defining Patient Centeredness in CCCNs

Informed by the umbrella review and survey findings, the subsequent definition for patient centeredness within a CCCN was formulated: patient centeredness in a CCCN is a philosophy

XSL•FO
RenderX

of care prioritizing the physical, emotional, and social needs and personal values of the patients with cancer at every step of the patient pathway. In patient-centered CCCNs, patients are empowered and engaged in becoming active partners in health care in relation to their individual preferences and capabilities with the goal of providing personalized, high-quality, holistic care with the best possible outcomes.

Out of the 23 participants who completed the survey, 22 (96%) either strongly agreed (11/23, 48%) or agreed (11/23, 48%) with the proposed definition of patient centeredness in CCCNs. The comments received from the participants supported the revision of the definition. Notably, participants highlighted that the level of patient involvement as "active" partners in care should also consider a patient's mental and physical capabilities. Therefore, the phrase "and capabilities" was added to the definition after analyzing the results of the survey. The participant who disagreed with the definition supported the revision of the framework but did not provide additional comments specifically addressing the definition. The feedback from patient representatives during the focus group did not lead to changes in the definition.

Discussion

Principal Findings

This study examines the concept of patient-centered care within the context of CCCNs in Europe. In this context, the study's findings elucidate a comprehensive definition and framework of patient centeredness. The identified framework, comprising 8 primary dimensions and 24 subdimensions, provides a structured understanding of the diverse facets that constitute patient-centered care. The combination of methods—an umbrella review, a survey of key stakeholders, and feedback from patient representatives—contributes to the robustness of the study's findings by capturing both theoretical and a multitude of practical perspectives.

Theoretical and Practical Contribution

The theoretical contribution of this paper lies in its support for the further conceptualization of patient centeredness within health care, particularly in the context of oncology and CCCNs. By using a robust method and delineating a comprehensive framework consisting of 8 primary dimensions and their corresponding subdimensions, this study refines and expands the understanding of patient-centered care. The framework not only encompasses the conventional theoretical elements of patient-centered care but also tailors them to suit the complex dynamics of CCCNs. The foundational principles, which could potentially apply to other medical conditions as well as singular cancer care institutions, were primarily derived from the umbrella review. However, the emphasis on cancer, particularly within the context of care delivery in CCCNs, was established by incorporating reviews specifically addressing patient centeredness in oncology, conducting surveys with key stakeholders within CCCNs, and facilitating the focus group with patients with cancer.

From a practical standpoint, the intention of this paper is to provide health care professionals, managers and coordinators of health care services, authorities, and further CCCN stakeholders with guidance to support the implementation of patient-centered care. Thus, the aim of this paper is to empower CCCNs in establishing an environment where patients feel genuinely heard, valued, and actively engaged in care. The paper offers concrete guidance and inspiration on what patient-centered activities can be put into action by CCCNs to enhance their focus on patients. The establishment of a consistent definition and framework of patient centeredness in CCCNs provides a foundation for health care institutions to prioritize patient needs and preferences, potentially leading to improved patient outcomes and experiences. By identifying specific actionable activities under each subdimension of the framework, the study provides tangible actions that CCCNs can take to implement patient-centered care effectively (complete list provided in Multimedia 4). These practical insights go beyond vague principles, empowering CCCNs and health care professionals with targeted strategies to, for instance, enhance patient engagement, promote a patient-centered culture, and establish effective therapeutic relationships.

In Multimedia Appendix 4, only the activities highlighted in light red, as well as the results obtained through the survey and the focus groups, are in direct relation to cancer care. The relevance of these activities to alternative contexts and diseases remains uncertain and necessitates further examination and empirical validation. However, the remaining actionable patient-centered activities exhibit a generic essence, suggesting their potential pertinence to diverse health care domains and institutions. This assumption lays the groundwork for their likely applicability to a range of health care entities beyond the scope of this study.

Comparison With Prior Work

This study shares several similarities with existing conceptualizations of patient centeredness, while also introducing notable differences. As the study is rooted in a thorough analysis of existing literature and frameworks, key principles, such as the therapeutic alliance, engagement, and holistic care, are integrated [18,19,31]. To discern the differences, especially in comparison to the dimensions established by Langberg et al [18], building on the study by Mead and Bower [19], is interesting, as this was the starting point for the category formation approach used in this study. Therefore, the dimensions formulated by Langberg et al [18] are clearly reflected in the results of this study. However, a new dimension, "enhancing a patient-centered culture," was added. Furthermore, the dimension "sharing power and responsibility" was divided into the 2 distinct concepts of patient engagement and empowerment [2]. Notably, the subdimensions provided in the framework of patient centeredness in CCCNs exhibit further differences. For instance, "providing holistic care," which aligns with the "biopsychological" dimension by Langberg et al [18], now includes involvement of family and friends.

These differences may stem from several factors, the most obvious being the focus on cancer care in CCCNs, informed incorporation of literature based in oncology, the survey with key CCCN stakeholders, and the focus group with patient

XSL•FO
RenderX

representatives in the field of oncology. Therefore, these delineations may be unique to the realm of cancer care in CCCNs. Another possibility is that the concept of patient centeredness has advanced in the last 5 years. This may be especially true, as other studies published at a later point in time (Multimedia Appendix 2) were also used as a basis for this paper.

Overall, our findings align with and extend existing theories of patient-centered care, reinforcing the notion that patient centeredness goes beyond mere patient satisfaction and, for instance, involves active patient participation, individualized care, and the recognition of the patient's psychological and emotional state [18].

Limitations

A limitation of this study, which warrants consideration, is the limited number of both included papers and participants. An umbrella review was chosen because of the large number of publications on the topic of patient centeredness. Only using existing reviews as a basis may warrant limitations, as it facilitates a dependence on the high quality of the performed reviews, and certain aspects of patient centeredness may have been missed. For instance, the topic of cancer survivorship is not addressed as prominently as we might have expected. Including more databases might have highlighted this topic more effectively. However, we observed a saturation of information regarding each dimension and subdimension, which likely moderated this effect. In addition, survey participants are experts in CCCNs with extensive experience either working within them or collaborating closely. Therefore, despite the limited number of participants, the quality of their responses is substantial.

It should also be considered that a patient-centered approach can vary from one patient to another. The diverse range of patient requirements, considerations, and preferences plays a role here. For instance, the level of active involvement a patient desires in their care can differ greatly. A patient-centered activity listed in Multimedia Appendix 1 may be ideal for one patient but unnecessary—or even unwelcome—for another. Moreover, the activities presented encompass a spectrum of possibilities aimed at enhancing patient-centered care. However, their suitability, feasibility, and acceptance can differ across various scenarios, necessitating further evaluation and testing. As the umbrella review focused exclusively on publications in English or German, it becomes imperative to conduct evaluations in various countries and among diverse cultural backgrounds.

Future Research

Building on the foundation established by this study, several promising avenues for future research emerge. One potential direction is to conduct empirical investigations that assess the implementation and effectiveness of the proposed patient-centered activities within CCCNs. This could involve longitudinal studies tracking patient outcomes, experiences, and health care provider practices before and after adopting certain activities. Such research could shed light on the tangible impacts of patient-centered care on patient satisfaction, treatment adherence, and overall well-being. In addition, these studies could help confirm the study's relevance in broader contexts, such as specific cancer care institutions or health care settings outside Europe.

In addition, exploring the contextual factors that facilitate or hinder the integration of specific patient-centered activities could provide insights into the dynamic nature of health care systems and inform strategies for successful implementation. Factors such as the competence and mindset of the medical team, economic constraints, legislation, and the interoperability or current state of digital health technologies may significantly influence the success of specific activities.

In terms of implementation support, reviews, best practices, and specific tool support would be desirable to enhance and facilitate the implementation of the individual patient-centered activities in CCCNs.

Conclusions

This study contributes to the understanding of patient-centered care in the unique context of cancer care. By providing a comprehensive framework and definition, the study equips CCCNs, and possibly also individual cancer care institutions, with actionable patient-centered activities to foster an environment where patients are actively engaged, valued, and empowered in their cancer care pathway. As health care systems strive to prioritize patient centeredness, the insights presented here hold the potential to reshape cancer care practices and inspire broader improvements in health care delivery.

Acknowledgments

The study is part of the work performed in the CraNE Joint Action (European Network of Comprehensive Cancer Centers). Further information on CraNE Joint Action can be found on the CraNE website [44]. The CraNE Joint Action has received funding from the European Union through the European Health and Digital Executive Agency within the framework of the EU Health Program (EU4Health) 2021-2027.

Abstract

Background: Colorectal cancer is now the leading cause of cancer-related deaths among young Americans. Accurate early prediction and a thorough understanding of the risk factors for early-onset colorectal cancer (EOCRC) are vital for effective prevention and treatment, particularly for patients below the recommended screening age.

Objective: Our study aims to predict EOCRC using machine learning (ML) and structured electronic health record data for individuals under the screening age of 45 years, with the aim of exploring potential risk and protective factors that could support early diagnosis.

Methods: We identified a cohort of patients under the age of 45 years from the OneFlorida+ Clinical Research Consortium. Given the distinct pathology of colon cancer (CC) and rectal cancer (RC), we created separate prediction models for each cancer type with various ML algorithms. We assessed multiple prediction time windows (ie, 0, 1, 3, and 5 y) and ensured robustness through propensity score matching to account for confounding variables including sex, race, ethnicity, and birth year. We conducted a comprehensive performance evaluation using metrics including area under the curve (AUC), sensitivity, specificity, positive predictive value, negative predictive value, and F_1-score. Both linear (ie, logistic regression, support vector machine) and nonlinear (ie, Extreme Gradient Boosting and random forest) models were assessed to enable rigorous comparison across different classification strategies. In addition, we used the Shapley Additive Explanations to interpret the models and identify key risk and protective factors associated with EOCRC.

Results: The final cohort included 1358 CC cases with 6790 matched controls, and 560 RC cases with 2800 matched controls. The RC group had a more balanced sex distribution (2:3 male-to-female) compared to the CC group (2:5 male-to-female), and both groups showed diverse racial and ethnic representation. Our predictive models demonstrated reasonable results, with AUC scores for CC prediction of 0.811, 0.748, 0.689, and 0.686 at 0, 1, 3, and 5 years before diagnosis, respectively. For RC prediction, AUC scores were 0.829, 0.771, 0.727, and 0.721 across the same time windows. Key predictive features across both cancer types included immune and digestive system disorders, secondary malignancies, and underweight status. In addition, blood diseases emerged as prominent indicators specifically for CC.

Conclusions: Our findings demonstrate the potential of ML models leveraging electronic health record data to facilitate the early prediction of EOCRC in individuals under 45 years. By uncovering important risk factors and achieving promising predictive performance, this study provides preliminary insights that could inform future efforts toward earlier detection and prevention in younger populations.

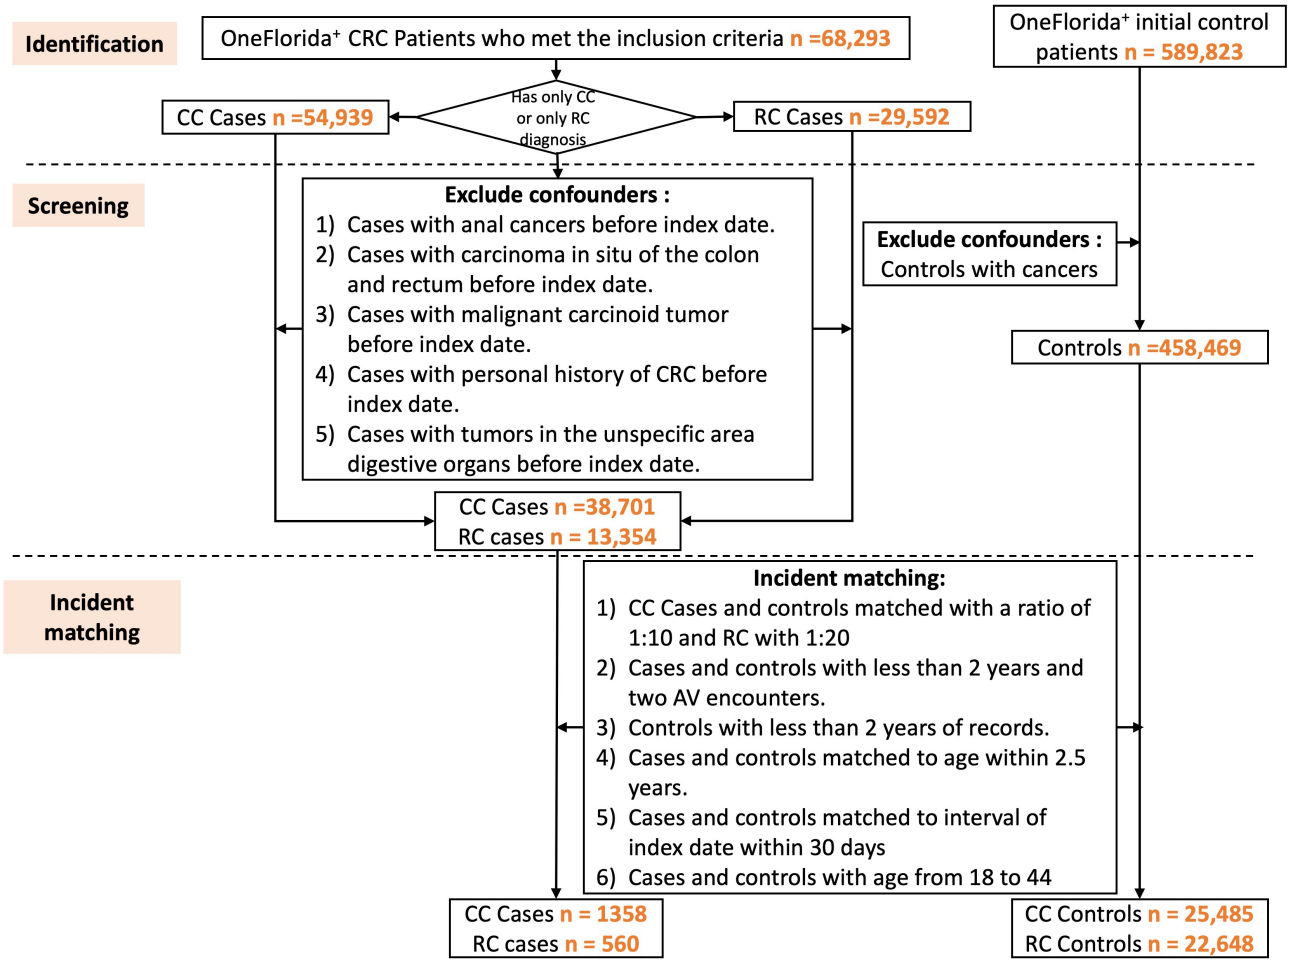
Introduction

Colorectal cancer (CRC) is a significant public health challenge, ranking as the third leading cause of cancer-related mortality among both males and females in the United States [1]. It is estimated that in 2023, approximately 153,020 individuals were diagnosed with CRC, and 52,550 succumbed to the disease [1]. While cancer is typically a disease of older age, a concerning trend has emerged—the increasing incidence of early-onset colorectal cancer (EOCRC) in individuals younger than the age of 50 years [1,2]. This increased incidence has led the US Preventive Services Task Force to modify its recommendations, lowering the age to start CRC screening to age 45 [3]. Patients diagnosed with EOCRC tend to present at later stages and face lower disease-specific survival rates, underscoring the need for early detection and treatment initiation [4]. Nevertheless, challenges in addressing EOCRC are compounded by poorly defined risk factors and the role of diagnostic delays. As a result, early prediction and comprehensive understanding of the risk factors of EOCRC are essential for prevention and treatment, particularly for patients who fall below the recommended screening age.

The rapid integration of artificial intelligence and big data analytics has significantly expanded the horizons of medical research and clinical care [5]. Diverse data sources, including imaging and genomic data, have been harnessed for CRC detection through the application of statistical and machine learning (ML) algorithms. Some approaches have included the analysis of tumor DNA and circulating RNA expression profiling data to identify potential pathogenic factors [6,7]. In addition, computer tomography (CT)–based radionics, combined with ML algorithms, have been used to predict the Kirsten rat sarcoma viral oncogene mutation in people with CRC, demonstrating the potential of ML in clinical decision support [8]. Further, a random forest (RF) model trained with standard clinical and pathological prognostic variables, coupled with magnetic resonance imaging (MRI) images, achieved an impressive area under the curve (AUC) score of 0.94 when predicting survival in CRC patients, highlighting the importance of MRI-based texture features in patient survival prediction [9]. However, imaging data produces a small number of unexplainable predictors (around 100), and does not consistently improve diagnostic accuracy and disease prediction, especially when only using imaging data [10]. Furthermore, advanced imaging modalities and genomic data can be costly, with limited accessibility, and lack diversity and representativeness in samples, which could impact timely and accurate diagnosis for all individuals affected by EOCRC or widen already present disparities in patient outcomes.

In contrast to imaging and genomic data, structured data from the electronic health record (EHR) offers a more accessible and cost-effective data source for initial research. Originally designed for administrative and billing purposes, structured EHR data have evolved into valuable tools for health care research, capturing a wealth of patient information, including clinical diagnoses, procedures, medications, and laboratory results, among others [11]. The integration of ML and deep learning with EHR data has demonstrated substantial potential for disease prediction, including Alzheimer disease, gestational diabetes mellitus, and coronary heart disease [12-14]. In the context of CRC, several ML approaches have been used to predict the risk of the disease. For example, Shanbehzadeh et al [15] used structured EHR data and four data mining algorithms to predict CRC risk, identifying critical attributes for the prediction model using the weight statistical χ^2 test. However, the weight statistical χ^2 test assumes independence among variables, which may not hold true in complex datasets where variables are likely correlated. Another study leveraged convolutional neural networks to predict CRC risk based on the structured EHR data from the Taiwan National Health Insurance database [16]. Hussan et al [17] explored multiple ML methods to construct predictive models for CRC among patients aged between 35 and 50 years. However, these studies faced challenges in effectively matching cases and control groups, leading to increased bias and concerns regarding confounding. Furthermore, another limitation across studies is the failure to distinguish between colon cancer (CC) and rectal cancer (RC), despite the differences in clinical presentation, molecular carcinogenesis, pathology, surgical topography and procedures, and multimodal treatment strategies between these 2 cancers [18]. In addition, the lack of model explanations regarding clinical diagnosis of CRC undermined the interpretability and reliability of their strategies. As a result, there is a pressing need for improved methodologies to enhance the reliability and understanding of ML models in EOCRC prediction.

Methods



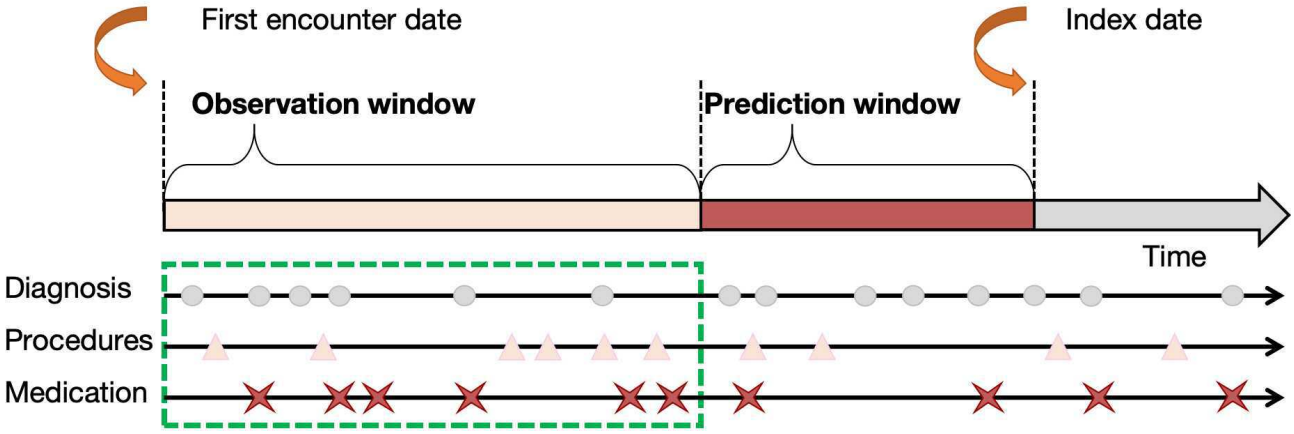
Data Source and Study Population

This study used deidentified EHR data from the OneFlorida+ Clinical Research Consortium, which operates within the PCORnet Clinical Research Network funded by the Patient-Centered Outcomes Research Institute. PCORnet serves as a national resource dedicated to advancing high-priority health research and improving outcomes through a robust, integrated research infrastructure [19,20]. By combining extensive health data, research expertise, and patient perspectives, it enables network partners to rapidly generate reliable, actionable evidence to support public health and clinical decision-making [19,20]. The OneFlorida+ data encompasses a wide range of patient characteristics from health systems across the southeast, including EHR data collected using the PCORnet Common Data Model [19] regarding demographics, diagnoses, medications, procedures, vital signs, lab tests, and more.

XSL•FO
RenderX

The construction of our study cohort using OneFlorida+ is outlined in Figure 1. OneFlorida+ identified individuals from the OneFlorida+ network, with encounters from January 2012 to January 2023 who met our inclusion criteria as either a case or control. We identified cases of CC using the *International Classification of Diseases, Ninth Revision* (*ICD-9*) code of C18.x or C49A4 or the *International Classification of Diseases, Tenth Revision* (*ICD-10*) code of 153.x, or RC cases with the *ICD-9* code of C19.x, C20.x, C21.0, C21.1, and *ICD-10* code of 154.0 and 154.1. The initial cohort consisted of 68,293 CRC cases (54,939 CC cases and 29,592 RC cases), and 589,823 controls. From those, we excluded patients diagnosed with both CC and RC, other previous cancers, or those who were diagnosed ≥45 years of age. Our final study cohort comprised 1358 CC cases with 25,485 controls and 560 RC cases with 22,648 controls.

Figure 1. Flowchart of patient selection from OneFlorida+. CC: colon cancer; CRC: colorectal cancer; RC: rectal cancer; AV: Ambulatory Visit.



We used an incident matching process to match cases and controls to ensure a fair comparison across these groups. Initially, we retained cases and controls with more than 2 years of records and at least 2 encounters before the first onset date of either CC or RC and ensured that the age gap between matched cases and controls was within 2.5 years. By calculating propensity scores based on race, ethnicity, sex, and birth year (within 2.5 y), we used a narrow caliper of 0.05 with a nearest neighbor approach to achieve a 1:5 case-to-control ratio for each prediction window group [21]. This rigorous methodology ensures a balanced study population for reliable analysis and EOCRC prediction.

Study Setting

We then incorporated a range of different observation periods and prediction windows (Figure 2) to test our prediction algorithms, considering the different use cases. We considered 4 different prediction windows: 0 years, 1 year, 3 years, and 5 years before CRC diagnosis.

XSL•FO
RenderX

Figure 2. Visualization of the observation and prediction windows. For the prediction task. The index date for CRC cases is the date of diagnosis. For the control group, the index date is defined as the closest encounter date to the diagnosis date of the matched case group. The prediction window is the time period before the index date during which CRC cases are predicted. The observation window refers to the specific period during which data is collected or observed for analysis. CRC: colorectal cancer.

Data Preprocessing

The predictors we extracted included data from the demographics, vitals, diagnoses, medications, and procedures tables within the OneFlorida+ Clinical Research Network throughout the observation periods. Age at index date was calculated and categorized into 3 groups (eg, 18 - 29 y, 30 - 39 y, and 40 - 44 y). One-hot encoding [22] was used to represent age groups, race, and sex variables. Statistical analysis shows that the proportion of missing values is approximately 50% (4137/8148 in CC and 1554/3360 in RC). According to [23-25], mean imputation is less sensitive to high proportions of missing data and is more robust compared to other imputation methods, such as median and mode imputations, the indicator method, and regression. Thus, for missing data, we imputed the missing values with the mean of the numerical data derived from the entire sample within each prediction window group. Furthermore, BMI data was categorized into clinically relevant groups, including underweight (≤18.5 y), normal (18.5 - 23 y), overweight (23-30 y), and obese (≥30). Diastolic and systolic measurements were categorized into distinct hypertension stages.

Diagnoses, which were initially represented using *ICD-9* and *ICD-10* codes, were subjected to a data dimensionality reduction process that mapped them into Phecodes [26,27]. Revenue codes and current procedural terminology codes [28] were leveraged to capture billed medical procedures. To integrate these data, we also used the clinical classifications software code [29]. For drug information, National Drug Code [30] and RxNorm codes were used for encoding. National Drug Codes were mapped into RxNorm codes, and further consolidated into anatomical therapeutic chemical classes [31]. To ensure completeness, all features that could not be mapped were retained to prevent any missing information. These steps to transform the data enhanced interpretability and relevance of our predictive models.

Experiments and Validation

We explored several widely used ML models, including linear models such as logistic regression (LR) and the support vector machine (SVM), as well as nonlinear models like XGBoost (Extreme Gradient Boosting) and RF. We adopted two modeling strategies, including (1) prediction without CRC-related features and (2) prediction without cancer-related features, covering the CRC-related features. For the first strategy, features that may be indicative of CRC differential diagnoses (eg, neoplasm of unspecified nature of digestive system) or treatments for CRC (eg, chemotherapy and radiotherapy) were removed from the models and not used as predictors. For the second strategy, we took a more stringent approach by eliminating all diagnoses, drugs, and procedures that could be associated with any cancer from the extracted predictors. This step aimed to identify risk factors while eliminating the influence of other types of cancers, enabling us to focus exclusively on noncancer-related predictors. Regardless of the feature engineering strategy, we maintained a consistent experimental setup. The entire dataset was randomly split into a training dataset and a testing dataset with a ratio of 4:1. Model optimization was conducted on the training set through 5-fold cross-validation, and we fine-tuned hyperparameters using Bayesian optimization. To ensure reproducibility, we fixed the random state seed across all model runs.

To assess the effectiveness of our models comprehensively, we used a battery of evaluation metrics, including AUC, sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and F_1-score. To mitigate the risk of overfitting and to derive robust CIs, we implemented a bootstrapping strategy. This involved conducting 100 experiments by randomly resampling the training and testing datasets. In addition to traditional performance metrics, we delved into the interpretability of the XGBoost models. Specifically, we computed Shapley Additive Explanations (SHAP) values [32] to gain insights into the inner workings of the ML algorithms and to identify the core contribution predictors. This approach aimed to unveil the high-risk factors associated with EOCRC, shedding light on the most influential features in our prediction model. To further assess generalizability, we performed temporal validation on all CC and RC groups, using data before January 1, 2015, for training and data after for testing. We then trained an XGBoost model to evaluate its performance on the test set.

Ethical Considerations

The study was approved and the requirement to obtain any informed consent was waived by the University of Florida

XSL•FO
RenderX

Institutional Review Board (protocol number IRB202201561). The research does not involve greater than minimal risk for participation. Analyses only involve the secondary analysis of data that are either limited datasets or deidentified. Our research team has no direct contact with human participants. All methods were carried out in accordance with relevant guidelines and regulations.

Results

Table 1 provides an overview of the identified study cohorts after propensity score matching for both CC and RC across various prediction windows. Notably, CC cases outnumber RC cases, with approximately twice as many CC cases. Patients in the RC groups were slightly older compared to those in the CC group. Sex distribution in the RC groups was closer to parity (2:3 male to female) than in the CC group (2:5 male to female). Both RC and CC groups exhibited diverse racial and ethnic representation. In addition, as the prediction window lengthened, the number of cases decreased. Specifically, there were 560, 560, 383, and 225 RC cases, and 1358, 1358, 884, and 532 CC cases in prediction windows for 0 years, 1 year, 3 years, and 5 years, respectively.

[a]CC: colon cancer.

[b]RC: rectal cancer.

Table 2 presents the results of CC prediction using 2 feature engineering strategies: 1 excluding CRC-related features and the other excluding cancer-related features. Additional evaluation metrics for CC prediction across all settings can be found in Tables S1-S2 in Multimedia Appendix 1. In most cases, tree-based models (XGBoost and RF) outperformed linear models (SVM and LR), yielding higher AUC values. Specifically, after removing CRC-related features, the RF model achieved the highest AUC for the 0-year prediction (0.811, 95% CI 0.808-0.814), while RF performed best for the 1-year (0.748, 95% CI 0.745-0.751), 3-year (0.689, 95% CI 0.684-694), and 5-year (0.686, 95% CI 0.68-0.692) predictions for CC. However, after removing features associated with previous cancers, the model performance decreased: LR achieved AUC values of 0.788 (95% CI 0.786-0.791) for 0-year prediction; RF achieved AUC values of 0.716 (95% CI 0.713-0.719) for 1-year, 0.684 (95% CI 0.679-0.688) for 3-year, and 0.663 (95% CI 0.658-0.668) for 5-year prediction. Performance metrics, including specificity, sensitivity, PPV, NPV, and F_1-score, exhibited similar trends.

Table . AUC[a] comparison for colon cancer prediction using machine learning models across different prediction windows (0, 1, 3, and 5 years).

Feature strategy and model	0-year AUC (95% CI)	1-year AUC (95% CI)	3-year AUC (95% CI)	5-year AUC (95% CI)
Excluding CRC-related[b] features				
LR[c]	0.809 (0.806-0.812)	0.733 (0.73-0.736)	0.683 (0.679-0.688)	0.674 (0.668-0.679)

Table 3 provides RC prediction results using the same feature engineering strategies and 4 prediction windows. Additional evaluation metrics for RC prediction across all settings can be found in Tables S3-S4 in Multimedia Appendix 1. Again, after removing CRC-related features, the XGBoost model achieved the highest AUC for the 0-year prediction (0.829, 95% CI 0.825-0.834), while RF performed best for the 1-year (0.771, 95% CI 0.766-0.777), and XGBoost did best for 3-year (0.727, 95% CI 0.721-0.732), and 5-year (0.721, 95% CI 0.713-0.729) predictions for RC. Eliminating cancer-related features resulted in a performance decrease: XGBoost achieved AUC values of 0.811 (95% CI 0.806-0.815) for 0-year prediction; RF achieved AUC values of 0.756 (95% CI 0.751-0.76) for 1-year, 0.724 (95% CI 0.718-0.73) for 3-year, and 0.711 (95% CI 0.704-0.719) for 5-year predictions. Performance metrics exhibited consistent trends. In both the CC and RC prediction tasks, we observed a decline in model performance as the prediction window length increased. Notably, when we removed cancer-related features, the AUC declined. This highlights the pivotal role these features play in enhancing prediction performance.

Table . AUC[a] comparison for rectal cancer prediction using machine learning models across different prediction windows (0, 1, 3, and 5 years).

Feature strategy and model	0-year AUC (95% CI)	1-year AUC (95% CI)	3-year AUC (95% CI)	5-year AUC (95% CI)
Excluding CRC[b]-related features

XGBoost	0.811 (0.806-0.815)	0.749 (0.744-0.753)	0.724 (0.718-0.729)	0.679 (0.672-0.687)

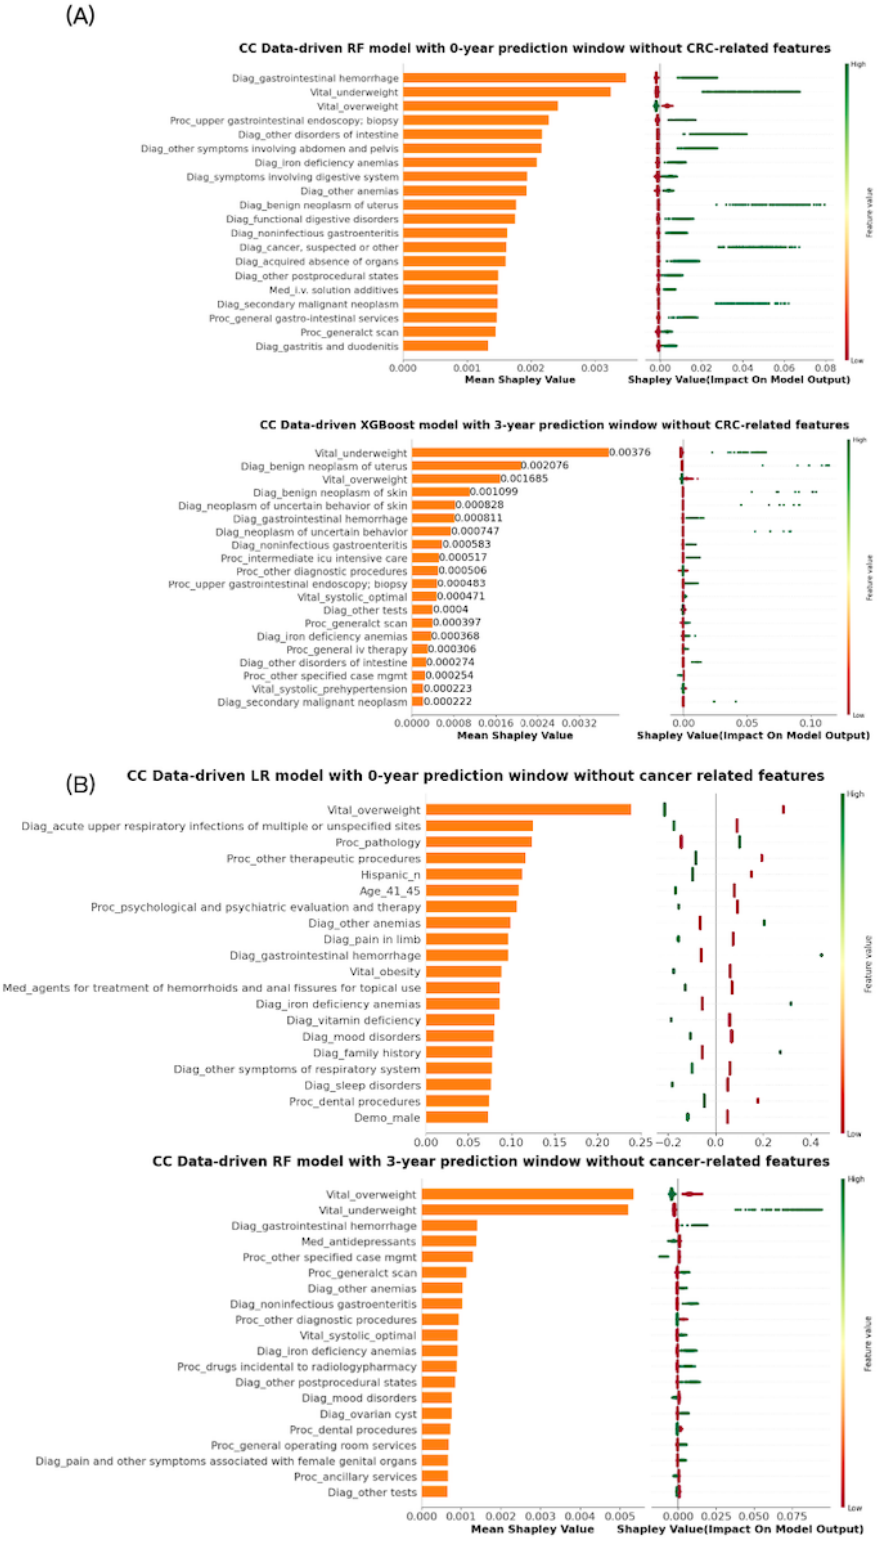
[a]AUC: area under the curve.

[b]CRC: colorectal cancer.

[c]LR: logistic regression.

[d]SVM: support vector machine.

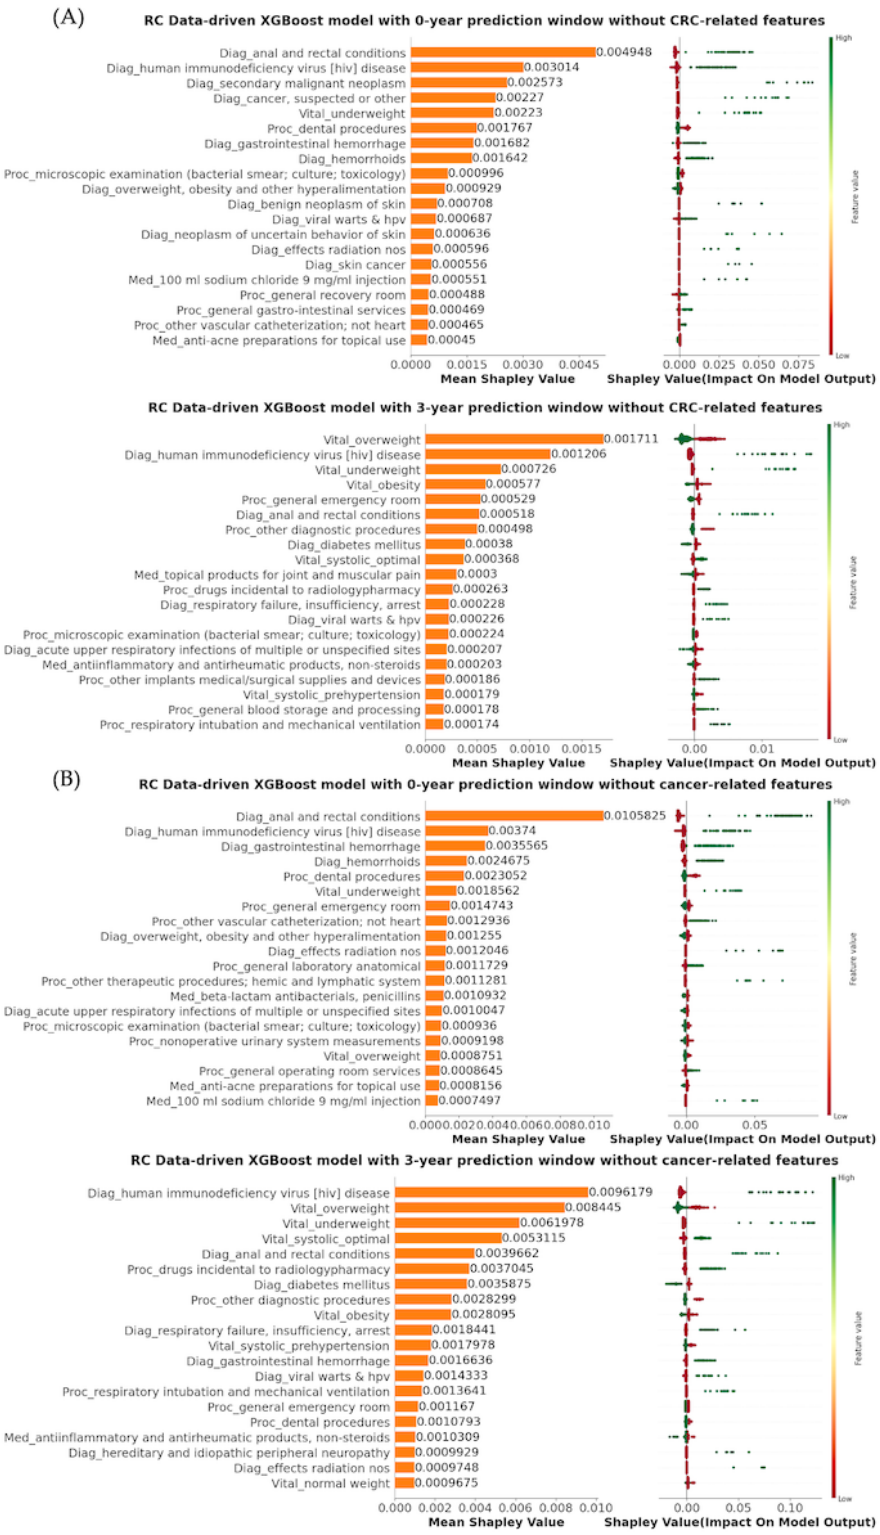
[e]RF: random forest.



[f]XGBoost: Extreme Gradient Boosting.

To further evaluate model performance, we integrated XGBoost and RF using soft voting. The AUC fluctuated around 0.01, showing no significant change from the best prevoting performance (Table S9 in Multimedia Appendix 1). For temporal validation, the overall AUC decreased slightly by around 0.02, suggesting potential distribution shifts over time that may have affected generalizability. While the model fit earlier data well, its weaker performance on newer data hints at possible drift (Tables S5-S8 in Multimedia Appendix 1).

To gain deeper insights into the risk factors associated with these findings, we present SHAP summary plots for CC and RC predictions using 2 feature engineering strategies and for 0-year and 3-year prediction windows in Figures 3 and 4. Supplementary SHAP summary plots for all other models can be found in Figures S1-S2 in Multimedia Appendix 1. Within the CC group, several predictors emerged as positively associated with the risk of CC. Notably, several diagnoses involving various tumors, such as suspected cancer, secondary malignant neoplasm, benign neoplasm of uterus, benign neoplasm of skin, neoplasm of uncertain behavior, neoplasm of uncertain behavior of skin, cancer of other female genital organs and myeloproliferative diseases were identified as influential factors. Gastrointestinal symptoms, encompassing conditions like gastrointestinal hemorrhage, other disorders of intestine, other symptoms involving the abdomen and pelvis, noninfectious gastroenteritis, appendiceal conditions, diverticulosis and diverticulitis, intestinal obstruction without hernia, and disorders of the intestine also exhibited a positive association with CC risk. In addition, medical procedures related to gastrointestinal diseases and symptoms, including upper gastrointestinal endoscopy, were significantly associated with the development of CC.



XSL•FO
RenderX

Figure 3. SHAP (Shapley Additive Explanations) summary plot of the top 20 features in CC prediction using best-performing models with 0-year and 3-year prediction windows: (**A**) excluding CRC-related features; (**B**) excluding cancer-related features. The prefix before the "_" in the y-axis labels of plots indicates the source of the corresponding features in the PCORnet data model. Specifically, these sources are: Diagnosis (Diag), Procedure (Proc), Medication (Med), Vital Signs (Vital), and Demographics (Demo). CC: colon cancer; CRC: colorectal cancer; LR: logistic regression; RF: random forest; XGBoost: Extreme Gradient Boosting.

XSL•FO

Figure 4. SHAP (Shapley Additive Explanations) summary plot of the top 20 features in RC prediction using best-performing models with 0-year and 3-year prediction windows: (**A**) excluding CRC-related features; (**B**) excluding cancer-related features. CRC: colorectal cancer; RC: rectal cancer; XGBoost: Extreme Gradient Boosting.

In the RC group, similar positive predictors were identified, mirroring the trends observed in the CC group, including gastrointestinal symptoms (eg, gastrointestinal hemorrhage, anal, and rectal conditions) and the presence of other cancers or tumors (eg, secondary malignant neoplasms and benign neoplasms of the uterus or skin). In addition, the presence of autoimmunity, diseases associated with a potentially weakened immune system (eg, HIV, viral warts, and human papillomavirus [HPV]), and conditions like hemorrhoids were linked to a heightened long-term risk of RC. Being underweight was a significant symptom associated with both CC and RC. Conversely, obesity, overweight, and normal weight appeared to be negatively associated with RC development. Importantly, after removing cancer-related features from consideration, the

XSL•FO
RenderX

significance of anemias surged to the forefront in both the CC and RC groups. These included indicators such as iron deficiency anemias and other anemias. Nevertheless, gastrointestinal diseases and immunodeficiency pathological changes remained substantial factors contributing to CC risk, while factors such as HPV and weight retained their significance as primary determinants of RC. The use of anti-inflammatory or antirheumatic medications were associated with decreased risk of RC.

Discussion

Principal Findings

In this study, we used 4 traditional ML algorithms (ie, XGBoost, RF, SVM, and LR) and obtained informative results predicting EOCRC using structured EHR data. In most cases, the tree-based models, (XGBoost and RF) outperformed linear models, achieving the best AUC scores for various prediction windows. In addition, even after excluding cancer diagnosis variables (eg, pancreatic, skin, and thyroid cancer), undergoing cancer-related procedures (eg, liver biopsy and bone marrow biopsy), cancer treatments (eg, cisplatin and doxycycline), our models continued to achieve acceptable AUC scores. Immune and digestive system disorders, blood diseases, and secondary cancers were identified as significant predictors.

Comparison to Previous Work

Most of our experimental findings were consistent with existing published research. Cancer-related diseases and diagnoses emerged as risk factors leading to the diagnosis of EOCRC, both for CC and RC. For example, uterine cancer was identified as a driver of EOCRC, suggesting a potential genetic association between these malignancies in younger patients [33]. Research also demonstrates that the incidence rate of second primary cancers among survivors is significantly higher than cancer in the general population, and survivors experience notable morbidity and mortality from their cancer treatment [34]. In addition, the use of CT scans for other medical reasons could contribute to the incidental identification of EOCRC cases [35]. Notably, we know that some forms of cancer treatment (eg, radiation) predisposes one to an increased risk for secondary malignancies, including EOCRC, particularly in patients surviving childhood cancer [36].

Inflammatory bowel diseases (IBDs) are well established risk factors for CRC, particularly during young adulthood. The chronic inflammation associated with IBD leads to the release of growth cytokines, excess blood flow, and metabolic free radicals, all of which contribute to the heightened risk of developing CRC [37]. Therapies for IBD sometimes involve immune suppression, another known risk factor for cancers. Furthermore, many gastrointestinal diseases can cause malabsorption or malnutrition [38], resulting in patients being underweight which can also contribute to immune dysfunction or suppression [39]. However, overweight patients were at low risk of EOCRC as our analysis demonstrated despite emerging evidence that being overweight may be associated with an increased risk of tumor recurrence and colorectal carcinogenesis [40,41]. The temporal use of antibiotics in relation to subsequent development of EOCRC is an interesting finding as it supports several previously reported roles that the gut microbiome may plan in CRC protection and development [42]. Our analysis highlighted that the diagnosis of iron deficiency anemia predated CC, but had less association with rectal cancers. It is logical, given that CC are situated more proximal in the gastrointestinal tract, causing occult chronic blood loss and subsequent anemia rather than overt gross bleeding as is typically evident from RC.

In addition, our study observed a significantly higher incidence of CRC cases among HIV-infected patients compared to HIV-uninfected individuals [43]. The heightened risk can be attributed to disruptions in immune function caused by immunodeficiency, which exposes individuals to a higher susceptibility against cancer-causing viruses, including HPV, Epstein–Barr virus, Kaposi sarcoma-associated herpesvirus, etc, as evidenced in our analysis [44]. Another notable finding was the association between CC and diseases of myeloproliferative disease. Similar to other cancers, the potential link could be related to genetics, treatments that induce DNA damage that could predispose to EOCRC, and chronic immune dysregulation. Overall, our study sheds light on the complex interplay between IBD, malnutrition, immune function, and specific blood-related diseases in the development of CRC. Understanding these relationships is crucial in advancing our knowledge of EOCRC risk factors and devising targeted interventions for at-risk populations. It can help health care providers identify individuals who may benefit most from screening between the ages of 18 and 44 years. In this case-control study, we identified several factors independently associated with an elevated risk of EOCRC. These findings could inform patient-provider discussions about the need for and approach to CRC screening and support targeted interventions to improve screening uptake among high-risk individuals.

Strengths and Limitations

The strength of our study is to develop an early diagnostic tool that can help identify individuals at higher risk for EOCRC before the onset of clinical symptoms or suspicion. To further clarify, we test the algorithm across different prediction windows—0, 1, 3, and 5 years—meaning we use data from these periods before a patient's first CRC diagnosis to predict whether they will develop CRC in the future. This approach enables us to assess how the algorithm can detect early risk signals well in advance of diagnosis, providing actionable insights for clinicians to consider for individuals who may not yet exhibit symptoms or be under suspicion for CRC. For individuals without clear clinical suspicion (ie, those who are not yet exhibiting symptoms or are below typical screening age), our algorithm could serve as a risk stratification tool. By analyzing real-world data, such as demographic information, medical history, and other relevant factors, the model can help identify patients who may benefit from earlier screening or closer monitoring, even in the absence of overt symptoms. This can be particularly important in populations with no established risk factors for CRC, but who may still be at risk for early-onset cases.

Our study does have several limitations. First, the mechanism through which identified medical factors are associated with

XSL•FO
RenderX

EOCRC is speculative. For example, CT scans contributed significantly to the model's performance, but the specific reasons are unclear. EHRs did not record the reason why patients underwent CT scans. Perhaps some patients obtained CT scans because of symptoms related to undiagnosed CRC while others received CT scans for other reasons with the incidental finding of CRC. It is less likely that CT scans could be associated with causing CRC due to radiation exposure. For that to occur, the cumulative lifetime exposure would need to be very high with exposure over a number of decades for that to occur. Perhaps CT imaging itself is just a surrogate for access to care whereby EOCRC is more likely to be eventually diagnosed as opposed to patients who might expire for other reasons with CRC, but before a diagnosis. Second, the exclusion of confounder samples and features posed difficulties, given the lack of universally accepted standards for phenotype definitions and ambiguous descriptions. These challenges hindered the design of the most optimal experiment [45]. Third, our experiments are carried out based on the EHR data, which inherently contains flaws, including missing values and potential mistakes in records. Efforts were made to fill in missing values, but comprehensive amendments remained challenging. The characteristics of the EHR data, such as temporality, irregularity, sparsity, and data imbalance, can result in abnormal outcomes when applying ML models [46,47]. Fourth, we primarily focused on metrics related to discrimination or classification (eg, AUC), as we believe these provide essential insights into how effectively the model differentiates between cases and noncases. We acknowledge that a more holistic evaluation—including calibration, fairness, stability, and net benefit—would provide a fuller picture of the model's real-world applicability.

Future Directions

Future research should focus on refining the experimental design, exploring alternative feature selection techniques, incorporating large language models based on both ambulatory and inpatient data, and integrating domain knowledge to enhance the performance of the prediction models. Ultimately, these efforts will contribute to early detection and better management of CRC, with the goal of improving patient outcomes. Using techniques like Synthetic Minority Over-sampling Technique or cost-sensitive learning could further improve the model's ability to detect the minority class. These methods were not used in this study but could be considered in future work to explore their potential impact on model performance, especially in terms of improving recall for the minority class.

Conclusion

In conclusion, our study demonstrated the potential of traditional ML algorithms in predicting EOCRC using real-world data for individuals below the screening age guideline. The identification of significant predictors and their consistency with academic research findings provide valuable insights for pursuing additional hypotheses or targeting potential patients at risk for EOCRC. However, addressing the challenges and limitations related to data quality, experimental design, and ML models' development is essential for improving the accuracy and reliability of EOCRC prediction models.

Authors' Contributions

CS, EM, MQ, MP, RW, and JX were responsible for the overall design, development, and evaluation of this study. CS and JX did the initial drafts and the revisions of the manuscript. CS was responsible for rerunning all experiments and creating Shapley Additive Explanation plots. EM and MD were responsible for providing accurate *International Classification of Diseases* codes to define cases and filter colorectal cancer–related and cancer-related features. All authors reviewed the manuscript critically for scientific content and provided edits, and all authors gave final approval of the manuscript for publication.

Conflicts of Interest

TG serves on the Data and Safety Monitoring Board (DSMB) for Seagen, Nihon Medi-Physics, KAHR Medical, and Arbele and has served as a consultant for Avammune Therapeutics, BillionToOne, Exact Sciences, and Summit Therapeutics. Research support has been provided to his institution by Bristol-Myers Squibb, Merck, AstraZeneca, Lilly, Bayer, Incyte, Ipsen, Genentech, Astellas Pharma, GlaxoSmithKline, Amgen, OncoC4, BillionToOne, Jounce Therapeutics, Elicio Therapeutics, AMAL Therapeutics/Boehringer Ingelheim, Seagen, Regeneron, and Deciphera. All other authors declare no conflicts of interest.

Abstract

Background: Patients with hepatocellular carcinoma (HCC) exhibit a high rate of recurrence and poor prognosis after surgery, and effective prognostic indicators and stratification strategies are currently lacking. Hence, this study proposes new prognostic markers to provide a theoretical basis for patients with HCC.

Objective: We aim to build and evaluate a model estimating the effect of alpha-fetoprotein-tumor size ratio (ATR) on the prognosis of patients undergoing hepatectomy for HCC.

Methods: We retrospectively reviewed hospital records to identify patients who underwent hepatectomy for HCC at the First Affiliated Hospital of Guangxi Medical University from January 2013 to December 2018. Outcomes (recurrence events and mortality) not available in the outpatient medical records were determined through telephone interviews until February 2022. The optimal cutoff value was determined using X-tile (Yale School of Medicine). Independent risk factors for prognosis were investigated by Cox regression modeling, and between-group differences were reduced through propensity score matching. A predictive model for HCC prognosis was constructed using a nomogram, and the predictive performance of the model was evaluated using the C-index.

Results: Of the 1628 eligible patients, 1204 patients were included in the analysis. Patients were stratified into low, medium, and high ATR groups with X-tile. Before propensity score matching, ATR was identified as an independent risk factor for overall survival (low vs medium: HR 1.41, 95% CI 1.03 - 1.94; *P*=.03; medium versus high: HR 1.59, 95% CI 1.02 - 2.47; *P*=.04) and relapse-free survival (low vs medium: HR 1.33, 95% CI 1.03 - 1.70; *P*=.03; medium versus high: HR 2.10, 95% CI 1.40 - 3.15; *P*<.001) of patients with HCC following hepatectomy. A nomogram incorporating ATR, China Clinic Liver Cancer staging, bleeding, and postoperative transcatheter arterial chemoembolization was developed to predict moderate predictive efficacy for overall survival (C-index: 0.73) and relapse-free survival (C-index: 0.73). ATR was found to be associated with microvascular, macroinvasion, and poor tumor differentiation.

Conclusions: ATR is an independent prognostic risk factor in patients with HCC after hepatectomy and is associated with microvascular, macroinvasion, and poor tumor differentiation.

Introduction

Primary liver cancer is among the leading causes of tumor-related deaths worldwide. In 2022, liver cancer registered the highest incidence and mortality rates, representing a considerable public health challenge. Hepatocellular carcinoma (HCC) accounts for over 75% of primary liver cancer cases [1,2]. Although mortality rates from other cancers are declining, HCC continues to exhibit increasing cancer-related mortality. The primary treatment modality for HCC encompasses a combination of surgical interventions and interventional,

XSL•FO
RenderX

targeted, immunological, and herbal treatments. Hepatectomy remains the most prominent curative approach for patients with HCC [3]. The high malignancy and heterogeneity of HCC, coupled with the lack of well-defined stratification strategies and postoperative follow-up protocols, contribute to the poor prognosis of HCC. The 5-year survival rate remains only 15%, and the rate of early recurrence reaches approximately 70% within 5 years [3-5]. In this regard, identifying reliable prognostic markers is essential to identify high-risk patients, and informing the development of effective stratification and postoperative follow-up strategies is urgently needed.

Serum alpha-fetoprotein (AFP) is mainly produced by the liver and yolk sac during the fetal and neonatal periods, and its levels decline rapidly following birth (<5 ng/mL) [6]. AFP is an important marker for HCC diagnosis, and more than 70% of patients are AFP positive [7]. AFP serves not only as a diagnostic biomarker for HCC but also as an important indicator of its prognosis [8]. Tumor size is also an important prognostic factor for patients and should not be overlooked [9]. It has long been considered an important determinant of tumor staging and plays an important role in widely used staging systems, such as in the Milan criteria, Barcelona Clinic Liver Cancer (BCLC) staging system, and China Clinic Liver Cancer (CNLC) staging system [10,11]. AFP is secreted by tumor cells and is positively correlated with tumor size. Given this relationship, AFP and tumor size may exert a combined effect on HCC prognosis, warranting further investigation into their joint prognostic value.

AFP levels reflect the degree of HCC malignancy to some extent [12]. We speculate that when the tumor size is comparable, elevated AFP levels indicate a high degree of tumor malignancy and poor prognosis. This study focuses on the effect of the AFP-tumor size ratio (ATR) on the prognosis of patients with HCC and investigates the correlation between the ratio and the degree of tumor malignancy.

Methods

Participants

We retrospectively reviewed the records of patients who underwent hepatectomy for HCC at the First Affiliated Hospital of Guangxi Medical University from January 2013 to December 2018. Clinical data were obtained from the hospital's database. Patients with missing postoperative follow-up data or other essential clinical information were excluded. The inclusion criteria were as follows (outlined in the flowchart): (1) pathological diagnosis of HCC, (2) complete postoperative follow-up and pathological information, and (3) hepatectomy as the initial treatment upon HCC diagnosis. The exclusion criteria were as follows: (1) comorbidities with other malignant tumors, (2) postoperative death within 30 days, (3) loss to postoperative follow-up, (4) diagnosis of recurrent liver tumor, and (5) history of previous hepatectomy.

Surgical Approach

The First Affiliated Hospital of Guangxi Medical University is one of the largest hospitals in Guangxi Zhuang Autonomous Region of China, with approximately 2750 beds. The hospital conducts 70,000‐80,000 surgeries every year, including 400‐1000 liver resections. All patients undergo preoperative evaluation to confirm the absence of contraindications to surgery, cardiac function, pulmonary function, blood routine, liver function, and renal function. Postoperative residual liver volume and function are assessed on the basis of 15-minute indocyanine green retention rate and preoperative liver volumetry data. The surgical plan of all patients is determined through multidisciplinary or intradepartmental expert discussions. All 10 surgeons in the surgical group are highly experienced. Intraoperative hepatic tumor resection was performed using the Pringle maneuver, and postoperative abdominal lavage with indwelling drains was routinely conducted.

Data Collection

Researchers (SM, TL, and YH) retrospectively collected baseline information in June 2021, including gender, age, BMI, history of smoking, alcohol consumption, hypertension, and diabetes mellitus. Preoperative liver function assessments included the presence of cirrhosis, Child-Pugh classification, and hepatitis status. Tumor-related information comprised tumor size, preoperative AFP level, number of tumors, macrovascular invasion, microvascular invasion (MVI), and degree of tumor differentiation. Tumor staging status was recorded using the BCLC and CNLC staging systems. Surgery-related parameters included surgery time, surgical bleeding, surgical approach, radical resection, major hepatectomy, and postoperative transcatheter arterial chemoembolization (TACE) treatment. Data were missing for 122 patients.

Postoperative Follow-Up of Patients

Patients were followed up every 3 months within the first year following surgery and every 6 months thereafter for imaging, liver function tests, and AFP measurements. The primary outcome indicators were status and duration of tumor recurrence and overall survival (OS). Postoperative follow-up evaluations adhered to institutional clinical practices and were performed at 1, 3, 6, 12, and 18 months postoperatively and every 12 months thereafter until February 2022. These evaluations involved monitoring recurrence events, time to recurrence, OS, and mortality. Postoperative survival statuses were routinely updated in our cancer database annually through telephone interviews or by reviewing outpatient medical records. SM was responsible for patient postoperative follow-up, and for patients whose prognostic data were available in the hospital database, we obtained the patients' prognostic data from the hospital database. If prognostic data were not available in the hospital database, we obtained patient prognostic data by telephone interview. Missing data in the database, wrong phone numbers, refusal to interview, and failure to connect after calling up at least three times were considered lost to postoperative follow-up. Finally, 302 patients were lost to postoperative follow-up.

Nomogram

We used R-project with the "rms" and "survival" packages to construct prediction models for OS and relapse-free survival (RFS), incorporating independent risk factors for OS and RFS into the models. The predictive performance of the model was

XSL•FO
RenderX

assessed using the C-index, and the accuracy of the model was evaluated using correction curves.

Statistical Analysis

Continuous variables were expressed as mean (SD) or median (IQR) and statistically analyzed using a 2-tailed *t* test or Wilcoxon test. Categorical data were statistically analyzed using continuity correction or Fisher exact test. RFS and OS were calculated using the Kaplan-Meier method and compared using the log-rank method. X-tile (Yale School of Medicine) software was used to determine the optimal cutoff value [13]. Cox proportional risk models were used to determine independent risk factors for OS and RFS. Factors with *P* <.05 in the univariate analyses were included in the subsequent multivariate analyses. Hazard ratios (HRs) and 95% CIs were calculated for each variable in the models. Propensity score matching (PSM) using the greedy nearest neighbor method was performed to match covariates to minimize potential selection bias. Variables that showed statistically significant differences (*P*<.05) in the baseline data of the patients (Table 1) were included in the subsequent PSM analysis. The following variables were included: gender, BMI, diabetes, cirrhosis, tumor size, tumor number, macroinvasion, BCLC, CNLC, bleeding, radical resection, major resection, MVI, pathological grade, and postoperative follow-up TACE. A *P* value of <.05 indicated statistical significance.

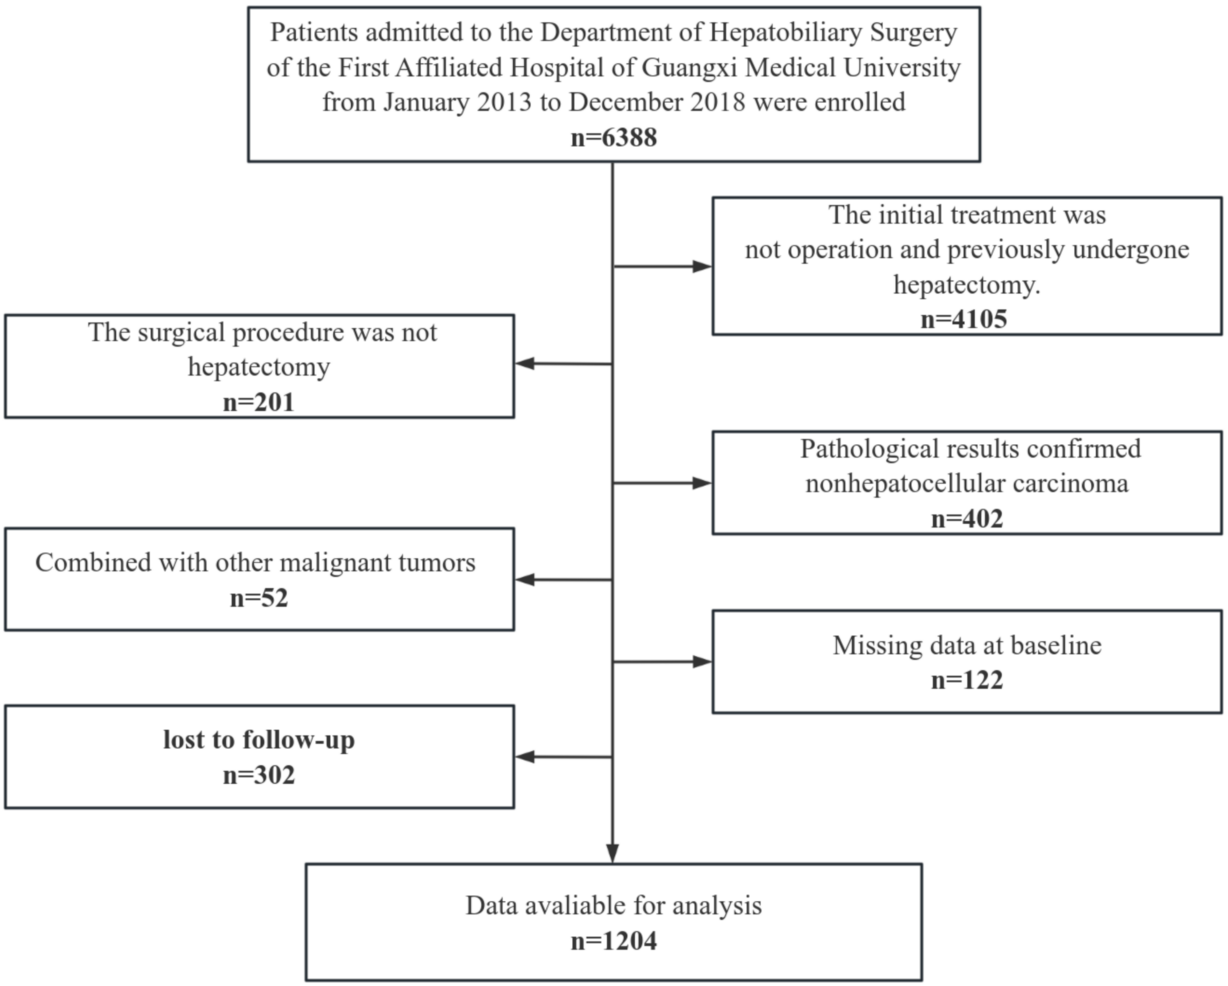
Ethical Considerations

The data used in this study were obtained from the First Affiliated Hospital of Guangxi Medical University. The procedures followed were in accordance with the ethical standards of the responsible committee on human experimentation (China) and with the WMA Declaration of Helsinki. This study was reviewed and approved by the medical ethics committee of the hospital (2023-E704-01). During postoperative follow-up, informed consent was obtained orally from each participant, and the investigator explained the purpose of the study to the patient or caregiver. The participants were informed of their right to withdraw from the study at any time without penalty or prejudice to their future care, a principle that was strictly upheld throughout the study period. In addition, participants who were interviewed by telephone and completed the postoperative follow-up received a complimentary disease knowledge resource as a token of appreciation and compensation for their participation. All participants' information was kept confidential, and each patient was assigned an ID to ensure anonymity in data handling and analysis.



Results

Risk Stratification

The study included 1204 patients. The participant flowchart is provided in Figure 1. We determined the optimal cutoff ATR level by using X-tile. The patients were divided into low- (OS<873.6; RFS<1469.6) and high-ATR groups (OS>873.6; RFS>1469.6; Figures S1 and S2 in Multimedia Appendix 1). ATR was found to be effective in distinguishing high-risk patients from low-risk patients. We then stratified the ATR cases into low (OS<5.7; RFS<2.8), medium (OS: 5.7 - 1469.6; RFS: 2.8 - 1469.6), and high (OS>1469.6; RFS>1469.6; Figures S3 and Figure S4 in Multimedia Appendix 1) groups. We found a significant difference in prognosis among the three groups. Stratifying patients into three groups demonstrated higher discriminatory power in predicting prognosis than the two-group classification. The cutoff values of OS and RFS were more closely aligned in the three-group model than in the two-group model. Hence, the patients were categorized into low-, medium-, and high-ATR groups for subsequent analyses.

XSL•FO
RenderX

Figure 1. Participant flowchart.

Patient Characteristics

The median OS time was 32.6 (IQR 21.0 - 52.1) months, and 444 (36.9%) patients experienced tumor recurrence, and 211 (18.3%) patients died. We found significant differences in OS (Figure 2A,B) and RFS (Figure 2C,D) among patients in the low-, medium-, and high-ATR groups. Moreover, ATR was negatively correlated with patient prognosis.

XSL•FO
RenderX

Figure 2. Kaplan-Meier curves estimate the cumulative incidence of HCC recurrence based on ATR and the relationship of ATR and MVI, microinvasion, and tumor differentiation. (A) Survival curves of OS when patients were divided into two groups based on ATR. (B) Survival curves of OS when patients were divided into three groups based on ATR. (C) Survival curves of RFS when patients were divided into two groups based on ATR. (D) Survival curves of RFS when patients were divided into three groups based on ATR. (E) Survival curves of OS when patients were divided into two groups based on ATR after PSM. (F) Survival curves of RFS when patients were divided into two groups based on ATR after PSM. Relationship between (G) ATR and MVI, (H) microinvasion, and (I) tumor differentiation. AFP: alpha-fetoprotein; ATR: alpha-fetoprotein-tumor size ratio; HCC: hepatocellular carcinoma; MVI: microvascular invasion; OS: overall survival; PSM: propensity score matching; RFS: relapse-free survival.

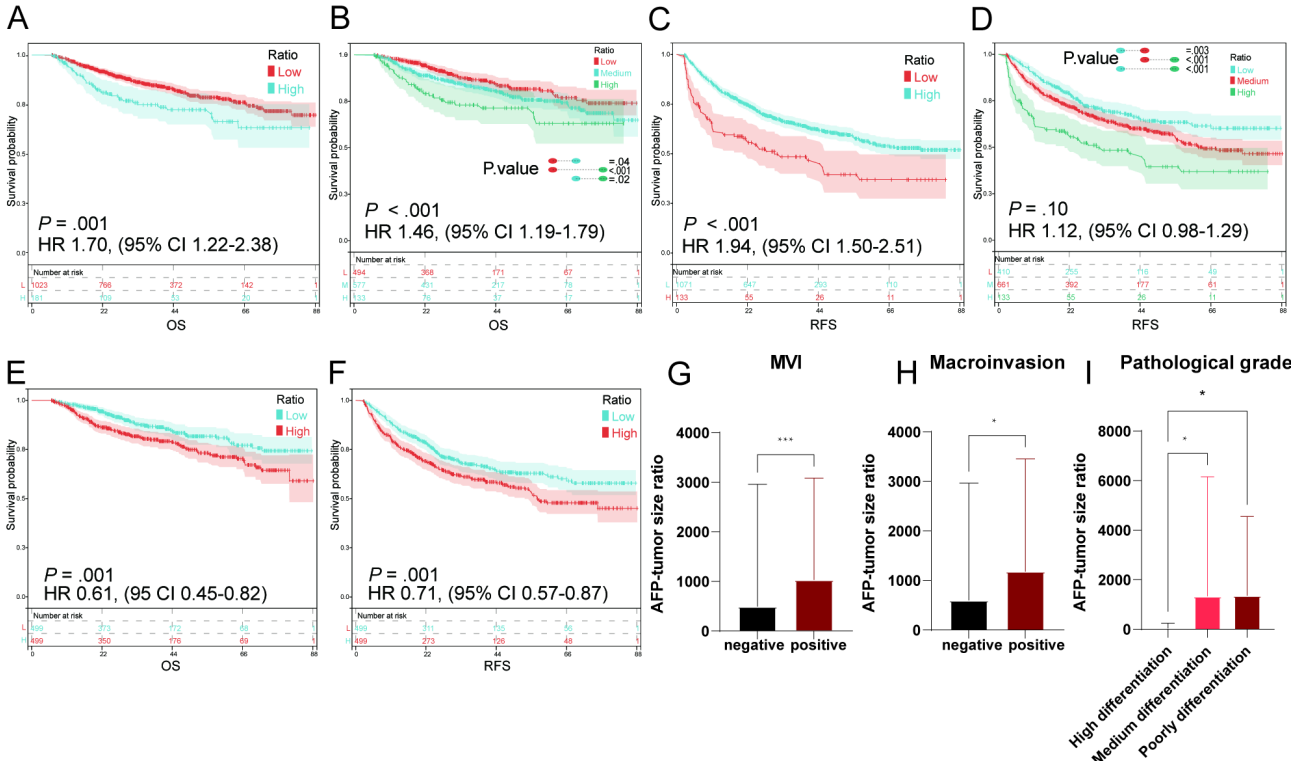


Table 1 summarizes the clinical characteristics and surgical variables of patients stratified according to serum ATR level. Differences in gender, BMI, diabetes mellitus, background of liver disease, tumor size, tumor number, MVI, BCLC staging, CNLC staging, AFP level, and surgical bleeding were statistically significant among the three groups (P<.05).

The proportion of female patients, macrovascular invasion, MVI, AFP>400 ng/mL, and advanced stages according to the BCLC and CNLC staging systems increased in the high-ATR group. However, the proportion of patients with radical resection, well-differentiated tumor, and BMI>24 was lower in this group.

ATR is an Independent Risk Factor for OS and RFS in Patients With HCC Who Underwent Hepatectomy

We performed univariate Cox analyses on clinicopathologic parameters. Gender, cirrhosis, Child-Pugh classification, tumor size, tumor number, macrovascular invasion, BCLC staging, CNLC staging, surgical approach, bleeding, radical resection, MVI, postoperative TACE, and ATR were statistically significant contributors to OS and RFS. Variables significantly associated with prognosis in univariate Cox regression analysis were included in multivariate Cox regression analysis.

For OS, cirrhosis (HR 1.47, 95% CI 1.11 - 1.96; P=.008), CNLC stages IIIa (HR 4.52, 95% CI 1.48 - 13.82; P=.008) and IIIb (HR 5.04, 95% CI 1.43 - 17.76; P=.01), bleeding volume (HR 1.47, 95% CI 1.10 - 1.97; P=.009), postoperative TACE (HR 4.38, 95% CI 3.22 - 5.97; P<.001), medium-ATR group (HR 1.41, 95% CI 1.03 - 1.94; P=.03), and high-ATR group (HR 1.59, 95% CI 1.02 - 2.47; P=.04) showed statistically significant results (Table 2).

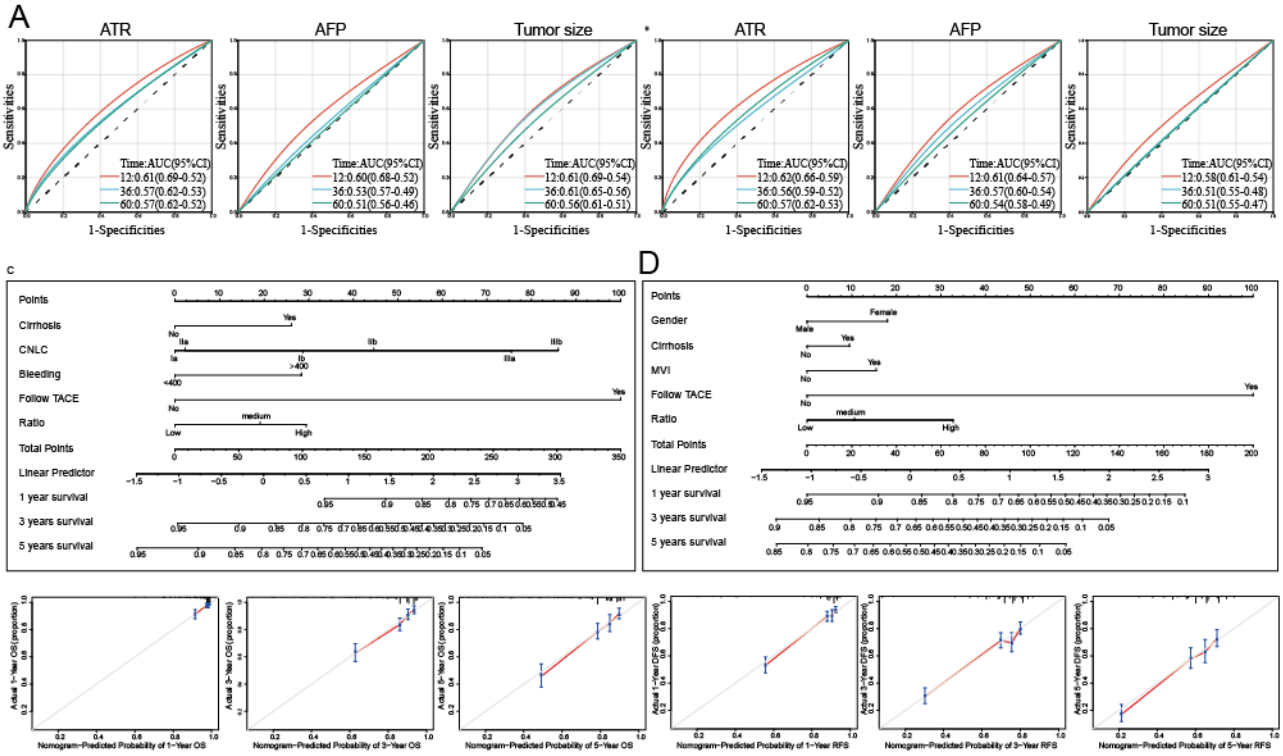
Figure S5A,B in Multimedia Appendix 1 displays the distribution trend of ATR in the OS and RFS of patients with HCC, indicating the potential of ATR to categorize patients into three distinct groups. Figure S5C,D in Multimedia Appendix 1 illustrates the distribution of ATR and its correlation trend with prognosis in the OS and RFS of patients with HCC, revealing a negative correlation between ATR levels and patient prognosis.

PSM Cohort Analysis

PSM was performed to validate the findings and adjust the effect of confounding factors. We performed 1:1 PSM on patients in the low-ATR group. After PSM, most variables were controlled, and significant differences in MVI and degree of pathological grade remained (Table S1 in Multimedia Appendix 1). Univariate and multivariate Cox analyses were also conducted. The results revealed that ATR was statistically significant in OS (HR 1.30, 95% CI 1.05 - 1.61; *P*=.02; Figure 2E and Table S2 in Multimedia Appendix 1) and RFS (HR 1.61, 95% CI

XSL•FO
RenderX

1.18 - 2.19; *P*=.008; Figure 2E,F and Table S3 in Multimedia Appendix 1), demonstrating that ATR is an independent risk factor for the prognosis of patients with HCC who underwent hepatectomy following PSM. These results corroborate the conclusion. Although we performed PSM, significant differences in MVI and tumor differentiation were still found.



Correlation of ATR With Tumor Malignancy Level

MVI and poor pathological grade are recognized as independent risk factors for an unfavorable prognosis in patients with HCC. We analyzed the relationship of MVI, pathological grade, and macrovascular invasion with ATR. An elevated ATR was significantly associated with positive MVI, macrovascular invasion, and poor tumor differentiation (Figure 2G-I). These findings support the notion that in HCC cases with comparable tumor sizes, a poor prognosis is associated with elevated levels of AFP.

Construction of a Prognostic Model for HCC Based on ATR

To enhance the foundation for clinical decision-making, we developed a prediction model. We found that ATR was more effective in predicting OS and RFS than AFP or tumor size alone (Figure 3A,B). We developed a prognostic model using the ATR. In the prediction model for OS, the C-index of the model was 0.73, achieving moderate predictive efficacy. The correction curve confirmed that the model predictions were stable (Figure 3C). In the prediction model for RFS, the C-index of the model was 0.73, achieving moderate predictive efficacy, and the correction curves confirmed that the model predictions were stable (Figure 3D).

Figure 3. Prediction model of patients with HCC following surgical treatment. (A) The ROC curve of ATR, AFP, and tumor size was used to predict the OS of patients. (B) The ROC curve of ATR, AFP, and tumor size was used to predict the RFS of patients. (C) Nomogram and calibration curve for the OS of patients. (D) Nomogram and calibration curve for the RFS of patients. AFP: alpha-fetoprotein; ATR: alpha-fetoprotein-tumor size ratio; CNLC: China Clinic Liver Cancer; HCC: hepatocellular carcinoma; MVI: microvascular invasion; OS: overall survival; RFS: relapse-free survival; ROC: receiver operating characteristic; TACE: transcatheter arterial chemoembolization.

Discussion

Principal Findings

This study demonstrated that the ATR is an independent risk factor for OS and RFS in patients with HCC who underwent hepatectomy. The prognostic model based on the ATR was found to be effective in predicting prognosis. Moreover, ATR was positively correlated with the degree of HCC malignancy.

The cutoff values of OS and RFS in the low- and medium-ATR groups were 5.7 and 2.8, respectively, and the OS and RFS in the medium- and high-ATR groups shared the same cutoff value of 1469.6. The cutoff values for OS and RFS were identical in the medium- and high-ATR groups, and the difference between the groups was minimal. This result indicates that the ATR can effectively and stably predict patient prognosis. According to the HCC data statistics, the recurrence rate of patients with HCC following surgery is higher than the mortality rate, and the causes of recurrence and mortality are highly heterogeneous. Thus, differences in cutoff values are often observed in the prediction of postoperative OS and RFS of patients with HCC [3]. Our results demonstrated small differences in the cutoff values of OS and RFS between the low- and medium-ATR groups.

Comparison to Prior Work

Elevated AFP and increased tumor size are prognostic risk factors for HCC, and the combination of tumor burden and AFP

XSL•FO
RenderX

serves as an important indicator of poor prognosis [14,15]. However, the potential correlation between AFP and the number of tumor cells is often overlooked. We found that AFP and tumor size showed a statistically significant association in univariate Cox analysis. However, in Cox multivariate regression analysis, AFP and tumor size exhibited no statistically significant association with prognosis. Hence, compared with AFP or tumor size, ATR may be a more suitable prognostic marker.

Notably, AFP levels have been associated with MVI [16], macrovascular invasion, and poor tumor differentiation [17,18]. In this study, MVI, macrovascular invasion, and poor tumor differentiation were found to be associated with elevated ATR levels. This result shows that the ATR is an effective marker for assessing the degree of malignancy in HCC. Therefore, this study offers a theoretical basis for identifying the malignancy of small HCC tumors and supports informed medical decision-making.

Many in vitro studies have shown that AFP is associated with tumor progression and metastasis. AFP can inhibit programmed death by inhibiting the Fas/FADD apoptotic pathway and activating the PI3K/AKT signaling pathway [12,19]. Moreover, it plays an important role in the metastasis of HCC [20] and can induce tumor immunosuppression and evade immune surveillance [21,22]. AFP levels are elevated in response to the biological behavior of HCC, contributing to tumor proliferation, invasion, and metastasis. However, the relationship between the amount of AFP secreted by HCC cells per unit volume and the degree of tumor malignancy and patient prognosis remains unclear. This study demonstrates that an increase in AFP secreted by HCC cells per unit volume is associated with a high degree of malignancy in HCC and poor patient prognosis.

We used the ATR to construct a nomogram, and the model effectively predicted the prognosis of patients with HCC. This study introduced a novel approach involving the use of the ATR for prognostic prediction in patients with HCC following hepatectomy. Previous studies have proposed a pre- to postoperative AFP ratio-based nomograms for the prognostic assessment of patients with HCC, yielding an area under curve of approximately 0.72 [23]. However, these prognostic models demonstrated limited efficacy in patients with AFP-negative.

Cirrhosis is a risk factor for poor postoperative prognosis in patients with HCC [24,25]. The association of intraoperative bleeding with poor patient prognosis has been well established; moreover, intraoperative bleeding has been associated with perioperative blood transfusion, which has been shown to be associated with poor patient prognosis [26,27]. Gender factors are also associated with the prognosis of patients with HCC, with men having a higher risk of recurrence than women [4]. We included cirrhosis and bleeding in the model for predicting OS, in addition to gender, cirrhosis, and MVI, in the model for predicting RFS. Both models showed good predictive efficacy.

Strengths

This study uses the ATR to predict the prognosis of patients with HCC, and a prognostic prediction model was constructed using the ATR, which provides a theoretical basis for clinical prognosis prediction, recurrence risk stratification, and postoperative follow-up strategies.

Limitations

First, most of the patients included in this study were patients with hepatitis B virus–related HCC. Second, uncontrollable bias possibly existed despite the matching of MVI and pathological grade in PSM.

Conclusions

ATR was demonstrated to be an independent risk factor for prognosis in patients with HCC undergoing surgery and is associated with MVI, macrovascular invasion, and poor tumor differentiation. Hence, the ATR can be considered a promising prognostic marker for HCC.

Abstract

Background: Surgeons often face challenges in distinguishing between benign and malignant follicular thyroid neoplasms (FTNs), particularly small tumors, until diagnostic surgery is performed.

Objective: This study aimed to identify the size-specific predictors for the malignancy risk of FTNs preoperatively.

Methods: A retrospective cohort study was conducted at Peking University Third Hospital in Beijing, China, from 2012 to 2023. Patients with a postoperative pathological diagnosis of follicular thyroid adenoma (FTA) or follicular thyroid carcinoma (FTC) were included. FTNs were classified into small- and large-sized categories based on the cutoff value of the tumor diameter derived from spline regression, which indicated the turning point of malignancy risk. We identified the 5 most important predictors from 22 variables including demography, sonography, and hormones, using machine learning methods. We also calculated the odds ratios (OR) with 95% CI for these predictors in both small- and large-sized FTNs.

Results: Altogether, we included 1494 FTNs, comprising 1266 FTAs and 228 FTCs. FTNs with a maximum diameter less than 3.0 cm were grouped as small-sized tumors (n=715), while those with larger diameters were categorized as large-sized tumors (n=779). In the small-sized group, tumors with macrocalcification (OR 2.90, 95% CI 1.50-5.60), those with peripheral calcification (OR 4.50, 95% CI 1.50-13.00), and those in younger patients (OR 1.33, 95% CI 1.05-1.69) showed a higher malignancy risk. In the large-sized group, tumors presenting with a nodule-in-nodule appearance (OR 3.30, 95% CI 1.30-7.90) exhibited a higher malignancy risk. In both groups, lower thyroid-stimulating hormone levels (OR 1.49, 95% CI 1.20-1.85 for small-sized FTNs; OR 1.61, 95% CI 1.37-1.96 for large-sized FTNs) and a larger mean diameter (OR 1.40, 95% CI 1.10-1.70 for small-sized FTNs; OR 1.50 95% CI 1.20-1.70 for large-sized FTNs) were associated with the malignancy risk of FTNs.

Conclusion: This study identified size-specific predictors for malignancy risk in FTNs, highlighting the importance of stratified prediction based on tumor size.

Introduction

In recent years, the incidence of thyroid cancer has been growing fast [1], and it is expected to continue to increase in a pronounced manner; the 5-year average annual percent change in the incidence of thyroid neoplasms from 1983 to 2017 in China was 7.82% in men and 8.59% in women [2]. Follicular thyroid neoplasms (FTNs) are one of the most important types of thyroid tumors in addition to papillary thyroid tumors; FTNs

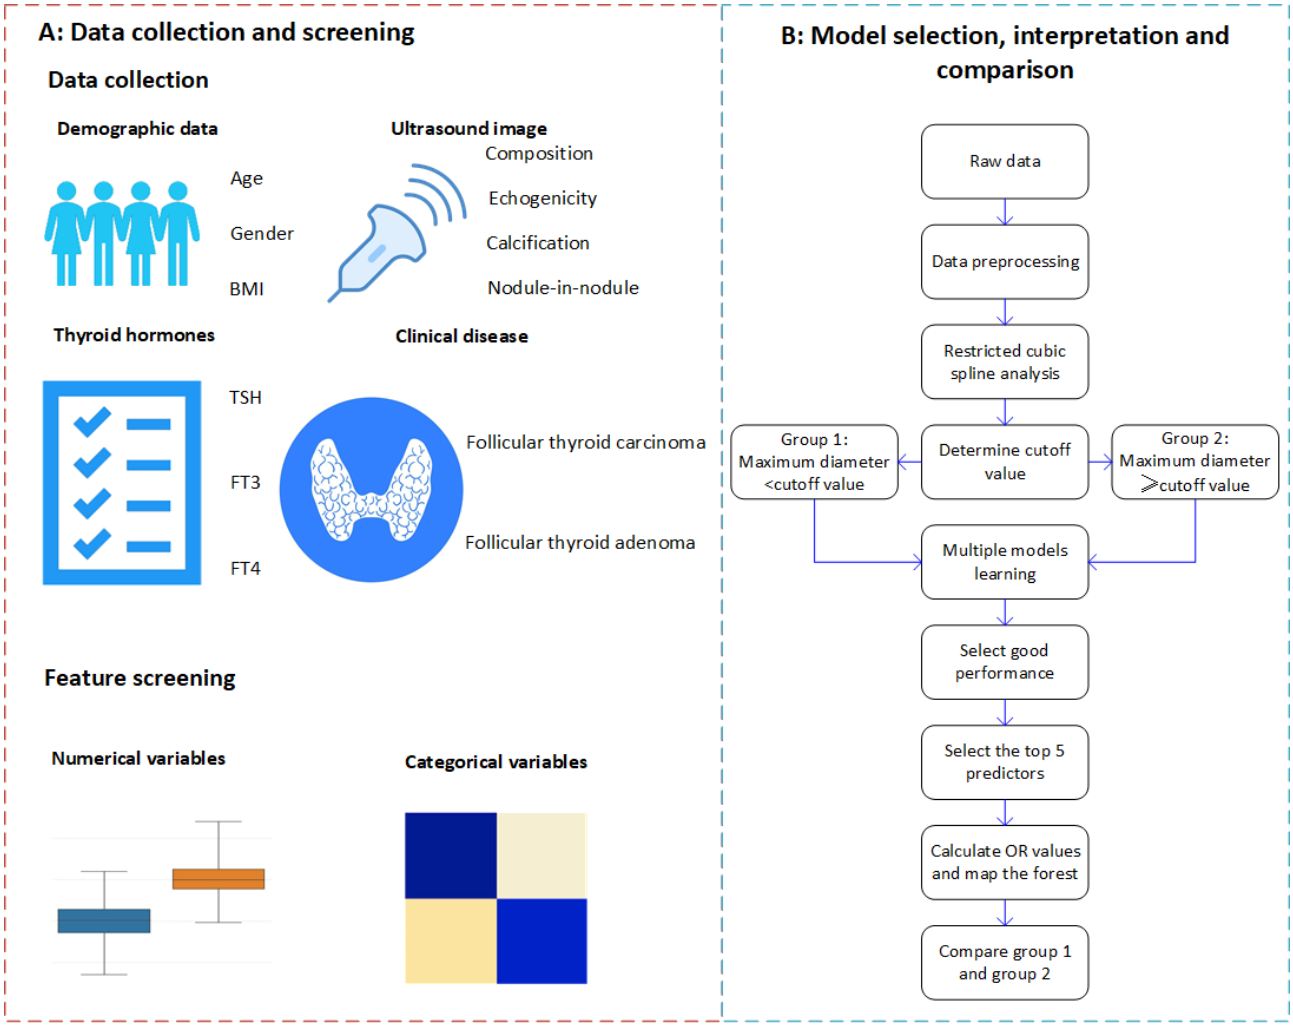
XSL•FO
RenderX

account for approximately 10‐15% of all thyroid cancers [3]. Notably, FTNs are much more challenging for clinical management compared with papillary thyroid tumors [4,5]. This situation results from the fact that over 95% of FTNs cannot be accurately diagnosed as benign or malignant, regardless of using ultrasound, cytology, or biomarkers. Currently, clinicians often use diagnostic surgery to distinguish between benign and malignant FTNs. Still, this might lead to unnecessary diagnostic surgery for patients finally diagnosed with the benign type of FTN (ie, follicular thyroid adenoma (FTA]) or a second surgery after the initial diagnostic surgery for those finally diagnosed with the malignant type of FTN (ie, follicular thyroid carcinoma (FTC]) [6]. It is thus crucial to improve the accuracy for the prediction of the malignancy risk of FTNs prior to the diagnostic surgery, which could not only avoid the unnecessary diagnostic surgery for patients with FTA, but also provide timely clinical decisions for patients with FTC.

In the clinical context, three approaches are typically used to predict the malignancy risk of FTNs before the diagnostic surgery: cytology, biomarkers, and ultrasound. Concerning cytology, neither fine needle aspiration cytopathology nor core needle histopathology can reliably differentiate FTA from FTC. The reason is that the pathological diagnosis of FTN requires comprehensive sampling of the entire tumor following surgical dissection to determine the presence of capsular or vascular invasion across all tumor margins. Regarding the use of biomarkers, the routine clinical application, in most cases, is still hindered by the cost-ineffectiveness of testing, as well as suboptimal predictive performance in terms of sensitivity and specificity. Therefore, the ultrasound examination of FTNs is of great significance in facilitating the evaluation of the malignancy risk of FTNs and the necessity for further diagnostic surgery.

Despite considerable efforts to preoperatively distinguish between FTA and FTC, research gaps remained, particularly concerning small-sized FTNs [7-10]. This is attributable to the fact that, on average, FTC exhibits a larger tumor diameter compared to FTA [10,11]; nevertheless, clinicians have reported the existence of small-sized FTC in routine clinical care [12]. If the suboptimal performance of existing prediction models for small-sized FTNs remains inadequately elucidated [13], there would continue to be a significant risk of misdiagnosis and undertreatment of small-sized FTNs. Consequently, it is imperative to identify important predictors (especially those from ultrasound examination) associated with the malignancy risk of both large- and small-sized FTNs.

Our study aimed to (1) use machine learning to identify crucial predictors for the malignancy risk of both small- and large-sized FTNs, and (2) compare the differences in the direction and magnitude of predictors between the small- and large-sized FTNs. Findings from our study would facilitate the precision of differentiating between benign and malignant FTNs.



Methods

Overview

We reported this retrospective cohort study following the suggestion of the TRIPOD [14] (Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis Statement), TRIPOD-AI [15] (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis-Artificial Intelligence Statement), and Guidelines for Developing and Reporting Machine Learning Predictive Models in Biomedical Research [16] (Multimedia Appendix 1). The framework of the study is shown in Figure 1.

XSL•FO

Study Population

Our research team included multidisciplinary experts in the field of epidemiology, pathology, ultrasound, surgery, and endocrinology. We conducted a retrospective cohort study at Peking University Third Hospital in Beijing, China, from January 2012 to September 2023. The primary data source for this retrospective cohort study was the electronic medical record system of Peking University Third Hospital. Patients were included if they were pathologically diagnosed with FTC or FTA after surgical treatment; patients were excluded if they did not have ultrasound examinations before surgery. To ensure the accuracy of the pathological diagnosis of FTN, we invited the experienced pathologists to double-check all the pathological diagnoses of FTN based on the 2022, 5th edition WHO Classification of Thyroid Neoplasm [17].

Classification of FTNs Into Small- and Large-Sized Categories

We first scanned the entire dataset to identify and remove duplicate patient records by using a combination of unique identifiers such as patient ID, date of surgery, and specific pathological report numbers. For categorical variables with a relatively low proportion (5% or less) of missing values, we used imputation based on the majority class. For numerical variables such as patient age or tumor size, we used mean imputation. To classify the FTNs into small- and large-sized categories, we developed a restricted cubic spline model to identify the cutoff value. Specifically, we used the maximum tumor diameter as the continuous variable (predictor); the malignancy risk of FTNs as the outcome; and the covariates included composition, echogenicity, margin, halo, taller-than-wide, calcification, internal blood flow, vascularity, trabecular formation, nodule-in-nodule appearance, mean diameter, thyroid-stimulating hormone (TSH), free triiodothyronine (FT3), free thyroxine (FT4), mean TSH score (interval-adjusted detailed TSH score [18]), tRMSSD of TSH (the time-adjusted root mean square of successive differences of TSH [19]), mean TSH (mean value of preoperative TSH), and coefficient of variation of TSH (the ratio of the SD of preoperative TSH to the mean value of preoperative TSH). To determine the optimal number of nodes for the restricted cubic splines, we employed the Akaike information criterion to strike the balance between the model goodness of fit and complexity that most effectively aligns with the data [20]. Finally, we divided FTNs into two groups: small- (maximum diameter less than the cutoff value) and large-sized (maximum diameter greater than the cutoff value) FTNs.

Predictors for the Malignancy Risk of FTNs

We selected the predictors for the malignancy risk of FTNs based on our domain knowledge [21,22] and data available. The

XSL•FO
RenderX

predictors mainly included patients' gender, age, BMI, ultrasound features, thyroid hormones, and Hashimoto thyroiditis. To ensure the validity of measurements of predictors, both researchers and clinicians carefully checked the data source of the predictors.

Ultrasound features included composition (solid, predominantly solid, predominantly cystic, or cystic), echogenicity (hyperechoic, isoechoic, hypoechoic, or anechoric), margin (circumscribed, ill-defined, irregular, or lobulated), halo (absent halo, even thickness halo, present halo without evenness of thickness reported, or uneven thickness halo), taller-than-wide (absent or present), calcification (no echogenic foci, microcalcification, macrocalcification, peripheral calcification, microcalcification with comet-tail artifacts, or punctate echogenic foci of undetermined significance), internal blood flow (absent or present), vascularity (mainly central vascularity, mainly peripheral vascularity, mixed vascularity, or avascularity), trabecular formation (absent or present), nodule-in-nodule appearance (absent or present), and mean diameter.

The measurements of thyroid hormones included TSH, FT3, FT4, and TSH-related features. As listed in Table S1 in Multimedia Appendix 2, TSH-related features included the mean TSH score, the tRMSSD of TSH, mean TSH, and coefficient of variation of TSH. The diagnostic criteria for Hashimoto thyroiditis referred to the ultrasonography describing the thyroid tissue as substantial diffuse lesions and the pathology report describing the thyroid tissue as Hashimoto thyroiditis.

Development and Validation of Machine Learning–Based Models

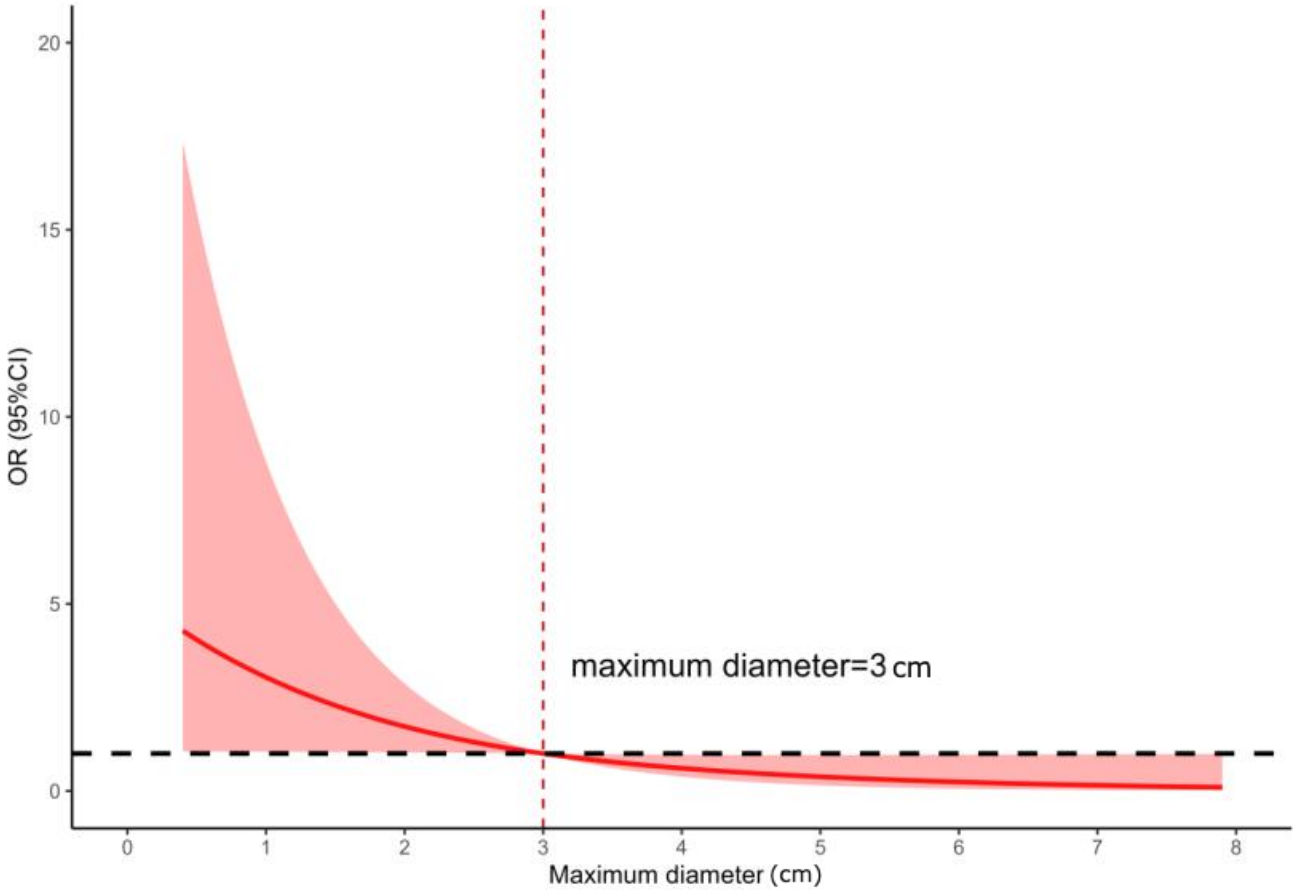
We established the machine learning–based models, as shown in Figure 1. We trained eight classification models including logistic regression, lasso regression, weighted k-nearest neighbor, decision tree, random forest, naive bayes, XGBoost, and support vector machine (SVM). In total, 70% of the dataset was allocated for model training and selection, while the remaining 30% was reserved for internal validation. We developed and validated the models stepwise through predictor preprocessing, model training, hyperparameter tuning, and 5-fold cross-validation. It is important to note that our study population was from the real-world, naturally distributed population so that the outcome variable was slightly imbalanced (approximately 30% was FTC among all types of FTNs). We adopted the synthetic minority over-sampling technique (SMOTE), which increased the sample size of a few classes by creating new synthetic samples rather than simply copying existing ones [23]. We evaluated the model performance using accuracy, F1 score, the area under the receiver operating characteristic curve (AUROC), the area under the precision-recall curve (AUPRC), sensitivity, and specificity. We comprehensively considered the performance and interpretability of models and selected the most suitable model. We used the mlr3 [24] ecosystem in R 4.4.1 to conduct machine learning.

Comparison of Important Predictors for Malignancy Risk Between Small- and Large-Sized FTNs

We selected important predictors for small- and large-sized FTNs, respectively. We evaluated the importance of predictors (feature importance) by computing the cross-entropy loss (loss: ce) of all features and visualized the importance of features. We identified the first five most important predictors that could both predict the outcome and not overlap with other predictors based on medical expertise and a novel information-gain approach. Based on the concept of entropy from information theory, the information gain approach is used to assess the extent to which features reduce uncertainty or increase the amount of information [25]. This approach helps to determine which features most effectively enhance classification accuracy by calculating the difference in information entropy before and after feature classification [25]. After the selection of important predictors, we calculated the odds ratio (OR) with 95% CI and drew the forest maps using multivariate logistic regression models.

Ethical Considerations

This study was approved by the Medical Research Ethics Committee of Peking University Third Hospital (No. IRB00006761- M2023168). As a retrospective analysis, the study was granted a waiver for additional informed consent. During the data extraction process, strict confidentiality measures were implemented to ensure patient privacy and data security. All extracted data were anonymized, with any information that could directly identify patients being removed.



Results

Characteristics of the Study Population and Selection of the Cut-Off Value for the Size of FTNs

Among the included 1494 patients, 1266 (84.7%) were diagnosed with FTA, and the remaining were diagnosed with FTC; the average (SD) age of the patients was 48.25 (0.75) years, and 1127/1494 patients (75.4%) were female. We used a restricted cubic spline model with three nodes that optimally balanced fitting the nonlinear relationship within the data while minimizing the overfitting risk. This analysis revealed a key turning point: the slope of the curve changed distinctly at a maximum diameter of 3 cm for FTNs (Figure 2), indicating that the influence of the maximum diameter on the risk of FTN malignancy shifted at this threshold. As such, 715/1494 tumors (47.9%) were classified as small-sized FTNs (maximum diameter <3 cm), while 779/1494 tumors (52.1%) were large-sized FTNs (maximum diameter ≥3 cm). The characteristics of the study population and FTNs are listed in Tables 1 and 2, respectively.

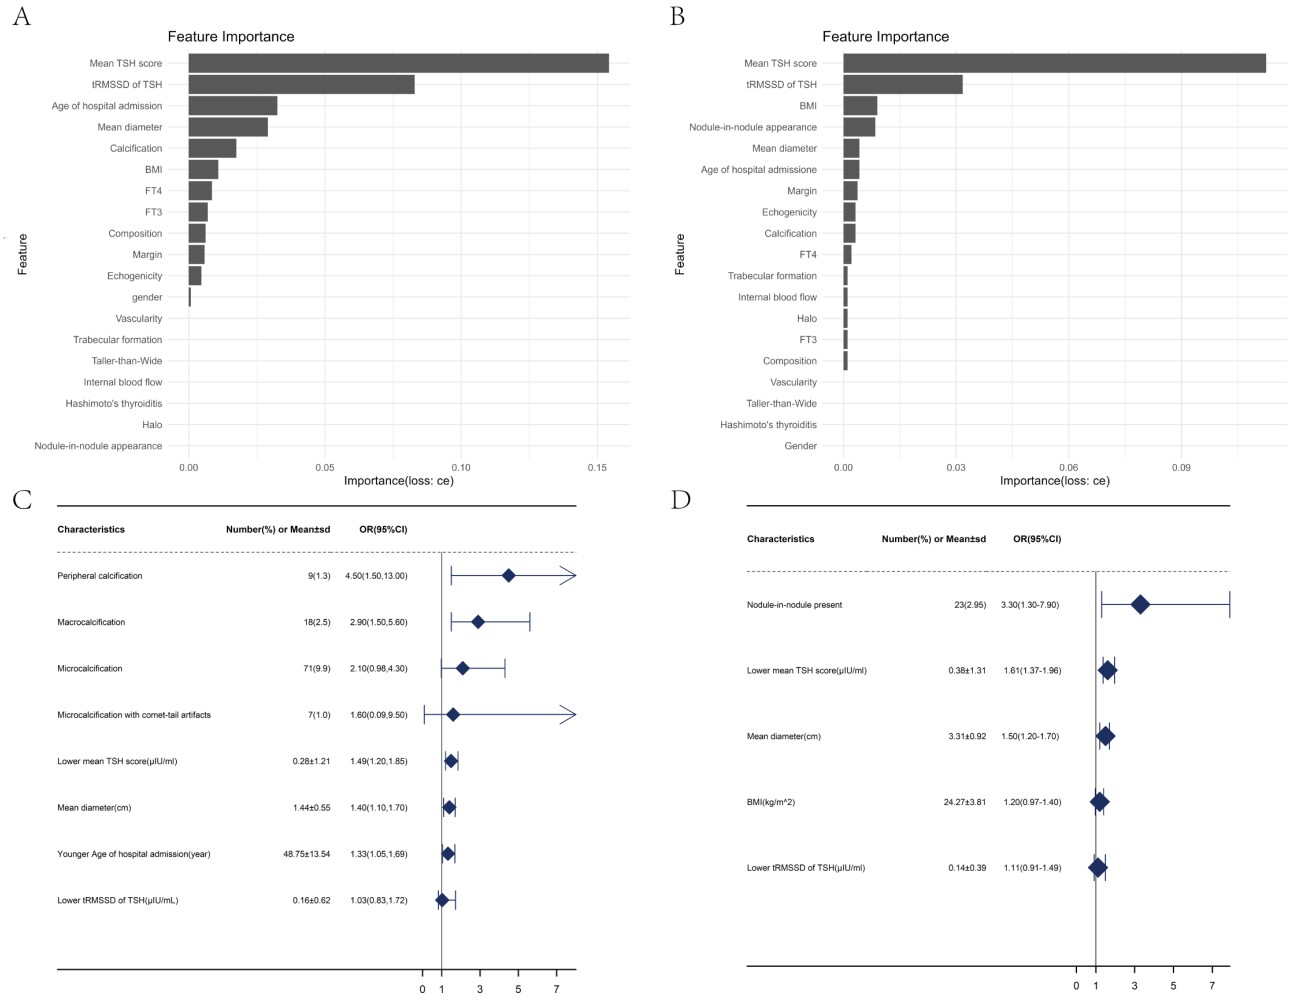
Distinct Predictors for the Malignancy Risk in Small- and Large-Sized FTNs

We compared the performance in discrimination among the eight models (logistic regression, weighted k-nearest neighbor, lasso regression, decision tree, random forest, naive bayes, XGBoost, and SVM). The XGBoost and random forest models performed broadly better in the small- and large-sized FTN groups, respectively (Table 3, Table S2 in Multimedia Appendix 2).

Table . Model performance in predicting the malignancy risk of small- and large-sized follicular thyroid neoplasms (FTNs).

Models	Small-sized FTNs (maximum diameter <3 cm)			Large-sized FTNs (maximum diameter ≥3 cm)		
	Accuracy	F1 score	AUPRC[a]	Accuracy	F1 score	AUPRC
Logistic regression	0.654	0.301	0.238	0.701	0.450	0.337
Weighted k-nearest neighbor	0.587	0.233	0.140	0.611	0.380	0.350
Lasso regression	0.752	0.299	0.227	0.669	0.411	0.368
Decision tree	0.614	0.205	0.134	0.646	0.381	0.274
Random forest	0.790	0.286	0.206	0.704	0.459	0.422
Naive bayes	0.577	0.220	0.163	0.623	0.297	0.251
XGBoost	0.811	0.330	0.248	0.695	0.403	0.380
SVM[b]	0.643	0.226	0.151	0.691	0.312	0.199

[a]AUPRC: area under the precision-recall curve.



[b]SVM: support vector machine.

In the small-sized FTN group, the top five predictors were the mean TSH score, tRMSSD of TSH, age at hospital admission, mean diameter, and calcification in the XGBoost model (Figure 3). Compared to tumors with no echogenic foci in the ultrasound image, the small-sized FTNs expressing microcalcification (OR 2.10, 95% CI 0.98-4.30), macrocalcification (OR 2.90, 95% CI 1.50-5.60), peripheral calcification (OR 4.50, 95% CI 1.50-13.00), and microcalcification with comet-tail artifacts (OR 1.60, 95% CI 0.09-9.50) had a higher risk of malignancy. Additionally, the risk of malignancy was higher in the patients with small-sized FTNs with a lower mean TSH score (OR 1.49, 95% CI 1.20-1.85), lower tRMSSD of TSH (OR 1.03, 95% CI 0.83-1.72), younger patients (OR 1.33, 95% CI 1.05-1.69), and larger mean diameter (OR 1.40, 95% CI 1.10-1.70).

By contrast, in the large-sized FTN group, the top 5 predictors were the mean TSH score, tRMSSD of TSH, BMI, nodule-in-nodule appearance, and mean diameter in the random forest model (Figure 3). The risk of malignancy was higher in the large-sized FTN, which included the lower mean TSH score (OR 1.61, 95% CI 1.37-1.96), lower tRMSSD of TSH (OR 1.11, 95% CI 0.91-1.49), higher BMI (OR 1.20, 95% CI 0.97-1.40), the presence of nodule-in-nodule (OR 3.30, 95% CI 1.30-7.90), and larger mean diameter (OR 1.50, 95% CI 1.20-1.70).

The feature importance and forest map of the top 5 predictors for malignancy risk in small- and large-sized follicular thyroid neoplasms (FTNs). **(A)** The feature importance using the XGBoost model in small-sized follicular tumors, and loss: ce is the cross-entropy loss. **(B)** The feature importance using the random forest model in large-sized follicular tumors, and loss: ce is the cross-entropy loss. (C) The forest map of the top 5 predictors using multivariate logistic regression in small-sized follicular tumors, and the OR and 95% CI of microcalcification, macrocalcification, peripheral calcification, and microcalcification with comet-tail artifacts is based on no computed echogenic foci. (D) The forest map of the top 5 predictors using multivariate logistic regression in large-sized follicular tumors, and the OR and 95% CI of nodule-in-nodule presence is based on the computed nodule-in-nodule absence. FT3: free triiodothyronine; FT4: free thyroxine; tRMSSD: time-adjusted root mean square of successive differences; TSH: thyroid-stimulating hormone.

Discussion

Principal Findings

Taking advantage of a long-term cohort based on the real-world data, we found distinctive predictors for the malignancy risk of FTNs between the small- and large-sized tumors. Specifically, the tumor's calcification appearance, mean diameter, and patients' age were more important in predicting the malignancy risk of small-sized FTNs, whereas the tumor's nodule-in-nodule appearance and patients' BMI were more important in that of large-sized FTNs.

Comparison to Prior Work

It remained unclear regarding the cut-off value of tumor size that indicated the malignancy risk or surgical indications of FTNs. Concerning clinical guidelines, we observed that neither domestic nor international guidelines have recommended a cut-off value of tumor size for surgical treatment in FTNs [26-28]. Regarding existing research, among the 5 studies included in this review, the cut-off value of tumor size used to predict the malignancy risk of FTNs remained contradictor[29-33]. The included studies reported the associations between tumor size and the malignancy risk of FTNs, but all of them lacked a solid basis for their tumor-size classification criteria prior to surgical treatment.

Based on our literature review, previous studies on this topic often employed a one-size-fits-all model to predict the malignancy risk of FTN, without considering the tumor size[34,35]. For example, a retrospective multicenter study developed a prediction model for FTNs using the Thyroid Imaging Reporting and Data System (TI-RADS), and the validation dataset showed that the follicular TI-RADS model improved the performance in differentiating between FTA and FTC (AUROC 0.81) [34]. Additionally, a model combining the prior-based level set method with a deep convolutional neural network achieved an AUROC of 0.913 in distinguishing FTC from FTA using features extracted from ultrasound images [35]. Furthermore, we evaluated the follicular TI-RADS scoring criteria developed by Li et al [34] with our data and found a lower sensitivity (0.044 with a threshold for FTC risk set at

XSL•FO
RenderX

>90%, and 0.269 with using a >50% FTC risk threshold) in evaluating the prediction model. These inconsistencies and the reduced sensitivity observed in external datasets may, at least in part, be attributed to the limitation of not considering tumor size when predicting the malignancy risk.

Our findings suggest that clinical differentiation between benign and malignant FTNs should be more precisely tailored according to the size of the FTNs. For example, the nodule-in-nodule appearance, a characteristic feature of FTC, was more frequently observed in larger FTNs [36]. This sign may reflect heterogeneous tumor cell proliferation, a phenomenon more commonly associated with larger tumors. Conversely, the incidence of this sign is relatively low in small-sized FTNs, complicating the identification of small-sized FTCs. Calcification, however, demonstrates a higher predictive value for malignancy in smaller FTNs. Our study focused on commonly used and easily obtainable predictors in clinical practice, including clinical features, TSH levels, and ultrasound characteristics. The limited number of predictors and the straightforward model design enhance its practicality for physicians. This research assists thyroid specialists in customizing predictor selection to assess the malignancy risk in FTNs of different sizes, ultimately improving the accuracy of FTC identification, patient outcomes, and quality of life while reducing postoperative complications.

Our finding also suggests that the mean TSH score ranked among the top 5 predictors for determining malignancy in tumors of both sizes. A cohort study from the EPIC (European Prospective Investigation into Cancer and Nutrition) cohort has revealed a negative association between elevated TSH levels and an increased risk of thyroid cancer [37]. Similarly, Gudmundsson et al [38] propose that low TSH levels may reduce the differentiation of thyroid epithelium, potentially increasing the predisposition to malignant cell transformation.

In evaluating the predictive performance of our machine learning models, we employed metrics distinct from those used in prior studies. For instance, Li et al [34] reported an AUROC of 0.76 for the LASSO regression model (the ratio of FTA to FTC: training set, 2.74; validation set, 3.70), and also in the LASSO regression model, the AUROC reached 0.913 for discriminating FTA from FTC [35] (the ratio of FTA to FTC: 4.00). However, neither study incorporated the F1 score or AUPRC as evaluation metrics. Given the imbalanced nature of our data (FTA to FTC ratio: 7.00 for small follicular tumors and 5.00 for large follicular tumors), AUPRC provides a more informative and intuitive measure of model performance compared to AUROC [39]. Additionally, the F1 score offers a comprehensive evaluation by integrating precision and recall, ensuring a balanced assessment of model performance in the context of skewed category distributions [40].

Limitations and Strengths

Our study had several strengths. It was among the first to classify FTNs into two subgroups based on tumor diameter for machine learning analysis, revealing significant differences between these subgroups. Additionally, our models benefit from a large sample size, the use of clinically accessible and validated predictors, and a comprehensive evaluation using metrics appropriate for imbalanced data [41]. Importantly, the distribution of FTA and FTC in our study population was fully consistent with that of patients with FTNs in real-world settings, avoiding any exaggeration of sample sizes during model training.

However, our study had certain limitations. First, our classification of small- and large-sized FTNs based on a threshold of 3 cm was determined by our dataset rather than established guideline consensus, which may limit its generalizability to external datasets. We recommend that future clinical guidelines refine specific ultrasound risk indicators for FTNs based on the findings of this study and subsequent related research. Second, while we applied the SMOTE oversampling strategy to address imbalanced data, this approach may introduce bias when predicting new data [42]. Finally, the lack of external validation for our trained model limits our ability to assess its generalizability, potentially affecting its practical applicability and reliability in predicting new cases [43].

Future Directions

Our study had important clinical implications. In current clinical practice, it primarily relies on the ultrasonographic features of FTNs to assess the tumors' malignancy risk under the observation period (ie, before surgical treatment). It is thus crucial to emphasize the need for personalized predictive models in FTNs. Achieving this requires a more refined stratification of tumors based on the clinical characteristics of FTNs, which can enhance the customization of predictive models for tumors of individual cases. This tailored approach acknowledges the inherent variability within FTN categories, suggesting that further stratification within FTNs based on tumor size can facilitate more precise diagnostic and treatment decisions.

To advance this research, we intend to conduct a prospective study to validate the accuracy and reliability of the identified predictors in real-world clinical settings. The prospective evidence will enable updates and refinements to existing medical knowledge and practices for managing FTNs. For FTNs with tumor diameters <3 cm, surgical decision-making should prioritize TSH levels, age at admission, tumor diameter, and calcification status. For FTNs ≥3 cm, TSH levels, BMI, nodule-in-nodule architecture, and tumor diameter should guide clinical recommendations. Furthermore, we advocate that professional medical societies and health care organizations collaboratively develop evidence-based practice guidelines integrating these predictors.

Conclusion

In our study, we identified differences in predictors among follicular tumors of varying sizes. Clinically, these findings emphasize the importance of considering the size during the preoperative diagnosis of benign versus malignant FTNs. We found that both clinical guidelines and the existing research literature have not sufficiently addressed the optimal size of FTNs for surgical intervention or its correlation with malignancy risk. There is a significant research gap in precisely determining the preoperative size-based classification of FTNs. Thus, further investigations are imperative to address this knowledge deficit.

Abstract

Background: Immune checkpoint inhibitors represent an effective therapeutic approach for advanced gastric cancer. Their efficacy largely depends on the status of tumor biomarkers including human epidermal growth factor receptor 2 (HER2), programmed death-ligand 1 (PD-L1; combined positive score ≥1), and microsatellite instability-high (MSI-H). To noninvasively evaluate these biomarkers, researchers have developed radiomic models for individual biomarker prediction. However, in clinical practice, holistic prediction of these biomarkers as an integrated system is more efficient. Currently, the feasibility of implementing radiomics-based comprehensive biomarker prediction remains unclear, requiring further investigation.

Objective: This study aimed to develop a radiomics-based predictive model using multiphase computed tomography (CT) images to holistically evaluate HER2, PD-L1, and MSI-H status in patients with gastric cancer.

Methods: A retrospective analysis was conducted on 461 patients with gastric cancer who underwent radical gastrectomy between 2019 and 2022. Clinical data, contrast-enhanced CT images (arterial phase [AP] and portal venous phase [PP]), and pathological results were collected. Patients were categorized into two groups: (1) the programmed cell death protein-1 inhibitor panel-positive group, comprising patients with HER2 overexpression, PD-L1 positive, or MSI-H status; and (2) the negative group, comprising patients without HER2 amplification, PD-L1 negative, or microsatellite instability-low or microsatellite stable condition. Radiomic features (including first-order statistics, shape features, and wavelet-derived textures) were extracted from both AP and PP images, yielding 1834 features per phase. Least absolute shrinkage and selection operator regression was applied to select key features. In total, 3 models were constructed using the Extreme Gradient Boosting algorithm: AP-only (8 features), PP-only (22 features), and a fused model combining AP and PP features (20 features: 6 AP and 14 PP features). Model performance was evaluated using area under the curve (AUC), sensitivity, specificity, and decision curve analysis.

Results: Of the 461 patients, 147 patients (31.9%) were classified into the panel-positive group. The clinical features were similar between the 2 groups. The fused model demonstrated superior performance in the test set (AUC 0.82, 95% CI 0.68 - 0.95), significantly outperforming AP-only (AUC 0.61, 95% CI 0.47 - 0.74) and PP-only models (AUC 0.70, 95% CI 0.49 - 0.91). Sensitivity and specificity for the AP-only, PP-only, and the fused model were 0.33 and 0.85; 0.50 and 0.86; and 0.60 and 0.83, respectively. Decision curve analysis confirmed that the fused model provided higher clinical net benefit across threshold probabilities.

Conclusions: The construction of integrated biomarker prediction models through radiomics demonstrates technical feasibility, offering a promising methodology for comprehensive tumor characterization.

Introduction

Gastric cancer remains a leading cause of cancer-related mortality worldwide [1]. Patients with advanced gastric cancer have poor prognoses. Conventional therapies, such as surgery and chemotherapy, show limited effectiveness. The 5-year survival rate for these patients is only 40% [2,3]. Recent advancements in immunotherapy, notably the application of programmed cell death protein-1 (PD-1) inhibitors, have markedly improved patient prognosis. These agents not only effectively suppress tumor progression but also enable surgical intervention in selected cases of late-stage disease.

Many previous studies have shown that programmed death-ligand 1 (PD-L1) positive expression (combined positive score [CPS] ≥1) [4,5], human epidermal growth factor receptor 2 (HER2) overexpression [6-8], and microsatellite instability-high (MSI-H) status all indicate a higher sensitivity to PD-1 inhibitor [9,10]. A meta-analysis revealed that patients with PD-L1-positive expression (CPS≥1) receiving PD-1 inhibitor monotherapy demonstrated significantly improved objective response rates (13% vs 3%) and prolonged overall survival (hazards ratio 0.84) [11]. The KEYNOTE-811 trial further showed that combining PD-1 inhibitor with trastuzumab and chemotherapy in patients with HER2-overexpressing advanced gastric cancer substantially enhanced objective response rates (74.4% vs 51.9%) and progression-free survival (hazards ratio 0.73, 95% CI 0.61 - 0.87) [6,7]. In addition, KEYNOTE-059 findings indicated that patients with MSI-H gastric cancer achieved markedly higher objective response rates than non–MSI-H counterparts following PD-1 inhibitor therapy (57.1% vs 9%) [9]. These collective results suggest that PD-1 inhibitors may provide survival benefits in biomarker-positive populations.

For biomarker detection, immunohistochemistry (IHC) remains the gold-standard method, although technical limitations, such as interobserver variability, should be considered. In addition to the low concordance rate between biopsy and resected specimens [12], the invasive nature of biopsy procedures further limits the utility of these tests in patients with coagulopathy, cardiopulmonary dysfunction, or deep-seated tumors. Furthermore, biomarkers exhibit dynamic changes throughout treatment [13], and repeated sampling poses significant challenges for patient compliance.

In recent years, radiomics has enabled noninvasive characterization of tumor biology. Contrast-enhanced computed tomography (CT), a standard imaging modality for gastric cancer staging, captures spatial heterogeneity across entire tumors. These conventional CT images encode critical data about underlying molecular features, including protein expression profiles and genetic alterations [14,15]. Researchers have constructed machine learning models using texture or deep features extracted from preoperative contrast-enhanced CT imaging to predict several biomarkers in patients with gastric cancer: PD-L1 positive expression (area under the curve [AUC] 0.77 - 0.78) [16,17], HER2 overexpression (AUC 0.72 - 0.91) [18,19], and MSI-H status (AUC 0.76 - 0.91) [20-22]. These radiomic approaches demonstrate promising discriminatory performance in noninvasive biomarker assessment.

In clinical practice, candidate selection for PD-1 inhibitor therapy relies on a multimodal evaluation of biomarkers, such as HER2 overexpression, PD-L1 positive expression, or MSI-H status. That is to say, as long as one of the parameters is positive, we can consider using PD-1 inhibitor without verifying each parameter separately. Previous studies have suggested that HER2 overexpression [23,24], MSI-H status [25], and PD-L1 positivity are all related to increased tumor heterogeneity [26], which is reflected in texture features. Accordingly, it will be feasible and more efficient to develop an integrated radiomic model capable of holistic prediction for the aforementioned biomarker panel. In this study, we aim to assess the status of the integrated panel, which includes HER2 overexpression, PD-L1 positive expression, and MSI-H status, using the texture features of preoperative enhanced CT.

Methods

Study Design and Participants

Our hospital is a tertiary hospital located in western China. There are 9 surgeons specialized in radical gastrectomy in our department, and over 200 cases of gastrectomy were performed annually. The clinical records of all consecutive patients who underwent radical gastrectomy in our department between January 2019 and July 2022 were retrospectively reviewed. The following clinical features were recorded: sex, age, smoking history, BMI, location of gastric adenocarcinoma, degree of differentiation, and levels of carcinoembryonic antigen.

The inclusion criteria were: advanced stage was verified by the postoperative pathological report ($T_{3\text{-}4}N_{0\text{-}3}$); received IHC test for HER2 overexpression, PD-L1 positive status, and MSI-H status.

The exclusion criteria were: tumor that was invisible in CT images, received any type of antitumor treatment before surgery, and gastric stump cancer. A total of 461 patients were selected for this study.

Ethical Considerations

This study was approved by the Ethical Committee of the First Affiliated Hospital Of Air Force Military Medical University (20222174-F-1). Dr Yan Jia issued the approval on July 22, 2022. As a retrospective study, the requirement for informed consent was waived. All personal identifiers were removed from the dataset before analysis, and access to raw data was strictly limited to authorized researchers. Confidentiality of participant information was maintained in accordance with the Declaration

XSL•FO
RenderX

of Helsinki and relevant data protection regulations throughout the research process.

HER2, PD-L1, and MSI-H Analysis

The status of HER2, PD-L1, and MSI-H was derived from the postoperative pathology report. These markers were tested by the IHC or additionally by fluorescence in situ hybridization, as appropriate. We defined HER2 overexpression as HER2 IHC 3+ or IHC 2+/fluorescence in situ hybridization–positive, PD-L1 positivity as CPS≥1, and MSI-H status as loss of expression in any of the 4 proteins, that is, MSH2, MSH6, MLH1, and PMS2.

According to the test results of the above parameters, patients were defined as the programmed cell death protein-1 inhibitor panel-positive group (PPP group) when results showed HER2 positive status, CPS≥1, or MSI-H status. Otherwise, patients were classified as the programmed cell death protein-1 inhibitor panel-negative group (PPN group).

CT Examination

All patients underwent a full abdominal contrast-enhanced CT scan within 3 weeks before surgery. Patients were required to fast for at least 6 hours before the CT examination. Furthermore, 10 minutes before the CT scan, each patient was required to drink 1500 mL of water to distend the stomach. A variety of CT scanners were used to obtain CT images, including 2 from United Imaging (United Imaging Healthcare uCT 760), and 2 from Siemens (Siemens SOMATOM Definition Flash CT). The scanning parameters were as follows: the average acquisition parameter was 110 (ranging from 80 to 140) kVp, exposure time was 751 (ranging from 500 to 1782) milliseconds, and tube current was 170 (ranging from 100 to 450) milliamperes. The thickness of the image reconstruction layers varied from 1 to 5 (averaging 2.5) millimeters. For the enhanced scans, nonionic contrast media (with iodine content of 350 mg/mL and 320 mg/mL, respectively) were used, with an injection rate of 3.5 mL/second, and the total contrast medium volume was 1.2 mL per kilogram of body weight. Arterial phase (AP) and portal venous phase (PP) were scanned at 25 seconds and 50 seconds after injection, respectively.

Image Acquisition and Standardization

AP and PP contrast-enhanced CT images were retrieved from the institutional Picture Archiving and Communication System (CARESTREAM PACS v8.1.2, Carestream Health Inc) using standardized Digital Imaging and Communications in Medicine export protocols.

To mitigate interscanner heterogeneity across multiple CT platforms, all Digital Imaging and Communications in Medicine datasets were subjected to voxel resampling using a trilinear interpolation algorithm in 3D Slicer (version 5.4.0), an open-source software platform developed and maintained by the Surgical Planning Laboratory at Brigham and Women's Hospital, Harvard Medical School (Boston, MA, USA), with collaborative support from Kitware, Inc. and contributions from a global research consortium. This standardized the spatial resolution to isotropic 1.0 mm^3 voxels (x-, y-, or z-axes) and normalized Hounsfield Units values using a B-spline deformation field, ensuring consistency in texture feature extraction across heterogeneous acquisition protocols.

Tumor Segmentation Protocol

In total, 2 fellowship-trained abdominal radiologists (NC and JX), each with 7 and 12 years of experience in gastrointestinal oncology imaging respectively, conducted independent volumetric tumor delineation under blinded conditions to pathological and molecular data.

On the AP and PP images, the radiologists meticulously traced tumor boundaries on the largest cross-sectional area of the tumor using the 3D Slicer's Segment Editor module. During the manual delineation process, the selection of the region of interest carefully avoided areas of gastric air, necrosis, and adipose tissue.

One radiologist (NC) manually segmented the tumor region on all CT slices in the largest cross-sectional area using 3D Slicer software (version 5.4.0), after which the segmentation was secondarily reviewed and edited by the second radiologist (JX). The intra- and interobserver reproducibility was assessed by calculating the interclass and intraclass correlation coefficients (ICCs) of the first-order texture features (energy, entropy) and Gray-Level Co-occurrence Matrix features.

Texture Feature Extraction and Analysis

We used the PyRadiomics package (version 3.7.12) and the scikit-learn (version 0.22) package to systematically extract radiomic features from the manually segmented regions of interest. The extraction process was performed on both the AP and PP phases of the contrast-enhanced CT images. The radiomic features included a comprehensive set of histogram-based features (eg, mean, SD, skewness, kurtosis, and percentiles) and wavelet texture features (eg, energy, entropy, and correlation), capturing both intensity distribution and spatial heterogeneity of the tumor.

To ensure robustness and reproducibility, the feature extraction pipeline was implemented with the following standardized settings. First, Gray-Level Discretization: the raw pixel intensity values were discretized into 256 bins using a uniform quantization method to reduce noise and enhance feature stability. Second, wavelet decomposition: features were extracted at 3 decomposition levels (low pass - low pass [characterizes smooth approximation], low pass - high pass [characterizes vertical details], high pass - low pass [characterizes horizontal details], high pass - high pass [characterizes diagonal details]) using the Haar wavelet transform to capture multiscale texture information. Third, neighborhood settings: a 3D isotropic kernel with a radius of 1 voxel was applied to compute neighborhood-based texture features, ensuring consistency across different tumor sizes. Through the aforementioned extraction process, we obtained AP features and PP features. Furthermore, we achieved dual-phase feature fusion by means of horizontal concatenation of feature vectors, thereby acquiring integrated fusion features.

The feature selection process was conducted in a multistep, hierarchical manner to identify the most stable, discriminative, and nonredundant features: (1) reproducibility assessment: intra-

XSL•FO
RenderX

and interreader reproducibility was evaluated on a resegmentation dataset comprising 30 randomly selected cases. The intraclass correlation coefficient (ICC) was calculated for each feature, with features demonstrating ICC >0.75 for both intra- and interreader reproducibility retained for subsequent analysis. (2) All radiomic features were normalized using *z* score standardization to ensure comparability across different imaging protocols and scanners. (3) Statistical screening: a 2-tailed independent samples *t* test was performed to compare the feature distributions between the PD-1 inhibitor PPP and PPN groups. Features with a *P* value<.05 were selected as potentially discriminative. (4) Redundancy removal: a correlation analysis was conducted to eliminate redundant features with high collinearity. A Pearson correlation coefficient threshold of 0.9 was applied, retaining only 1 feature from each highly correlated pair.

Feature Sparsity and Penalized Regression

First, the least absolute shrinkage and selection operator (LASSO) logistic regression algorithm was applied to identify the most predictive features while controlling for model complexity. Second, the penalty parameter (λ) was optimized using a 10-fold cross-validation procedure, with λ tuned to minimize the cross-validation error. Third, the optimal λ value was determined based on the "one-standard-error" rule, ensuring a balance between model performance and feature parsimony. Finally, features with nonzero coefficients in the LASSO model were selected for final model construction.

Prediction Model Building

The feature selection and modeling processes were conducted in the training set, with feature selection performed using LASSO regression to iteratively screen and optimize penalty coefficients, thereby reducing dimensionality and extracting important features.

The Extreme Gradient Boosting (XGBoost) algorithm, a gradient-boosted decision tree-based method, was used to develop the classification models, with hyperparameters such as learning rate, tree depth, and subsample ratio optimized through grid search or random search to enhance model performance. In addition, several other algorithms, such as random forest, linear regression, and support vector machines, were also used.

Model performance was comprehensively evaluated using the area under the receiver operating characteristic curve, AUC, sensitivity, and specificity. To demonstrate clinical utility, decision curve analysis was performed to evaluate net benefit across different threshold probabilities and to assess clinical net benefit. The efficacy of the constructed model was evaluated using 10-fold cross-validation with stratified sampling. In addition, receiver operating characteristic curves and calibration curves were plotted to further assess model discrimination and calibration, ensuring reliable and accurate results.

Statistical Analysis

Categorical data were reported as numbers with proportions, and quantitative data were reported as the mean with SD. Categorical data were compared using the chi-square test or Fisher exact test, where appropriate. For continuous data, the Student *t* test or Mann Whitney *U* test was used. A 2-sided *P* value of <.05 was considered statistically significant. AUC was used to assess the performance of each model.

Results

Clinical Characteristics

The study population consisted of 461 patients who underwent radical gastrectomy. The proportion of patients with HER2 overexpression, PD-L1 positive status (CPS≥1), and MSI-H status was 5.4% (25/461), 24.1% (111/461), and 5.6% (26/461), respectively. Based on HER2, PD-L1, and MSI-H status, 32.2% (147/461) of patients were classified into the PPP group. The demographic data and clinical characteristics of the patients are listed in Table 1.

[a]PPP: programmed cell death protein-1 inhibitor panel-positive.

[b]PPN: programmed cell death protein-1 inhibitor panel-negative.

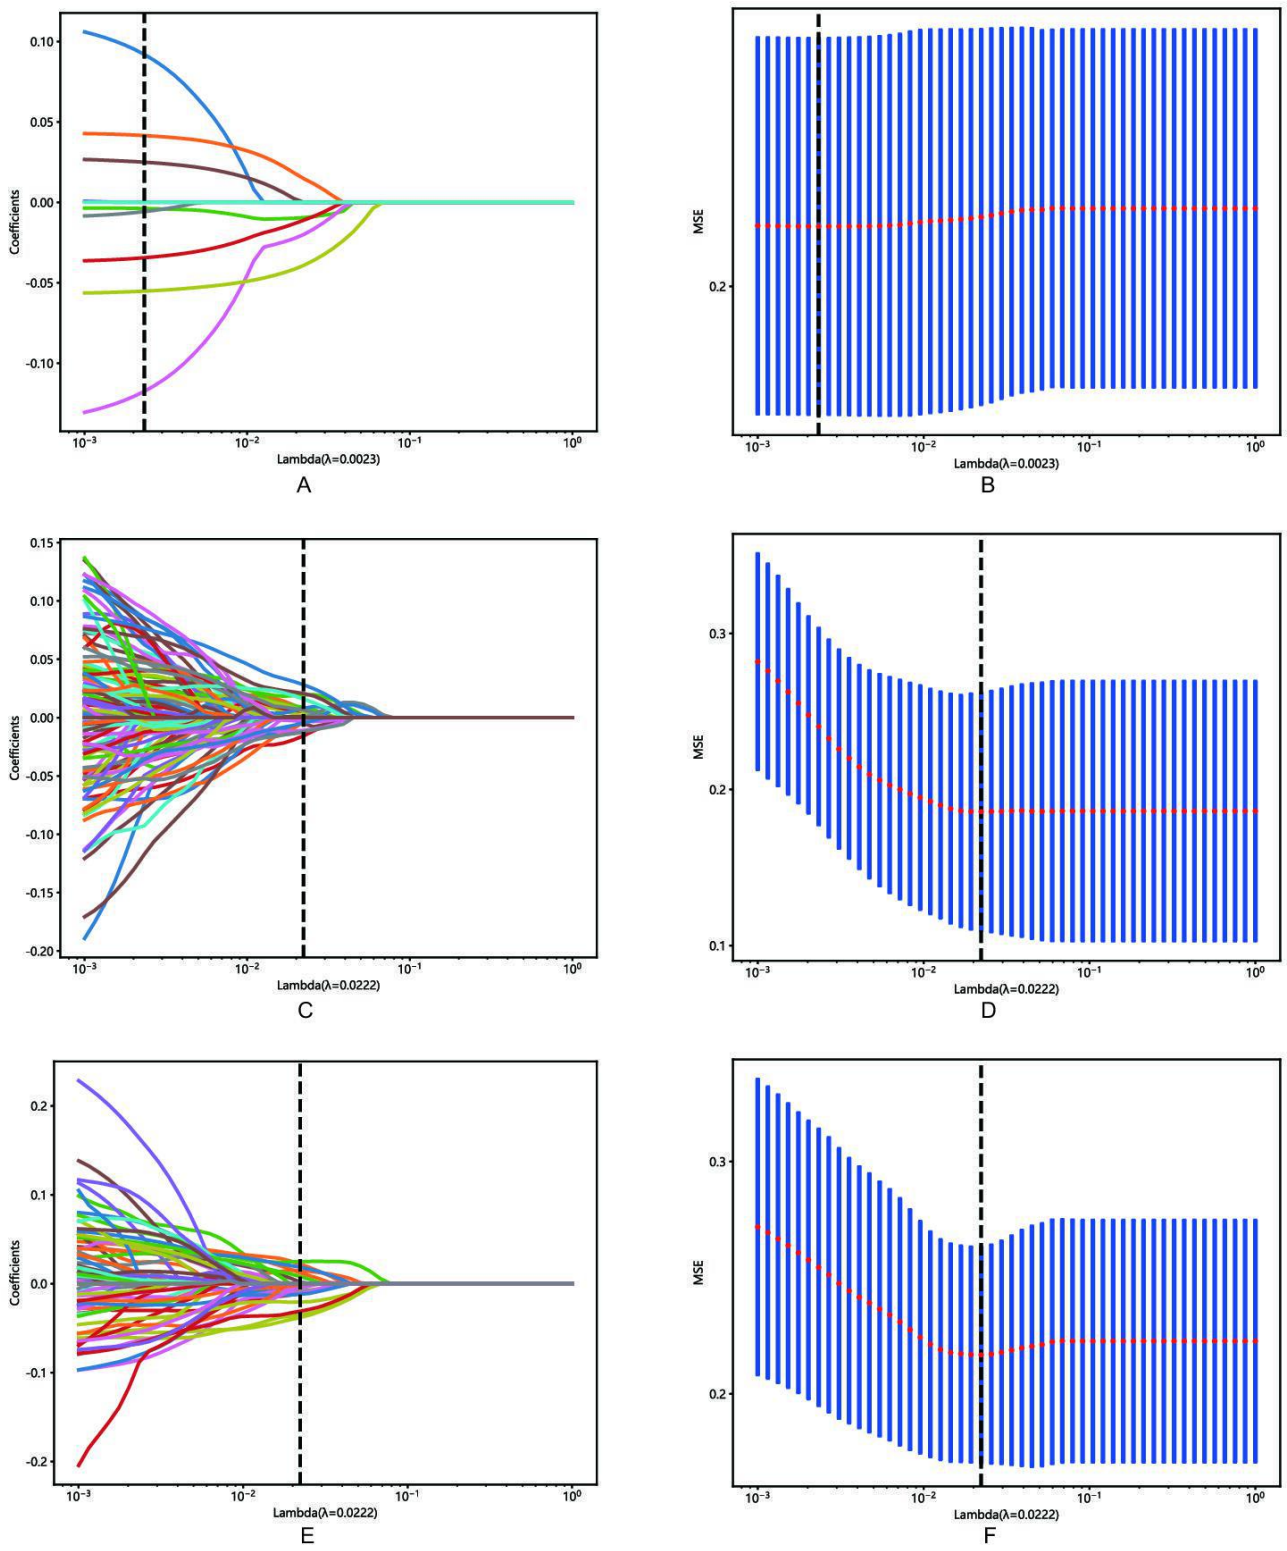
[c]GEJ: gastroesophageal junction.

[d]CEA: carcinoembryonic antigen.

[e]NEUT#: neutrophil absolute value.

[f]LYM#: lymphocyte absolute value.

[g]T3 indicates that the tumor has penetrated the muscularis propria of the gastric wall with potential invasion into the subserosal tissue or adjacent adipose tissue, but without breaching the overlying serosal layer.



[h]N: regional lymph nodes metastasis.

Retrieved CT Texture Features and Feature Selection

A total of 1834 features were retrieved from the segmentation areas on the AP or PP CT images, respectively. The features included first-order features, shape features, and wavelet texture features. Reproducibility analysis retained 1325 and 1506 features with an ICC >0.75 from AP and PP CT images, respectively. The AP and PP features were horizontally concatenated to construct the fusion dataset, and *z* score standardization was performed for each dataset. Following a 2-tailed independent samples *t* test, 11, 666, and 210 features from the AP, PP, and fusion datasets were retained, respectively (Multimedia Appendix 1). Correlation analysis to remove redundant features further reduced these to 10, 147, and 89 features for the AP, PP, and fusion datasets, respectively. Subsequently, LASSO regression was applied to select the most relevant features. The LASSO path plot for the training set is presented in Figure 1, with the relative weights of the selected features shown in Figure 2. Ultimately, feature selection yielded 8 AP features, 22 PP features, and 20 fusion features (comprising 6 AP and 14 PP features).

Model Construction and Evaluation in Assessing the ICC Panel

The selected features were used to construct classification models. Table 2 lists the classification performances of the AP, PP, and fusion features based models (XGBoost algorithms) both in the training and the testing sets. In the testing set, the AP features-based model predicted the PPP group with AUC of 0.61 (95% CI 0.47 - 0.74), sensitivity of 0.33, and specificity of 0.85; the PP model showed AUC of 0.7 (95% CI 0.49 - 0.91), sensitivity of 0.50, and specificity of 0.86; the fusion model performed better, with an AUC of 0.82, (95% CI 0.68 - 0.95), sensitivity of 0.60, and specificity of 0.83. The performances of the models are illustrated in Figure 3. The performances of other models are demonstrated in Multimedia Appendix 2.

Table . Predictive performances of the radiomics models in the training and testing set.

	AUC[a] (95% CI)	Accuracy	Sensitivity	Specificity
AP[b] model[c]	0.90 (0.87 - 0.94)	0.81	0.86	0.79
AP model	0.61 (0.47 - 0.74)	0.68	0.33	0.85

Discussion

Principal Results

Based on texture features from multiphase CT images, this study first develops a radiomics model that holistically evaluates HER2, PD-L1, and MSI-H status in patients with gastric cancer. By using texture features from both the AP and PP images, the holistic prediction model (XGBoost algorithms) demonstrated an AUC of 0.95 in the training set and 0.82 in the testing set. These results demonstrate the feasibility of radiomics models in achieving holistic prediction for a panel of biomarkers, thereby enhancing the assessment efficiency.

Limitations

There are some limitations in our study. First, this is a single-center study with a relatively small sample size. Second, the predictive performance of the model was evaluated solely through internal cross-validation rather than external validation, introducing potential overfitting risks. Owing to the retrospective design and limited sample size, we currently lack access to independent external datasets for validation. Therefore, future studies should rigorously assess the model's predictive performance by incorporating external validation and calibration curve analysis. Third, 2D segmentation on a single slice was applied instead of 3D segmentation encompassing the entire tumor. However, this less labor-intensive approach is recommended in radiomic studies of gastric cancer [27].

Comparison With Previous Work

Several studies have proved the efficacy of enhanced CT image texture features in predicting PD-L1 expression (AUC 0.74-0.77) [16,17], HER2 overexpression (AUC 0.79-0.83) [18,19], or MSI-H status (AUC 0.76-0.91) [20-22]. Our study demonstrated comparable AUC (0.82) in predicting the biomarker as an integrated panel. These findings demonstrate that the integrated model maintains robust predictive performance while improving assessment efficiency.

The primary distinction from previous research lies in our comprehensive evaluation of biomarkers as an integrated panel. Although aggregating patients with diverse biomarker profiles as a single cohort may obscure heterogeneity in treatment sensitivity to PD-1 inhibitor among individuals within the same group, this does not preclude sensitivity evaluation or clinical application of PD-1 inhibitor therapy in this group. Furthermore, collective analysis of these biomarkers could potentially enhance the predictive capacity of radiomics. First, it improves the clinical applicability. As long as one of the parameters is positive, we can consider using the PD-1 inhibitor without verifying each parameter separately. Second, it enhances the stability of the model. Due to the limited rates of HER2 overexpression and MSI-H status, previous studies often encountered imbalanced outcome events, and too few positive events may weaken the robustness of the model. For example, patients with HER2 amplification constituted only 19.2% (198/1033) of the population [28]. Patients with MSI-H status accounted for only 9% (37/396) of the overall cohort [20]. Although methods, such as synthetic minority oversampling technique, can be used to handle imbalanced datasets before constructing the model, a better approach is to ensure an adequate number of positive events. In our study, the positivity rate of the ICC panel reached 32.2%, which may enhance the robustness of the model in this aspect. Third, considering these parameters as a panel may theoretically improve the predictive performance of the model. The fundamental rationale for employing radiomics in biomarker classification may lie in distinguishing heterogeneity levels. Since factors such as HER2 overexpression, PD-L1 positivity, or MSI-H may elevate tumor heterogeneity [21,29,30], independent grouping based on any single biomarker could increase heterogeneity within control cohorts, thereby compromising the model's discriminative capacity. Classifying these biomarkers as an integrated entity may mitigate confounding effects arising from suboptimal heterogeneity discrimination during the categorization process.

Previous models showed that increased tumor heterogeneity can be reflected by some texture features, such as log.sigma.2.5.mm.3D glrlm run entropy, wavelet.LLL Gray-Level Co-occurrence Matrix difference entropy [17], log.sigma.3.0.mm.3D GLSZM zone entropy [16], GLSZM gray level non uniformity, and size zone non uniformity [20,21]. This study demonstrated similar results. We found that the 3 features that most strongly correlated with the integrated model were wavelet HHH first order skewness (AP), gradient gldm dependence variance (PP), and wavelet LHL first order root mean square (PP), and these features characterize tumor spatial and metabolic heterogeneity by quantifying the symmetry of regional gray-level distribution, the dispersion degree of adjacent pixel intensity variations, and the overall energy intensity of regional signals, respectively.

CT images acquired at different contrast phases may yield complementary radiomic parameters. To leverage this advantage, features extracted from both AP and PP were integrated into the analysis. Previous studies predominantly extracted features from either venous phase [16,17,20], AP [18], or PP images individually [22], while others combined features across multiple phases [19,21]. However, no comparative analysis has been conducted to determine the optimal imaging phase. To identify the most suitable phase for biomarker assessment, we developed separate models using AP and PP features, along with an early-fusion model incorporating both phases. Our results demonstrate that PP images provide more discriminative texture features for biomarker evaluation, yielding superior predictive performance compared with AP models. Furthermore, feature fusion from both phases significantly enriched the texture feature repertoire for model construction and enhanced predictive efficacy (Table 2). The underlying reason may lie in the fact that AP and PP images capture distinct tumor characteristics, thereby achieving complementary information gain. For instance, AP features emphasize vascular-related texture patterns (eg, microvascular density variations), while PP features predominantly reflect morphological attributes and stromal interactions (eg, extracellular matrix distribution). Integrating dual-phase signatures enhances model robustness by mitigating overfitting risks inherent in single-phase feature extraction. These findings underscore the clinical value of multiphase feature integration.

XSL•FO
RenderX

Regarding algorithm selection, multiple methods (including random forest [16-19], support vector machines [18], and linear regression [20-22]) have been employed for classification model development. However, no consensus exists regarding the optimal algorithm for classification performance. Our systematic comparison of multiple machine learning approaches revealed that XGBoost-based models demonstrated superior classification accuracy (Multimedia Appendix 2). This advantage likely stems from three technical innovations within XGBoost's gradient boosting framework: (1) regularization robustness: integration of L1/L2 regularization with randomized subsampling (row and column subsampling) effectively controls model complexity, ensuring stable performance with heterogeneous medical data containing missing values and outliers; (2) computational efficiency: parallelized feature splitting and sparse data-aware architecture enable efficient processing of high-dimensional biomarkers without manual feature selection; and (3) clinical data adaptability: native handling of missing values mitigates imputation bias, while the scale_pos_weight parameter directly addresses class imbalance in disease cohorts. However, algorithm selection should be task-specific, as no universally optimal solution exists across all clinical prediction scenarios.

To enhance predictive performance, some studies have incorporated clinical characteristics and radiomic features [16,18,20,22]. However, the integration of clinical variables does not universally improve model efficacy. For instance, 1 MSI-H prediction model demonstrated no AUC improvement after adding clinical parameters (from 0.91 to 0.89) [22]. In our study, although the PPP group exhibited a higher proportion of T3 staging, we were unable to accurately distinguish between T3 and T4 stages based on CT imaging characteristics. Furthermore, no statistically significant differences were observed in other clinical parameters between the 2 groups. Consequently, clinical features were not incorporated into the predictive model.

Conclusions

This study demonstrates the feasibility of a multiphasic CT-based radiomics model for the holistic prediction of HER2, PD-L1, and MSI-H status in patients with gastric cancer. The proposed model exhibits predictive performance comparable with conventional single-biomarker approaches while demonstrating superior operational efficiency. Our analysis incorporated both AP and PP CT imaging features, with their combined integration yielding significantly enhanced predictive accuracy relative to single-phase methodologies. However, comprehensive clinical validation remains necessary to establish the model's utility for evaluating PD-1 inhibitor therapeutic efficacy in real-world settings.

Abstract

Background: Machine learning (ML) has been increasingly applied to cervical cancer (CC) research. However, few studies have combined both clinical parameters and imaging data. At the same time, there remains an urgent need for more robust and accurate preoperative assessment of parametrial invasion and lymph node metastasis, as well as postoperative prognosis prediction.

Objective: The objective of this study is to develop an integrated ML model combining clinicopathological variables and magnetic resonance image features for (1) preoperative parametrial invasion and lymph node metastasis detection and (2) postoperative recurrence and survival prediction.

Methods: Retrospective data from 250 patients with CC (2014‐2022; 2 tertiary hospitals) were analyzed. Variables were assessed for their predictive value regarding parametrial invasion, lymph node metastasis, survival, and recurrence using 7 ML models: K-nearest neighbor (KNN), support vector machine, decision tree, random forest (RF), balanced RF, weighted DT, and weighted KNN. Performance was assessed via 5-fold cross-validation using accuracy, sensitivity, specificity, precision, F1-score, and area under the receiver operating characteristic curve (AUC). The optimal models were deployed in an artificial intelligence–assisted contouring and prognosis prediction system.

Results: Among 250 women, there were 11 deaths and 24 recurrences. (1) For preoperative evaluation, the integrated model using balanced RF achieved optimal performance (sensitivity 0.81, specificity 0.85) for parametrial invasion, while weighted KNN achieved the best performance for lymph node metastasis (sensitivity 0.98, AUC 0.72). (2) For postoperative prognosis, weighted KNN also demonstrated high accuracy for recurrence (accuracy 0.94, AUC 0.86) and mortality (accuracy 0.97, AUC 0.77), with relatively balanced sensitivity of 0.80 and 0.33, respectively. (3) An artificial intelligence–assisted contouring and prognosis prediction system was developed to support preoperative evaluation and postoperative prognosis prediction.

Conclusions: The integration of clinical data and magnetic resonance images provides enhanced diagnostic capability to preoperatively detect parametrial invasion and lymph node metastasis detection and prognostic capability to predict recurrence and mortality for CC, facilitating personalized, precise treatment strategies.

KEYWORDS

cervical cancer; integrated prediction model; machine learning; multimodal integration; diagnostic model; prognosis prediction model

Introduction

As the fourth leading cause of cancer-related death in women, cervical cancer (CC) accounted for approximately 661,000 new cases and 341,800 deaths worldwide in 2022 [1]. Despite advances in clinical management, up to 30% of patients continue to succumb to the disease, resulting in a disproportionately high global burden [2]. However, current methods for preoperative evaluation and postoperative prognosis prediction in patients with CC remain insufficiently comprehensive. Preoperative assessment relies heavily on pelvic magnetic resonance (MR)

XSL•FO
RenderX

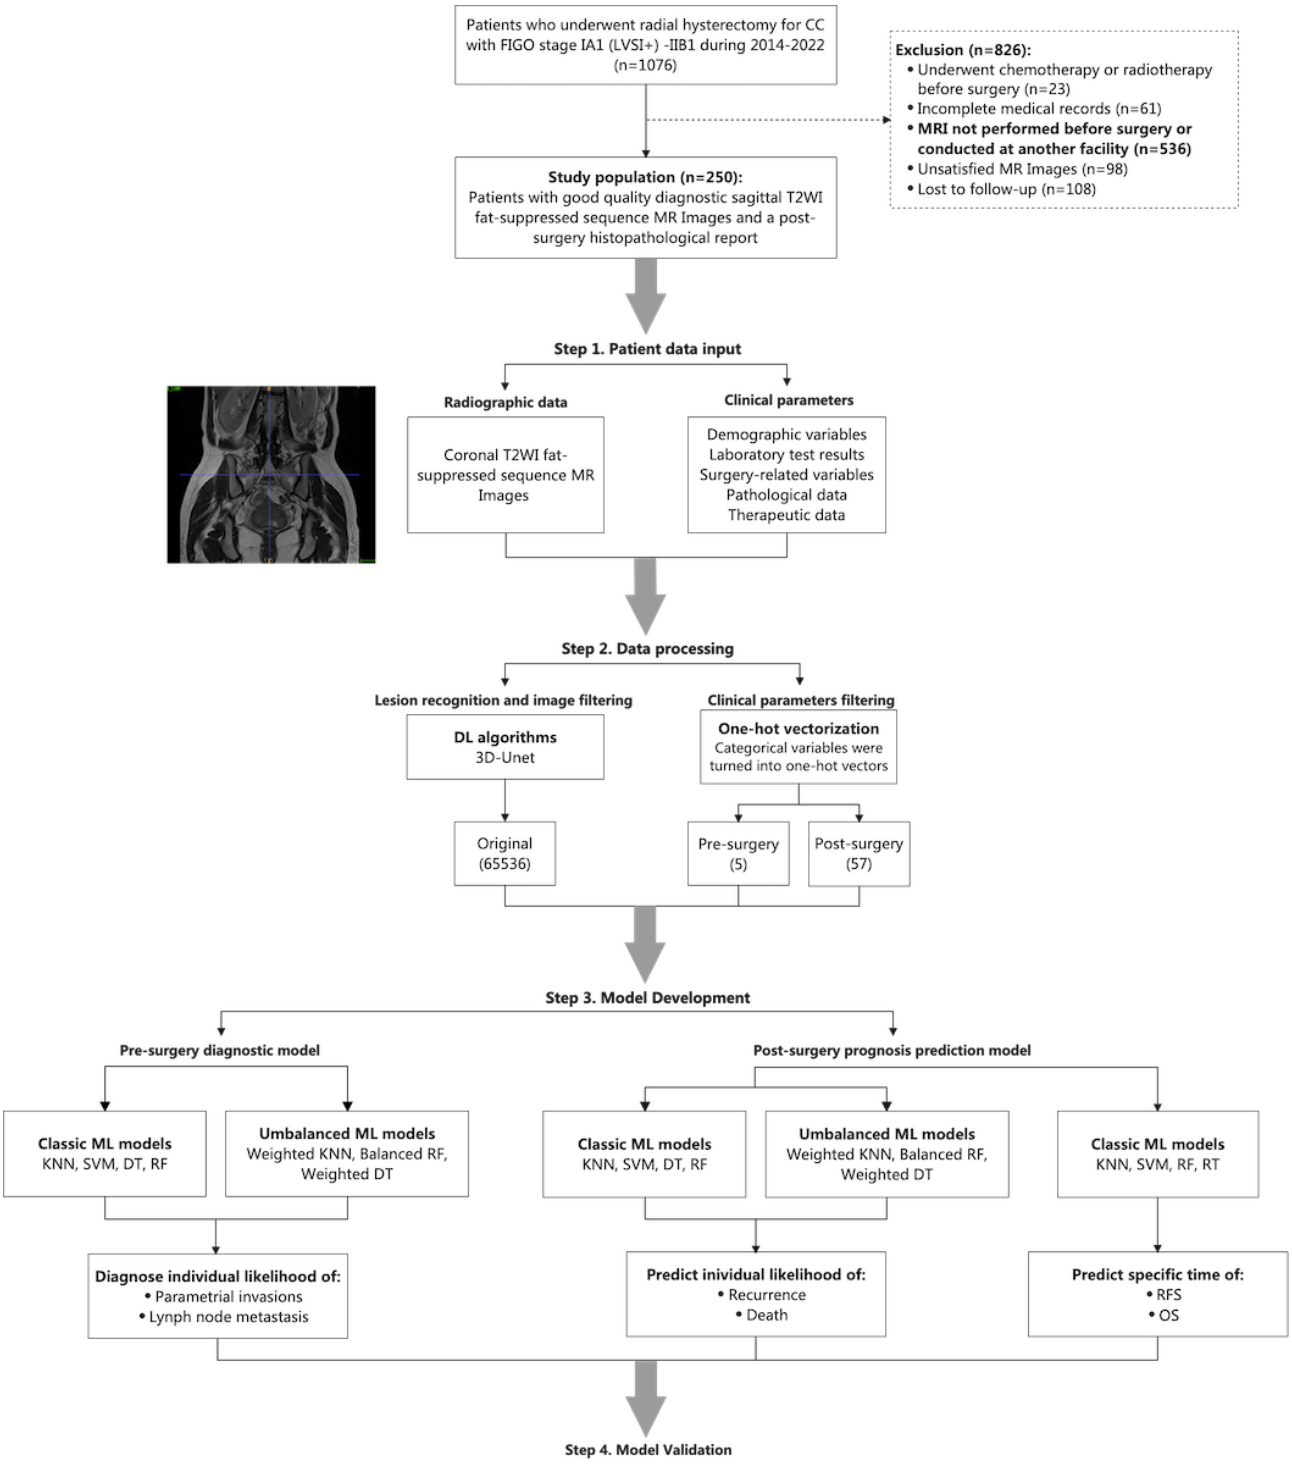
imaging to identify primary lesions [3], whereas the recognition rates for parametrial invasion and lymphatic metastases remain inconsistent [4]. Furthermore, for postoperative prognosis prediction, the International Federation of Gynecology and Obstetrics (FIGO) staging system is currently accepted as the clinical standard. However, it fails to fully account for patient heterogeneity, including factors such as age, general health status, and tumor markers. Therefore, a personalized prognostic estimation system is urgently needed. To address this, researchers have explored various statistical methods—such as logistic regression and Cox proportional hazards models—to estimate survival and recurrence outcomes on an individual basis [5,6]. Nonetheless, traditional statistical models are often limited in their ability to handle large, complex datasets and make accurate predictions in dynamic clinical environments. To this end, a more accurate and personalized prediction model—incorporating both preoperative and postoperative evaluation—is urgently needed to optimize treatment decisions and follow-up strategies for patients with CC.

In recent years, machine learning (ML)—which involves the development of dynamic algorithms capable of making data-driven decisions—has emerged as a novel method for processing medical data and has been widely applied to various diseases [7]. In the field of CC, our previous multicenter study developed a web-based calculator to predict prognosis in 5112 patients with CC using various ML models, which demonstrated better predictive accuracy than traditional statistical models [8]. However, similar to other studies [9-11], only clinicopathological information was included in the development of this ML model. Notably, with technological advancements, medical imaging can now reveal information imperceptible to the naked eye—even for experienced clinicians. Consequently, an increasing number of studies have used deep learning (DL) algorithms on MR images for the diagnosis [12,13] and classification [14] of CC. However, most existing studies have focused on lesion identification [15,16] and radiotherapy response prediction [17,18]. Currently, there is a lack of ML models that integrate both clinical and imaging data to predict prognosis in patients with CC. Therefore, we aimed to develop an integrated ML model that uses both clinical and imaging data to enhance preoperative evaluation and postoperative prognosis prediction.

Specifically, the model is designed to (1) accurately evaluate parametrial involvement and lymph node metastasis on pelvic MR images prior to surgery to better inform surgical planning, and (2) predict individualized postoperative recurrence and survival outcomes to support precise, personalized adjuvant treatment and follow-up strategies.

Methods

Ethical Considerations



This retrospective multicenter cohort study received ethical approval from the Institutional Review Board of the Obstetrics and Gynecology Hospital of Fudan University (Shanghai, China; approval no. 2019‐87) and registered with the Chinese Clinical Trial Registry (ChiCTR1900028702). Oral informed consent was obtained from all participants via telephone follow-up in accordance with institutional ethical standards. All personally identifiable information was permanently removed prior to analysis. Data were coded using unique identifiers and stored securely on encrypted, password-protected servers with role-based access controls to ensure confidentiality. No compensation was provided to participants.

Patients

A total of 1076 patients with CC who underwent surgical resection between January 2014 and December 2022 were identified from 2 tertiary hospitals in China: the Obstetrics and Gynecology Hospital affiliated with Fudan University and Shanghai First Maternity and Infant Hospital. The inclusion criteria were as follows: (1) pathologically confirmed FIGO stage IA1 with positive lymph-vascular space invasion (LVSI) to stage IIB CC; (2) radical hysterectomy performed according to National Comprehensive Cancer Network (NCCN) guidelines appropriate to the disease stage at the time [19-21]; (3) availability of high-quality preoperative pelvic contrast-enhanced MR images, including the coronal T2-weighted imaging (T2WI) fat-suppressed sequence; and (4) at least 3 years of follow-up data. The exclusion criteria were as follows: (1) receipt of chemotherapy or radiotherapy before surgery (n=23); (2) incomplete medical records (n=61); (3) absence of preoperative MR imaging (MRI) or MRI performed at another institution (n=536); (4) unsatisfactory MR image quality (n=98); and (5) loss to follow-up (n=108). The final study population comprised 250 patients (Figure 1).

Figure 1. Flow diagram illustrating the selection process for the study population and the sequential stages of machine learning model development. FIGO: International Federation of Gynecology and Obstetrics; LVSI: lymph-vascular space invasion; T2WI: T2-weighted imaging; MR: magnetic resonance; KNN: K-nearest neighbor; SVM: support vector machine; DT: decision tree; RF: random forest; RT: regression tree; RFS: recurrence-free survival; OS: overall survival.

Clinical Information

For eligible patients, demographic data, laboratory test results, treatment details, and tumor characteristics were collected from medical records. All records were reviewed concurrently by 3 experts and independently verified for accuracy by 2 additional reviewers. Following diagnosis, demographic variables—including age and comorbidity (hypertension or diabetes)—as well as laboratory data, including squamous cell carcinoma antigen levels and human papillomavirus (HPV) infection status, were recorded. The history of the loop electrosurgical excision procedure was also noted.

All surgical procedures during the study period were performed by faculty members with completed fellowship training in gynecologic oncology. Surgical data included surgical approach, operative time, estimated blood loss, and use of blood transfusion. Tumor characteristics included FIGO stage, tumor size, histologic type, depth of stromal invasion (DSI), LVSI,

XSL•FO
RenderX

surgical margin status, parametrial involvement, lymph node metastasis, keratinization, degree of differentiation, and expression of P53, P16, and Ki-67. According to the NCCN guidelines [3], all patients received adjuvant therapy if they met one of the following criteria: (1) presence of any high-risk factor, including positive surgical margins, parametrial involvement, or lymph node metastasis; or (2) fulfillment of any Sedlis criteria [22] for intermediate-risk factors, including tumor size, LVSI, and DSI.

Patients were followed according to the 2022 NCCN guidelines [3] after discharge and completion of initial treatment. HPV testing, liquid-based cytology, tumor marker evaluation, and ultrasonography were conducted every 3 months for the first 2 years, every 6 months for the next 2 years, and annually thereafter. Chest computed tomography (CT), contrast-enhanced upper abdominal CT, and pelvic MRI were performed annually. Telephone follow-ups were also conducted, and patients with symptoms or abnormal findings suggestive of recurrence were advised to undergo the aforementioned tests. In cases of suspected organ or lymph node metastasis, needle aspiration biopsy was performed when clinically indicated.

Region of Interest Delineation on MR Images

Coronal preoperative T2WI fat-suppressed pelvic contrast-enhanced MR images were collected for all 250 patients. This included both the original MR sequence source images and lesion segmentation images annotated by radiologists. The MR source images were first normalized before further processing. To standardize the 2 types of MR source image resolutions (256×256 pixels and 320×320 pixels), images of 320×320 pixels were center-cropped to 256×256 pixels. Meanwhile, the pixel intensity values, which originally ranged from 0 to over 1000, were rescaled to the range [0, 1]. After obtaining standardized MR source images, 2 experienced radiologists performed lesion annotations. The region of interest for CC was manually delineated on T2WI images using ITK-SNAP (version 3.8.0). Each radiologist delineated half of the cases and independently reviewed the other half. In cases of disagreement, the final decision was reached through discussion or by consulting a third radiologist. During the segmentation process, the radiologists were blinded to the patients' clinical information.

After obtaining standardized MR source images, 2 experienced radiologists performed lesion annotations. The region of interest for CC was manually delineated on T2WI images using ITK-SNAP (version 3.8.0). Each radiologist delineated half of the cases and independently reviewed the other half. In cases of disagreement, the final decision was reached through discussion or by consulting a third radiologist. During the segmentation process, the radiologists were blinded to the patients' clinical information.

Subsequently, cervical lesion identification was modeled using the radiologist-annotated MR images. An optimized algorithm based on the 3D U-Net architecture [23], embedded with a squeeze-and-excitation layer [24], was adopted to segment the lesion pixels. Following multiple preprocessing steps (see Supplementary Materials in Multimedia Appendix 1), the input data (C×W×H×D) were compressed and normalized using the Sigmoid activation function [25], then reshaped to their original dimensions. The grayscale output was segmented by computing the probability of each pixel being classified as a positive sample through the Sigmoid function. To address the issue of sample imbalance—where MR image sequences contained significantly more frames with lesion markers than without—an improved Focal Loss function [26] was implemented. A weighting factor (α) was applied to balance positive and negative samples, while a power function was used to reduce the loss contribution of easy samples. The optimal parameters used in this study were α=.25 and γ=2.

Outcome

Parametrial invasion and lymphatic metastasis were 2 key pathological indicators derived from the surgical specimens of cervical carcinoma. Parametrial invasion refers to the infiltration of neoplastic cells beyond the cervix into the surrounding connective tissue (parametrium), while lymphatic metastasis denotes the spread of malignant cells to regional lymph nodes.

For survival outcomes, recurrence-free survival (RFS) was defined as the interval from the initial CC diagnosis to either the first documented recurrence or the last follow-up. Overall survival (OS) was defined as the interval from diagnosis to CC–related death or the last follow-up. Regarding recurrence classification, local recurrence was defined as the pathologically confirmed first reappearance of cancer in the cervix or vagina following complete treatment, confined to the pelvic region. Distant recurrence was defined as the first pathologically confirmed relapse beyond the pelvis, including peritoneal dissemination or metastasis to distant organs.

Dataset Processing

After selecting MR source images that corresponded to lesion-annotated segmentation files, the filtered original images (256×256 pixels) were flattened into 65,536-dimensional vectors. The clinical dataset consisted of 22 variables (Table S1 in Multimedia Appendix 1), including both continuous and categorical features. Continuous variables were normalized using min-max scaling, rescaling each feature into the [0, 1] range using the following formula:

$$Xnorm=X-XminXmax-Xmin$$

where Xmin and Xmax represent the minimum and maximum observed values of that feature. For example, for a variable ranging from 2 to 10, a value of 5 would be transformed as: (5–2)/(10–2)=0.375. Categorical variables were encoded using one-hot encoding, which converts nominal variables into orthogonal binary vectors. For a categorical feature with 3 classes (1, 2, 3), the transformation was as follows: Class 1 → [1, 0, 0]; Class 2 → [0, 1, 0]; and Class 3 → [0, 0, 1].

After preprocessing, categorical and continuous variables were concatenated into 5-dimensional (preoperative) and 57-dimensional (postoperative) clinical feature vectors. These clinical vectors were then fused with the 65,536-dimensional image vectors, resulting in integrated feature vectors of 65,593 dimensions.

XSL•FO
RenderX

Establishment of Integrated Models

Two integrated models were developed: (1) The preoperative recognition model integrated preoperative clinical parameters (age, comorbidity, HPV status, squamous cell antigen carcinoma level, and loop electrosurgical excision procedure history) and MR images to generate binary classifications for parametrial invasion and lymph node metastasis; and (2) the postoperative prognostic model combined 21 postoperative clinical parameters (Table S1 in Multimedia Appendix 1) and MR images to predict recurrence, mortality, and individualized RFS or OS times.

A total of 7 ML algorithms were used for model construction. These included classical ML algorithms such as K-nearest neighbor (KNN), support vector machine (SVM), decision tree (DT), and random forest (RF), as well as their imbalanced-data variants—weighted KNN, balanced RF, and weighted DT. Weighted KNN adjusted sample weights inversely proportional to class frequency. Specifically, minority class samples (in this study, positive cases) were assigned higher weights in distance calculations, forcing the algorithm to prioritize minority class neighborhoods during prediction. Balanced RF used under-sampling by randomly removing majority class samples (negative cases) in each bootstrap iteration to create balanced subsets for training individual trees. Weighted DT modified the splitting criterion by incorporating a class-weighted penalty: a weight of misclassifying a positive sample was set to amplify the cost of false negatives during node splitting. Besides, to mitigate the influence of class imbalance during model development, negative samples were down-sampled to achieve a 1:1 ratio with positive cases during training.

Validation, Evaluation, and Implementation

The study process consisted of 4 main stages: patient data input, data preprocessing, model development, and model evaluation (Figure 1). Stratified random sampling was used to divide the complete dataset from the 2 hospitals into training and test sets at a ratio of 8:2. Model training was conducted using the training set, while final validation was performed on the test set. To minimize overfitting and reduce bias, 5-fold cross-validation was used on the training set for hyperparameter tuning.

Model performance for classification tasks was evaluated using sensitivity, specificity, accuracy, precision, F1-score, weighted accuracy, and area under the receiver operating characteristic curve (AUC). The mean absolute error (MAE) and concordance index (C-index) were used to assess the accuracy of individual-specific RFS and OS time predictions.

To facilitate clinical application and enhance accessibility for physicians, a web-based predictive diagnostic support tool was developed using Python, enabling DICOM upload and automated prediction.

Statistical Analysis

Continuous variables were reported as means with standard deviations (SDs) for normally distributed data and as medians with interquartile ranges (IQRs) for non-normally distributed data, while categorical variables were summarized as counts and percentages. No significant interactions were observed among variables based on correlation matrix analysis. Concordance of continuous variables was assessed using intraclass correlation coefficients to evaluate consistency between pathology and imaging reports. Categorical variables were analyzed using the χ^2 test and the Kappa coefficient.

All statistical analyses were performed using R statistical software (version 4.1.1; R Foundation for Statistical Computing) and Python programming software (version 3.10.4; Python Software Foundation). All tests were 2-sided, and a *P* value of less than .05 was considered statistically significant unless otherwise stated.

Results

Baseline Characteristics of 250 Patients with Early-Stage CC

A total of 250 patients with FIGO stage IA1 (LVSI+) to IIB CC who underwent radical hysterectomy between 2014 and 2022 were included in the study population (Table 1). The median age was 48.8 years. Most patients were at stage I (n=182, 72.8%) and had a squamous histologic type (n=200, 80%). More than half of the patients (n=191, 76.4%) received adjuvant therapy. In total, 24 women (9.6%) experienced recurrence, and 11 (4.4%) died during the follow-up period. Among the recurrence cases, 9 (37.5%) were local recurrences and 15 (62.5%) were distant. Among the distant recurrences, 4 (16.7%) occurred in the thoracic region, 5 (20.8%) in the abdominal region, and 6 (25%) in bone. The median RFS was 33.8 (IQR 24.9 - 42.4) months, and the median OS was 34.6 (IQR 26.0 - 42.8) months. The 1-year RFS and OS rates were 94.4% and 99.2%, respectively, while the 3-year RFS and OS rates were 90.1% and 95.4%, respectively (Figure S1 in Multimedia Appendix 1).

Preoperative Diagnostic Performance

Integrated models combining MR images with 5 clinical parameters demonstrated variable performance across 7 ML algorithms (Table 2).

For parametrial invasion diagnosis, classical ML models generally exhibited poor sensitivity (0.00 - 0.57). Specifically, RF and KNN failed to detect any positive cases (sensitivity=0.00), while SVM and DT showed low sensitivity (0.57 and 0.50) and specificity (0.56 and 0.59). On the contrary, imbalanced-data variants exhibited improved performance: (1) Balanced RF achieved balanced metrics (sensitivity=0.81, specificity=0.85, F1-score=0.64); (2) weighted KNN attained high sensitivity (0.98), while weighted DT prioritized specificity (0.93).

For lymph node metastasis detection, classical ML models showed limited sensitivity (0.31 - 0.66), with RF achieving high specificity (0.87) and SVM delivering the best traditional performance (sensitivity=0.66, specificity=0.52, F1-score=0.54). Imbalanced-data variants exhibited enhancements: (1) Weighted KNN demonstrated optimal overall performance (sensitivity=0.67, specificity +=0.61, F1-score=0.58); (2) balanced RF achieved high specificity (0.87) and precision (0.68); and (3) weighted DT showed marginal improvement over classical DT (sensitivity=0.38 vs 0.53, F1-score=0.42 vs 0.49).

Postoperative Prediction Performance

For prognostic prediction (Table 3), all classical ML models (KNN, SVM, DT, and RF) failed to identify recurrence or mortality cases (sensitivity=0.00). Imbalanced data variants exhibited divergent outcomes: For recurrence prediction, (1) weighted KNN achieved clinically actionable performance (sensitivit=0.80, specificity=0.96, F1-score=0.73); (2) balanced RF detected recurrences effectively (sensitivity=0.80) but exhibited poor specificity (0.37); and (3) weighted DT failed to identify recurrence cases (sensitivity=0.00). For mortality prediction, (1) weighted KNN showed perfect specificity and precision (specificity=0.99, precision=0.99) but demonstrated low sensitivity (0.33); (2) balanced RF showed limited detection capability (sensitivity=0.33, F1-score=0.11); and (3) weighted DT failed to identify mortality cases (sensitivity=0.00). Among all models, weighted KNN yielded the highest AUC for recurrence (0.861) and mortality (0.765) (Figure 2). Given the importance of sensitivity in guiding postoperative treatment and follow-up, weighted accuracy was introduced as an evaluation metric, and multiple weighting strategies were tested (Table S2 in Multimedia Appendix 1). Results revealed that increasing the weight of sensitivity led to improved detection accuracy for potential recurrence and mortality cases.

For individualized survival time prediction (Table 4), weighted KNN achieved the best performance for recurrence with the lowest MAE (8.53 mo) and highest C-index (0.83), while regression tree (RT) achieved the best performance for mortality (MAE=4.36 mo; C-index=0.99).

AI-Assisted Contouring and Prognosis Prediction System

To enhance the clinical applicability of the prediction model and improve physicians' access, usability, and integration into practice, the optimal artificial intelligence (AI) prediction models were embedded into a web-based software platform designed to assist in preoperative evaluation and prognosis prediction on MR images (Figure 3) [27]. By inputting key preoperative clinical parameters and uploading DICOM (DCM) files of preoperative MR images, the system can automatically identify possible lesions and generate predictions regarding the patient's risk of parametrial invasion and lymphatic metastasis. Similarly, by entering relevant postoperative clinical, surgical, and pathological data along with uploading postoperative MR images, the system can estimate the patient's risk of recurrence and mortality, as well as predict individualized durations of RFS and OS.

XSL•FO
RenderX

Figure 3. Screenshots of the web-based diagnostic software [27] developed to assist with preoperative evaluation of parametrial invasion and lymph node metastasis, and to predict postoperative recurrence and mortality, including individualized recurrence-free survival (RFS) and overall survival (OS) estimations. (A) By inputting the required clinical parameters and uploading MR images in DICOM format, users initiate analysis through the "submit" function. (B) Following submission, the software evaluates the possible lesion area and generates predictions for parametrial invasion and lymph node metastasis. If the "surgery status" is set to "postoperative," probabilities of recurrence and mortality as well as specific RFS and OS estimations will be generated.

Discussion

Principal Findings

This study developed integrated ML models combining clinicopathological characteristics with MRI data for preoperative assessment of parametrial invasion and lymph node metastasis, alongside postoperative prognosis prediction in early-stage CC. Our key findings demonstrate the following: (1) Integrated models improved diagnosing sensitivity of parametrial invasion and lymph node metastasis, enhancing preoperative staging accuracy to better guide surgical plan; (2) postoperative prognostic models achieved robust performance in individualized recurrence (AUC 0.861) and survival prediction (AUC 0.765), providing a novel tool for precise adjuvant treatment and individualized follow-up strategy; and (3) a clinically deployable AI platform operationalizes these models for clinical workflow integration, enabling automated risk stratification.

Comparison to Prior Work

Preoperative Assessment

Our integrated models outperformed existing approaches. For parametrial invasion, balanced RF achieved substantially higher sensitivity (0.81) and F1-score (0.64) than a pathology-based clinical model (sensitivity 0.53, F1-score 0.54 calculated) [9], suggesting complete MRI provides more comprehensive prognostic information. While some studies reported better predictive performance for lymph node metastasis using axial T2WI + ADC sequences (sensitivity 0.87, specificity 0.70) [15], this discrepancy likely stems from our use of coronal T2WI versus their multi-planar/functional protocols. Crucially, our integrated models surpass radiologist assessments for both parametrial invasion (sensitivity 0.62 - 0.75, specificity 0.84 - 0.87) [28,29] and lymph node metastasis (sensitivity 0.54, AUC 0.65) [30], further validating the advantage of integrating clinical and imaging data in preoperative staging and surgical planning [31].

Postoperative Prognosis

Weighted KNN's strong performance (recurrence AUC 0.861; survival AUC 0.765) reflects its unique suitability for our clinical context. Unlike DL architectures requiring massive datasets to realize their potential, this non-parametric method leverages local neighborhood patterns while resisting overfitting, proving particularly effective for limited-sample scenarios where conventional DL advantages remain constrained [32,33]. Critically, this technical alignment serves a fundamental clinical imperative: prognostic prediction prioritizes minimizing missed recurrences (false negatives), where diagnostic harm substantially outweighs false positives, reflecting radiologists' conservative tendency to avoid overdiagnosis. To operationalize this priority, we implemented weighted accuracy metrics—demonstrating that elevating sensitivity weights enhances high-risk case detection (Table S2 in Multimedia Appendix 1). This strategic focus enables superior identification of positive cases compared to conventional clinical diagnosis, aligning with established ML advantages in sensitivity-driven contexts [8,34]. This multimodal integration resonates with advancements [^{1}F]Fluorodeoxyglucose (FDG)-positron emission tomography/CT feature integration [35], confirming that combining data sources overcomes single-modality constraints.

Strengths and Limitations

The core strength of our study lies in developing a comprehensive AI-driven clinical support system that uniquely bridges preoperative staging and postoperative prognosis. By integrating MRI with clinicopathological data through imbalanced-data algorithms (eg, balanced RF and weighted KNN), we significantly enhanced sensitivity for detecting parametrial invasion and lymph node metastasis preoperatively alongside postoperative recurrence and mortality. Crucially, this framework was operationalized through a clinically deployable platform enabling automated DICOM analysis, risk stratification, and individualized survival time prediction, thus forming a closed-loop decision pathway from diagnosis to follow-up.

Despite these advances, several limitations merit careful consideration. Foremost among these is the limited population and tertiary-center recruitment bias. The patient population in this study was limited and may not adequately represent the broader clinical population, particularly individuals in primary care settings or from different geographic regions. Patients were recruited from 2 specialized hospitals, which may have introduced selection bias due to potential differences in disease severity or demographic characteristics. Crucially, only 23.2% of the patients with CC initially identified possessed the necessary MRI data for modeling inclusion. This limitation stemmed primarily from the requirement for locally archived DICOM files. Importantly, most excluded patients underwent initial MRI scans at external institutions—predominantly primary care hospitals where only non-digitalized paper reports were available, precluding DICOM file retrieval. While subtle technical variations in MRI scanners or protocols across institutions may exist, their impact on model generalizability is likely minor compared to the dominant limitation of sample size scarcity. Second, the relatively short follow-up period (<5 y) restricted our ability to evaluate long-term outcomes. This limitation may hinder the detection of delayed disease recurrence and treatment-related effects, especially in chronic disease contexts where complications can take several years to manifest. Third, although DL models are widely recognized for their superior performance when applied to large datasets, this study exhibited suboptimal performance due to the limited sample size and parameter constraints.

Future Directions

To bridge these gaps and advance clinical translation, 3 strategic priorities emerge. First, we will expand the cohort through multicenter collaborations targeting 1200+ patients—deliberately enriching underrepresented positive cases—while extending follow-up beyond 5 years to capture long-term outcomes. Second, transfer learning will be implemented to develop advanced 3D CNN architectures using volumetric DICOM data, overcoming current sample size barriers and unlocking DL's latent potential. Third, recognizing that coronal T2WI—while optimal for bilateral tumor

assessment—represents only one facet of MRI's diagnostic capability, we will implement multidimensional sequence analysis. Concurrently, we will systematically integrate axial/sagittal planes and functional sequences (DWI, DCE-MRI) to refine microinvasion detection, ultimately validating this optimized system through prospective trials assessing its impact on surgical planning and survival outcomes.

Conclusions

In conclusion, this study used ML techniques to develop diagnostic and prognostic models using clinical and MRI data for patients with FIGO stage IA1 (LVSI+) to IIB CC. These models were designed to detect preoperative parametrial invasion and lymph node metastasis and to predict postoperative survival and recurrence. We trained and externally validated the models using data from 250 patients across 2 tertiary hospitals. In both diagnostic and prognostic applications, integrated ML models, particularly weighted KNN, demonstrated favorable performance with clinically applicable sensitivities. These findings suggest that integrated ML models may offer a valuable tool for improving preoperative staging and individualized prognosis prediction in CC, supporting more personalized and precise treatment strategies.

Acknowledgments

This study was supported by the Shanghai Municipal Science and Technology Commission (No. 22Y31900500; awarded to KH) and Fudan University (Medical-Engineering Interdisciplinary Project; awarded to JQ). The authors acknowledge the Institutional Ethics Committee of Fudan University Obstetrics and Gynecology Hospital for approving this retrospective multicenter cohort study (approval number: 2019‐87) and the Chinese Clinical Trial Registry (ChiCTR1900028702) for its registration. An exemption was granted by the Ethics Committee for this study.

Generative AI (ChatGPT-4, OpenAI; September 2023 version) was used exclusively for minor language editing (<3% of text), with all outputs verified by authors. No AI was used in research design, data handling, or clinical assessments.

Data Availability

Data can be made available upon reasonable request.

Authors' Contributions

SL and CG contributed to methodology, data acquisition, formal analysis, writing – original draft, and writing – reviewing and editing. YF, XP, and CJ contributed to methodology, data acquisition, formal analysis, and writing – reviewing and editing. HZ, LL, JX, and JW contributed to conceptualization, methodology, data acquisition, formal analysis, and writing – reviewing and editing. KH contributed to resources and supervision. JQ involved in project administration, funding acquisition, and writing – reviewing and editing.

Abstract

Background: Patients with cancer and cancer survivors often experience multiple chronic health conditions, which can impact symptom burden and treatment outcomes. Despite the high prevalence of multimorbidity, research on cancer prognosis has predominantly focused on cancers in isolation. There is growing interest in machine learning techniques for cancer studies. However, these methods have not been applied in the context of supportive care for patients with cancer who have multimorbidity. Furthermore, few studies have investigated the associations between comorbidity clusters and mortality outcomes.

Objective: This study investigated comorbidity clusters among patients with cancer using machine learning and examined their associations with mortality outcomes in two large representative samples from the United States and Hong Kong.

Methods: This study used data from the National Health and Nutrition Examination Survey (NHANES) and the Hospital Authority Data Collaboration Laboratory (HADCL). Participants aged ≥20 years with a history of cancer were included. The study used a two-step framework to identify clusters of comorbidities in NHANES. In the first step, we used four machine learning techniques, including the Bernoulli mixture model and partition-based methods, to cluster the comorbidities. In the second step, domain experts reviewed and ranked the identified clusters to ensure clinical relevance. The clusters that had the highest average rank were selected for further analysis. The associations between comorbidity clusters and mortality outcomes were analyzed using Cox proportional hazards models. We conducted an external validation to evaluate the generalizability of the clusters identified in the NHANES cohort and their associations with mortality using HADCL. The same number of clusters was replicated based on the distinctive patterns and distribution of comorbidities observed within each cluster.

Results: The study included 4390 participants in NHANES and 12,484 participants in HADCL. Four comorbidity clusters were identified: low comorbidity, metabolic, cardiovascular disease (CVD), and respiratory. In NHANES, participants in the respiratory cluster had the highest risk of all-cause mortality (adjusted hazard ratio [aHR] 1.62, 95% CI 1.26 - 2.08; P<.001), followed by the CVD cluster (aHR 1.50, 95% CI 1.26 - 1.80; P<.001) compared to the low comorbidity cluster. The 3 clusters were associated with higher risks of CVD-related mortality (aHR 1.48 - 3.05, 95% CI 1.14-4.07; P<.003). The effects of comorbidity clusters on mortality were modified by income-to-poverty ratio (P for interaction=.04), diet quality (P for interaction=.02), and cancer prognosis (P for interaction=.005). In the HADCL (validation) cohort, participants in the respiratory and CVD clusters had a higher risk of all-cause mortality.

Conclusions: High comorbidity burden clusters showed increased all-cause and CVD-related mortality in patients with cancer. These findings highlight the significance of considering comorbidity burden in cancer care. Machine learning approaches can provide valuable insights into complex multimorbidity profiles. Further research is needed to deepen understanding of the relationships between multimorbidity and cancer-specific outcomes.

KEYWORDS

comorbidity; multimorbidity; machine learning; cluster; clustering; cancer; mortality; oncology; multiple chronic conditions; metabolic

Introduction

Advancements in cancer treatment have significantly increased survival rates and life expectancy for patients with cancer [1]. However, survivors may also experience multiple chronic health conditions. The prevalence of multimorbidity, which refers to the presence of two or more medical conditions simultaneously, is steadily rising with improvements in life expectancy [2,3]. In the United States, 40% of patients with cancer have at least one other chronic condition, and 15% have two or more comorbidities [4]. Comorbidities are believed to influence cancer detection, treatment uptake, and treatment toxicity [5,6]. Hence, there is an urgent need to shift the focus of health care from individual diseases to a more comprehensive approach that considers clusters of medical conditions [2]. Despite the high prevalence of multimorbidity, clinical and epidemiological research on cancer prognosis has largely focused on cancers in isolation. It is crucial to recognize that the co-occurrence of chronic health conditions can impact symptom burden and treatment outcomes in patients with cancer [7].

Recently, there has been growing interest in machine learning techniques, including unsupervised and supervised learning, for use in cancer detection, classification, staging, and treatment evaluation [8]. However, these methods have not been extensively applied in the context of supportive care for patients with cancer who have multimorbidity. Several studies have used clustering methods or factor analysis to identify clusters of chronic conditions or symptoms among patients with cancer [9-12], but few studies have investigated the associations between these clusters and survival outcomes. A rare example is the study of Hahn et al [13], who used latent class analysis to identify 4 comorbidity classes and found that clusters characterized by cardiovascular diseases (CVDs), diabetes, and chronic obstructive pulmonary disease were associated with worse overall survival rates in patients with colorectal cancer. It is currently unclear whether similar associations hold for people with other cancers.

There is a clear need to identify comorbidity clusters to provide prognostic information regarding cancer and coexisting health conditions [5]. Such information could greatly assist in making treatment decisions for patients with cancer who have comorbidities. Therefore, the objective of this predictive modeling study was to investigate clusters of comorbidities among patients with cancer in a nationally representative sample and examine their associations with survival outcomes. We also attempted to validate the association finding between comorbidity clustering patterns identified from machine learning and mortality using another large representative cohort from a different geographical location.

Methods

The reporting of the study adheres to the Guidelines for Developing and Reporting Machine Learning Predictive Models in Biomedical Research (Table S1 in Multimedia Appendix 1) [14].

Part 1: Cluster Identification (National Health and Nutrition Examination Survey Data)

Study Population

This retrospective study used data from 10 National Health and Nutrition Examination Survey (NHANES) survey cycles, a periodic cross-sectional survey conducted from 1999 to 2018 [15]. The NHANES assessed the health and nutritional status of a nationally representative sample of the civilian population in the United States. Detailed information about the sampling methodology has been reported elsewhere [15]. The NHANES was approved by the National Center for Health Statistics Institutional Review Board, and informed consent was obtained from all participants.

We included participants aged ≥20 years with a self-reported history of cancer in this study. They were asked, “Have you ever been told by a doctor or other health professional that you had cancer or a malignancy of any kind?” A positive response to this question indicated a cancer diagnosis. We excluded participants if they (1) were diagnosed solely with nonmelanoma skin cancer and had no other cancer types or (2) did not report the age at which they were diagnosed with cancer.

Covariates

Information on sociodemographic and lifestyle characteristics was collected through at-home interviews. This included the participants’ sex, age, ethnicity, education level, income level, smoking status, alcohol consumption, physical activity, diet, and supplement use (Table S2 in Multimedia Appendix 1). Body weight and height measurements were taken at a mobile examination center. The Healthy Eating Index (HEI) score, a validated measure of diet quality, was calculated using dietary recall data to evaluate conformance with federal dietary guidelines in the United States [16]. They also provided information about their age at cancer diagnosis and the type of cancer diagnosed. We further classified the cancer diagnoses based on their prognosis according to US statistics [17,18].

Ascertainment of Comorbidities

Fifteen specific conditions were consistently assessed in all waves of the survey. These conditions included CVDs (ie, congestive heart failure, coronary heart diseases, angina, heart attack [myocardial infarction], and stroke) [19], metabolic syndromes (hypertension, diabetes, and hyperlipidemia) [20], respiratory diseases (chronic bronchitis, asthma, and emphysema), arthritis, liver conditions, thyroid problems, and kidney disease. For most comorbidities, the participants were categorized as having a specific condition if they answered “Yes” to the question: “Has a doctor or other health professional ever told you that you have [condition]?” In addition to self-reported information, this study also defined diabetes (fasting glucose level or glycated hemoglobin A_{1c} level) and

XSL•FO
RenderX

hypertension (systolic or diastolic blood pressure) based on quantitative measurements.

Clustering of Comorbidities

The study used a 2-step framework to identify clusters of comorbidities. In the first step, we used 4 machine learning techniques to cluster the comorbidities based on the binary (categorical) nature of the comorbidity data. One of these was the Bernoulli mixture model. Mixture models have previously been applied to clustering and dimensionality reduction problems [21,22]. The Bernoulli variant was chosen here, as previous studies have shown its suitability for modeling binary data [21,23]. The three other models were partition-based methods, which divide the data into a predefined number of partitions corresponding to the number of clusters [24]. Due to the highly sensitive nature of noises and outliers, traditional K-means algorithms are not suitable for clustering categorical data. Instead, K-modes and K-medoids should be used. K-modes replace means with modes to find the clusters and use a simple matching dissimilarity measure for clustering the data objects, which were characterized by the categorical attributes only [25], while K-medoids select an actual and representable data object for each cluster in each iteration that is the most centrally located object within the cluster [26]. The final approach was based on K-medoids and incorporated a bisecting methodology [27]. Previous studies have successfully applied these methods to identify clusters of symptoms [28], clinical prognostic features in oncology [29], and comorbidities with other chronic diseases [30].

In the second step, the study incorporated domain knowledge into the interpretation of the clusters [31,32]. As this step required knowledge in clinical oncology, survivorship, and data analytics, domain experts who were clinicians or clinician researchers with relevant experience were invited to review the results from the first step. One medical oncologist (HHL), one cancer epidemiologist (YTC), one pharmacist (CSL), and one data scientist (CN) participated in this step. First, they were provided with the clustering results from the four approaches without identification of the specific method used. Then, they were asked to examine the relative distribution of comorbidities across the clusters generated by the machine learning methods and to assess the distinguishability of patterns of comorbidities between the clusters. After that, they ranked the most clinically relevant clusters. The clusters with the highest average rank were selected for further analysis to investigate their associations with mortality outcomes. We also used performance metrics, including Silhouette analyses, Calinski-Harabasz index, and Davies-Bouldin index, to support the selection [33,34]. This ensured that the clusters chosen for detailed investigation were those with the most potential to provide clinical insights into the relationship between comorbidities and mortality in patients with cancer. The clustering process was performed using Python (version 3.10; Python Software Foundation) and R (version 4.0.1; R Foundation).

Mortality Outcomes

The NHANES was linked to the death certificate records from the National Death Index using a probabilistic match method [35]. The participants were followed up from the date of interview to the date of death or December 31, 2019, whichever came first (the last date for available mortality data). Causes of death were coded using the *ICD-10* (*International Statistical Classification of Diseases, 10th Revision*). The primary outcomes comprised all-cause mortality and the top three cause-specific mortalities: cancer (*ICD-10* codes C00-C97), CVD (*ICD-10* codes I00-I09, I11, I13, I20-I51, and I60-I69), and respiratory diseases (*ICD-10* codes J40-J47).

Statistical Analysis

We conducted data analyses in accordance with the NHANES guidelines [15]. The survey design was taken into account by applying sample weights, clustering, and stratification in all analyses. Participants with missing data on death, comorbidities, or other covariates were excluded from the study.

Cox proportional hazards models were used to examine the associations between comorbidity clusters and mortality outcomes. We ran three models: model 1 (unadjusted), model 2 (adjusted for the age and sex of the participants), and model 3 (further adjusted for socioeconomic factors [educational level, ethnicity, and income-to-poverty ratio], lifestyle behaviors [BMI, HEI score, smoking status, alcohol drinking, physical activity, and supplement use], cancer prognosis, and time since the cancer diagnosis). Multiple imputation using the MICE (Multivariate Imputation by Chained Equations) package was conducted to address missing values [36]. We conducted stratified analyses to assess potential effect modification by covariates on the associations between comorbidity clusters and mortality.

Statistical analyses were carried out using SAS 9.4 (SAS Institute Inc) and R 4.0.1 (R Foundation). A $P<.05$ was considered statistically significant.

Part 2: Cluster Verification (Hospital Authority Data Collaboration Laboratory Data)

Study Population

In Hong Kong, the Hospital Authority is a statutory body that governs all public hospital services. These hospitals provide approximately 90% of all secondary and tertiary care services in Hong Kong [37]. Hospital Authority Data Collaboration Laboratory (HADCL) provides comprehensive deidentified data, including sociodemographic details, clinical diagnoses, medications, and hospital admission data from the Hospital Authority, and has been used in large-scale epidemiological studies [38]. A large subset of the data, including approximately 200,000 participants who used public health care services in 2007 and 2017, was accessed through a self-service data platform. To ensure the representativeness of the sample, HADCL used a proportionate random sampling approach [39]. This HADCL cohort is a relatively representative sample of the general population in Hong Kong and has been used widely in epidemiological studies [40,41].

For this study, we included participants diagnosed with malignant cancer (*ICD-10* code C00-C97). Similar to the NHANES cohort, we excluded participants if they were (1)<20 years of age, (2) diagnosed solely with nonmelanoma skin cancer (*ICD-10* code C44) and had no other cancer types.

XSL•FO
RenderX

Covariates

Information on sociodemographic and clinical characteristics was collected from the data repository. They included the individuals' sex, residential area, age at cancer diagnosis, and cancer site. The income level of individuals was determined based on the income level of their residential areas (Table S2 in Multimedia Appendix 1). Cancer diagnoses were further classified according to their prognosis, using classifications consistent with our previous NHANES cohort and local statistics [42].

Ascertainment and Clustering of Comorbidities

The HADCL data contained clinical diagnoses of patients documented using *ICD-10* codes. Based on the NHANES cohort, patient diagnoses of the same fifteen comorbidities (congestive heart failure, coronary heart diseases, angina, heart attack [myocardial infarction], stroke, hypertension, diabetes, hyperlipidemia, chronic bronchitis, asthma, emphysema, arthritis, liver conditions, thyroid problems, and kidney disease) were collected.

This part is an external validation study to evaluate the generalizability of the comorbidity clusters identified in the NHANES cohort and their associations with mortality within a different group of patients [43]. As this was an external validation, instead of a de novo clustering analysis, we replicated the same number of clusters based on the distinctive patterns and distribution of comorbidities observed within each cluster identified in the main cohort [44,45]. We then examined whether the associations between these clusters and all-cause mortality remained consistent.

Mortality Outcomes and Statistical Analysis

The date of death was documented in the HADCL dataset. Participants were followed up until the date of death or the end of follow-up (ie, June 1, 2021, which was the last day of captured data available in the database), whichever occurred first. The index date of the study was defined as the date when individuals first received a diagnosis of malignant cancer. Cox proportional hazards models were used to examine the associations between comorbidity clusters and all-cause mortality. Similarly, three models were used: the crude model (model 1), model adjusted for age at cancer diagnosis and sex (model 2), and model adjusted for age at cancer diagnosis, sex, income level of residential district, and cancer prognosis (model 3). Participants with missing data on death, comorbidities, or other covariates were excluded from the study.

Statistical analyses were carried out using R (version 4.0.1; R Foundation). A $P<.05$ was considered statistically significant.

Ethical Considerations

This study was approved by the Survey and Behavioural Research Ethics Committee of the Chinese University of Hong Kong (SBRE-23 - 0014), which allowed secondary analysis of HADCL and NHANES data without additional consent. The NHANES study protocol was approved by the Research Ethics Review Board of the National Center for Health Statistics, and informed consent was obtained from all NHANES participants. The data from HADCL and NHANES were deidentified.

Results

Characteristics of Participants in the NHANES Cohort

From the total of 101,316 individuals in the 1999 - 2018 waves of the NHANES, those without a diagnosis of cancer (n=96,150), those with a sole diagnosis of nonmelanoma skin cancer (n=576), and those with missing data (n=200) were excluded. Ultimately, the analysis included 4390 individuals (Figure 1).

Figure 1. Flowchart of individual inclusion and exclusion in the National Health and Nutrition Examination Survey cohort.

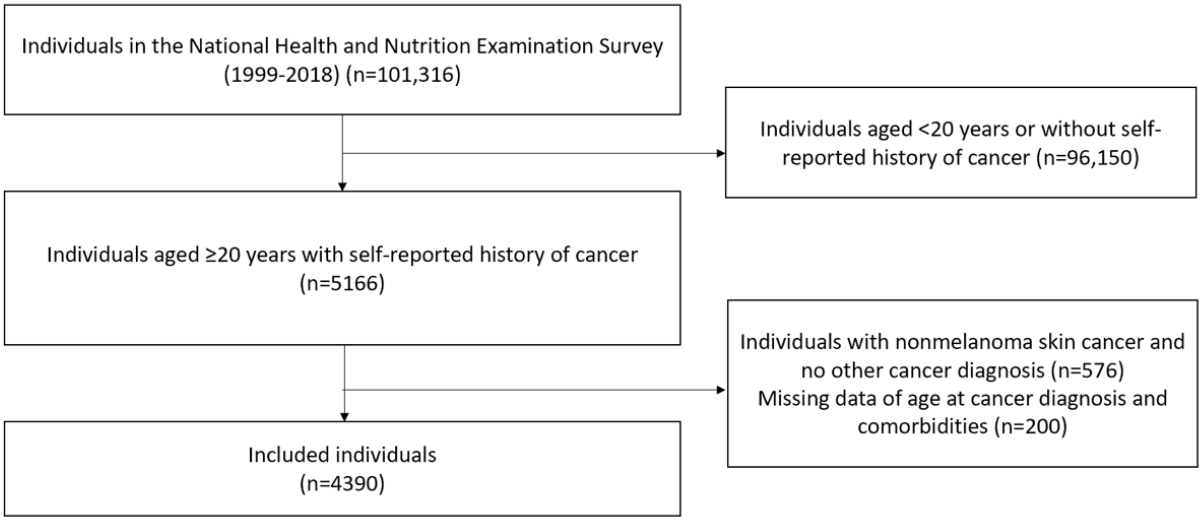

Table 1 presents the characteristics of the included individuals. The mean age of the participants was 66 (SD 14.6) years, and 54% were female (n=2376). The majority of them were non-Hispanic White (n=2870, 65.4%). The median time since

XSL•FO
RenderX

cancer diagnosis was 7 (IQR 3-15) years, and the mean age at cancer diagnosis was 55.4 (SD 17.6) years. Among the individuals, the most common cancer diagnoses were genitourinary cancer (n=1102, 25.1%). More than half of them self-reported a diagnosis of hypertension (n=2812, 64.1%), while approximately half reported having hyperlipidemia (n=2234, 50.9%) and approximately half reported having arthritis (n=2206, 50.3%).

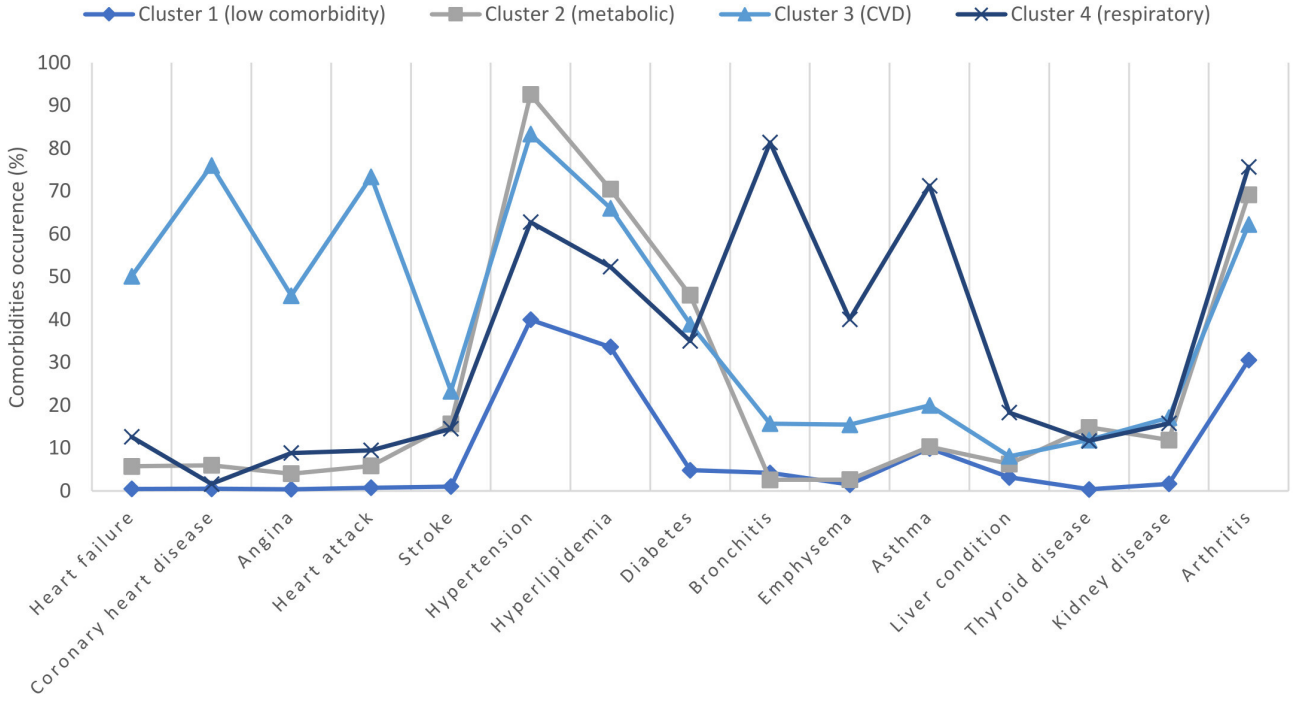
[c]Cancer diagnoses were further classified according to their prognosis, based on previous classification in the National Health and Nutrition Examination Survey cohort and local statistics.



Clustering of Comorbidities Using the NHANES Cohort

Figure S1 in Multimedia Appendix 1 shows the clusters generated using the 4 selected approaches. According to the reviews of domain experts, the Bernoulli mixture model ranked the highest (unanimously ranked highest by all experts based on the distinguishability of clusters and clinical relevance), followed by bisecting K-medoids and K-medoids, while K-modes ranked the lowest due to its inability to identify distinguishable clusters. Table S3 in Multimedia Appendix 1 presents the evaluation of clustering results from the 4 approaches using Silhouette analyses, Calinski-Harabasz index, and Davies-Bouldin index. It also shows the quality of the clusters generated by the Bernoulli mixture model being the highest among the 4 approaches.

Based on the distribution patterns of comorbidities in the NHANES cohort, 4 clusters derived from the Bernoulli mixture model were chosen due to the notable differences in comorbidity patterns across the clusters. Table S4 in Multimedia Appendix 1 presents the characteristics of the individuals in each of the 4 clusters, which comprised 2127 (48.5%), 1525 (34.7%), 421 (9.6%), and 317 (7.2%) individuals.

Figure 3 and Table S5 in Multimedia Appendix 1 illustrate the comorbidity patterns observed in the 4 clusters. The patients in cluster 1 (low comorbidity cluster) exhibited significantly lower percentages of all comorbidities than the patients in the other clusters. Cluster 2 (metabolic cluster) was characterized by the highest burden of metabolic syndrome (hypertension, hyperlipidemia, and diabetes) among all 4 clusters. Cluster 3 (CVD cluster) was characterized by the highest burden of CVD among the clusters and also displayed a relatively high burden of metabolic syndromes (although lower than that of cluster 2). Cluster 4 (respiratory cluster) exhibited a significantly higher burden of respiratory diseases, while also having a moderate burden of metabolic syndromes (although lower than those of clusters 2 and 3).

Figure 3. Distribution of comorbidities among the 4 comorbidity clusters in the National Health and Nutrition Examination Survey cohort. CVD: cardiovascular disease.

XSL•FO
RenderX

Clustering of Comorbidities Using the HADCL Cohort

Based on the comorbidity clusters identified in the NHANES cohort, 4 clusters were manually categorized according to observed patterns and the distribution of comorbidities within those clusters. Individuals with metabolic diseases were first grouped into cluster 2 (metabolic cluster), and then those with CVD or respiratory comorbidities were assigned to cluster 3 (CVD cluster) and cluster 4 (respiratory cluster), respectively. The remaining individuals were classified into cluster 1 (low comorbidity). Table S6 in Multimedia Appendix 1 shows the characteristics of the individuals in the 4 clusters, which comprised 7392 (59.2%), 2521 (20.2%), 2188 (17.5%), and 383 (3.1%) participants. Figure S2 and Table S7 in Multimedia Appendix 1 illustrate the comorbidity patterns observed in the 4 clusters.

Association Between Comorbidity Clusters and Mortality Outcomes in the NHANES Cohort

After a median follow-up of 6.6 (IQR 3.3 - 11) years, 1700 deaths (38.7% of individuals) were recorded. As shown in Table 3, all 3 models suggested that there was a significant association between the comorbidity clusters and all-cause mortality. After adjusting for confounders (model 3), compared with the low comorbidity cluster, the individuals in the respiratory cluster had the highest risk of mortality (adjusted hazard ratio [aHR] 1.62, 95% CI 1.26 - 2.08; $P<.001$), followed by the CVD cluster (aHR 1.50, 95% CI 1.26 - 1.80; $P<.001$) and the metabolic cluster (aHR 1.15, 95% CI 1.02 - 1.29; $P=.03$).

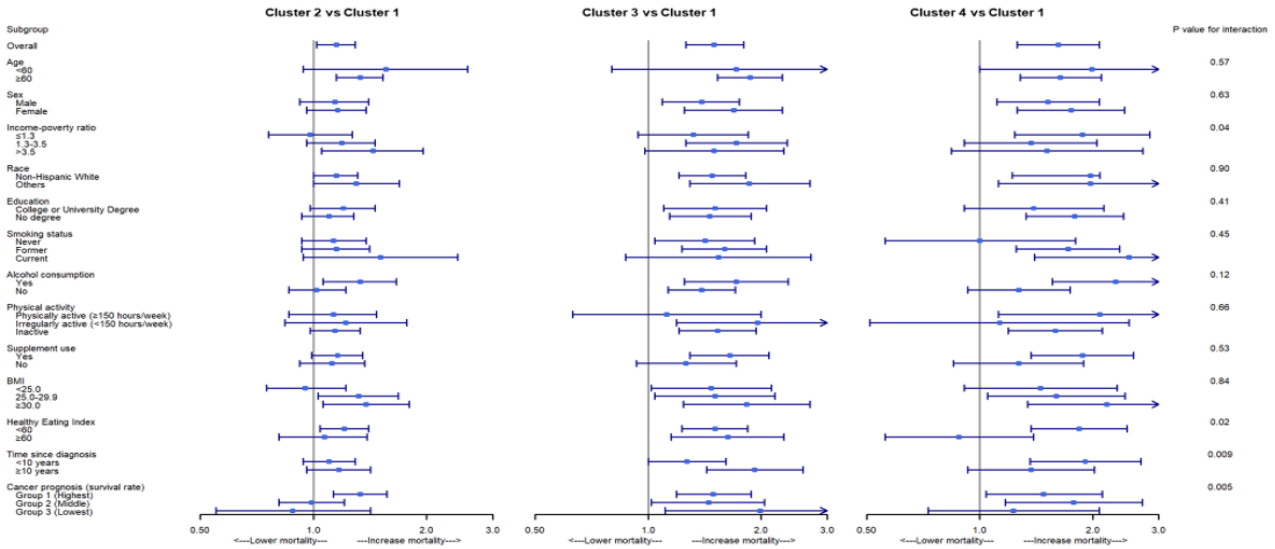
[a]In the NHANES cohort, model 2 was adjusted for age and sex, model 3 was adjusted for age at assessment, sex, socioeconomic status (education level, ethnicities, and income-to-poverty ratio), lifestyle behaviors (BMI, Healthy Eating Index, smoking and alcohol status, physical activity, and supplement use), years since cancer diagnosis, and cancer prognosis. In the HADCL cohort, model 2 was adjusted for age at cancer diagnosis and sex, and model 3 was adjusted for age at cancer diagnosis, sex, income level (based on the median household income of the districts), and cancer prognosis.

[b]NHANES: National Health and Nutrition Examination Survey.

[c]Ref: reference group.

[d]Not applicable.



[e]CVD: cardiovascular disease.

[f]HADCL: Hospital Authority Data Collaboration Laboratory.

Regarding cause-specific mortality, the metabolic, CVD, and respiratory clusters were associated with higher risks of CVD-related mortality than the low comorbidity cluster, with the CVD cluster (aHR 3.05, 95% CI 2.29 - 4.07; *P*<.001) showing the highest risk. Only individuals in the respiratory cluster had a higher risk of respiratory disease mortality than those in the low comorbidity cluster (aHR 3.99, 95% CI 2.03 - 7.83; *P*<.001) after adjusting for all confounders, although the metabolic and CVD clusters were also significantly associated with higher respiratory disease mortality in the crude models. However, no significant differences in the risk of cancer mortality were observed among the clusters (all *P*>.05).

The subgroup analysis (Figure 4) indicated that the effects of the comorbidity clusters on mortality were modified by the income-to-poverty ratio (*P* for interaction=.04), HEI score (*P* for interaction=.02), time since cancer diagnosis (*P* for interaction=.009), and cancer prognosis (*P* for interaction=.005) after adjusting for all confounders. The individuals in the respiratory cluster had a significantly higher risk of mortality (*P*=.003) if they had a lower income-to-poverty ratio, while those in the metabolic cluster (*P*=.02) had a higher risk of mortality if they reported a higher income-to-poverty ratio. Individuals with low HEI scores in all 3 other clusters had a higher risk of mortality than those with low HEI scores in the low comorbidity cluster (all *P*<.01). However, for individuals with high HEI scores, only those in the CVD cluster had a higher risk of mortality than those with high HEI scores in the low comorbidity cluster (*P*=.006).

Figure 4. Effect modification by factors on the association of clusters with mortality in the National Health and Nutrition Examination Survey cohort (a more detailed figure is presented in Figure S4 in Multimedia Appendix 1).

XSL•FO
RenderX

Verification of the Association Between Comorbidity Clusters and All-Cause Mortality in the HADCL Cohort

After a median follow-up of 8.9 (IQR 3.8 - 13.5) years, 3922 deaths (31.4% of individuals) were recorded. As shown in Table 3, the crude model and the age- and sex-adjusted model suggested that there was a significant association between the comorbidity clusters and all-cause mortality. After adjusting for confounders (model 3), compared with the low comorbidity cluster, the individuals in the CVD cluster (aHR 1.33, 95% CI 1.23 - 1.45; *P*<.001) and respiratory cluster (aHR 1.32, 95% CI 1.13 - 1.54; *P*<.001) had a higher risk of mortality. The metabolic cluster also tends to have a higher risk of mortality compared with the low comorbidity cluster; however, the association was not significant (aHR 1.08, 95% CI 0.99 - 1.17; *P*=.08).

Discussion

Principal Findings

This is one of the largest studies to use machine learning in identifying multimorbidity clusters and as a prognosis marker of mortality in patients with different types of cancer. This study focused on clustering comorbidities in 2 distinct patient cohorts from different geographical locations. The following four clusters were identified: low comorbidity (cluster 1), metabolic (cluster 2), cardiovascular (cluster 3), and respiratory (cluster 4) clusters. Compared with the low comorbidity cluster, the CVD and respiratory clusters were consistently associated with higher all-cause mortality in both cohorts, and all clusters were associated with higher CVD mortality rates in the NHANES cohort. No associations were identified between specific clusters of comorbidities and cancer mortality. These observed associations may inform the development of cluster-specific care management and clinical guidelines for common comorbidities for people living with and beyond cancer.

Machine Learning Approaches in the Study of Multimorbidity

The use of machine learning is especially relevant in the study of comorbidities due to the complex interactions between cancer and other coexisting health conditions. Compared with traditional methods, unsupervised learning is more effective and flexible at identifying unknown patterns among patient subgroups, without the need for prior human knowledge and intervention (eg, determining cutoff values). In this study, mixture models outperformed the partition-based methods in distinguishing patterns across the identified clusters, which may be due to their advantages in clustering data with different shapes and sizes [46,47]. Also, Bernoulli mixture models are specifically designed for binary data, where each feature is a Bernoulli distribution [23]. In contrast, methods such as K-modes, K-medoids, and bisecting K-medoids are more general and suitable for categorical data but may not capture the nuances of binary data as Bernoulli mixture models do. Mixture models also offer other advantages to K-modes, K-medoids, and bisecting K-medoids; for instance, they can provide soft clustering assignments to allow for flexibility and handle missing data more effectively [48,49].

Consistent with emerging evidence supporting the role of artificial intelligence in health care [50], our findings suggest that, in the near future, such algorithms may be incorporated into health care systems as risk stratification tools to assist clinicians in identifying patients at risk of adverse outcomes. Clustering and other machine learning approaches have been used in the development of risk prediction models for various diseases. Notably, several of these models have included comorbidities as one of the components, such as in predicting the risk of complications in patients with diabetes [51] and mortality risk in patients with chronic obstructive pulmonary disease [52]. Hence, the clustering approach used in this study may be applied to assist in predicting mortality risk upon the initial cancer diagnosis.

Comorbidity Clusters in Cancer

There are similarities between the comorbidity clusters identified in previous studies [13,53,54] and those in this study, despite some variations in the scopes of health conditions. For instance, clusters associated with cardiovascular and respiratory conditions have been observed in patients with breast, colorectal, and lung cancers [13,53,54]. This suggests that the multimorbidity profile may be similar across different types of cancer. Our study revealed that the increased risk of mortality across all three comorbidity clusters (compared with the low comorbidity cluster) remained in cancers with good prognoses. This finding is reasonable, as patients with cancers of poor prognosis are more likely to die from their cancer regardless of their comorbidity status [55]. Overall, the individuals in the respiratory and CVD clusters had a higher risk of all-cause mortality than individuals from other clusters. Recent data from the United States indicate that the majority of patients with cancer die from noncancer-related causes, most commonly heart disease [56,57]. In comparison, respiratory diseases account for a smaller proportion of noncancer-related deaths [56]. The fact that the patients in the respiratory cluster also experienced poor prognosis in our study suggests the need for improved screening and management of comorbidities in this group of patients. Many cancer treatment modalities, including radiotherapy, chemotherapy, and immunotherapy, can potentially lead to pulmonary toxicities [58-60]. Future epidemiological studies should explore how cancer and its treatment impact comorbidity outcomes, particularly regarding pulmonary conditions and their subsequent effects on survival outcomes. Conversely, this study did not find significant differences in cancer mortality across the four comorbidity clusters. One possible reason may be competing risks from mortality due to other causes, such as mortality from CVD. The high cardiovascular mortality risk in patients with a high comorbidity burden could overshadow any differences in cancer mortality that might be observed in later stages of life. Given the improving management and tighter control of cardiovascular risk factors in cancer patients over the recent years, it may be worthwhile to examine these associations again in future waves of data collection within NHANES.

Notably, our study uncovered a unique cluster that was prevalent among patients with cancer in the NHANES and HADCL

XSL•FO
RenderX

cohorts. This cluster was characterized by metabolic syndromes, which are known risk factors for CVDs [20,61], but a low burden of CVD. Previous research has indicated that the prevalence of metabolic syndromes may be higher in patients with cancer or survivors of cancer than in individuals without cancer [61]. Cancer and metabolic syndromes share common risk factors, such as age, obesity, and lifestyle factors [62]. In terms of mortality outcomes, the CVD cluster exhibited an all-cause mortality rate 1.3 times higher and a CVD mortality rate more than 2 times higher than the rates observed for the metabolic cluster in the NHANES cohort. Considering the important connections between metabolic syndromes and CVD, patients in this cluster are likely to develop CVD if these risk factors are not well controlled. This finding underscores the importance of early interventions to manage metabolic risk factors and reduce CVD risk in patients with cancer.

The Modification Effect of Lifestyle and Socioeconomic Factors

We observed effect modification of some lifestyle factors in the NHANES cohort. One important modifiable factor that may impact the associations between comorbidity clusters and mortality is diet. Our findings suggest that patients with multimorbidity who follow an unhealthy diet may have higher all-cause mortality rates in all 3 clusters compared with the low comorbidity cluster, with a particularly significant difference in the respiratory cluster. Previous studies have demonstrated an inverse relationship between adherence to healthy dietary patterns and mortality in patients with cancer and survivors of cancer [63,64]. In addition, diet quality has been found to be associated with multimorbidity. For instance, a Western dietary pattern is associated with an increased risk of multimorbidity [65]. Notably, metabolic syndrome, which was prevalent across the high comorbidity clusters, may serve as a surrogate marker for dietary risk factors in cancer [62]. Taken together, adopting a healthier diet may help reduce mortality in patients with cancer by lowering the incidence of chronic health conditions. Therefore, it is crucial to include dietary interventions as part of a holistic care plan for patients with cancer, especially those with high comorbidity burdens.

Another effect modifier to consider is the income-to-poverty ratio, which has been found to modify the association between comorbidity clusters and mortality in varying ways. Previous studies have shown that a lower socioeconomic status is associated with higher mortality rates in patients with cancer [66,67]. While it is known that comorbidities can contribute to inequities in survival, there is a lack of research exploring the impact of different comorbidities on the socioeconomic disparities in survival. Our study shows that a low socioeconomic status is associated with poorer survival in patients with cancer who have respiratory conditions, but the opposite is observed for patients with metabolic diseases. It has previously been demonstrated that modifiable risk factors, such as obesity and smoking, are important mediators of the associations between socioeconomic status and mortality [68,69]. Therefore, one possible explanation for the differences in the associations between socioeconomic status and mortality across comorbidity clusters may be variations in the mediating effects of these lifestyle factors. For example, mortality in patients with cancer who have respiratory comorbidities and a lower socioeconomic status may be more strongly influenced by smoking status and poor access to health care services, whereas the mortality risk in patients with metabolic diseases may be increased by other lifestyle factors associated with high socioeconomic status, such as a sedentary occupation, unhealthy dietary patterns, and excess alcohol consumption. Future studies should investigate the mediating effects of modifiable risk factors on the associations between socioeconomic status and mortality among patients with different comorbidities. This may assist the development of targeted interventions to reduce the inequities in mortality among patients with cancer.

Strengths and Limitations

The strength of this study lies in its use of a nationally representative sample of patients with cancer to identify the clusters and the validation of the results using another large sample of patients from a different geographical location. However, there are several limitations to this study. First, the data for cancer and comorbidities were self-reported in the NHANES cohort, which may have introduced the possibility of recall bias. However, previous studies have shown generally good agreement between health records and self-reports for conditions including diabetes, hypertension, and myocardial infarction [70,71]. We further validated the associations between comorbidity clusters and mortality using the HADCL cohort, which includes documented disease diagnoses. Second, the study lacked information regarding the staging of cancer diagnosis. However, studies have shown that differences in survival at diagnosis between stage groups largely disappeared after having survived for 5-10 years [72]. As the main cohort in this study consists of survivors (with a median survival of 7 y) rather than patients on active treatment, the comorbidity clusters identified in this study may be more relevant to cancer survivors instead of newly diagnosed patients. Moreover, the study did not provide information on the severity and treatment of comorbidities. Previous studies have demonstrated that the impact of comorbidities increases with their severity, which may be due to differential effects on treatment toxicities and tolerance, direct impacts on cancer progression, or other factors [5]. These may limit the mechanistic insights into mortality drivers. Future studies should use electronic health records to ascertain these clinical characteristics for verification of the findings. The manually assigned clusters in the validation cohort (ie, the HADCL data) may introduce a certain degree of confirmation bias. However, the purpose of the validation cohort is to confirm the association between comorbidity clusters identified from the NHANES data and mortality; hence, we reckoned that a manual assignment approach is still reasonable. Future studies should use another external cohort to validate the identified clusters in our study.

Conclusions

This study used machine learning techniques to investigate clusters of comorbidities and mortality outcomes among two large samples of patients with cancer in the United States and Hong Kong. Compared with individuals with low comorbidity burdens, those in the respiratory and CVD clusters showed higher all-cause mortality in both samples, and all 3 clusters

XSL•FO
RenderX

showed higher CVD-related mortality rates in the NHANES cohort. However, no significant associations between these clusters and cancer-specific mortality were observed. Diet quality and socioeconomic status are effect modifiers of the associations between comorbidity clusters and mortality. Overall, the results demonstrate the potential of using machine learning approaches to gain valuable insights into the complex multimorbidity profiles of patients with cancer. Further studies using similar methodologies may provide deeper insights into the relationships between multimorbidity, mortality, and cancer-specific outcomes, ultimately enabling the incorporation of multimorbidity considerations to improve strategies for the personalized care of patients with cancer.

Acknowledgments

The authors received no specific funding for this work. A portion of the results was presented at the American Society of Clinical Oncology Annual Meeting 2024. The abstract was awarded the Conquer Cancer–New Rhein RWE Endowed Merit Award.

Data Availability

Data are presented in the main manuscript. NHANES data are publicly available on the web [15]. Owing to Hospital Authority Data Collaboration Laboratory policy, the raw data remain confidential and will not be shared.

Authors' Contributions

All authors contributed to the conceptualization and design of the study. Data analysis was performed by CSL and RH, while all authors were involved in the interpretation of the data. CSL drafted the original manuscript, and all authors participated in the review and editing process.

Conflicts of Interest

None declared.

Abstract

Background: Breast cancer is the most prevalent form of cancer worldwide, with 2.3 million new diagnoses in 2022. Recent advancements in treatment have led to a shift in the use of chemotherapy-targeted immunotherapy from a postoperative adjuvant to a preoperative neoadjuvant approach in select cases, resulting in enhanced survival outcomes. A pathological complete response (pCR) is a critical prognostic marker, with higher pCR rates linked to improved overall and disease-free survival.

Objective: The objective of this study was to develop robust, machine learning–based prediction models for pCR following neoadjuvant therapy, leveraging clinical, laboratory, and imaging data.

Methods: A retrospective cohort study was conducted using data from the Taipei Medical University Clinical Research Database from 2015 to 2022. Eligible patients were those with breast cancer who received neoadjuvant therapy followed by curative surgical resection. Machine learning models were developed using 3 distinct sets of variables. Model 1 included 14 clinical features such as age, height, weight, tumor stage, receptor status, tumor markers, and intrinsic subtype. Model 2 expanded on this by incorporating additional laboratory data and comorbidities (29 variables in total). Model 3 added breast sonography response data to the clinical variables in model 1. Algorithms including logistic regression, random forest, support vector machines, and extreme gradient boosting were used. Feature selection was performed using recursive feature elimination with cross-validation, and model performance was assessed using accuracy and area under the receiver operating characteristic curve (AUROC).

Results: A total of 334 patients were analyzed, with 199 in the non-pCR group and 135 in the pCR group. The application of logistic regression with recursive feature elimination with cross-validation was found to demonstrate the optimal performance among the various algorithms that were evaluated in this study. Model 1 attained a mean accuracy of 0.66 (SD 0.02) and a mean AUROC of 0.73 (SD 0.01). The incorporation of laboratory data and comorbidities in model 2 did not yield significant enhancement, with a mean accuracy of 0.67 (SD 0.02) and a mean AUROC of 0.73 (SD 0.01). The incorporation of breast sonography response in model 3 led to a modest enhancement in predictive performance for the sonography group (accuracy 0.68; AUROC 0.60) in comparison to the nonsonography group (accuracy 0.66; AUROC 0.55). Despite the modest sample size (41 patients) of model 3, the integration of sonography data appeared to offer additional value in predicting pCR and warrants further investigation.

Conclusions: This study suggests that incorporating breast sonography into models with clinical and laboratory data may modestly improve pCR prediction. It is important to note that the findings of this study are preliminary and require cautious interpretation. Further studies are required to validate this approach and support its integration into a machine learning–based clinical workflow.

Introduction

Breast Cancer and Treatment Strategies

Breast cancer is the most prevalent cancer worldwide, with approximately 2.3 million women diagnosed and 670,000 deaths reported in 2022 [1]. In Taiwan, the disease is also the most prevalent form of cancer among women, with an annual incidence of 15,000 new cases [2]. Treatment strategies for breast cancer are highly personalized, encompassing surgery, chemotherapy, targeted therapy, immunotherapy, hormone therapy, and radiotherapy [3,4]. Historically, the sequence of chemotherapy, targeted therapy, and immunotherapy was implemented as an adjuvant treatment following surgery. However, in certain circumstances, it is now used as neoadjuvant therapy, administered prior to surgery, to optimize outcomes [5].

The Role and Advantages of Neoadjuvant Therapy

Neoadjuvant therapy confers a number of clinical advantages, including the potential to reduce the size of the tumor, thereby enabling breast-conserving surgery in patients who might otherwise require mastectomy. This approach also provides a critical window to monitor tumor regression and assess pathological responses, which are strongly correlated with improved overall survival and disease-free survival [6-8]. It is imperative to acknowledge that the efficacy of neoadjuvant therapy exhibits substantial intrinsic subtype variability, underscoring the necessity for subtype-specific therapeutic strategies.

Current guidelines recommend neoadjuvant therapy for patients with ≥ cT2 or cN(+) luminal-type breast cancer and ≥ cT1c, cN0 human epidermal growth factor receptor 2 (HER2)-positive or triple-negative breast cancer (TNBC) [9]. In the context of HER2-positive breast cancer, the Adjuvant Paclitaxel and Trastuzumab trial has demonstrated the efficacy of a de-escalated regimen of TH (paclitaxel and trastuzumab) for 12 cycles in achieving excellent outcomes for lower-risk patients [10]. In the context of TNBC, the incorporation of carboplatin into standard neoadjuvant chemotherapy has been shown to result in a substantial enhancement in pathological complete response (pCR) rates [11]. Moreover, the addition of pembrolizumab in conjunction with chemotherapy has been observed to further augment pCR rates and event-free survival, particularly in cases classified as high risk [12].

An accurate assessment of tumor response is imperative for the optimization of neoadjuvant therapy strategies. Previous studies have investigated a multitude of factors to predict pCR in patients with breast cancer undergoing neoadjuvant therapy [13]. Imaging modalities, such as breast sonography, are valuable for evaluating tumor size and margins, with a sensitivity of 61% and specificity of 78% [14]. Breast sonography plays a pivotal role in assessing response during treatment and complementing clinical examination, which remains a reliable and accessible method for evaluating palpable lesions. This dual approach enables the timely identification of nonresponders, who can then be spared the adverse effects of ineffective chemotherapy and redirected to alternative therapeutic strategies with potentially greater efficacy [15].

Despite the variability in pCR rates (10% - 60%) across different breast cancer intrinsic subtypes, accurate prediction of pCR using a combination of clinical features, imaging techniques, and pathology remains critical for tailoring treatment and improving outcomes [16,17].

Study Objective

The objective of this study is to develop a user-friendly prediction model for pCR after neoadjuvant therapy by integrating clinical features, advanced machine learning techniques, and breast sonography data. The implementation of such a model has the potential to facilitate the early identification of nonresponders, thereby enabling timely therapeutic adjustments and averting the administration of ineffective treatments. The ultimate implementation of this model in clinical practice could enhance personalized treatment plans, improve patient outcomes, and optimize health care resource use.

Methods

Study Design and Data Source

This retrospective cohort study used data from the Taipei Medical University Clinical Research Database (TMU-CRD), an electronic medical record system established in 2015. The dataset used in this study was exclusively derived from the TMU-CRD, which consolidates data from 3 affiliated academic hospitals: Taipei Medical University Hospital, Wan Fang Hospital, and Shuang Ho Hospital. The database is managed and maintained by these academic centers, ensuring high data quality and reliability. The TMU-CRD encompasses both structured data, including patient demographics, International Classification of Diseases codes, laboratory results, treatment procedures, medication records, and cancer registry entries, as well as unstructured data, comprising physician notes, imaging reports, and pathological reports. As of 2024, the database encompasses data from 1998 to 2022 and contains the medical records of nearly 4.3 million patients across Taiwan.

Patient Selection

The population of this study included patients diagnosed with breast cancer who underwent neoadjuvant therapy followed by curative-intent surgical resection. Patients were identified using a specific label in the cancer registry that indicated neoadjuvant treatment. Exclusion criteria encompassed instances where chemotherapy records were incomplete, where chemotherapy was not administered prior to surgery, and the presence of metastatic disease. Following the application of these criteria,

XSL•FO
RenderX

a final cohort of 334 patients was identified for the purposes of analysis.

Data Collection

A comprehensive dataset, encompassing clinical and imaging parameters, was meticulously collected to develop predictive models for pCR. The demographic variables included age, height, and weight, clinical tumor size, clinical TNM stage, hormone receptor (estrogen receptor [ER] or progesterone receptor [PR]) status, HER2 status, Ki-67 expression, breast cancer intrinsic subtype, Nottingham Bloom Richardson (NBR) grading, carcinoembryonic antigen (CEA) levels, carbohydrate antigen 15‐3 (CA15-3) levels, laboratory test results, and comorbidities. The intrinsic subtypes of breast cancer were categorized as hormone receptor-positive, HER2-positive, and triple-negative. The evaluation of imaging data, specifically breast sonography responses, was conducted based on Response Evaluation Criteria in Solid Tumors criteria and categorized into complete response, partial response, stable disease, or progression disease. The pathological response was classified as complete response (ypT0/Tis and ypN0) or residual disease.

The Allred scoring system was used to determine hormone receptor (ER or PR) status. The assessment of HER2 status was conducted through immunohistochemistry, and cases that yielded a score of 2+ underwent additional evaluation via fluorescence in situ hybridization. The TNM staging was determined according to the American Joint Committee on Cancer guidelines.

Machine Learning Models

Three models were constructed for the development of machine learning models to predict pCR. Model 1 consisted of 14 clinical parameters, including age, height, weight, BMI, tumor size, clinical N stage, ER status, PR status, HER2 status, Ki-67 expression, NBR grading, CEA levels, CA15-3 levels, and breast cancer intrinsic subtype. Model 2 expanded upon model 1 by incorporating additional laboratory test results and comorbidities, resulting in a total of 29 variables. Model 3 included the parameters from model 1 and integrated breast sonography response data as an additional feature. Due to limited sonography data availability, this dataset included only 41 patients. Model 2 expanded upon model 1 by incorporating additional laboratory test results and comorbidities, resulting in a total of 29 variables.

Statistical Analysis and Machine Learning Approach

Univariate analysis was performed using 2-tailed *t* tests and chi-square tests to identify significant differences between the pCR and non-pCR groups. Features that exhibited statistical significance ($P<.05$) and those that were supported by existing literature were selected for model construction. Missing values were addressed through the implementation of imputation methods, with mean imputation being applied to continuous variables and an additional category being created for categorical variables. With regard to missing values, we excluded variables for which more than 30% of data points were missing.

The performance of the model was evaluated using accuracy and the area under the receiver operating characteristic curve (AUROC). The AUROC is a metric that quantifies a model's ability to distinguish between 2 classes (eg, pCR vs non-pCR) by plotting the true positive rate (sensitivity) against the false positive rate (1−specificity) at various thresholds. An AUROC value of 1.0 indicates perfect classification, while a value of 0.5 represents no better performance than random chance. The College of American Pathologists asserts that an area under the curve below 0.6 indicates inadequate discriminative ability, values between 0.6 and 0.75 suggest beneficial discrimination, and values above 0.75 reflect substantial clinical utility. It is therefore generally recommended that an AUROC of at least 0.6 is attained for a prognostic model if its use in clinical settings for the prediction of cancer outcomes is to be considered beneficial [18].

The 3 models were analyzed using the following algorithms: logistic regression (LR), random forest, support vector machine, and extreme gradient boosting. The feature selection process was optimized through the implementation of recursive feature elimination with cross-validation. The training and testing datasets were partitioned into 80% and 20% of the total data, respectively, with the exception of model 3, where leave-one-out cross-validation (LOO-CV) was used due to the limited sample size. To interpret the importance of breast sonography in model 3, Shapley Additive Explanations (SHAP) were used. The SHAP values were computed using the SHAP Python package in order to quantify the contribution of each feature to the model's output. The mean absolute SHAP value was used to summarize feature importance, and the median rank of sonography response was calculated by comparing its importance across all features for each prediction. The performance of each model was evaluated using accuracy and AUROC metrics.

Ethical Considerations

The study was reviewed and approved by the institutional review board (IRB) of Taipei Medical University, Taipei, Taiwan (IRB N202305036). The study entailed secondary analysis of deidentified data procured from the Taipei Medical University Clinical Research Database. In accordance with the regulations established by the IRB and the institutional policy, the requirement for informed consent was waived due to the fact that no personally identifiable information was accessed. The research was conducted in accordance with the ethical standards outlined in the Declaration of Helsinki. The participants did not receive any form of financial compensation, and no direct interaction occurred between the participants and the investigators. The maintenance of data privacy and confidentiality was strictly enforced throughout the study.

Results

Basic Characteristics

We identified 334 patients from the 3 hospital datasets. These patients were stratified into 2 groups based on their pCR status: the non-pCR group, comprising 199 (59.5%) individuals, and the pCR group, comprising 135 (40.4%) individuals. Univariate analysis revealed significant differences between the 2 groups in several clinical parameters, including tumor size, clinical T stage, ER status, PR status, HER2 status, Ki-67 expression, breast cancer intrinsic subtype, CA15-3 levels, and hemoglobin

XSL•FO

concentrations. However, no significant differences were observed in age, BMI, clinical N stage, overall clinical stage, NBR grading, or CEA levels (Table 1).

[a]pCR: pathological complete response.

[b]*P* values are based on univariate analysis results using 2-tailed *t* tests and chi-square tests.

[c]ER: estrogen receptor.

[d]PR: progesterone receptor.

[e]HER2: human epidermal growth factor receptor 2.

[f]HR: hormone receptor.

[g]TNBC: triple-negative breast cancer.

[h]NBR: Nottingham Bloom Richardson.

[i]CEA: carcinoembryonic antigen.

[j]CA15-3: carbohydrate antigen 15-3.

[k]WBC: white blood cell.

[l]BUN: blood urea nitrogen.

[m]GOT: glutamic oxaloacetic transaminase.

[n]GPT: glutamic pyruvic transaminase.

Although breast sonography response did not achieve statistical significance in univariate analysis, a trend toward a higher pCR rate was observed in patients demonstrating superior sonography response (Table 2).

Table . Breast sonography responses with complete response and partial response are more likely to predict a pathological complete response (pCR) in final pathological result.

Sonography response	Non-pCR (n=28), n (%)	pCR (n=13), n (%)
Complete response	2 (7.1)	3 (23.1)
Partial response	13 (46.4)	8 (61.5)
Stable disease	12 (42.9)	2 (15.4)
Progression disease	1 (3.6)	0 (0)

Machine Learning Features and Algorithms

The model 1 was analyzed using 6 machine learning algorithms, with LR incorporating recursive feature elimination and cross-validation demonstrating the best performance, yielding a mean accuracy of 0.66 (SD 0.02) and a mean AUROC of 0.73 (SD 0.01; Table 3).

XSL•FO
RenderX

Table . Performance of the predication model for models 1 and 2.

Algorithm	Accuracy, mean (SD)	AUROC[a], mean (SD)
Model 1		
RF[b]	0.60 (0.02)	0.62 (0.04)
LR[c]	0.66 (0.01)	0.72 (0.02)

XGB with RFECV	0.66 (0.03)	0.72 (0.01)

[a]AUROC: area under the receiver operating characteristic curve.

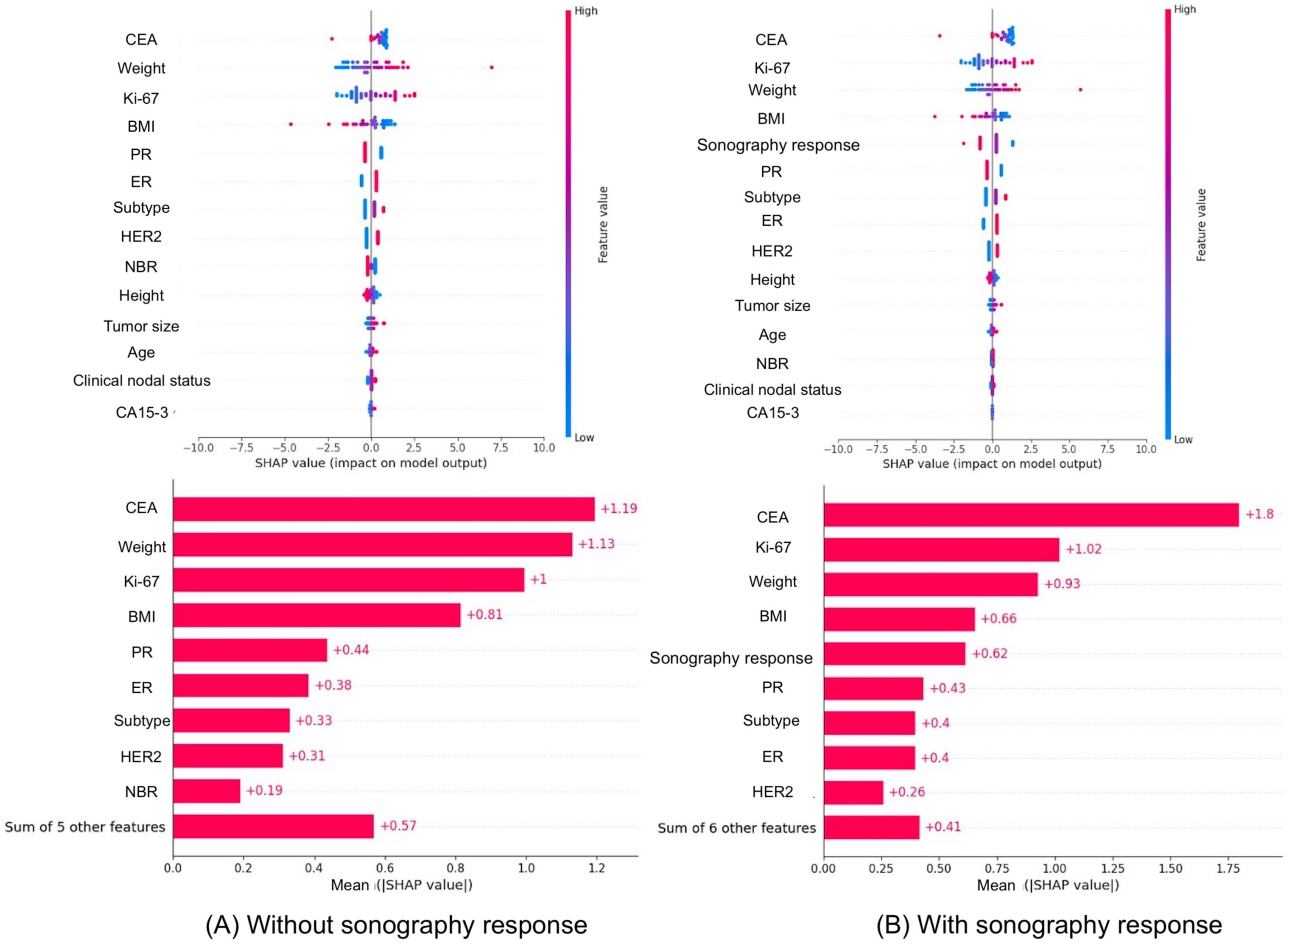
[b]RF: random forest.

[c]LR: logistic regression.

[d]SVM: support vector machine.

[e]XGB: extreme gradient boosting.

[f]RFECV: recursive feature elimination with cross-validation.



[g]The values in italics format indicate that LR with RFECV demonstrated the best performance among all evaluated algorithms.

In model 2, additional variables, including laboratory test results and comorbidities, were integrated with the clinical parameters from model 1, resulting in a total of 29 variables. However, the inclusion of these additional variables did not significantly improve predictive performance, with a mean accuracy of 0.67 (SD 0.02) and a mean AUROC of 0.73 (SD 0.01; Table 3).

In model 3, the incorporation of breast sonography response data into the variables from the first model resulted in a dataset comprising 15 variables. Due to the limited sample size, the analysis used the LR algorithm with LOO-CV. The findings demonstrated that the incorporation of sonography response enhanced the predictive accuracy of the model, with an accuracy of 0.68 and an AUROC of 0.60 for the sonography group, as opposed to an accuracy of 0.66 and an AUROC of 0.55 for the nonsonography group. Furthermore, a SHAP value for sonography response was 0.62 (Figure 1), and the median rank of sonography response was 5 (IQR 3-7) among all samples in model 3 (Figure 2).

(A) Without sonography response

(B) With sonography response

XSL•FO
RenderX

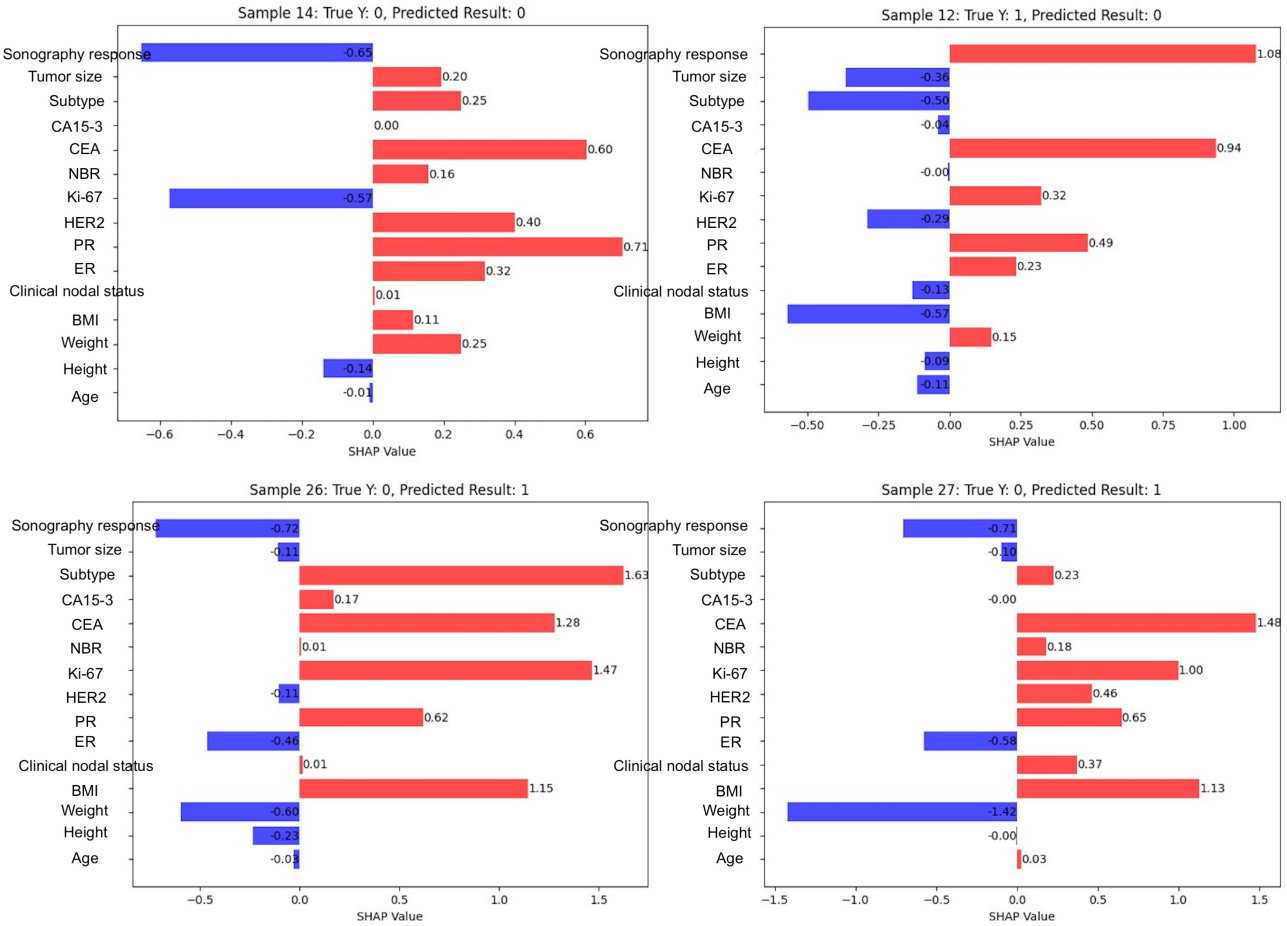

Figure 2. Boxplot illustrating the ranking of sonography response across all samples in model 3. The median rank of sonography response was 5 (IQR 3-7).

Subsequent analysis of specific samples in model 3 was undertaken to investigate the value of sonography response (Figure 3). In sample 14, the predicted and true results were non-pCR; however, most variables predicted pCR, with only the sonography response correctly indicating non-pCR, aligning with the final result. A similar pattern was observed in samples 12, 26, and 27, where the predicted results were incongruent with the true outcomes; nevertheless, the sonography response accurately reflected the actual results.

XSL•FO
RenderX

Figure 3. Selected samples from model 3 highlighting the significance of sonography response in prediction accuracy. In sample 14, the true and predicted results were non-pCR, but most variables incorrectly predicted pCR—except for the sonography response, which correctly indicated non-pCR. Similarly, in samples 12, 26, and 27, the predicted results were opposite to the actual outcomes; yet, the sonography response correctly aligned with the true results. CA15-3: carbohydrate antigen 15 - 3; CEA: carcinoembryonic antigen; ER: estrogen receptor; HER2: human epidermal growth factor receptor 2; NBR: Nottingham Bloom Richardson; pCR: pathological complete response; PR: progesterone receptor; SHAP: Shapley Additive Explanations.

Discussion

The objective of this study was to develop machine learning–based models to predict pCR in patients with breast cancer receiving neoadjuvant therapy, using clinical, laboratory, and imaging data. Three models were subjected to a rigorous testing process, and their predictive performance was thoroughly evaluated.

Principal Findings

Model 1 incorporated clinical parameters alone, yielding an AUROC of 0.73. Model 2, which added laboratory data and comorbidities, demonstrated no significant improvement over model 1. Model 3, which incorporated a further integration of breast sonography response, demonstrated a modest enhancement in its predictive performance. This enhancement was characterized by an increase in AUROC from 0.55 to 0.60 and an increase in accuracy from 0.66 to 0.68. Furthermore, SHAP analysis indicated that sonography response contributed significantly to the model, ranking fifth among all the features considered. In some cases, sonography response aligned with true outcomes, despite the failure of other variables to do so. These findings indicate the potential value of incorporating imaging data into prediction models to enhance individualized treatment strategies.

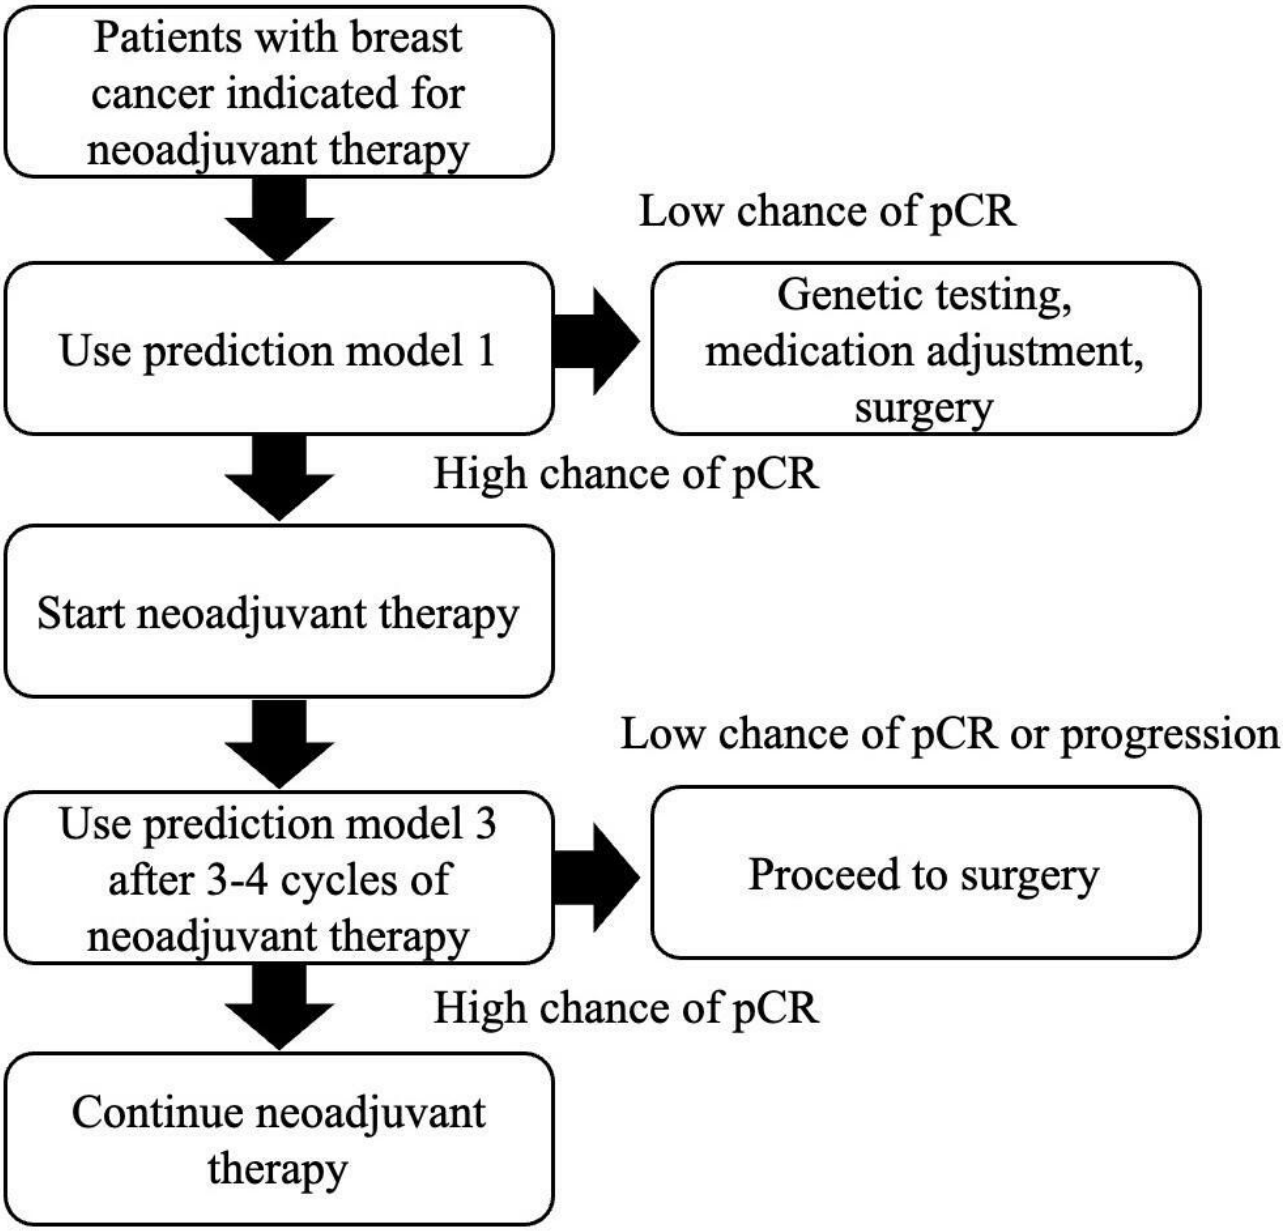
Comparison to Prior Work

The predictive performance of model 1 is consistent with that reported in previous studies, which used clinical parameters alone and reported AUROCs ranging from 0.65 to 0.77 [13,19-21]. The limited incremental value observed in model 2 is consistent with the findings in the literature that laboratory and comorbidity variables may not independently enhance prediction unless integrated with molecular or genetic data [21]. This study's finding that breast sonography provides added predictive value is consistent with previous evidence highlighting the clinical utility of imaging in assessing tumor response, as demonstrated in model 3.

The observed pCR rates for the different intrinsic subtypes (HER2-positive, TNBC, and hormone receptor–positive) also reflect established trends in neoadjuvant therapy responsiveness [12,22-25].

Challenges With Small Sample Size and Machine Learning Approaches

Despite extensive data mining, only 41 cases with sonography response data were available for model 3, thereby limiting the sample size and potentially increasing the risk of overfitting. To address this issue, we used an LR model with LOO-CV, a method that has been demonstrated to be particularly effective



XSL•FO
RenderX

when dealing with small datasets. Initially, algorithms such as support vector machines (and decision trees were considered; however, imbalances in the dataset led to classification bias, which resulted in the adoption of more straightforward LR models. It is recommended that future research endeavors place a priority on the acquisition of more substantial datasets with a view to enhancing the model's robustness and mitigating the risk of overfitting [26,27].

Clinical Implications

The predictive models developed in this study have practical applications in clinical decision-making. Specifically, model 1, which uses only baseline clinical data, facilitates initial treatment planning by predicting the likelihood of pCR subsequent to a decision to proceed with neoadjuvant therapy. The third model, which incorporates midtreatment sonography response, enables dynamic reassessment of pCR probability, facilitating timely adjustments to therapeutic strategies, such as switching to alternative treatments or surgical interventions. The integration of machine learning into standard clinical workflows may offer potential benefits for improving outcomes in breast cancer care (Figure 4). Given the small sample and lack of validation, the prediction model has not reached clinical maturity, and it is therefore not prudent to make recommendations regarding its application.

Figure 4. Conceptual flowchart outlining a potential application of the prediction model to support clinical decision-making. This framework is intended for illustrative purposes only and does not represent a validated clinical tool. pCR: pathological complete response.

Strengths and Limitations

A significant strength of this study is its multimodal approach, integrating clinical, laboratory, and imaging data within machine learning models. The use of SHAP values enhances interpretability and facilitates the identification of relevant predictors, including sonography response.

XSL•FO
RenderX

However, it is important to note several limitations of this study. First, the sample size for model 3 was limited (n=41), thereby restricting statistical power and increasing the risk of overfitting. To mitigate this issue, the LOO-CV and LR methods were applied. Second, the data extracted from semistructured reports may have been subject to inconsistencies. Despite the evident benefits of text mining in enhancing the quality of the results, the use of standardized data collection methods in future studies would be a preferred approach. Third, the models did not include genetic or molecular biomarkers, which may limit their predictive performance. Fourth, as a retrospective, single-center study, there is a risk of selection bias and limited generalizability. Variables with over 30% missing data were excluded, a process that potentially resulted in the omission of important predictors. Furthermore, the absence of external validation of the model is a notable shortcoming.

Future Directions

Future research endeavors should explore the integration of genomic, molecular, and radiomic data to further refine prediction models. Conducting prospective, multi-institutional studies with larger and more diverse patient cohorts is imperative to validate findings and support generalizability. Standardizing imaging report formats and leveraging natural language processing tools may also enhance data quality for imaging-based predictors. Consequently, these advancements have the potential to facilitate the development of robust clinical decision-support tools, thereby optimizing neoadjuvant treatment planning in breast cancer care.

Conclusions

This study provides preliminary insight into the potential role of breast sonography response data in improving pCR prediction for patients with breast cancer receiving neoadjuvant therapy. The clinical and laboratory parameters that were provided served as a useful foundation for the models, and the addition of imaging data appeared to offer modest improvements in predictive accuracy. However, given the relatively small sample size, these findings should be interpreted with caution. The incorporation of imaging data into clinical workflows could potentially represent a valuable step toward the development of more personalized treatment approaches.

Acknowledgments

The authors would like to acknowledge the support of the Health Data Analytics and Statistics Center, Office of Data Science, Taipei Medical University, Taiwan, for their technical assistance. This study was supported by the National Science and Technology Council, Taiwan (project NSTC113-2321-B-038-012). Abstract

Background: While numerous models have been developed to predict overall survival in postoperative patients with esophageal squamous cell carcinoma (ESCC), few have specifically focused on predicting postoperative recurrence.

Objective: This study aimed to develop and validate a support vector machine (SVM)-based predictive model for evaluating recurrence risk and identifying associated factors in ESCC patients following surgery.

Methods: We retrospectively analyzed clinical data from 311 ESCC patients who underwent surgery at Jinling Hospital between June 2014 and November 2016, with follow-up until October 2021 (median of 36 follow-up months, range 0-93.5 months). After excluding cases with incomplete data (n=1), 310 eligible patients were randomly allocated into test (n=106), validation 1 (n=103), and validation 2 (n=101) cohorts. Using SVM algorithms, patients were stratified into high- or low-recurrence-risk groups. Model performance was assessed using sensitivity, specificity, the Youden index, positive predictive value, and negative predictive value. Calibration curves were generated to evaluate model accuracy and reliability. Statistical analyses were performed using SPSS (version 22.0; IBM Corp) and R (version 3.6.1; R Foundation for Statistical Computing).

Results: In all cohorts, SVM7 (incorporating tumor node metastasis [TNM] stage, adjuvant therapy, differentiation, tumor size, and complications) demonstrated significantly higher sensitivity in predicting recurrence than SVM6 (based on the Eastern Cooperative Oncology Group performance status, neutrophil-to-lymphocyte ratio, and CY211) (P<.001). The composite model SVM6+8 (combining SVM6 and SVM8 [SVM7 excluding complications]) achieved recurrence prediction sensitivities of 94%, 79.59%, and 72.73% in the test, validation 1, and validation 2 groups, respectively; with specificities of 98.11%, 69.84%, and 78.43%. These results were comparable to SVM6+TNM (SVM6 combined with TNM staging) but outperformed SVM6 alone (P<.001). Survival analysis revealed significantly longer disease-free survival in the SVM6+TNM-predicted low-risk group compared to the high-risk group, with a marked difference in recurrence rates (P<.001).

Conclusions: The proposed SVM-based model enables accurate prediction of postoperative recurrence in ESCC patients with high sensitivity, specificity, and discriminative power, offering a valuable tool for clinical risk stratification.

Introduction

Esophageal cancer poses a threat to public health due to its high morbidity and mortality rates [1,2]. Postoperative tumor node metastasis (TNM) staging is the most valuable index for evaluating the prognosis of patients with esophageal squamous cell carcinoma (ESCC). However, it is an index that can only be confirmed after surgery and can only provide a theoretical basis for postoperative treatment strategies. Thus, it is of little significance for the planning of surgical strategies before surgery in individual patients, especially for those with a poor physical condition or in whom performing surgery is difficult, as it is difficult to evaluate the TNM staging of these patients.

Numerous factors affect the postoperative recurrence rate in patients with ESCC [3], including postoperative complications,

XSL•FO
RenderX

Eastern Cooperative Oncology Group (ECOG) performance status, clinicopathological characteristics, tumor markers, and inflammatory as well as nutritional indicators. These inflammatory and nutritional indicators include the neutrophil-to-lymphocyte ratio (NLR), C-reactive protein-to-prealbumin ratio (CPR) [4], platelet×C-reactive protein multiplier (P-CRP), lymphocyte-to-monocyte ratio, Glasgow prognostic score (GPS), and other inflammatory markers [5], all of which affect postoperative survival and prognosis. Tumor marker levels are widely recognized for their prognostic value in predicting postoperative recurrence of esophageal cancer [6,7]. However, studies that include other clinical indicators are relatively limited. A comprehensive and systematic analysis of preoperative blood indicators, patient-specific conditions, intraoperative factors such as duration of surgery and blood loss, and postoperative complications is necessary to identify key risk factors. Screening these indicators and constructing an optimal predictive model will have significant clinical value in improving postoperative management and patient outcomes.

Recently, an increasing number of studies have focused on predictive models. Here, we present the development and validation of a clinical prediction model using a support vector machine (SVM). The SVM was used to develop a more robust model for predicting postoperative recurrence compared with other approaches. As a new data mining methodology, SVM has been applied to predict tumor progression and clinical outcomes by integrating molecular markers and clinical features [8-10]. Furthermore, this method is suitable for small patient cohorts, where independent and random assignment into 3 groups enhances the reliability of analysis and validation. Given its advantages, SVM is likely to continue to provide valuable insights into the accurate prediction of the recurrence of ESCC [11,12]. We collected information on commonly used clinical blood indicators and surgical data, and the patients were followed up to analyze potential risk factors. Through iterative combinations of these factors weighted by their relative importance, we developed an optimal recurrence prediction model. Our goal is to integrate the indices from the optimal SVM model into an artificial intelligence model for patients with ESCC who have not yet had an individualized treatment plan developed.

Methods

Patients and Follow-Up

Baseline data was obtained from the medical records of patients diagnosed with ESCC between June 2014 and November 2016 at Jinling Hospital. Data was abstracted in December 2016 by 2 independent researchers (MQX and ZSJ) and a study database created, of which basic information was used for follow-up. These patients were followed up until October 2021. The collected data primarily comprised preoperative information, including basic information, blood indicators (inflammation, infection, and tumor markers), presence or absence of adjuvant therapy, intraoperative blood loss, duration of surgery, and postoperative complications. Follow-ups were conducted approximately every 3 months, primarily through phone calls. If the patients could not be reached, we obtained their contact details from the outpatient department, and additional attempts were made to establish communication. When phone contact was unsuccessful, we sent letters to or conducted home visits. Patients who remained unreachable were considered lost to follow-up and were excluded from the study.

Inclusion and Exclusion Criteria

We included patients who met the following criteria: (1) patients had a diagnosis of ESCC confirmed by a postoperative histopathological examination, (2) they had radical resection for ESCC, (3) they had complete clinical and follow-up data, and (4) the surgery was performed by the same surgeon. Patients who met the following criteria were excluded: (1) they had liver or kidney dysfunction or hematological disease; (2) they had a concurrent or previous history of other malignant tumors; (3) they had perioperative death, defined as mortality due to serious complications within 1 month postoperatively; and (4) they were receiving preoperative chemoradiotherapy.

Statistical Analysis

Data were analyzed using SPSS (version 22.0; IBM Corp) and R (version 3.6.1; R Foundation for Statistical Computing [13]). Univariate and multivariate analyses of the relative prognostic importance of parameters were performed using the Cox proportional hazards model. An SVM uses implicit mapping of input data into a high-dimensional feature space using a kernel function [14]. Learning occurs in this feature space based on the “kernel trick.” Due to its popularity in machine learning and pattern classification, numerous SVM packages are available, such as *LIBSVM* and *KERNLAB*. In this study, we used the R package *KERNLAB*. The SVM model was developed using perioperative data, inflammation markers, and tumor markers to predict ESCC recurrence. From SVM model 1 (SVM1) to SVM6, in the initial analysis, we evaluated all potential predictors through correlation and Cox proportional hazards regression. Candidate variables showing statistically significant associations with esophageal cancer recurrence ($P<.05$) underwent receiver operating characteristic (ROC) curve evaluation. All risk factors were area under the curve (AUC)-ranked and iteratively pruned to optimize the SVM model’s predictor set. An identical approach was applied from SVM7 to SVM10. SVM1 included all preoperative markers (ECOG, NLR, CPR, CY211, squamous cell carcinoma antigen [SCC], P-CRP, GPS, and age); SVM2 included factors in SVM1 excluding P-CRP; SVM3 included factors in SVM2 excluding GPS; SVM4 included factors in SVM3 excluding SCC; SVM5 included factors in SVM4 excluding age; SVM6 included factors in SVM5 excluding CPR (final variables: ECOG, NLR, and CY211); SVM7 included TNM, adjuvant therapy, differentiation, tumor size, and complications; SVM8 included factors in SVM7 excluding complications; SVM9 included factors in SVM8 excluding tumor size; and SVM10 included factors in SVM9 excluding differentiation. ROC curve analysis was performed for each SVM model, and the AUC values were used to calculate the predictive ability of the SVM models for recurrence.

All patients included in the study were randomly assigned to the test, validation 1 (Val1), or validation 2 (Val2) groups. Using

XSL•FO
RenderX

the SVM algorithm, each group was further assigned to a high- or low-risk of recurrence group. In the test group, we combined several predictive indicators of recurrence to stratify patients into high- and low-risk subgroups. The predictive performance of this integrated predictive model was then validated in 2 independent cohorts (Val1 and Val2). The Kaplan-Meier method was used to calculate and plot recurrence curves, further validating the ability of the SVM models to distinguish patients with a high and low risk of recurrence. Sensitivity, specificity, the Youden index, the positive predictive value (PPV), and the negative predictive value (NPV) were assessed to evaluate the practical value of the model. χ^2 tests were used to analyze differences in sensitivity, specificity, PPV, and NPV among the SVM models. A calibration curve was created using the Hosmer-Lemeshow goodness-of-fit test to assess the degree of calibration of the model to ensure its accuracy and reliability. All tests were 2-sided, and $P<.05$ was considered statistically significant.

Ethical Considerations

This study was approved by the Institutional Ethics Review Board (IERB 2018NZKY-021‐03) of the Ethics Committee of Jinling Hospital. Verbal informed consent was obtained by telephone during follow-up communications. Standard university hospital guidelines, in accordance with the principles detailed in the Declaration of Helsinki, were followed in handling patient tissues and publication, ensuring confidentiality and anonymity. All participants who completed the survey received a complimentary disease knowledge resource as a token of appreciation and compensation for their participation.

Results

Basic Patient Information

We collected data from 311 patients with postoperative ESCC, which included 241 men (77.5%) and 70 women (22.5%) with a median age of 66 years (range 40-83 y). Preoperative data, blood indicators, intraoperative blood loss, duration of surgery, TNM stage, degree of differentiation, postoperative adjuvant therapy, and complications are shown in Multimedia Appendix 1. The results of quantitative correlation analysis between preoperative tumor markers and postoperative clinical indicators are shown in Multimedia Appendix 2. Postoperative complications included pulmonary infection, incision infection, gastrointestinal dysfunction, recurrent nerve injury, severe pulmonary infection, respiratory failure, hydropneumothorax, anastomotic fistula, anastomotic or thoracic fistula, and hemorrhage requiring re-operation. On October 15, 2021, 144 (46.3%) patients were recurrence-free, whereas 167 (53.7%) had a recurrence. The postoperative follow-up period ranged from zero to 93.5 months (median 36 mo), concluding in October 2021. The postoperative disease-free survival (DFS) was 78.7% at 1 year, 59% at 3 years, and 53.6% at 5 years (see Multimedia Appendix 3).

Risk Factors for Recurrence and Predictive Ability

According to univariate and multivariate Cox regression model analyses, age, ECOG performance status, NLR, CPR, CY211, TNM staging, and postoperative complications were identified as independent risk factors (see Tables 1 and 2). Postoperative adjuvant therapy and ECOG performance status showed the highest predictive ability, as measured using the AUC values (AUC=0.63, 95% CI 0.570-0.695), followed by NLR (AUC=0.599, 95% CI 0.536-0.663). The predictive ability of CY211, CPR, tumor size, and cell differentiation was lower than that of TNM staging (AUC=0.676, 95% CI 0.615-0.737; see Table 3).

SVM Combined With the ROC Model for Predicting Recurrence

The SVM model combined with ROC analysis was used to predict recurrence. In the test, Val1 and Val2 groups, the sensitivity of SVM2—which included all preoperative markers—for predicting recurrence was 94.12%, 70.59%, and 60.98%, respectively, with a specificity of 98.21%, 63.33%, and 56.86%, respectively. The sensitivity of SVM6—which included ECOG, NLR, CY211—in the test, Val1, and Val2 groups was 67.86%, 60.47%, and 68.18%, respectively, with a specificity of 86%, 63.33%, and 64.91%, respectively. The sensitivity of SVM7—which included TNM, adjuvant therapy, differentiation, tumor size, and complications—in the test, Val1, and Val2 groups was 92.86%, 76.74%, and 84.09%, respectively, with a specificity of 76%, 61.67%, and 71.93%, respectively (see Multimedia Appendix 4). No significant difference was observed between the sensitivity and specificity of SVM2 and SVM7 (P>.05). However, SVM6 had a lower sensitivity for predicting recurrence than SVM7. The sensitivity of SVM6+8 for predicting recurrence was 94%, 79.59%, and 72.73% in the test, Val1, and Val2 groups, respectively, with a specificity of 98.11%, 69.84%, and 78.43%, respectively. These sensitivities were comparable with those of SVM6+TNM, and the specificities were higher than those of SVM6+TNM (P<.001; see Table 4).

[k]χ2 test was used in comparisons between markers of SVM 6+8 and SVM6+TNM.

Multifactor Integrated Analysis for the Prediction of Postoperative DFS

We generated a heatmap showing the high- and low-distribution profiles of risk factors affecting recurrence in patients with ESCC (see Figure 1 and Multimedia Appendix 5). Postoperative survival analysis revealed that the DFS of the predicted low recurrence risk group in the SVM6 and SVM6+TNM models was much longer than that of the predicted high recurrence risk group. A considerable difference in cumulative survival rates was also observed (see Figure 2).

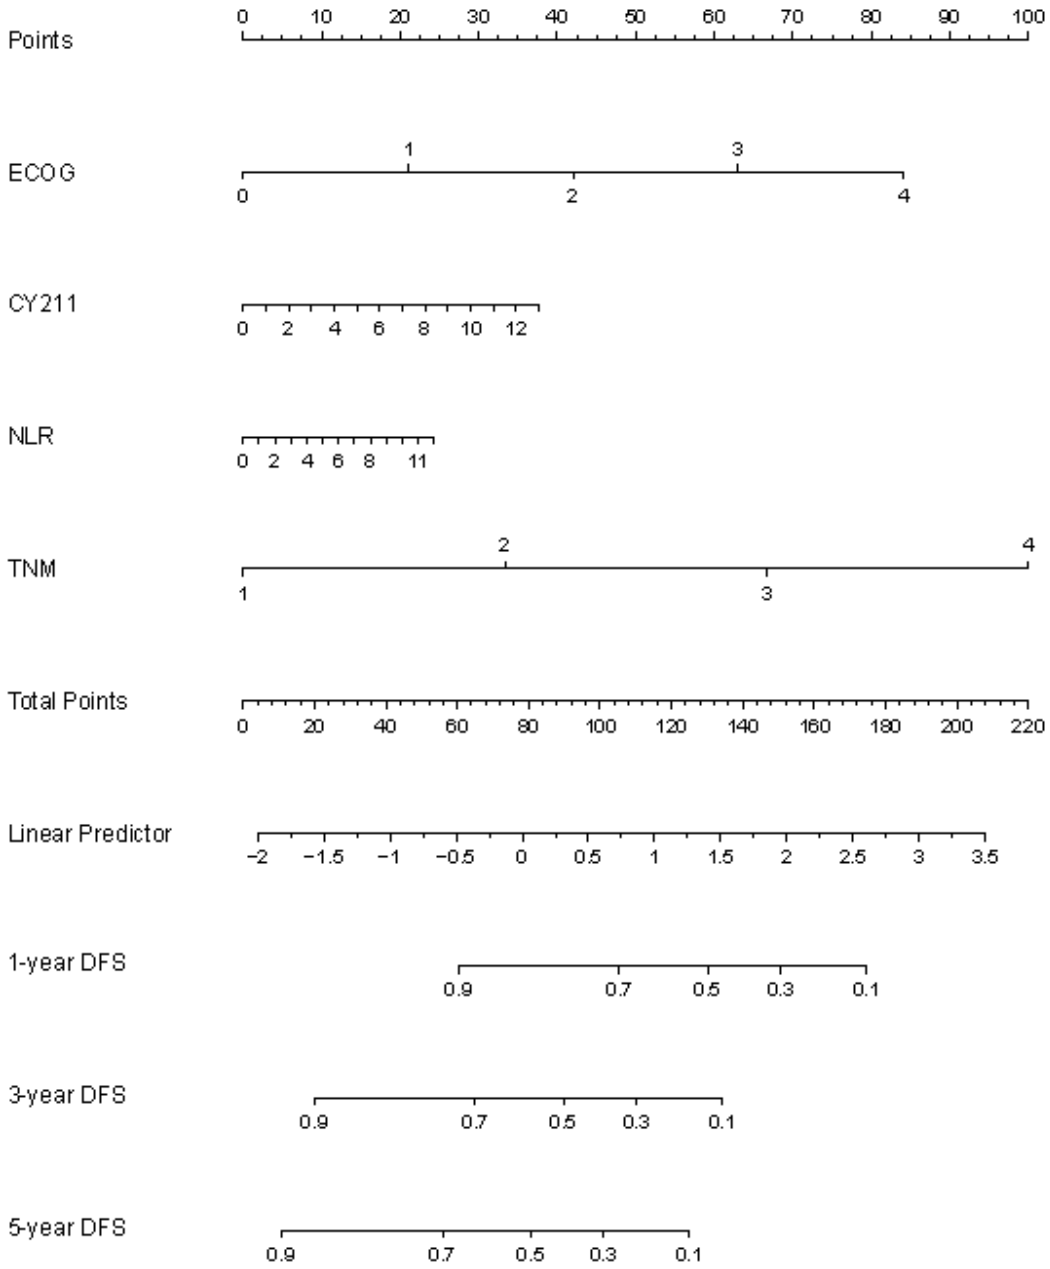
Figure 2. Survival analyses were performed for the low-risk versus high-risk groups of SVM6, SVM7, and SVM6+TNM models. We randomly divided the 311 patients into test, Val1, and Val2 groups, and then each group was divided into a high-risk recurrence group and a low-risk recurrence group. Kaplan-Meier survival analysis showed that the average postoperative survival time of patients with esophageal squamous cell carcinoma (ESCC) in the low-risk recurrence group was longer than that of the high-risk group among test, Val1, and Val2 groups (SVM6, SVM7, and SVM6+TNM models). (P<.001). SVM: support vector machine; PLRR: predicted low-recurrence-risk; PHRR: predicted high-recurrence-risk; TNM: tumor node metastasis.



Development and Validation of a Nomogram for the Prediction of DFS

A nomogram was developed using the available data to predict DFS. Vertical lines were drawn from the correct status of each prognostic factor on the top axis (points). Summing all points allowed for the projection of a vertical line from the "total points" axis to the bottom axes, facilitating the conversion into 1-, 3-, and 5-year DFS rates (see Figure 3 and Multimedia Appendix 6). The SVM6-based nomogram demonstrated reliable performance in predicting DFS, with an AUC of 0.769. Postoperative outcomes were predicted and evaluated with a sensitivity of 65.73%, specificity of 70.66%, and PPV of 83.54%. Similarly, the SVM6+TNM-based nomogram effectively predicted DFS with an AUC of 0.847 (see Table 5), offering sufficient sensitivity (81.12%) and specificity (71.86%) for postoperative assessment. This nomogram provides valuable insights for guiding treatment decisions and follow-up plans in patients with ESCC. The calibration curves were used to evaluate the consistency of the nomogram (SVM6+TNM and SVM 6). The findings indicated a high degree of uniformity between the predicted and observed probabilities of survival in the training set and internal validation set (see Figure 4 and Multimedia Appendix 7).

XSL•FO
RenderX

Figure 3. The nomogram (SVM 6+TNM) predicted individual patient-level 1-, 3-, and 5-year disease-free survival (DFS) based on preoperative and postoperative clinical index. Vertical lines were drawn from the correct status of each prognostic factor to the top axis (points). After the addition of all the points, a vertical line was drawn from the "total points" axis to the bottom axes. This helps in the conversion into a 1-, 3-, and 5-year DFS probability. ECOG: Eastern Cooperative Oncology Group; NLR: neutrophil-to-lymphocyte ratio; TNM: tumor node metastasis; DFS: disease-free survival.

Discussion

Principal Findings

Cancer recurrence remains a major challenge in oncology, significantly impacting patient prognosis. To address this, we developed a machine learning model that predicts recurrence risk, facilitating timely interventions to optimize DFS. Given that surgical and pharmaceutical standards in ESCC treatment generally provide consistent benefits in terms of mortality, DFS is influenced by a combination of multiple factors [15]. Currently, ESCC has a low DFS and imposes a high financial burden on patients, and solely relying on endoscopic follow-up to reduce postoperative recurrence has proven ineffective. In this study, we collected perioperative data from patients with ESCC and conducted follow-ups to develop an artificial intelligence–derived model capable of predicting postoperative recurrence. Implementing this approach is expected to improve DFS. While TNM staging is useful [14], such staging can only be confirmed postoperatively and is only suitable for patients who have already undergone surgery, offering limited value in preoperative planning. Therefore, identifying predictive indicators for DFS preoperatively is important.

Assays for preoperative tumor markers and inflammatory factors [16-20] are cost-effective, convenient, and reliable for diagnosing, treating, and evaluating ESCC prognosis. Surgical factors, such as surgery type, duration of surgery, and intra-operative blood loss, are known risk factors for postoperative recurrence [21-23]; thus, we included these factors into our analysis. In addition, postoperative adjuvant therapy [24] and complications [25] affect prognosis. Collecting comprehensive perioperative data will assist in identifying independent risk factors and facilitate the development of a predictive model for postoperative recurrence. We identified three key findings: (1) Univariate and multivariate Cox regression analyses identified age, ECOG performance status, NLR, CRP, TNM stage, and postoperative complications as independent risk factors for esophageal cancer recurrence. While these factors showed robust predictive value, their combined discriminative ability (AUC=0.676; P<.001) was marginally inferior to that of TNM staging alone; (2) The sensitivity of SVM6+8 (combining SVM6 and SVM8, SVM7 excluding complications) for predicting recurrence in patients with ESCC was comparable with that of SVM6+TNM (SVM6 combined with TNM staging) and higher than that of SVM6+TNM. We used a nomogram to input the indexes in the SVM6 into the artificial intelligence program for patients with ESCC who have not yet developed an individualized plan. It can predict and evaluate the postoperative recurrence outcome of patients with ESCC with a sensitivity of 65.73%, specificity of 70.66%, and accuracy of 68.38%. For patients who have undergone surgery, we can enter the indicators in SVM6+TNM into the artificial intelligence program, which can predict and evaluate the postoperative recurrence outcomes of patients with ESCC with sensitivity (81.12%), specificity (71.86%), and accuracy (76.13%); and (3) Survival analysis stratified patients into predicted low-recurrence-risk and high-recurrence-risk groups, based on the SVM model, exhibited significantly prolonged disease-free survival and a markedly lower recurrence rate compared to the predicted high-recurrence-risk group. These findings may contribute to the formulation of personalized follow-up strategies in clinical practice.

Comparison With Previous Work

Numerous models have been developed to predict the overall survival in postoperative patients with ESCC, but only a few have focused on predicting postoperative recurrence, and their predictive accuracy remains low. Many models, such as logistic

XSL•FO
RenderX

regression, decision trees, and random forests, are better suited for large cohort studies. By contrast, the SVM model is suitable for small cohorts that can be independently assigned to 3 groups: 1 test group and 2 verification groups. These groups can be randomly assigned, internally, to assess the practical value of the model. This study was conducted in accordance with the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines, which provide guidance for transparently reporting studies that develop, validate, or update diagnostic or prognostic prediction models using clustered data [8]. We developed a model to predict postoperative recurrence based on perioperative data, which we deem essential for improving the overall survival rate of patients with ESCC. Surgical method, duration of surgery, and intraoperative blood loss were not identified as risk factors for postoperative recurrence. Considering the single-center study design and that intraoperative indicators are influenced by the experience and skill level of the surgeon, differences in the duration of surgery and intraoperative blood loss were relatively small, resulting in minimal impact on postoperative recurrence. As the prognostic significance of preoperative blood tests (inflammatory and tumor markers), postoperative pathological stage, and degree of differentiation in patients with ESCC has been previously confirmed [5], we included these indicators into the SVM model. The optimal combination was continuously screened to predict the risk of recurrence of postoperative patients with ESCC to provide guidance for surgical evaluation.

Strengths and Limitations

Esophagectomy is currently the ideal treatment for patients with ESCC. However, because of the complexity, extensive trauma, and prolonged duration of the surgery, patients experience physiological stress and a high incidence of postoperative complications [24], including anastomotic fistula, pulmonary infection, and respiratory failure. Because of swallowing difficulties and tumor-related metabolic consumption, malnutrition is commonly observed among patients with ESCC. Furthermore, the heightened stress response increases inflammation, weakens the immune system, and impairs tissue repair. Accordingly, reducing surgical risks and improving patient prognosis are crucial. In this study, we analyzed inflammatory indicators and identified NLR, P-CRP, GPS, and CPR as risk factors for postoperative ESCC recurrence [16-20]. Tumor markers are key factors influencing postoperative survival. The results also showed that SCC and CY211 were risk factors for postoperative ESCC recurrence. Additionally, age, ECOG [26], NLR, CPR, TNM stage, and complications were identified as independent risk factors. Our study has the following strengths. First, these prognostic factors were incorporated into an SVM learning model to determine an optimal combination that can be integrated into an artificial intelligence model [27] for a comprehensive evaluation of patient status and prognosis, thereby improving clinical practice. Second, the two validation cohorts further confirmed the model's accuracy and generalizability. However, this study has some limitations. First, as a retrospective study, it is subject to selection bias. This study's primary limitation involves potential selection bias from excluding patients lost to follow-up. We addressed this limitation by expanding our sample size, which minimized attrition effects and maintained adequate statistical power for robust conclusions. Second, given the extended follow-up period of this study, new postoperative adjuvant therapies have emerged in clinical practice. Our team has now updated the dataset with recently collected information from esophageal cancer surgery patients, which will enable further in-depth analysis. Finally, the sample size in this study was limited, including only retrospective data from a single health care institution, and randomized validation of the SVM model helps address the limitations of single-center data. However, external validation remains a critical step in ensuring the reliability, generalizability, and clinical applicability of research findings, even in studies with large sample sizes. Despite the advantages of a larger cohort, issues such as overfitting, selection bias, or dataset-specific artifacts may still arise. Thus, to further enhance its clinical usability, we plan to implement this predictive model across multiple hospitals.

Future Directions

In this study, we used the SVM model and analyzed the ROC curve to qualitatively and quantitatively evaluate the predictive ability of the model. In addition, a nomogram was generated to evaluate the DFS of patients with ESCC. Subsequently, treatment plans were adopted based on the predicted high- and low-risk of recurrence. Differences between the high- and low-risk groups guided individualized medical treatments, such as personalized surgical planning (or appropriate surgical procedures), optimization of radiotherapy and chemotherapy dosage and timing, and selection of appropriate follow-up intervals. Patients in the high-risk group for postoperative recurrence should undergo enhanced follow-up with close monitoring through gastroscopy, histopathological examination, and imaging studies. By contrast, follow-up schedules for the low-risk group should be based on blood test results to ensure appropriate monitoring. The development of this artificial intelligence model enables early prediction of postoperative recurrence risk in patients with ESCC while facilitating the generation of personalized medical plans, such as optimized postoperative radiotherapy and chemotherapy regimens as well as reasonable follow-up schedules [28]. By reducing unnecessary postoperative examinations, this model enhances the efficiency of follow-up care. It is particularly well-suited for use in towns and community health care settings to assist local medical practitioners in accurately assessing patient status, reducing the rate of recurrence of postoperative ESCC, and improving the 5-year survival rate.

Conclusion

Age, ECOG performance status, NLR, CPR, TNM, and complications were identified as independent risk factors for postoperative ESCC recurrence. These factors, which affect patient prognosis, were incorporated into the SVM learning model to determine the optimal risk-predictive combination. This model, integrated with an artificial intelligence model, provides a comprehensive assessment of patient status and prognosis, assisting the development of follow-up treatment plans.

Abstract

Background: The application of natural language processing in medicine has increased significantly, including tasks such as information extraction and classification. Natural language processing plays a crucial role in structuring free-form radiology reports, facilitating the interpretation of textual content, and enhancing data utility through clustering techniques. Clustering allows for the identification of similar lesions and disease patterns across a broad dataset, making it useful for aggregating information and discovering new insights in medical imaging. However, most publicly available medical datasets are in English, with limited resources in other languages. This scarcity poses a challenge for development of models geared toward non-English downstream tasks.

Objective: This study aimed to develop and evaluate an algorithm that uses large language models (LLMs) to extract information from Japanese lung cancer radiology reports and perform clustering analysis. The effectiveness of this approach was assessed and compared with previous supervised methods.

Methods: This study employed the MedTxt-RR dataset, comprising 135 Japanese radiology reports from 9 radiologists who interpreted the computed tomography images of 15 lung cancer patients obtained from Radiopaedia. Previously used in the NTCIR-16 (NII Testbeds and Community for Information Access Research) shared task for clustering performance competition, this dataset was ideal for comparing the clustering ability of our algorithm with those of previous methods. The dataset was split into 8 cases for development and 7 for testing, respectively. The study's approach involved using the LLM to extract information pertinent to lung cancer findings and transforming it into numeric features for clustering, using the K-means method. Performance was evaluated using 135 reports for information extraction accuracy and 63 test reports for clustering performance. This study focused on the accuracy of automated systems for extracting tumor size, location, and laterality from clinical reports. The clustering performance was evaluated using normalized mutual information, adjusted mutual information , and the Fowlkes-Mallows index for both the development and test data.

Results: The tumor size was accurately identified in 99 out of 135 reports (73.3%), with errors in 36 reports (26.7%), primarily due to missing or incorrect size information. Tumor location and laterality were identified with greater accuracy in 112 out of 135 reports (83%); however, 23 reports (17%) contained errors mainly due to empty values or incorrect data. Clustering performance of the test data yielded an normalized mutual information of 0.6414, adjusted mutual information of 0.5598, and Fowlkes-Mallows index of 0.5354. The proposed method demonstrated superior performance across all evaluation metrics compared to previous methods.

Conclusions: The unsupervised LLM approach surpassed the existing supervised methods in clustering Japanese radiology reports. These findings suggest that LLMs hold promise for extracting information from radiology reports and integrating it into disease-specific knowledge structures.

Introduction

Natural language processing (NLP) is vital in medicine as it allows the interpretation of textual content in medical documents. Radiology reports, written as free text by experienced radiologists, contain detailed information about medical imaging findings. While medical images are valuable, text-based analysis offers unique advantages in terms of computational efficiency and the ability to capture expert interpretations and observations of radiologists that may not be immediately apparent from images. Natural language processing can effectively extract this information, enhance its utilization, and provide new insights into medical imaging.

Advances in radiological NLP applications are driven by the availability of large datasets [1]. For example, the MIMIC Chest X-ray (MIMIC-CXR) includes more than 200,000 images, English-language reports, and structured data [2]. Numerous NLP models have been developed to summarize and extract clinical entities [3,4]. However, the availability of these datasets in languages other than English is limited.

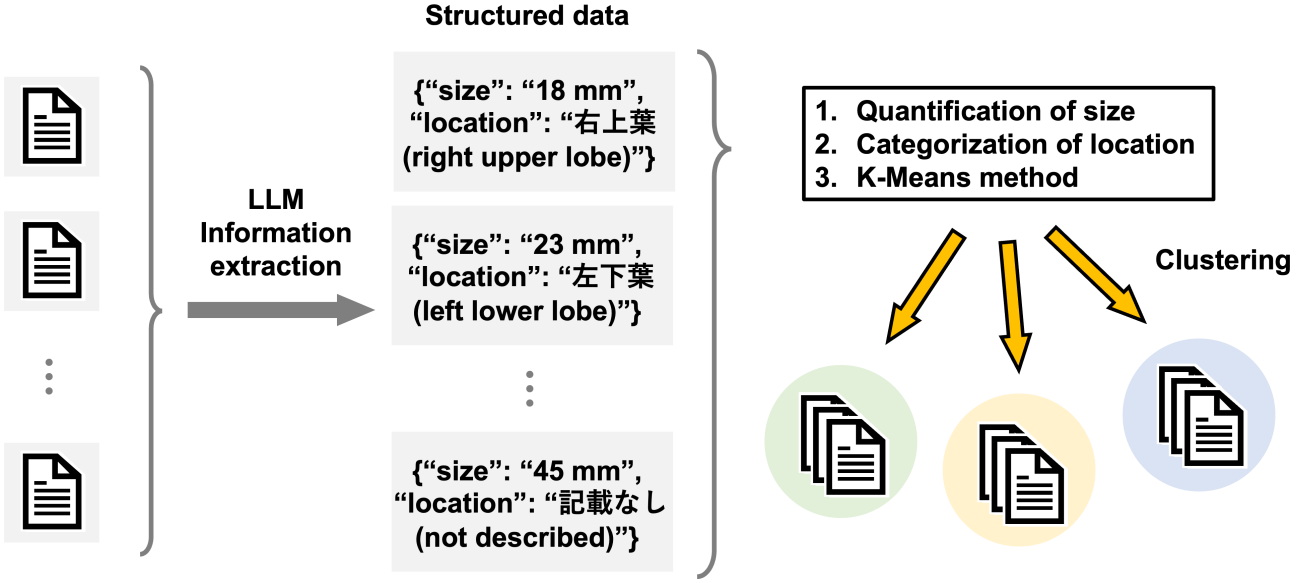
To address this challenge, the NTCIR-16 Real-MedNLP shared task focused on clustering Japanese radiology reports by case basis. It is a set of Japanese radiology reports authored by different radiologists for the same case series of lung cancer, and the task was to cluster reports that describe the same medical case together [5]. This benchmark evaluates the detailed understanding of radiology reports, as NLP systems must extract sufficient information to recognize reports by diagnosing the same image without being affected by different writing styles.

Clustering is a powerful analytical tool in medicine and has been successfully applied in various clinical domains. Studies have demonstrated its effectiveness in clustering patients based on their clinical characteristics to guide medical decisions, ranging from cancer aftercare planning to pulmonary embolism risk assessment [6,7]. Semantic grouping has enabled efficient insight discovery in medical documents [8] and revealed specialty-specific sublanguages in clinical narratives [9]. Radiology reports are particularly suited for such analyses, as they provide high-quality annotated data despite their free-form nature, offering a more tractable alternative to direct image analysis.

While the participants in the NTCIR-16 (NII Testbeds and Community for Information Access Research) shared task used deep-learning models, their clustering performance was constrained by limited training data. Since then, large language models (LLMs) trained on extensive text corpora, such as ChatGPT and LLaMA [10,11], have emerged. These LLMs, which are adaptable to new tasks with minimal instructions or examples, have demonstrated high performance in extracting information from medical documents, even under zero-shot conditions [12].

This study aimed to evaluate the ability of LLM to understand real radiological reports through an information extraction task and apply this information to clustering, which is a clinically meaningful task.

Methods



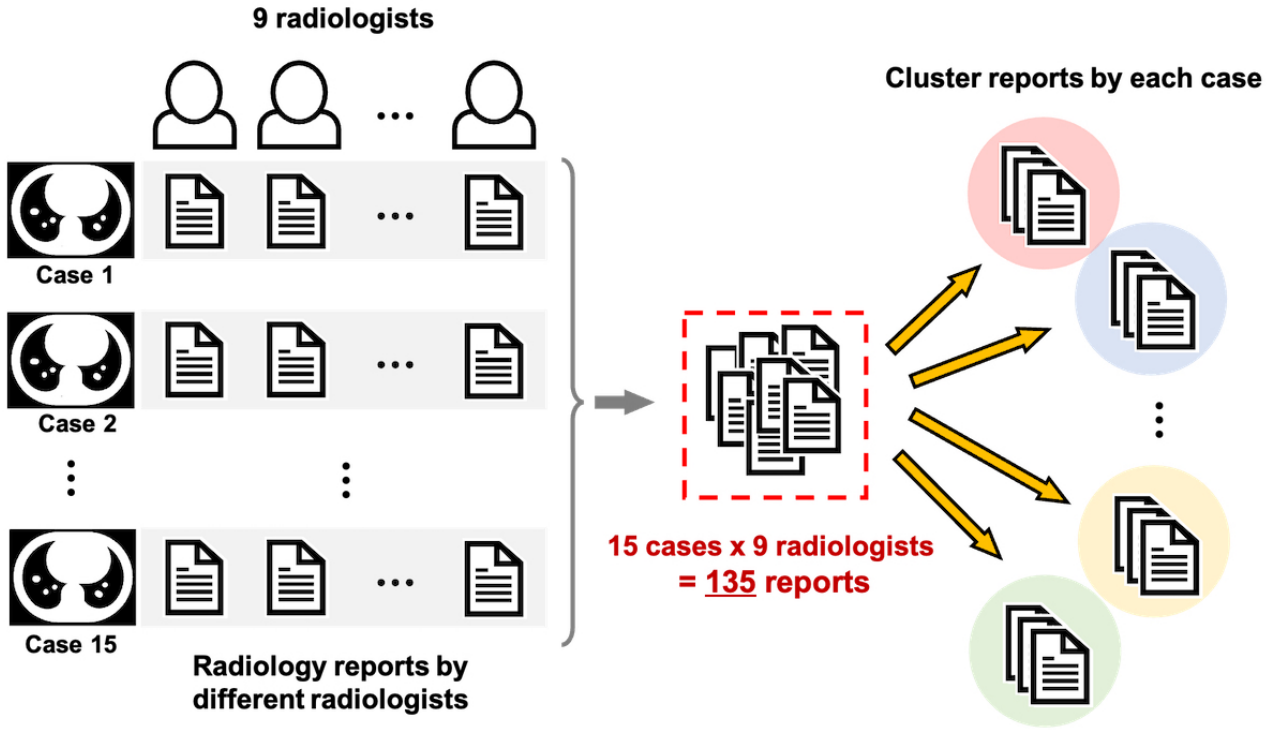
Study Design and Reporting Guidelines

This retrospective observational study followed the relevant items of the checklist for Artificial Intelligence in medical imaging (CLAIM) guidelines for methodology reporting [13,14]. Although this study analyzed text rather than images, CLAIM was followed because it is an established guideline for AI-based research in radiology and is deemed appropriate for NLP [15-17].

Algorithm Overview

The proposed algorithm is illustrated in Figure 1. Using the LLM, key lung cancer findings were extracted from radiology reports and quantified to obtain structured data. The structured data were subsequently used for clustering.

Figure 1. Flowchart of radiology reports clustering using LLM. LLM: large language model.



XSL•FO
RenderX

Dataset

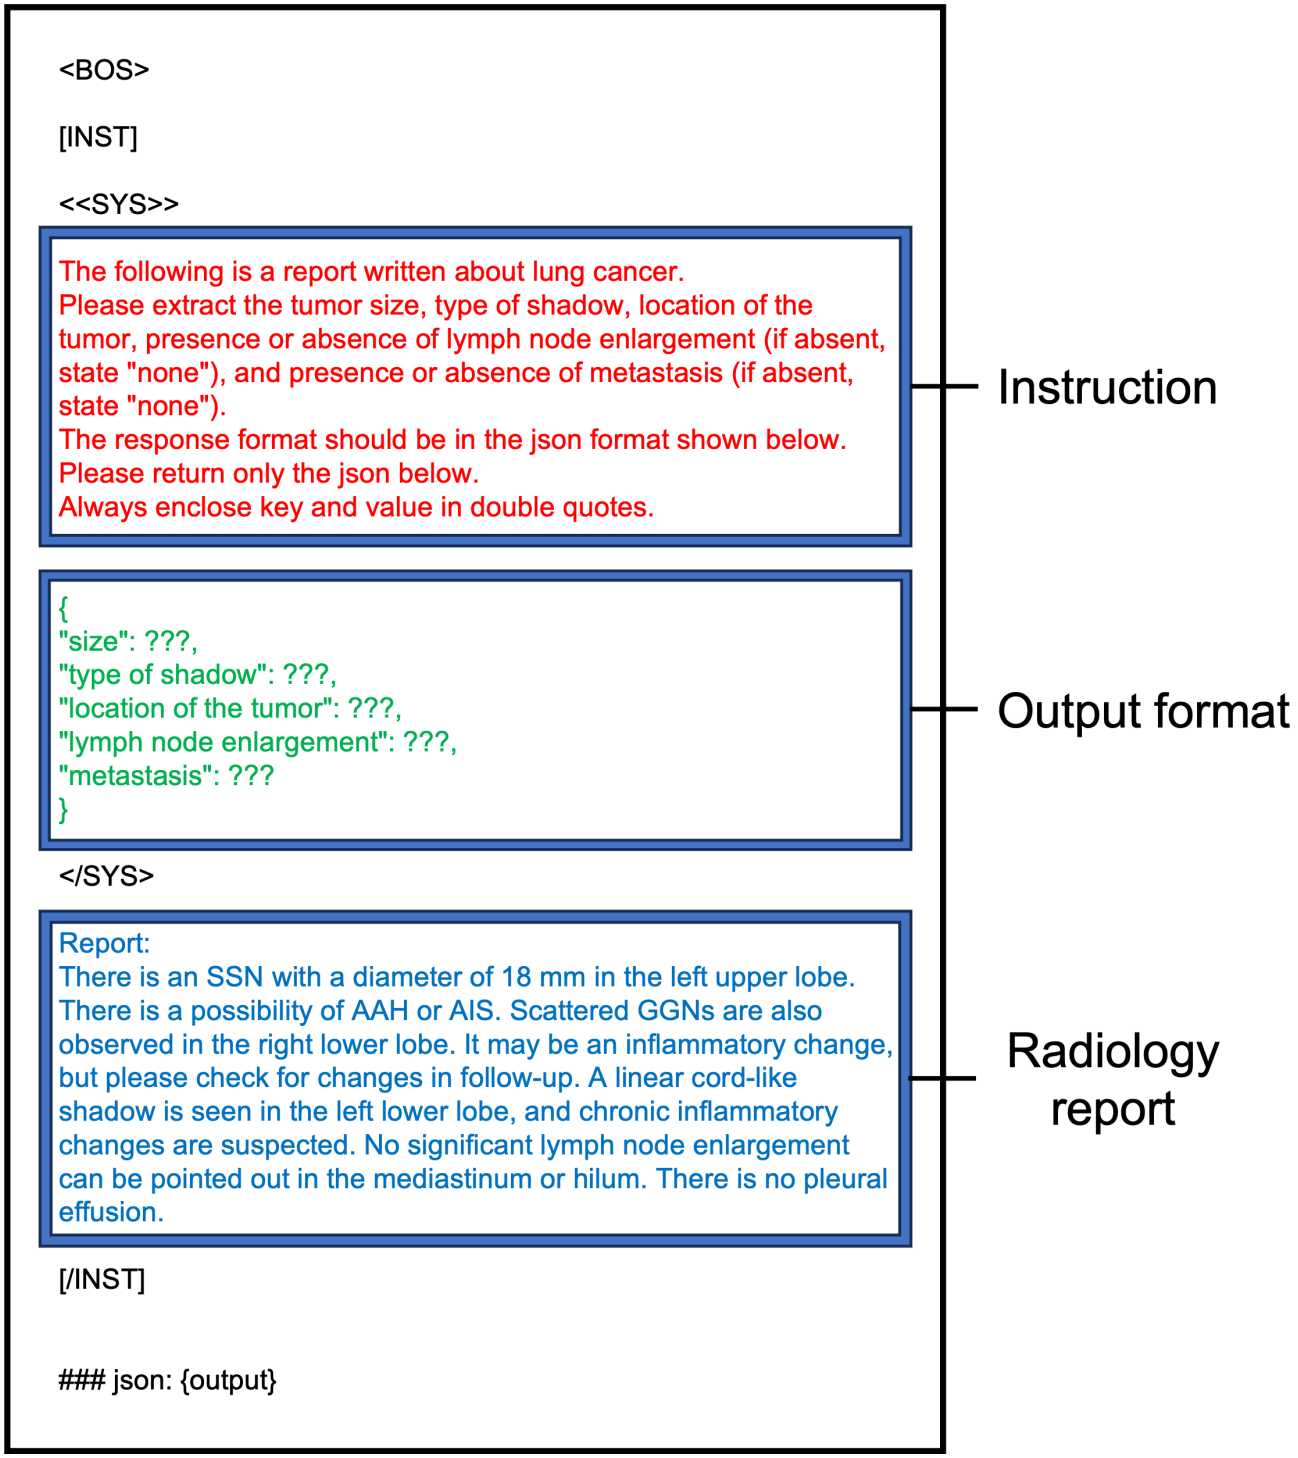
The MedTxt-RR dataset was used in this study [5,18], comprising 135 Japanese radiology reports generated by 9 radiologists who interpreted CT images of 15 lung cancer cases sourced from Radiopaedia [19]. This dataset was used in an NTCIR-16 shared task [5], where participants competed to achieve optimal clustering performance. With each case comprising reports from 9 radiologists, the dataset was suitable for evaluating the clustering performance on a per-case (Figure 2). Eight cases and seven cases were assigned to the development and test sets, respectively. While no model training was conducted using the development set in this study, performance was evaluated on the same data split to facilitate comparison with the shared task results.

Figure 2. Overview diagram of the radiology report clustering task.

LLM Approach

Radiology reports contain confidential patient information; processing them using a cloud-based LLM, such as ChatGPT, could expose sensitive data externally, raising significant medical safety concerns. Therefore, a publicly available offline model was selected as an alternative approach.

The ELYZA-Japanese-Llama-2-7b-fast-instruct model was employed as the LLM [20]. Adapted from Llama2 and pre-trained using Japanese datasets, this model demonstrated a performance comparable to that of GPT-3.5 on Japanese datasets [21-23].



Information Extraction

The LLM extracted multiple lung cancer staging parameters from radiology reports, including tumor size, tumor location, and the presence or absence of lymph node enlargement, suggesting metastasis and distant metastasis. To determine the optimal combination of features, clustering performance of the development set were repeatedly measured by using certain features. Consequently, sufficient clustering performance was confirmed achievable using only 3 parameters: tumor size, laterality (left or right), and lung location (upper, hilum, or lower region).

The prompt input into the LLM comprises system instructions and output format guidelines using json (JavaScript Object Notation), a standardized text-based format for structured information exchange, where data is organized in key-value pairs, such as {“size”: “45 mm,” “location”: “right upper lobe”}. These system instructions guided the LLM in extracting features from the radiology reports. The details of these prompts are shown in Figure 3 (English version) and Figure S1 in Multimedia Appendix 1 (original Japanese version).

XSL•FO
RenderX

Figure 3. Example of a prompt used as input for the LLM (English translated version). AAH: Atypical Adenomatous Hyperplasia; AIS: Adenocarcinoma in situ; GGN: Ground Glass Nodule; LLM: large language model; SSN: Subsolid Nodule.

The extracted data were converted into integer vectors comprising the tumor size and other categorical values. Unspecified tumor sizes only described as *large* were replaced with 71 mm, corresponding to the highest category in T classification, where T represents tumor categories in cancer staging. The details of this pipeline can be found in the GitHub Repository [24].

Moreover, a rule-based method was employed as the baseline approach and its performance was compared with that of the proposed method. The rule-based method performs context-sensitive word-based information extraction; the detailed algorithm is shown in Figure S2 in Multimedia Appendix 1.

Clustering

The resulting numerical matrices were clustered using the K-means algorithm in the scikit-learn library (version 1.3.1). The number of clusters was set to 8, aligning with expected classifications such as disease type or staging, since it was close to the number of test data cases. Centroid initialization used the k-means++ method, with default values for the centroid seed

XSL•FO
RenderX

and iteration count, because hyperparameter tuning was not conducted in this zero-shot study.

Information Extraction Evaluation

Two independent radiologists, a radiology resident with 1-year experience and a board-certified radiologist with 7 years of experience evaluated the accuracy of extracted information. In cases of discrepancy, the final assessment was determined by consensus. Evaluation focused on three key elements: tumor size, location (upper, hilum, or lower), and laterality (left or right). The performance of the LLM-based approach was compared to that of the rule-based method for information extraction. A detailed error analysis was conducted for cases with errors, categorizing them into missing information, false information generation, and extraction of multiple values.

McNemar's test was performed using Statsmodels (version 0.14.2) [25] to compare performance differences between the LLM-based and rule-based approaches for extracting tumor size and location.

Clustering Performance Evaluation

We assessed clustering performance using three metrics similar to those used in the shared task [5]: (1) normalized mutual information (NMI) that quantifies the mutual dependence between two clusters, normalized to a 0‐1 scale, with 1 indicating perfect clustering; (2) adjusted mutual information (AMI) which is an adjustment that corrects for NMI, accounting for its tendency to increase with the number of clusters; (3) Fowlkes-Mallows index (FM) that measures the similarity between two clusters by calculating the geometric mean of precision and recall, providing a balanced assessment of clustering accuracy.

Ethics Consideration

This study involved analysis of human subject data from publicly available radiology reports. All data were completely de-identified and accessible through MedTxt-RR [26]. In accordance with our institution's policy on research ethics, studies using exclusively de-identified, public datasets are exempt from institutional review board approval [27]. No additional privacy or confidentiality measures were required as the dataset contains no personally identifiable information, with all protected health information having been removed prior to public release.

Results

Information Extraction Performance

The details of the findings targeted at information extraction are summarized in Table 1 . The tumor size was correctly identified in 99 (73.3%) of 135 reports. Among the 36 outputs (26.7%) with errors, 23 (17%) lacked size information in their reports, and 22 (16.3%) contained false size information. The remaining errors were attributed to size inaccuracies or empty values despite size information being mentioned in the reports. Tumor location and laterality were accurately identified in 112 (83%) reports. All 23 (17%) reports with errors contained the necessary information but had empty values for laterality, location, or both, with one output indicating an incorrect location. The detailed error analysis is presented in Table 2.

Table . Summary of lung cancer cases.

Case no.	Side	Lobe	Size (mm)	Lymph node metastasis	Distant metastasis	Data split
Case 1	Left	Upper	18	No	No	Development
Case 2	Right	Lower	12	No	No	Development
Case 3	Left	Upper	28	No	No	Development
Case 4	Left	Upper	40	No	No	Test
Case 5	Left	Upper	48	Yes	No	Test
Case 6	Right	Hilum	Not measurable (due to invasion)	Yes	No	Development
Case 7	Right	Lower	55	Yes	No	Test
Case 8	Left	Upper	Not measurable (due to invasion)	No	No	Test
Case 9	Right	Hilum	43	No	Yes	Development
Case 10	Right	Upper	Not measurable (due to invasion)	No	No	Test
Case 11	Right	Upper	Not measurable (due to invasion)	No	No	Development
Case 12	Right	Lower	Not measurable (due to lung metastasis)	No	Yes	Development
Case 13	Left	Lower	78	Yes	No	Development
Case 14	Left	Upper	85	Yes	No	Test
Case 15	Left	Upper	Not measurable (due to invasion)	Yes	Yes	Test

Table . Detailed error analysis of tumor size, location, and laterality extraction from radiology reports using large language model (LLM) and rule-based methods.

Category	Extraction methods	
	LLM[a], n (%)	Rule-based, n (%)
Tumor size (details)		
Correctly identified	99 (73.3)	93 (68.9)
Errors (total)	36 (26.7)	42 (31.1)
Errors (no size information in reports)	23 (17)	0 (0)
False size information generated	22 (16.3)	0 (0)
T classification extracted instead of size	1 (0.7)	0 (0)
Errors (size mentioned in reports)	13 (9.6)	42 (31.1)
Size inaccuracies	8 (5.9)	3 (2.2)
Empty values	5 (3.7)	39 (28.9)
Tumor location and laterality (details)		
Accurately reported	112 (83)	46 (34.1)
Errors (total)	23 (17)	89 (65.9)
Empty values for laterality	9 (6.7)	0 (0)
Empty values for location	5 (3.7)	0 (0)
Empty values for both	8 (5.9)	80 (59.3)
Incorrect location	1 (0.7)	9 (6.7)

[a]LLM: large language model

XSL•FO
RenderX

The rule-based method correctly identified tumor size in 93 (68.9%) reports, whereas tumor location and laterality were accurately identified in only 46 (34.1%) reports. Among the errors in this method, only 1 case (0.7%) failed to accurately extract size information due to the extraction of multiple sizes. In contrast, for location, the number of errors reached 47 (34.8%) (Figure S3 in Multimedia Appendix 1). Unlike the LLM approach, due to the algorithmic nature of rule-based extraction, there were no cases of false-size information generation. Additionally, as the algorithm extracted laterality and location simultaneously as a single unit, there were no cases where only one of these values was empty; both were either extracted together or left empty.

McNemar's test showed that the LLM approach was significantly superior to the rule-based method in determining location (P<.001) but not size (P=.539).

Clustering Performance

The development data yielded an NMI score of 0.7152, an AMI score of 0.6516, and an FM index of 0.5959, whereas the test data yielded scores of 0.6414 (NMI), 0.5598 (AMI), and 0.5354 (FM).

The proposed method outperformed all previous methods in shared tasks across all evaluation metrics. The detailed results and methods are listed in Table 3. Further details of each method are available in a system paper describing this shared task [28-31].

Table . Clustering scores on the test data.

Method Description (System ID[a])	NMI[b]	AMI[c]	FM[d]	Supervised model	LLM[e]
Developed a matrix from word count in radiology reports and applied user-based collaborative filtering for case similarity and clustering, (D1) [28]	0.3569	0.1988	0.2674	No	No
Used paired radiology reports for BERT[f] input, fine-tuned for same-case identification and clustered based on predictions, (E1) [29]	0.5415	0.1489	0.1814	Yes	No
Generated embeddings from text via multilingual BERT trained on Wikipedia, followed by dimensionality reduction, and K-means clustering, (F1) [30]	0.1744	–0.0117	0.1170	No	No
Labels simplified from the TNM[g] classification of lung cancer were assigned to each document using BERT-based model for training, and in the test data, these predicted labels were used as groups for clustering, (J1) [31]	0.4622	0.3409	0.3622	Yes	No
This study	0.6414	0.5598	0.5354	No	Yes

[a]The System IDs are those used in previously shared tasks with the same dataset [5].

Discussion

Principal Findings

The extraction of lung tumor size showed minimal differences compared to the rule-based method, likely because size information is typically accompanied by standardized units (eg, mm or cm). However, the LLM method significantly outperformed the rule-based method in terms of location extraction, achieving over 80% accuracy and reducing the error rate by half. As demonstrated in Figure S3 in Multimedia Appendix 1, the rule-based method frequently generated multiple incorrect location extractions when reports mentioned various anatomical sites, whereas the LLM method successfully identified the correct tumor location. This finding empirically demonstrates the LLM's ability to understand and extract information based on context rather than predefined rules. This capability highlights its value for complex information extraction tasks in medical text analysis, where contextual understanding is crucial.

Comparison to Prior Work

This paper introduces a Japanese LLM algorithm for zero-shot information extraction and clustering that outperforms all previous methods [28-31]. The previous methods (E1, F1, and J1) relied on indirect features extracted by language models, whereas the current approach leverages accurate information extraction through unsupervised learning. The success of this method is particularly notable, given the historically low accuracy of unsupervised methods. By leveraging the LLM's contextual understanding of information extraction, this study demonstrated the potential for effective clustering of medical reports based on various attributes, including disease severity and lesion localization.

Strengths and Limitations

This study has several notable strengths including its methodology and implementation. Accurate information extraction and clustering without supervised learning requirements represent a significant advancement in the field. The flexibility of this method through prompt and algorithmic adjustments suggests broad potential applicability, with potential for further performance improvements through prompt optimization [32]. Furthermore, this method shows particular promise for languages with limited training data compared to English, by converting unstructured reports into language-independent structured data, thereby addressing a crucial gap in current medical text analysis.

However, the limitations must be acknowledged. First, validation was limited to small-scale Japanese datasets. While attempts were made to ensure the representativeness of the dataset by including diverse types of lung cancer cases, this limitation constrained the generalizability of the study findings and should be addressed in future studies through multi-institutional validation. Second, the evaluation focused primarily on clustering tasks; which although is a fundamental task in medical text analysis, its performance in other analytical tasks remains unexplored, suggesting the need for a comprehensive evaluation across various applications. Third, while this method shows promise for languages with limited training data, its generalizability to other languages and medical domains requires further investigation.

Conclusions

The LLM was used to successfully extract important findings from publicly available Japanese radiology reports as highly accurate structured data. By leveraging these structured data, superior results were achieved compared to existing supervised methods for clustering radiology reports. This indicates that employing existing LLMs is effective for solving specific tasks, particularly in languages with a significant shortage of training data compared to English.

Acknowledgments

Prior to submission, the initial draft was edited using ChatGPT by OpenAI for English language improvement, followed by professional editing by Editage. This study did not receive any specific grants from funding agencies in the public, commercial, or non-profit sectors.

Data Availability

The MedTxt-RR training dataset is openly accessible and downloadable via an official website [26]. Access to the test dataset requires approval and can be obtained by directly contacting the data providers.

Abstract

Background: Defining optimal adjuvant therapeutic strategies for older adult patients with breast cancer remains a challenge, given that this population is often overlooked and underserved in clinical research and decision-making tools.

Objectives: This study aimed to develop a prognostic and treatment guidance tool tailored to older adult patients using artificial intelligence (AI) and a combination of clinical and biological features.

Methods: A retrospective analysis was conducted on data from women aged 70+ years with HER2-negative early-stage breast cancer treated at the French Léon Bérard Cancer Center between 1997 and 2016. Manifold learning and machine learning algorithms were applied to uncover complex data relationships and develop predictive models. Predictors included age, BMI, comorbidities, hemoglobin levels, lymphocyte counts, hormone receptor status, Scarff-Bloom-Richardson grade, tumor size, and lymph node involvement. The dimension reduction technique PaCMAP was used to map patient profiles into a 3D space, allowing comparison with similar cases to estimate prognoses and potential treatment benefits.

Results: Out of 1229 initial patients, 793 were included after data refinement. The selected predictors demonstrated high predictive efficacy for 5-year mortality, with mean area under the curve scores of 0.81 for Random Forest Classification and 0.76 for Support Vector Classifier. The tool categorized patients into prognostic clusters and enabled the estimation of treatment outcomes, such as chemotherapy benefits. Unlike traditional models that focus on isolated factors, this AI-based approach integrates multiple clinical and biological features to generate a comprehensive biomedical profile.

Conclusions: This study introduces a novel AI-driven prognostic tool for older adult patients with breast cancer, enhancing treatment guidance by leveraging advanced machine learning techniques. The model provides a more nuanced understanding of disease dynamics and therapeutic strategies, emphasizing the importance of personalized oncology care.

Introduction

Breast cancer is more commonly diagnosed in older populations, particularly among women aged 65 years and older in wealthier countries. In the United States, the average age of breast cancer diagnosis is 62 years, and in 2020, women aged 70 years and older accounted for 30% of all new cases of the disease [1,2]. In the European Union, women older than 65 years made up about 44% of all breast cancer cases [3]. However, treatment approaches for early-stage breast cancer in these older age groups are often inadequate and unclear, largely due to a lack of solid evidence and the unreliability of web-based tools for making decisions about additional therapies, leading to less than ideal treatment outcomes [4,5].

The treatment plan for breast cancer is tailored based on the cancer's characteristics, the patients' overall health status, and their personal preferences. Standard care for early-stage breast cancer usually involves surgery, and may also include radiation, as well as neoadjuvant or adjuvant systemic therapy, used alone or in various combinations. Crafting postsurgical treatment strategies for older patients with breast cancer is complex due to their typically compromised health and the lack of data from

XSL•FO
RenderX

clinical trials, since older adults are seldom participants in such studies and are not well represented in meta-analyses that evaluate the effectiveness of adjuvant chemotherapy in reducing breast cancer mortality and improving survival rates [6,7]. Consequently, artificial intelligence (AI) has been investigated as a potential tool to support decision-making in the context of limited clinical trial evidence.

Early uses of AI in cancer treatment guidance involved knowledge-based systems [8,9]. Recently, a broader spectrum of machine learning methods has been examined to aid both clinicians and patients with breast cancer [10-15]. Nonetheless, most decision support tools are designed for patients aged between 18 and 65 years, reflecting the age group most studied, with limited research focusing on treatment outcomes for older patients with breast cancer [16-19]. The prognostic tool PREDICT [20], although popular, has shown limited effectiveness for older adult patients [21]. Adjutorium [22], which uses extensive datasets from the United Kingdom and the United States, provides more precise prognosis and treatment benefit predictions for breast cancer than PREDICT. Despite this, it primarily includes patients aged between 30 and 65 years, with fewer older patients in its datasets, and omits certain vital tumor information such as progesterone receptor (PR) status [19]. Another established tool, Adjuvant! Online, predicts 10-year overall survival, breast cancer survival, and recurrence rates, commonly used to inform expected outcomes from endocrine therapy and chemotherapy [23]. Its accuracy is questionable for older women with early-stage breast cancer, probably because it was trained on data with a maximum age limit of 69 years [24]. In a review by Engelhardt et al [25], various models could forecast breast cancer outcomes, typically based on genetic risk scores, but only Adjuvant! Online factored in comorbidity status. Yet, none had been thoroughly validated in older adult populations. The more recent PORTRET tool was designed to predict 5-year recurrence, overall mortality, and mortality from other causes in patients older than 65 years with early invasive breast cancer, as well as to estimate the benefits of adjuvant systemic treatment [26]. The tool's authors observed that their treatment effect estimates were based on data from pooled randomized clinical trials, which might not be entirely applicable to older adults due to the typically selective nature of older participants in these trials.

This study aims to develop models that overcome the shortcomings of past research by using cohorts that accurately reflect the demographic of older patients with breast cancer and by leveraging a detailed dataset that includes administrative, biological, treatment, primary tumor, and survival information. Our latest research uses manifold learning, an advanced tool for nonlinear dimensionality reduction that excels in unraveling complex geometric relationships within high-dimensional data, revealing intricate connections between clinical factors.

We introduce a new prognostic and predictive tool tailored for older adult patients with breast cancer, providing postoperative treatment recommendations. This tool is distinctive in its consideration of the interdependencies among variables within a patient population. It acknowledges the relative importance of prognostic factors in a way that many existing models do not. Our findings are set to be extremely beneficial for oncologists when determining suitable adjuvant treatment approaches for older adult patients with breast cancer, taking into account the nuances of both tumor-related and patient-specific characteristics.

Methods

Recruitment

In this retrospective study, we examined pseudonymized data from women aged 70 years and older who received a diagnosis of early-stage breast cancer and underwent surgery with the intent to cure (either lumpectomy or mastectomy, with or without axillary lymph node dissection) at the French Léon Bérard Cancer Center from January 1997 to December 2016. The French Léon Bérard Cancer Center is a 300-bed comprehensive cancer center located in Lyon, France, serving more than 30,000 patients annually, with a multidisciplinary team of 2000 health care professionals and a catchment area covering southeast France.

The inclusion criteria were not limited by the breast cancer's histological or molecular characteristics, the size of the tumor, or the status of the lymph nodes. However, the study did exclude patients who had noninvasive in situ carcinoma without invasive carcinoma, HER2 (human epidermal growth factor receptor 2) positive breast carcinoma, or who presented with distant metastases at the time of surgery. HER2-positive breast cancer cases were excluded because these patients typically receive trastuzumab-based targeted therapies, which dramatically improved their prognosis following its widespread adoption for nonmetastatic breast cancer around 2005. In contrast, chemotherapy protocols for HER2-negative cases remained consistent during the treatment period of the patients included in this study, ensuring uniformity in therapeutic strategies and outcomes across the cohort. The research concentrated on the 5-year survival rates, selecting only those who had at least 5 years of follow-up and whose vital status information was available.

The database was constructed using ConSore, a data-mining application developed by UNICANCER [27]. The ConSore platform extracts data from the electronic health records of the Léon Bérard Cancer Center, integrating patient demographics, clinical variables, and treatment details. To ensure accuracy, each record was also subject to a manual verification process. Data compiled included demographic details and clinical features of patients at diagnosis, alongside comprehensive biological and disease-specific information, and the treatments administered.

We included the following characteristics for patients diagnosed with early-stage breast cancer: age; Eastern Cooperative Oncology Group performance status; BMI; comorbidities such as diabetes, heart failure, coronary artery disease, chronic obstructive pulmonary disease, and cognitive impairments; history of hospitalizations; and polypharmacy. We also gathered biological indicators at the time of diagnosis, which included hemoglobin levels, lymphocyte counts, and creatinine clearance. We extracted data on disease attributes including histological subtype, hormone receptor status, HER2 status,

XSL•FO
RenderX

Scarff-Bloom-Richardson (SBR) grade, tumor count, size of the largest tumor, and the extent of lymph node involvement as per the Tumor," "Nodes," "Metastases (TNM) classification [28]. The statuses of estrogen receptors (ERs), PRs, and HER2 were determined from the histopathological analysis of pretreatment biopsies. Hormone receptor negativity was classified when fewer than 10% of cells were stained for ER and PR. HER2 negativity was assigned when immunohistochemistry staining was below 1+. For tumors scoring 2+, further in situ hybridization tests were conducted to assess HER2 amplification [29]. Treatment data collected encompassed the type of surgery performed, lymph node dissection, and adjuvant treatments including radiotherapy, chemotherapy, and endocrine therapy.

Outcome, Predictors, and Predictive Power

Outcome was overall survival in 5 years. Due to the high percentage of missing values for cause of death, cancer-specific survival was not considered. Nine predictors were selected: age, tumor size (mm), tumor grade (defined as either SBR low: 1 - 2; or high: 3), number of affected ganglions, hormone-receptor status (positive if either estrogen or PRs were immunohistochemically present in ≥10% of tumor cells; otherwise, patients were classified as triple negative), serum hemoglobin (g/dL) and lymphocyte count (G/L), BMI, and the presence of comorbidities.

The initial database, built using ConSore, compiled a range of clinical, biological, and disease-specific data, along with information on administered treatments. We aimed for a predictors representing a mixture of features typically tested before patients undergo treatment plans. Thus, we excluded features regarding treatments as (1) we wanted to gauge prediction accuracies based only on the initial testing of the patient, and (2) the efficacy of treatment strategies was also an outcome of interest in the study. We further excluded features with significant number of missing values so as to limit the loss of usable data. Creatinine was excluded due to its high correlation with patient's age and potential kidney disorders that are not uncommon in the study's demographic. The feature was found to correlate with negative patient outcome, but this was independent of cancer and introduced a bias. Following these steps, 9 predictors were isolated, a list comprising both continuous and categorical variables, as well as an acceptable mixture of relevant biological and clinical features. Random Forest Classification (RFC) and Support Vector Classifier (SVC) were used to evaluate the predictive power of the selected features. We used 5-fold cross-validation to mitigate overfitting and ensure the validity of our results.

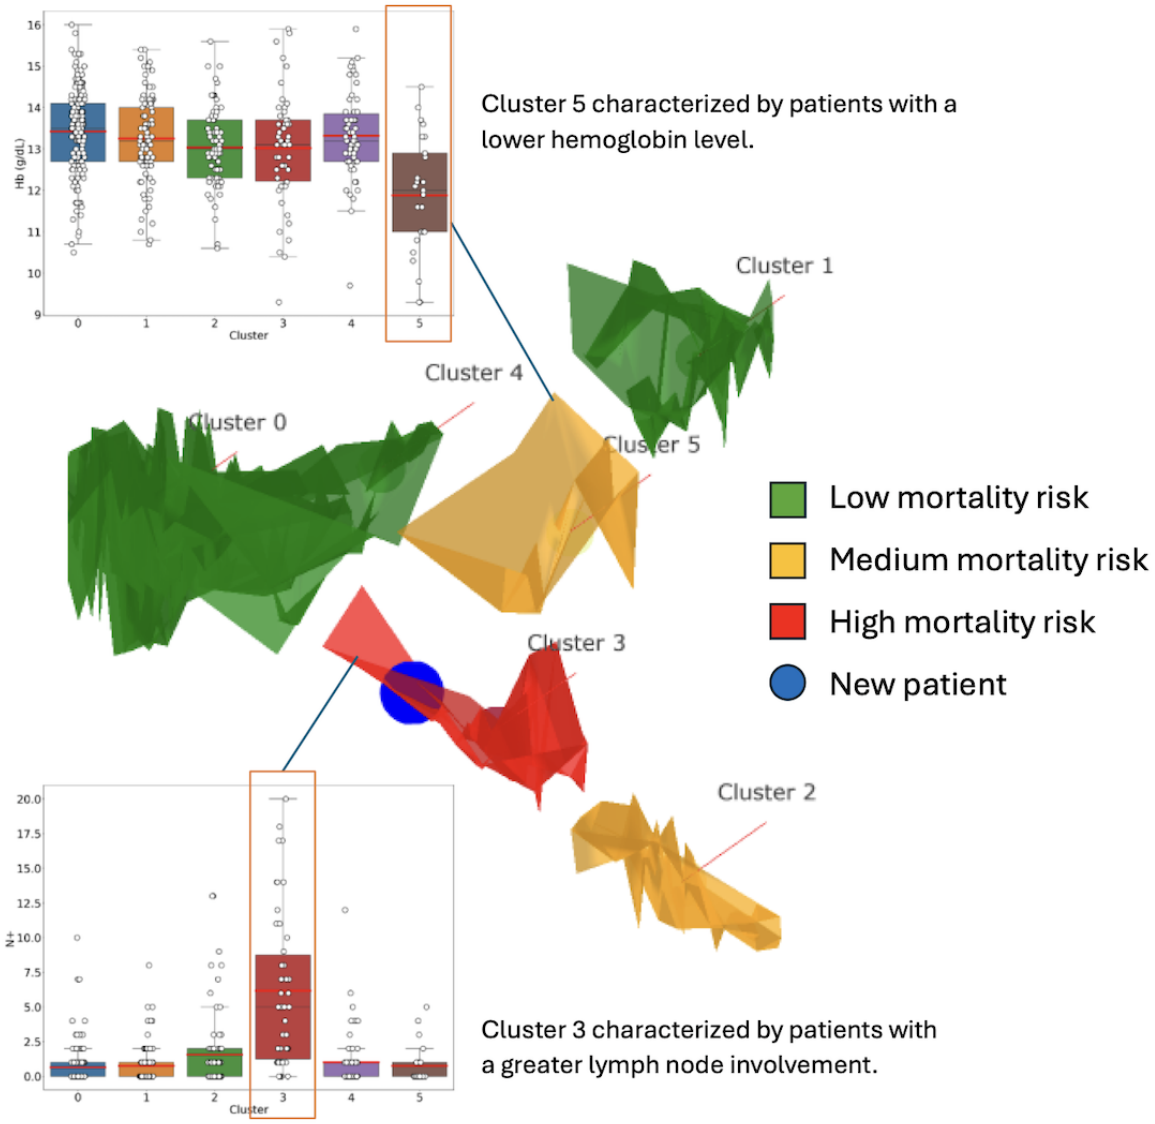
Model Development and Validation

Patients in the initial cohort with missing values for any of the 9 predictors were cut from the study. The remaining patients comprised the model development cohort. This was divided into reference and model data.

Reference Data and Digital Twins

The reference data inclusion criteria were positive outcome for survival in 5 years and remission without relapse by the last follow-up. The purpose of this group was to calibrate the our patented algorithm, generating digital twins for future test subjects. Digital twins refer to synthetic patient data derived from the reference group specifically similar in profile to a new test subject. The model uses these synthetic profiles to recognize complex variations within the test profile. Thus, digital twins are generated and used in the model to provide recommendations on a new patient but do not themselves constitute the result that a physician would need to interpret.

Model Data



The model data, distinct from the reference data to prevent data leaking, are the population that is run through the precalibrated model and scored against the reference group. The data are thus transformed from raw patient data to a numerical and standardized representation of their deviation from the reference group (their digital twins). The purpose of these transformed data is to populate the model with a range of patient profiles that will serve for future prognostic analysis.

PaCMAP, Mean-Shift Clustering, and Manifold Visualization

The transformed model data underwent dimensionality reduction using PaCMAP (Pairwise Controlled Manifold Approximation) [30] to generate 3D data referred to as a manifold, permitting easy visualization. The data were then stratified using mean-shift clustering [31], a nonparametric, density-based clustering algorithm that can be used to identify clusters in a dataset (Figure 1). Each cluster represents a local group of similar patients in the 3D space. Clusters represent typical patient profiles in the overall population. The advantage of clustering is that it captures the variability of subjects of a subgroup for easy analysis. A better understanding of the cluster and its variability allows clinicians to assess whether a new test subject aligns well with the cluster and to identify potential differences. When considering a new patient, estimates of prognosis and expected benefits of adjuvant treatment are ascertained by the examination of cluster-specific treatment outcomes pertinent to the patient's clinical profile.

XSL•FO
RenderX

Figure 1. Graphical representation of the 6 clusters of patients in the 3D manifold space. Patients in the reduced 3D space, or manifold, were grouped into clusters by their spatial distribution and profile similarity. Clusters were then colored based on the overall mortality rate of included patients. A newly tested patient is localized on the manifold and represented by a blue sphere.

Prediction of Chemotherapy Benefit

To estimate the benefit of chemotherapy, the position of a new patient is identified within the 3D manifold. Using the K-nearest neighbors algorithm, the 15 closest chemotherapy-treated patients and the 15 nearest non–chemotherapy-treated patients are pinpointed. Kaplan-Meier (KM) survival curves were plotted for each of these patient groups, providing a visual estimation of chemotherapy benefit for a clinical profile.

Validation of Treatment Benefit Predictions With Kullback-Leibler Divergence

To validate that the distributions of the 2 treatment subgroups are comparable, we used the Probability Density Function, which describes the spread of the data points in the 3D space. To measure the difference between these distributions, we applied the symmetrized Kullback-Leibler (KL) divergence, a statistical method that quantifies how much one distribution differs from another. To assess whether the observed difference was meaningful or just due to random chance, we conducted a permutation analysis. This technique works by randomly shuffling the data multiple times to create many new random comparisons; comparing the real result with the random results allows us to determine whether the observed difference between the distributions was statistically significant. If distributions of 2 different treatment groups were found to be similar, they could be compared to provide a prediction of treatment benefit.

Model Stability Validation

The original model data were split into 2 groups: 70% (327) of every cluster was pooled into the training group, and the remaining 30% (139) was pooled into the test group. A new manifold learning process was applied to the training group, and the test group was then projected onto this newly generated manifold. Patients in the test and model groups from the same cluster of origin were compared to evaluate whether data points would exhibit similar distributions (appear in proximity to each

XSL•FO
RenderX

other) in the new manifold space across 10 different manifold initializations.

Statistical Analysis

Kullback-Leibler Divergence and Permutation Test

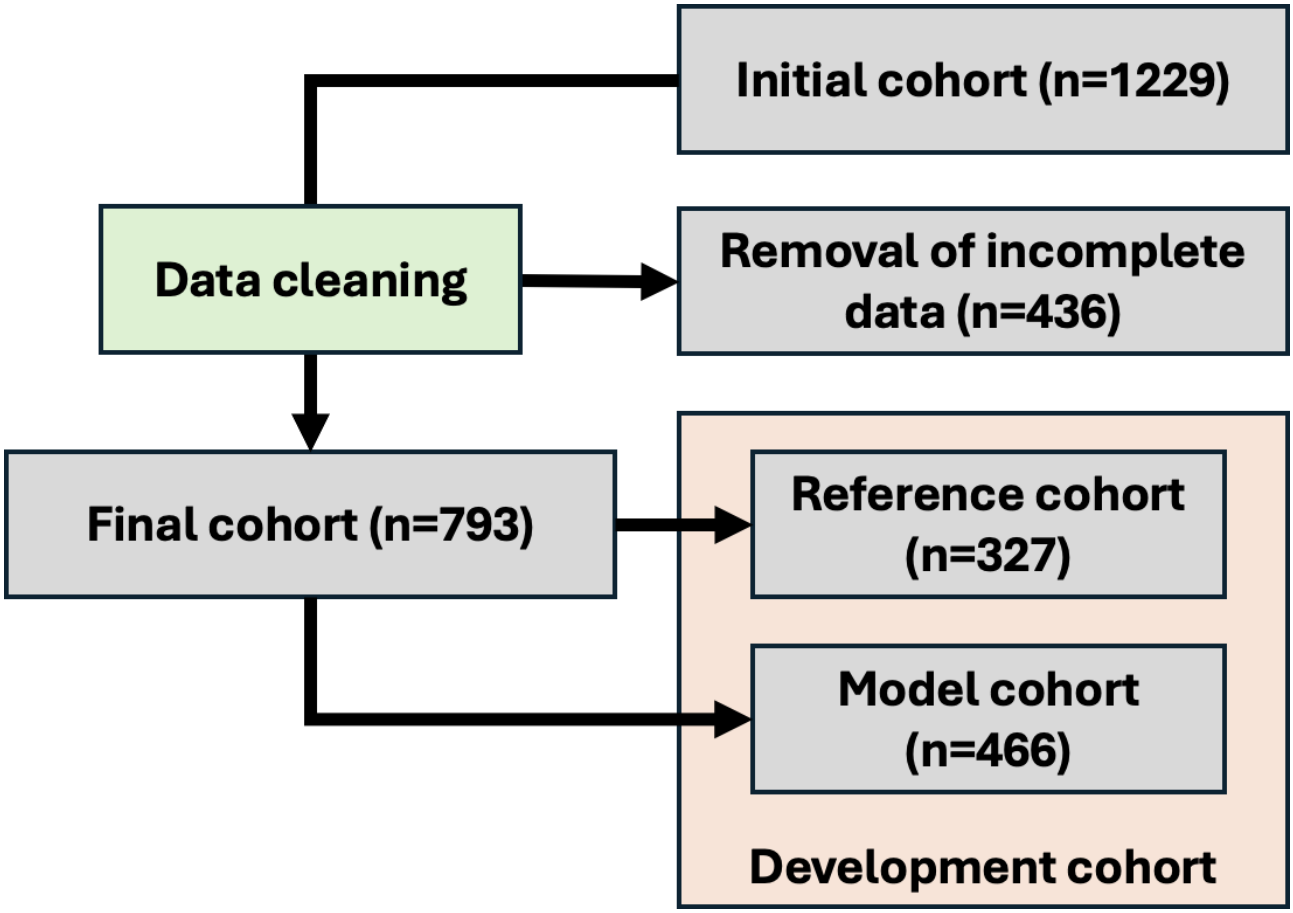
The symmetrical KL divergence was used to measure the difference between 2 probability distributions. A permutation test was subsequently conducted to assess the significance of the observed KL divergence. This involved calculating the KL divergence for a large number of permutations of the combined datasets and comparing these values with the original KL divergence. The *P* value is calculated as the proportion of permutations where the KL divergence is as extreme as, or more extreme than, the original KL divergence calculated between the actual groups, thus providing a measure of how likely it was to observe a divergence as extreme as the original, under the null hypothesis of no difference between the distributions. Mathematically, this *P* value is the ratio of the number of permuted KL divergences that are equal to the original KL divergence or greater to the total number of permutations. A low *P*-value suggests that the observed difference in distributions is unlikely to have occurred by chance, thus indicating a significant divergence between the 2 groups.

Survival Analysis using the KM Estimator and Log-Rank Test

The KM estimator was used to generate survival curves for different treatment subgroups. The log-rank test, a nonparametric test, was applied to compare the survival distributions and a *P* value was calculated to determine the statistical significance of the differences observed between the groups. A low *P* value suggests that the observed survival curves are significantly different. The statistical package used for the analysis is Lifelines 0.30.0 (Lifelines Developers) [32].

Ethical Considerations

This retrospective study involving human subjects was reviewed and approved by the French data protection authority, the Commission Nationale de l'Informatique et des Libertés, under authorization number 9191415, dated October 10, 2019. According to institutional and national guidelines, no additional approval from a research ethics board was required, as the data used were previously collected for clinical purposes. No new informed consent was required for this study. The analysis was conducted using data for which participants had provided general consent at the time of data collection. All data were pseudonymized prior to analysis to protect patient confidentiality. No identifiable personal information was retained in the research dataset. No compensation was provided to participants.



Results

Cohort Characteristics

A total of 1229 patients comprised the initial cohort. Of these, 793 (65%) remained after entries with missing values were removed (Figure 2). Eliminating the risk of introducing a bias, the initial cohorts' demographic and clinical characteristics were found to be strictly similar to that of the final cohort and are summarized in Tables 1 and 2.

RenderX

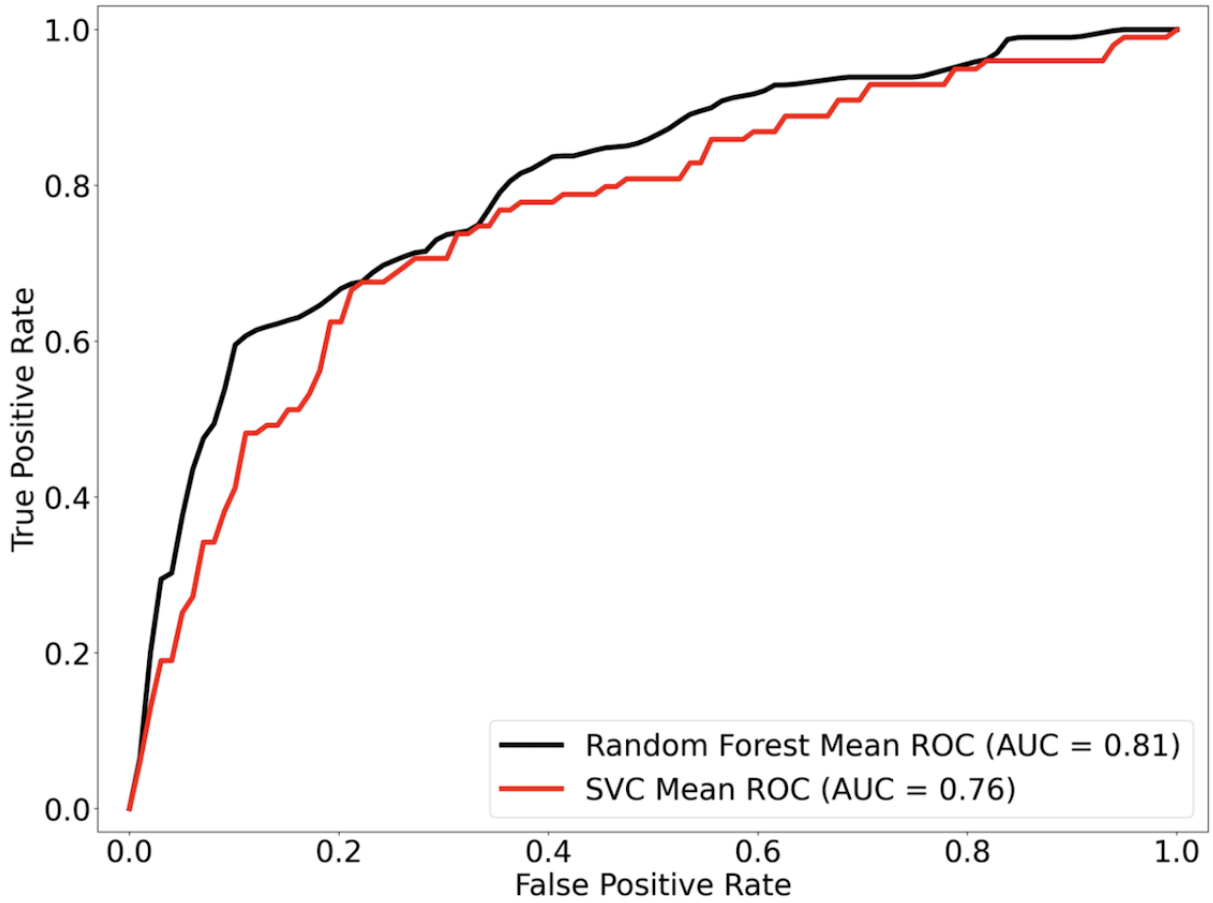
Patient demographics and characteristics were evaluated on the date of breast cancer diagnosis (Table 1). Median age was 75 years (range: 70 - 100 years), with 317/1229 (26%) patients aged 80 years or older. Performance status was generally good, as most are categorized as 0 or 1. The main comorbidities were diabetes (174/1229 patients, or 14%), followed by coronary artery disease (123/1229 patents, 10%) and cardiac insufficiency (105/1229 patients, 9%).

The majority presented early-stage tumors (T1 in 567/1229 patients, with a prevalence of 46%), and lymph node involvement was mostly absent (N0 in 614/1229 patients, or 50%). The tumors were typically SBR grade II and 80% (978/1229 patients) were ER-positive. Progesterone receptor positivity was also high at 68% (838/1229 patients). Twelve percent of patients (149/1229) were reported to have received chemotherapy (Table 2).



Development Cohort

The final cohort was divided into "reference" and "model" cohorts for model development (Figure 2). A total of 327 patients, that is, 50% of patients meeting the criteria for manifold-estimated derivation training were randomly selected. The purpose of this training group was to calibrate the manifold-estimated derivation–scoring algorithm. The model data comprised all remaining patients (466, 59% of the model development cohort).

Features Performance and Area Under the Curve Scores

In Figure 3, we ascertained the predictive efficacy of the selected variables using RFC and SVC. Analyzing the receiver operating characteristic curves, both models demonstrated commendable predictive capabilities. RFC yielded a mean area under the curve (AUC) of 0.81 (SD 0.06) and a mean accuracy of 0.82 (SD 0.02), while SVC followed closely with a mean AUC of 0.76 (SD 0.05) and a mean accuracy of 0.78 (SD 0.01). The overlapping SDs of these scores suggest that the differences in their performance are not statistically significant.

Figure 3. Receiver operating characteristic curves for 5-year mortality predictive models. The predictive efficacy of the selected features was ascertained using Random Forest Classification and Support Vector Classifier. Results are presented as the mean of ROC and AUC values derived from 5-fold cross-validation. AUC: area under the curve; ROC: receiver operating characteristic; SVC: Support Vector Classifier.

The overall relative importance of variables for the prediction of the 5-year outcome was also determined by RFC (Table 3). Age, tumor size, and hemoglobin were the top predictors, closely followed by lymphocyte count and BMI. Curiously, the cancer grade, axillary lymph nodes involvement, and the presence of comorbidities ranked low in overall importance. This indicates that although typically taken as important factors from a clinical perspective, comorbidities and cancer grade alone are not the best prognostic features in a patient; rather, a patient's overall

XSL•FO
RenderX

biological profile may be more valuable, underscoring the usefulness of manifold learning as a prognostic tool.

Table . Overall importance of predictors according to Random Forest Classification.

Variable	Importance (%)
Age	18.33
Tumor size	17.26
Hemoglobin (g/dL)	16.41
Lymphocytes (g/L)	14.84
BMI	13.06
Lymph nodes involvement	10.39
SBR[a] grade	4.06
ER[b] status	2.88
Comorbidities	2.78

[b]ER: estrogen receptor.

Model Stability

Patients in the test and model groups from the same cluster of origin were compared to evaluate whether data points would exhibit similar distributions (appear in proximity to each other) in the new manifold space across 10 different manifold initializations. The distributions of the test group (n=140) consistently matched closely with those of the model group (n=326), with all *P* values being above the threshold of .05 indicating a lack of significant variation between groups (Figure S1 in Multimedia Appendix 1).

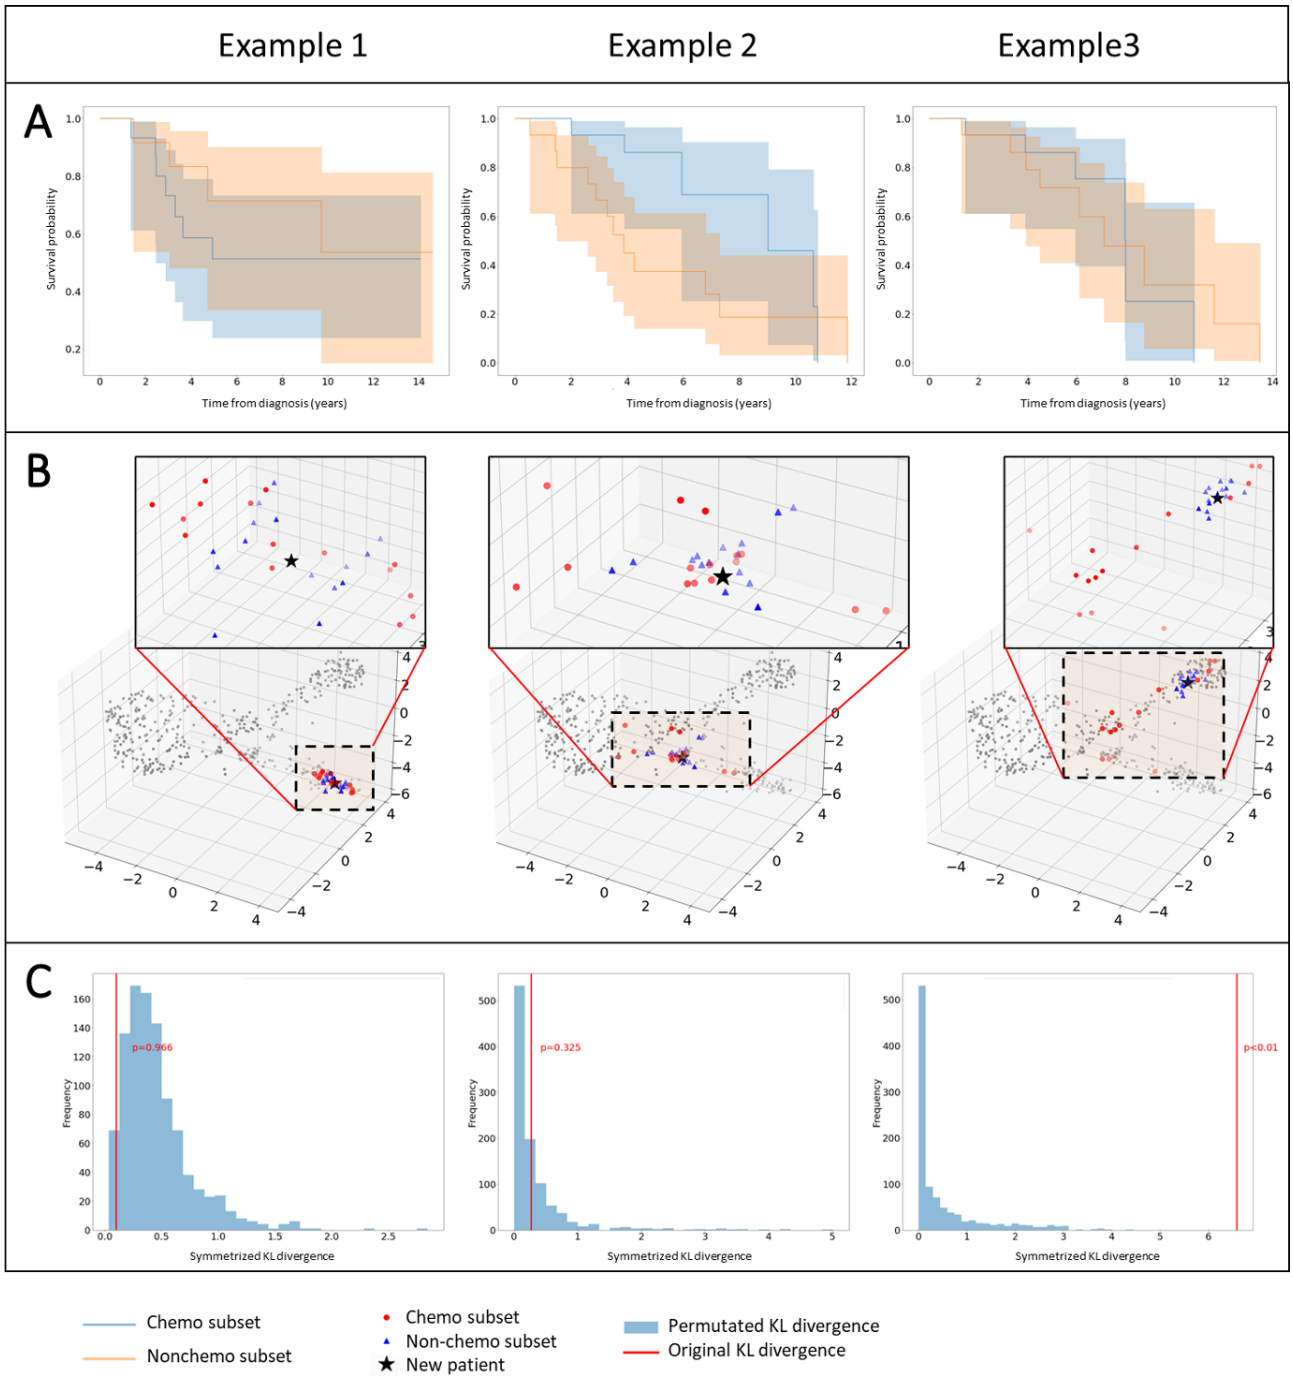
Prognostic Ability

The primary objective of our study is to evaluate the prognostic ability of the manifold learning model, as measured by the 5-year survival rate of our population. The 3D clusters in Figure 1 illuminated the landscape of our dataset, representing local groups of patients characterized by distinct clinical and prognostic profiles. Clusters are colored based on the overall mortality rate of included patients: Groups 0, 1, and 4 in green have the best prognosis with a 5-year survival rate of more than 80% while group 3 has the worst prognosis with a 5-year mortality rate of at least 35%.

Table 4 further elucidates the variability in values across the patient clusters, especially in BMI, tumor size (in mm), and median age, underscoring the diversity in our cohort.

Table . Characteristics of the 6 clusters defined by manifold learning.

Feature	Cluster					
	0	1	2	3	4	5
Hemoglobin (g/dL)	13.4	13.3	13	13	13.3	11.9
BMI	25	28.4	24.9	28.9	25.6	23
Lymph nodes involved	0.6	0.8	1.6	6.2	1	0.8
Tumor size (mm)	19.6	19.3	26.1	65.8	23.1	30.6
Age (years)	75.8	76.3	77.8	77.4	79.2	80.5
Lymphocytes (g/L)	1.8	2.1	2.1	1.6	3.4	1.6
Comorbidities	0	1	0.4	0.3	0	0.9
Estrogen receptor status	1	1	0	0.8	1	1
SBR[a] (high/low)	0	0.1	0.7	0.5	0.8	0.6



[a]SBR: Scarff-Bloom-Richardson.

XSL•FO
RenderX

Predictive Ability

Next, we attempted to ascertain the individual benefit of performing adjuvant chemotherapy, demonstrated in Figure 4 with 3 examples.

Figure 4. Three case examples assessing the individual benefit of adjuvant chemotherapy. (A) The closest chemotherapy-treated and non–chemotherapy-treated patients to a new patient are identified in the 3D manifold and their survival curves are compared to show the treatment's potential benefit or lack thereof. (B) The new patient's position in the 3D manifold (black star), with the 15 closest patients of each treatment groups are shown, displaying varying distributions of treatment subgroups. (C) To quantify distances between the subgroups, the real calculated KL divergence between the treatment groups' distributions (red line) was compared with that of permutated data (blue histograms) to verify whether observed divergences between treatment subgroups are significant or not. KL: Kullback-Leibler.

When a target patient is localized in the 3D manifold, the closest patient profiles are identified. This is done for 2 treatment groups based on whether the patients received chemotherapy (chemo and nonchemo groups), permitting the visualization of KM survival curves that would show the treatment's potential benefit or lack thereof (Figure 4A).

Figure 4B shows the target patient's position in the 3D manifold (black star), with the 15 closest patients of each treatment groups also marked. In examples 1 and 2, the 2 treatment groups are found to be well "mixed" in the local vicinity of the target, indicating that the target profile is well represented by similar chemotherapy-treated and non–chemotherapy-treated patients. To quantify distances between the subgroups, we used

XSL•FO
RenderX

permutation analysis (Figure 4C). The real calculated KL divergences between the treatment groups' distributions (red line) for examples 1 and 2 fall well within the range of what could be expected by chance (blue histograms) ($P>.1$), indicating that the observed divergences are not significant.

Example 3 showcases a situation where patients from the 2 treatment groups are not well mixed in the local vicinity of the target patient. In this case, the real KL divergence is far right of the histogram ($P<.01$), suggesting a significant difference between the distributions. Thus, the KM survival curves and any conclusion drawn from them must be taken with consideration of the heterogeneity in the profiles of the treatment groups being compared.

Discussion

Principal Findings

From an initial cohort of 1229 patients, we used 793 (65%) to develop a model that clustered patients by their clinical and biological features. These clusters represent a potential prognostic tool for physicians, attributing a risk of mortality in 5 years to patients with consideration to multivariate profiles. The model is further able to indicate the potential benefit or lack thereof of chemotherapy treatment in older adult patients. We found that the predictors used in our model gave a good overall result of 0.81 and 0.76 AUCs with RFC and SVC, respectively.

In summation, our multifaceted approach, blending manifold learning with classical machine learning paradigms and intuitive data visualizations, has unveiled profound insights into the prognosis determinants of early-stage breast cancer in older adults. These revelations bring a more nuanced understanding of the disease and hold promise for tailoring patient-specific therapeutic strategies. Our study's utilization of manifold learning and advanced machine learning algorithms represents a significant contribution to oncology. The accuracy of 81% in differentiating patient subgroups through manifold learning is impressive, showcasing an advancement beyond traditional linear models [33]. This approach is in line with recent trends in personalized medicine [34,35], which discuss the potential of machine learning in cancer prognosis. The high AUC values achieved by RFC and SVC reflect the importance of our combined predictors in medical diagnostics, aligning with the findings of recent studies on the application of machine learning in cancer detection [36,37]. The application of data visualization techniques such as heatmaps and 3D scatterplots in elucidating complex clinical relationships is noteworthy. This approach is supported by advancements in data visualization in medical research, as seen in the study by Borkin et al [38] on how data visualization supports medical decision-making [39,40].

Limitations

The present results should be interpreted in the light of some limitations. First, the monocentric nature of the research may impact the representativeness of the cohort, potentially affecting the generalizability of our findings. Second, the exclusion of specific patient characteristics, such as the ONCODAGE score [41], from our datasets may have limited the comprehensiveness of our prognostic tools. Third, the retrospective design of the study constrains our ability to establish causality between clinical characteristics and patient outcomes. A fourth limitation concerns the fact that patients may present with or have a history of multiple comorbidities. We chose to group together patients with any number of comorbidities for reasons related to (1) the reduction of the sample size for each category of comorbidity, and (2) the potential skewing of patient distribution in the 3D manifold due to multiple related qualitative variables. PaCMAP is susceptible to "overseparate" the population if provided with too many binary features. These reasons in mind, we nonetheless acknowledge that omitting the consideration of multiple comorbidities is a limitation of the study. Other notable limitations include the absence of cancer-specific or treatment-specific survival metrics, a lack of detailed analysis on specific comorbidities, and the need for more data to enhance the less populated clusters. Furthermore, the external validation of our model remains pending, which is crucial for assessing its generalizability.

Future Prospects

Looking forward, the promising application of manifold learning in oncology, as demonstrated in our study, aligns with the burgeoning field of personalized medicine. The integration of machine learning in personalized cancer therapy, as discussed by Danishuddin et al [42], supports the potential of such approaches. The development of advanced AI-driven prognostic tools, particularly for older adult patients who are often underrepresented in clinical trials, could revolutionize treatment guidelines and care approaches. The rapid advancement of machine learning techniques poses a challenge in ensuring the longevity and relevance of models, necessitating continuous updates. This is echoed in the broader context of AI in health care, as discussed in Topol's [43] comprehensive review of AI in medicine. Concerns about the adoption of AI tools due to accuracy, explainability, and ethical considerations are also prevalent, as reflected in the exploration of implementing AI in clinical practice by Char et al [44]. Our findings may open up avenues for the personalized treatment specifically catered to neglected populations in oncology, starting with geriatric patients with breast cancer. We expect our software to provide rapid guidance to physicians in the process of charting treatment plans for their patients, going beyond simple monovariate statistics and instead considering patients' combined clinical and biological profiles.

Conclusions

Our study aimed to further the management of early breast cancer in older adult patients by integrating cutting-edge AI techniques. We proposed a technique that uses patient data to create a visualizable 3D map of pathology profiles that allow rapid prognostic estimations for new patients. These prognostic predictions include the potential benefits of treatment strategies such as chemotherapy, aiding clinical decision-making. It reflects the ongoing evolution in oncology, emphasizing the importance of tailored treatment strategies and highlighting both the potential and the challenges of AI applications in health care. This study also prompts considerations for future research

XSL•FO
RenderX

directions and ethical implications in the rapidly evolving field of AI in medicine.

Data Availability

The data that support the findings of this study are not publicly available due to privacy and confidentiality agreements. However, pseudonymized data may be made available upon reasonable request to the corresponding author and following approval by the French Commission Nationale de l'Informatique et des Libertés under the data-sharing agreements of the Léon Bérard Cancer Center.

Authors' Contributions

FR and PH contributed to conceptualization, methodology, project administration, validation, writing (review and editing). MA contributed to methodology, investigation, data curation, validation, and writing (original draft and editing). AA contributed to conceptualization, supervision, writing (review and editing), and resources.

Conflicts of Interest

The model described in this study was developed by GeodAIsics, who are listed among the authors. PH reports : grants; personal fees; and nonfinancial support from PFIZER, LILLY, DAICHII, and ASTRAZENECA grants, and nonfinancial support from NOVARTIS and ROCHE—personal fees and nonfinancial support from SEAGEN, GILEAD, and MSD—cofounder and chief medical officer of GEODAISICS. AA is the founder and CEO of GeodAIsics. The remaining authors have no conflicts of interest.

Multimedia Appendix 1

Stability analysis of manifold learning applied to clustered data. The original cohort data were divided into 2 groups; 70% of every cluster was pooled into the model group, and the remaining 30% was pooled into the test group. A fresh manifold learning process was applied to the model group, and the test group was then projected onto the newly generated manifold. Patients in the test and model groups from the same cluster of origin were compared to evaluate whether they would exhibit similar distributions (appear in proximity to each other) in the new manifold space. (A) Examples of permutation analysis of clusters 0 and 1. The permutation test determined whether the observed KL (red line) divergence was significantly different from what can be expected from random shuffling of the 2 groups (blue histograms). (B) Table summarizing the median *P* values of the stability tests across 10 different manifold initializations. All *P* values above .05 indicated a lack of significant variation between groups.

Abstract

Background: Progression-free survival (PFS) is a crucial endpoint in cancer drug research. Clinician-confirmed cancer progression, namely real-world PFS (rwPFS) in unstructured text (ie, clinical notes), serves as a reasonable surrogate for real-world indicators in ascertaining progression endpoints. Response evaluation criteria in solid tumors (RECIST) is traditionally used in clinical trials using serial imaging evaluations but is impractical when working with real-world data. Manual abstraction of clinical progression from unstructured notes remains the gold standard. However, this process is a resource-intensive, time-consuming process. Natural language processing (NLP), a subdomain of machine learning, has shown promise in accelerating the extraction of tumor progression from real-world data in recent years.

Objectives: We aim to configure a pretrained, general-purpose health care NLP framework to transform free-text clinical notes and radiology reports into structured progression events for studying rwPFS on metastatic breast cancer (mBC) cohorts.

Methods: This study developed and validated a novel semiautomated workflow to estimate rwPFS in patients with mBC using deidentified electronic health record data from the Nference nSights platform. The developed workflow was validated in a cohort of 316 patients with hormone receptor–positive, human epidermal growth factor receptor-2 (HER-2) 2-negative mBC, who were started on palbociclib and letrozole combination therapy between January 2015 and December 2021. Ground-truth datasets were curated to evaluate the workflow's performance at both the sentence and patient levels. NLP-captured progression or a change in therapy line were considered outcome events, while death, loss to follow-up, and end of the study period were considered censoring events for rwPFS computation. Peak reduction and cumulative decline in Patient Health Questionnaire-8 (PHQ-8) scores were analyzed in the progressed and nonprogressed patient subgroups.

Results: The configured clinical NLP engine achieved a sentence-level progression capture accuracy of 98.2%. At the patient level, initial progression was captured within ±30 days with 88% accuracy. The median rwPFS for the study cohort (N=316) was 20 (95% CI 18-25) months. In a validation subset (n=100), rwPFS determined by manual curation was 25 (95% CI 15-35) months, closely aligning with the computational workflow's 22 (95% CI 15-35) months. A subanalysis revealed rwPFS estimates of 30 (95% CI 24-39) months from radiology reports and 23 (95% CI 19-28) months from clinical notes, highlighting the importance of integrating multiple note sources. External validation also demonstrated high accuracy (92.5% sentence level; 90.2% patient level). Sensitivity analysis revealed stable rwPFS estimates across varying levels of missing source data and event definitions. Peak reduction in PHQ-8 scores during the study period highlighted significant associations between patient-reported outcomes and disease progression.

Conclusions: This workflow enables rapid and reliable determination of rwPFS in patients with mBC receiving combination therapy. Further validation across more diverse external datasets and other cancer types is needed to ensure broader applicability and generalizability.

Introduction

Background and Significance

Real-world evidence (RWE) is increasingly accepted to augment traditional clinical trial findings to better understand the effectiveness of oncological interventions. RWE can be leveraged to improve novel therapy development programs and provide better postmarket surveillance of approved therapies [1-3].

Response evaluation criteria in solid tumors (RECIST) is broadly used to ascertain disease progression in clinical trials. However, assessing RECIST in retrospective electronic health record (EHR) data is challenging due to its strict assessment indicators [4]. RECIST considers changes in the size of individual target lesions over time and the presence or absence of new lesions to categorize disease status into complete or partial response, stable disease, or progression [5]. A similar assessment paradigm is adopted in routine clinical practice, where clinicians document the occurrence of progression through serial clinical and radiological examinations. This clinician-confirmed cancer progression in unstructured text (ie, clinical notes) has been shown to serve as a reasonable surrogate for real-world indicators in ascertaining progression endpoints. This is also more practical for real-world studies than purely RECIST-based approaches [6].

In earlier studies across different types of solid tumors, real-world progression (rwP) was captured either through manual abstraction from unstructured data or proxy measures were evaluated based solely on structured drug data [7,8]. Recent studies have also used machine learning models specifically trained to automate the capture and characterization of clinician documentation of tumor response. These specialized models have shown varying accuracies [9,10]. In the past decade, health care natural language processing (NLP) frameworks like Google's Healthcare Natural Language application programming interface (API), Amazon Comprehend Medical, IBM Watson Health, and Microsoft Text Analytics for Health have emerged and shown promise in clinical concept recognition, entity linking, and sentiment analysis. However, these general-purpose NLP frameworks have shown varying degrees of performance on different data sources [11-13]. While large language models (LLMs) are rapidly advancing, they currently have limitations in clinical concept identification and medical relation extraction as structured outputs for direct application. Even specialized clinical LLMs require further fine-tuning for such use cases [14].

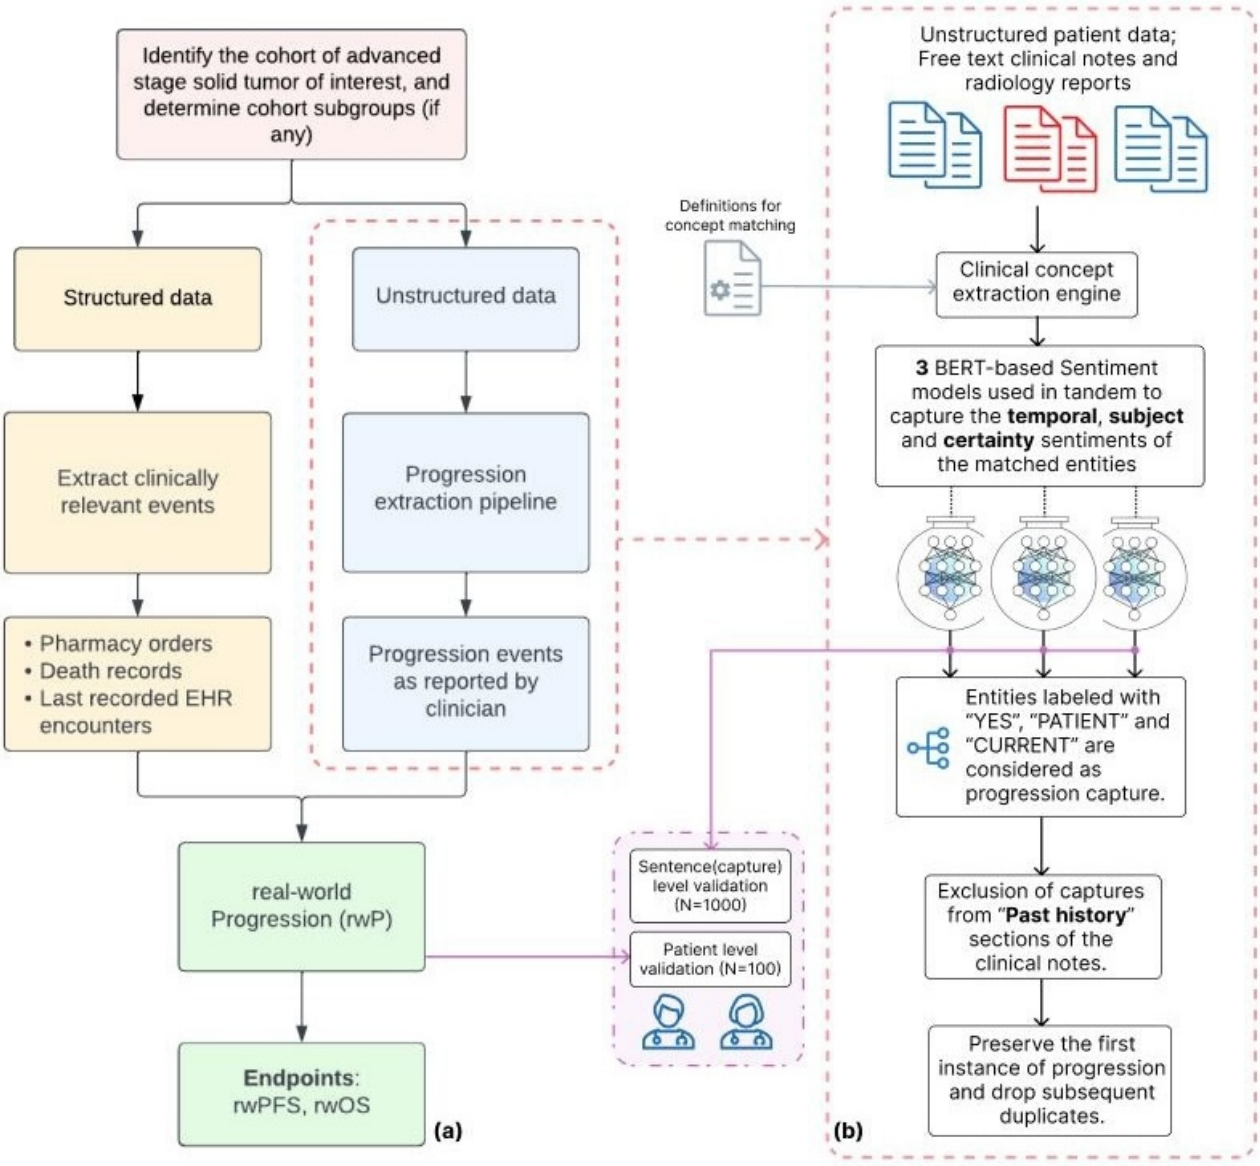
We aim to configure a pretrained, general-purpose health care NLP framework to transform free-text clinical notes and radiology reports into structured progression events. By combining these with structured drug records and encounter data, we will compute real-world progression-free survival (rwPFS) for metastatic breast cancer (mBC). This work can also guide other researchers in configuring a general-purpose health care NLP model to capture rwPFS. Developing a standardized and automated path for ascertaining rwP could help scale rwPFS computation across diverse subsets of solid tumors and maintain a better agreement across real-world studies.

Objectives

We aim to (1) develop and validate a novel semiautomated workflow that estimates rwPFS in patients with mBC, (2) explore the essentiality of each model in the general-purpose NLP framework through ablation analysis, and (3) investigate additional factors influencing rwPFS, such as the source of clinician-documented progressions (radiology reports versus routine clinical notes) and the presence of prior or concurrent medications during the observation period.

Method

Data Source



This study analyzed deidentified EHR data from a network of tertiary clinical centers tied to an academic medical center (Mayo Clinic) in the United States through the Nference nSights Analytics Platform [15]. In-house tools were used for the deidentification of EHRs. The tool performs with a recall of 0.992 and a precision of 0.979 on the i2b2 2014 dataset at replacing protected health information (PHI) with plausible but fictional surrogates [16]. Overall, the platform hosts data from approximately 7 million patients from across the United States of America, with about 1.8 million patients having a mention of cancer across the structured data. The platform hosts an array of multimodal data, both structured and unstructured, such as clinical notes, radiology reports, Digital Imaging and Communications in Medicine headers, and pathology reports.

Study Design and Definitions

This retrospective observational study demonstrates the estimation of rwPFS with a workflow that integrates clinician-reported progression events from free text (unstructured data) in clinical and radiology documents with structured patient events like drug orders, clinic or hospital encounters, and mortality records. The workflow was developed to leverage the pretrained, general-purpose, deep learning–based health care NLP framework developed at Nference called the clinical NLP engine, which enables clinical concept recognition, sentiment analysis, and linking associated concepts. The models that are a part of the clinical NLP engine were initially trained on human-annotated datasets, and later further augmented by additional ground truth datasets generated by LLM agents from the same parent EHR data source. A high-level overview of the workflow is illustrated in Figure 1.

Data Extraction and Augmentation

Breast cancer disease was identified using structured diagnosis codes 174 (*ICD-9* [*International Classification of Diseases, Ninth Revision*]), C50 (*ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*]), and NLP-based positive model confirmations (augmented curation) of the disease-related terms in clinical notes [17]. A similar approach was undertaken for identifying metastatic disease using structured codes 197, 198 (*ICD-9*), C78, and C79 (*ICD-10*). Further cohort attrition for the study population is outlined in Figure 2. Hormone receptor status, human epidermal growth factor receptor-2 (HER-2) status, and Eastern Cooperative Oncology Group scores were captured from clinical notes using the clinical NLP engine. A rule-based approach was used to identify the initiation date of first-line therapy in mBC by analyzing drug orders and administration records. To ensure reliability, only orders appearing for the first time after metastasis diagnosis were included. The same methodology was extended to identify second-line therapies.

Figure 2. Cohort attrition diagram: structured codes 174* (*ICD-9*) and C50* (*ICD-10*) or >4 positive disease sentiments from the augmented curation disease diagnosis model were used for breast cancer. For evidence of metastasis, 197*, 198* (*ICD-9*), C78*, and C79* (*ICD-10*) in conjunction with augmented curation were used; * represents all the children codes within the parent code. ECOG: Eastern Cooperative Oncology Group; EHR: electronic health record; HER-2: human epidermal growth factor receptor-2; HR: hormone receptor; *ICD-9*: *International Classification of Diseases, Ninth Revision*; *ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*; NLP: natural language processing.

XSL•FO
RenderX

Patient Population

The study cohort (N=316) consisted of female patients aged ≥18 years and diagnosed with mBC with hormone receptor–positive and HER-2–negative status with confirmed concurrent exposure to palbociclib and letrozole from January 1, 2015, to December 31, 2021 (study period), and with Eastern Cooperative Oncology Group performance scores of less than 3 around the start of the therapy (±60 d).

Demographics and baseline characterization of the study cohort, such as prior exposure to therapies, disease stage at the start of the study, stage at first cancer diagnosis, and other relevant metrics for the solid tumor of interest, were also documented.

Extracting Progression Events From Unstructured Text

To develop and evaluate our workflow, an initial rule-definition set of 200 cases from the overall mBC cohort (N=10,791) was sampled, and a preliminary manual abstraction was performed. This evaluation aimed to systematically identify a set of rules for configuring the baseline clinical concept extraction model to capture progression. Authors PKM, SKR, VK, and MM used internal clinical document (CD) exploration tools to cluster sentences based on initial pattern matches and iteratively refined these clusters to identify progression-indicative phrases. Independent reviews of oncology and radiology notes were conducted to extract commonly occurring phrases indicative of clinical progression. Authors GV and RHY subsequently collated these identified patterns into a set of regex search patterns. These patterns were tested on clinical notes to ensure they captured the appropriate progression-related contexts while removing duplicate or irrelevant verbatim such as general report headers, unrelated phrases (eg, “CR” for complete response or “PD” for progressive disease without patient-specific context), and noise. Downstream NLP models were applied to validate the extracted patterns by mapping the right set of label combinations that accurately reflected the progression status. This process was repeated iteratively until a consensus was reached among the authors, ensuring a robust set of rules for capturing progression events. The final progression capture configuration is detailed in Table S1 in Multimedia Appendix 1.

The rwP events were captured by configuring the clinical NLP engine. This baseline workflow is an ensemble of deep learning–based multi-BERT (Bidirectional Encoder Representations from Transformers) framework trained on unstructured patient data like CDs and radiology reports to perform named entity recognition and predict the sentiment labels for *subject*, *temporality*, and *certainty* of the captured named entities [18]. The ensemble also infers associations between related entities like disease-severity, drug-disease, and disease-anatomical_structure, among others. These proprietary models are fine-tuned versions of SciBERT-cased [19], a domain-specific transformer model pretrained on scientific text. The base models underwent further supervised fine-tuning for classification tasks on annotated sentences from CD texts of the overall Nference nSights database, but not specifically on the mBC patient note database. The details regarding their architecture, training, and performance of the individual models of the clinical NLP engine are detailed in Note S1 and Table S2 in Multimedia Appendix 1. The clinical NLP engine also uses a section header model to identify the clinical note sections from which the named entities were captured. The rules determined during the initial abstraction were used to capture cancer progression.

rwP Definitions

rwP events were identified by the earliest documentation of disease progression in a clinical or radiology note or by advancement to a new line of therapy. The addition of a new chemotherapy, endocrine therapy, or targeted therapy drug after 60 days of exposure to the initiating therapy of interest is considered line advancement. The following list of drugs were considered potential second-line drug candidates in the study period: tamoxifen, fulvestrant, elacestrant, paclitaxel, carboplatin, abemaciclib, docetaxel, cyclophosphamide, capecitabine, ribociclib, alpelisib, everolimus, doxorubicin, epirubicin, 5-fluorouracil, olaparib, talazoparib, ixabepilone, raloxifene, and toremifene. Censoring events included death, loss of follow-up, and the end of the observation period. Progression events captured within the first 30 days of therapy initiation were excluded as they occurred too early to reflect treatment effectiveness. The rwPFS was also assessed with variations in the origin of unstructured data, comparing radiology reports and CDs as data sources. The key contributing survival variables used for rwPFS were also stratified to understand the source of events.

Progression Capture Validation

Overview

For validation of the clinical progression captures, the manual review and abstraction were performed at 2 levels.

The raw progression captures were evaluated for accuracy independent of their temporality to the observation period. 1000 captures were sampled from the overall pool of progression captures for the sentence-level progression capture analysis.

A stratified sample (mBC validation set; n=100) was selected from the overall study cohort (N=316) to match the progression event occurrence observed in the overall set. This approach ensures that the sample mirrors the broader cohort’s characteristics for a valid comparison in patient-level evaluation for progression capture. These patients were not part of the initial rule-definition set and were evaluated for their first progression events. For the patient-level analysis, the elements of the confusion matrix were defined to account for temporality. We classified the captures into 4 categories: (1) true positives: automated progression captured is within ±30 days of manual capture; (2) false positives: progression was not found through manual capture, but automated progression was captured at any time or automated progression was captured >30 days before manual capture; (3) true negatives: progression was not found through manual review, nor was picked up by automated capture; and (4) false negatives: progression was identified through manual capture, but the automated method has not identified any progression (or) automated method captured progression >30 days after the date captured by manual review.

XSL•FO
RenderX

Ablation Analysis of the Progression Capture Pipeline

To evaluate the contribution of each workflow component to the overall performance, an ablation study was performed at 5 strategic points: (1) temporal model ablation, that is, the removal of the temporality assessment model; (2) subject model ablation, that is, the removal of the subject assessment model; (3) certainty model ablation, that is, the certainty assessment model was removed; (4) all 3 assessment models were removed; and (5) postprocessing ablation where the postprocessing steps, specifically the exclusion of specific note sections and dropping subsequent duplicate mentions of the same note contexts, were removed. Each ablation was analyzed in isolation to quantify its respective contribution to the final output's accuracy, aiding in identifying critical components of the pipeline and potential areas for optimization. This step is further illustrated in Figure S2 in Multimedia Appendix 1.

Validation on the External Dataset

To further assess the generalizability and robustness of the progression capture pipeline, external validation was performed using data from a different partner academic medical center (AMC). In the external dataset, 63 mBC patients on first-line therapy of the metastatic disease with palbociclib with or without aromatase inhibitors were identified for this analysis (see Figure S4 for cohort attrition in Multimedia Appendix 1). Similar NLP-based data augmentation techniques were applied on the external dataset for cohort identification. The proposed progression extraction workflow was applied on the external dataset for extraction of progression events during the defined study period (60 months) of the patients. For validation, similar to the primary cohort, a 2-tier approach was applied, including sentence-level and patient-level validation. For patient-level validation, the time of the first progression event in the patient cohort was manually abstracted and validated. Performance metrics such as precision, recall, accuracy, and F_1-score were calculated to evaluate the alignment of automated progression captures with manual annotations.

Sensitivity Analysis on rwPFS Estimates

Two sensitivity analyses were conducted to assess the robustness of rwPFS estimates: (1) to evaluate the effect of data incompleteness, 10%, 20%, and 30% of rows capturing progression events (missingness at random) were systematically removed from the Kaplan-Meier source data. Median rwPFS and survival probabilities were descriptively analyzed to quantify variations introduced by missing records. (2) The impact of treating death as a progression event versus censoring was assessed by generating Kaplan-Meier curves under both scenarios. Differences were evaluated using the log-rank test, with comparisons of median rwPFS and survival probabilities at predefined time points. These analyses ensured the robustness of rwPFS estimates by addressing potential biases from data structure and event definitions.

Patient-Reported Outcomes and Clinical Progression: Analysis Using the Patient Health Questionnaire-8

Patient-reported outcomes (PROs) were integrated by analyzing Patient Health Questionnaire-8 (PHQ-8) scores to complement clinician-documented progression events. Cumulative declines and peak reductions in PHQ-8 scores were compared between progressed and nonprogressed patients using a *t* test. Peak reduction was determined as the largest decrease observed between any 2 recorded scores during the study period. Cumulative decline, representing the total improvement over time, was calculated as the sum of all positive reductions (decline in PHQ-8 value) in scores across all pairwise comparisons during the study period. This approach aimed to provide a holistic perspective by linking patient-reported mental health outcomes to clinical progression.

Outcomes Assessment

The primary outcome was rwPFS, calculated as the time between the start of the intervention of interest and the first rwP event captured or a change in the line of therapy for the patient. The secondary outcome was real-world overall survival (rwOS), calculated as the time between the start of the intervention of interest and the date of death. A subgroup analysis was performed to assess the impact of prior and other concomitant medications on rwPFS and rwOS in the metastatic setting. The validation metrics of the primary outcome were reported as sensitivity, specificity, accuracy, precision, and F_1-scores.

Median follow-up time was computed from the date of the start of therapy till their last encounter in the EHR system. Time to treatment after the diagnosis of advanced disease (first evidence of metastasis) and follow-up after the start of therapy were imputed using *the date of the first evidence of metastasis* (identified by structured disease code or NLP-positive confirmation) and *the date of the first structured drug order for the combination therapy* (palbociclib and letrozole) as the anchor dates, respectively.

Ethical Considerations

This study analyzed deidentified primary patient-level data extracted from the Nference's, nSights electronic health record database under a data-use agreement that obviates the need for additional institutional review board review. Nference, in collaboration with the AMC data partner that provided the deidentified data for this study, has established a secure data environment, hosted by and within the AMC, that houses the AMC's deidentified patient data. The provisioning of and access to this data are governed by an expert determination that satisfies the Health Insurance Portability and Accountability Act Privacy Rule requirements for the deidentification of PHI. Each AMC's deidentified data environment is specifically designed and operated to enable access to and analysis of deidentified data without the need for institutional review board oversight, approval, or an exemption confirmation. Participants retain the right to opt out at any time. The data are accessible only to authorized users subject to a robust credentialing and authentication process. Data shown and reported in the manuscript have been extracted from this environment using an established protocol for data extraction, aimed at preserving patient privacy. The data have been deidentified pursuant to an expert determination in accordance with the Health Insurance Portability and Accountability Act Privacy Rule. No compensation was provided to individuals whose deidentified records were included.

XSL•FO
RenderX

Statistical Analysis

Data hosted on Nference's nSights environment were imported on demand into the secure code workspaces deployed with Python (version 3.10.6). Missing data imputation was not undertaken. The analysis workflow uses proprietary Python packages with APIs for database querying and data standardization. The descriptive statistics were reported as n (%) and median, IQR. Loss to follow-up was considered as a censoring event for survival estimates. The Kaplan-Meier estimator from the lifelines package 0.27.7 was used in this analysis. The median rwPFS and rwOS were reported, with a 95% CI.

Results

Workflow Configuration

We applied 3 selection conditions to ensure that the progression captures from the clinical NLP engine are relevant and up-to-date with the patient's current status with respect to the clinical note or report. First, entities labeled with "YES," "PATIENT," and "CURRENT," each having a sentiment prediction confidence of ≥0.9, were deemed relevant. Second, to address the issue of "copy-forwarding" in clinical notes, only the first chronological instance of each extracted sentence was retained. Finally, sentences from "Past History" sections were excluded, as they are unlikely to reflect events occurring at the time of documentation. The workflow configuration is illustrated in Figure 1.

Performance Evaluation

The accuracy of the progression capture was evaluated at 2 levels (Table 1): in level 1, sentence-level progression capture validation yielded an accuracy of 98.2% for the relevant progression captures, and in level 2, patient-level validation yielded an accuracy of 88.0%. Ablation analysis revealed the essentiality of the individual components of the clinical NLP engine for progression capture and selection conditions. All steps except the subject sentiment model labels substantially contribute to the overall model performance. This model can be disabled and the workflow performance remains the same. The patient-level workflow performance at each ablation step is outlined in Table 2.

Table . Manual validation was performed for progression at 2 levels.

	Values
Progression capture analysis in level 1[a] (manual validation of sampled raw progression captures [n=1000])	
Sensitivity	99.8%
Specificity	96.7%
Precision	96.6%
Accuracy	98.2%
F_1-score	98.2
First progression capture analysis in level 2[b] (manual validation of first progression [n=100])	
Sensitivity	92.5%
Specificity	83.0%
Precision	86.0%
Accuracy	88.0%
F_1-score	89.1

[a]Level 1: sentence-level review to validate the capture of progression sentiments at the sentence level. At this level, we reviewed the extracted sentences to ascertain the validity of the progression capture at a sentence level.

[b]Level 2: patient-level review to identify the first progression date. Here, we undertook a full review of patient records to ascertain the first progression capture of the metastatic disease.

[a]PFS: progression-free survival.

Cohort Description

The baseline characteristics are detailed in Table 3. The median age at metastasis was 59 (IQR 50.5 - 69) years. The median follow-up time after metastasis diagnosis was 43.3 (IQR 28.1 - 61.2) months and the median follow-up time after the start of the therapy was 39.8 (IQR 25.5 - 57.9) months. The starting dose of palbociclib and letrozole was available for 53.2% and 61%, respectively. The median number of drug orders for palbociclib and letrozole was 6 (IQR 3 - 12) and 4 (IQR 2 - 7), respectively. The treatment characteristics, including prior and concomitant exposure to other chemotherapy agents and a history of prior radiotherapy and breast surgery, are also detailed in Table 3. The breakdown of outcomes and censoring events that contributed to the Kaplan-Meier survival estimates are further detailed in Table 4.

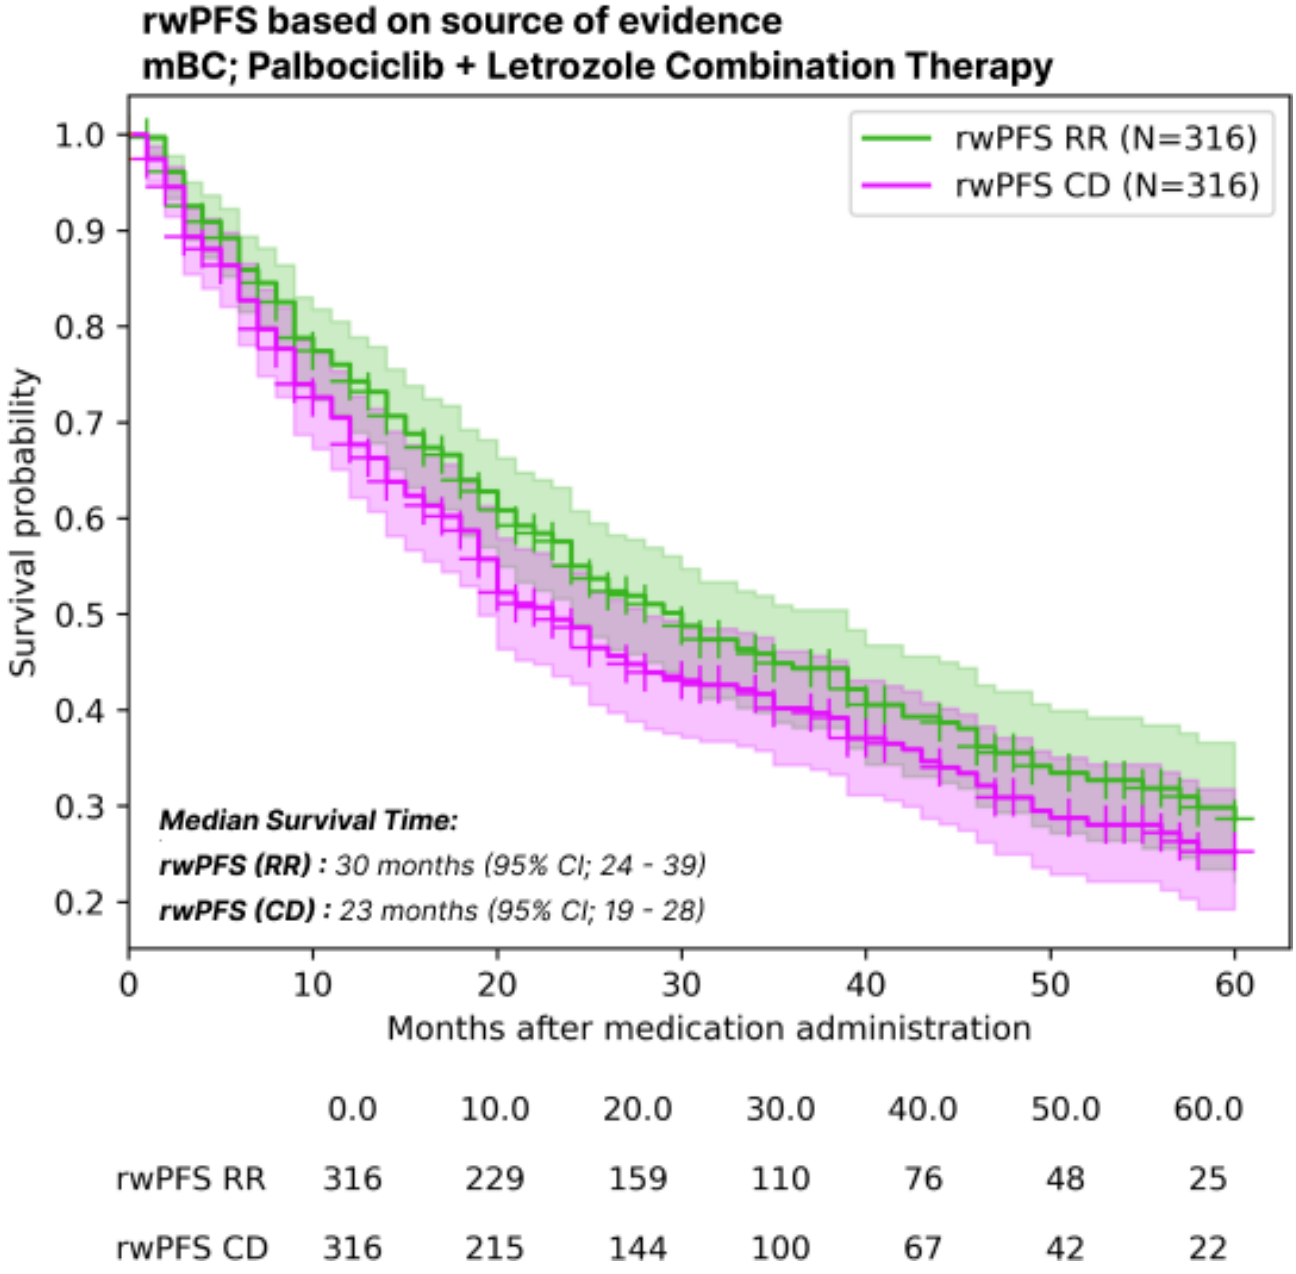
Patient death date		22 (18.8)
End of study period		19 (16.2)

[a]mBC: metastatic breast cancer.

Outcomes

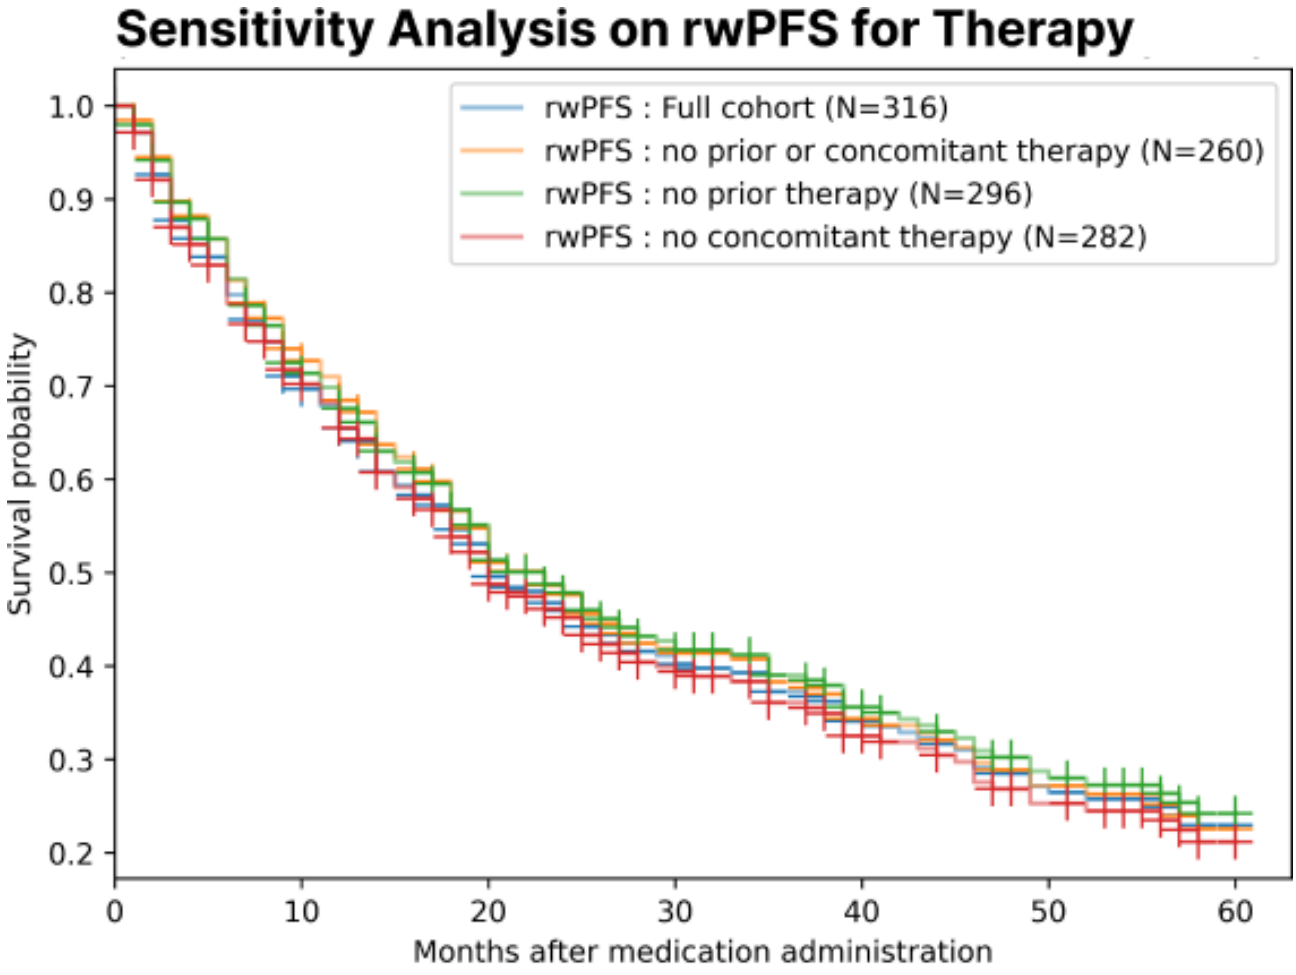
In the study cohort (N=316), 199 (62.9%) patients progressed during the observation period (60 mo starting from Jan 1, 2015). Out of the progressed patients, 152 (48.1%) were based on progression captures from unstructured data, and 47 (14.8%) were based on changes in the line of therapy from structured data. The median rwPFS for the overall cohort was 20 months (95% CI 18.0 - 25.0; Figure 3A). The median rwOS was not reached during the study period (95% CI 57- not reached [NR]).

Figure 3. Kaplan-Meier survival plots for the overall study cohort and validation sets: (**A**) Kaplan-Meier survival plots indicating the real-world progression-free survival (rwPFS) and real-world overall survival (rwOS) in the study cohort of patients with metastatic breast cancer using pooled note sources. (**B**) Patient-level validation of first progression capture and comparing outcomes estimated by computational workflow with manual curation. mBC: metastatic breast cancer.



In the mBC validation set of 100 patients, the median rwPFS was determined to be 25 (95% CI 15-35) months by manual curation and 22 (95%CI 15-35) months by the computational workflow outlined in Figure 3B. Based on the data source for progression capture, the rwPFS estimated exclusively from radiology reports was 30 (95% CI 24.0-39.0) months, compared to 23 (95% CI 19.0-28.0) months when estimated exclusively from CDs, as represented in Figure 4. Subgroup analysis on the

XSL•FO
RenderX



rwPFS based on prior or concomitant therapies is detailed in Figure 5.

Figure 4. Kaplan-Meier survival plots for real-world progression-free survival (rwPFS) based on the patient note source. Survival plots indicating the real-world rwPFS with progressions captured from solitary sources of radiology reports (RR) and routine clinical documents (CD). mBC: metastatic breast cancer.

RenderX

Figure 5. Kaplan-Meier survival curves for subgroup analysis. Each of the subgroups account for different variations in treatment patterns. The survival curves and risks table showcase the effect of other prior or concomitant systemic therapies on the median real-world progression-free survival (rwPFS).

Time	Median rwPFS estimate	Time(months)						
		0(N)	10	20	30	40	50	60
rwPFS : Full cohort	20.00 months (95% CI 18.0-25.0)	316	206	136	92	62	40	20
rwPFS : no prior or concomitant therapy	23.00 months (95% CI 19.0-27.0)	260	176	118	78	50	34	14
rwPFS : no prior therapy	23.00 months (95% CI 19.0-28.0)	296	196	132	89	60	39	19
rwPFS : no concomitant therapy	20.00 months (95% CI 18.0-25.0)	282	186	122	81	52	35	15

External Dataset Validation

External validation was conducted using data from a partner AMC, representing a health system distinct from the main study, to assess the generalizability and robustness of the progression capture pipeline. At Level 1, manual validation of 200 sampled raw progression captures achieved an accuracy of 92.5% and an F_1-score of 92.8%, while Level 2 validation of the first progression in 61 patients reported an accuracy of 90.2% and an F_1-score of 92.5%. Two patients were excluded from performance metrics because the textual evidence identified during manual abstraction of the first progression event was unavailable to the automated extraction pipeline. Comprehensive performance metrics, including sensitivity, specificity, and F_1-scores, are detailed in Table 5.

XSL•FO
RenderX

Table . Manual validation of the progression capture workflow on the external dataset.

Validation step	Sensitivity	Specificity	Accuracy	Precision	F_1-score
Level 1					
Manual validation of sampled raw progression captures (n=200)	89.7%	95.7%	92.5%	96%	92.8%
Level 2					
Manual validation of first progression (n=61)	97.4%	78.3%	90.2%	88.1%	92.5%

Sensitivity Analysis on rwPFS Estimates

The sensitivity analysis demonstrated that rwPFS estimates were robust under varying conditions. Systematic removal of 10%, 20%, and 30% of progression events resulted in median rwPFS values of 20 (95% CI 18-26) months, 20 (95% CI 18-27) months, 22 (95% CI 18-28) months, and 23 (95% CI 19-29) months for the complete, 10%, 20%, and 30% datasets, respectively, with widening CIs indicating increased uncertainty. Similarly, median rwPFS estimates were comparable when death was treated as censorship versus a progression event, with values of 20 months (95% CI 18-25) and 18 months (95% CI 15-21) in the main dataset. These findings, along with overlapping CIs, indicate that the rwPFS estimates were not meaningfully affected by missing data or event definitions. See Figure S5 in Multimedia Appendix 1 for Kaplan-Meier curves and event tables.

PHQ-8 Outcomes and Disease Progression

Of the 316 patients, 94 had at least 2 PHQ-8 scores recorded during the study period, including 30 nonprogressed and 64 progressed patients. Nonprogressed patients showed greater mean peak reduction (5.57, SD 5.90 vs 2.95, SD 4.30; t_{92}=−2.397, P=.02) and cumulative decline (mean 8.00, SD 12.68 vs 3.66, SD 6.40; t_{92}=−2.201, P=.03) in PHQ-8 scores compared to progressed patients. See Table S3 in Multimedia Appendix 1 for details.

Discussion

Overview

The study showcases the development and validation of a novel semiautomated workflow for estimating rwPFS in patients with mBC using deidentified EHRs. One of its key strengths lies in the integration of NLP techniques to extract clinician-reported progression events from unstructured data sources such as clinical notes and radiology reports, combined with structured patient data like drug orders and clinical encounters. This approach enhances the accuracy and comprehensiveness of capturing progression events, as evidenced by the high sensitivity (99.8%) and specificity (96.7%) at the sentence level with good patient-level accuracy (88%).

While our initial goal was to develop a fully automated workflow for capturing disease progression, we have successfully implemented a semiautomated approach. This is advantageous because the semiautomated method allows for disease-specific adjustments to clinical concept recognition configurations, ensuring relevance across various cancer types. This flexibility underscores the potential for broader applicability beyond mBC, making it a valuable tool for oncological research and RWE generation.

Principal Findings

The median rwPFS of 20 months (95% CI 18 - 25) reported in this study is comparable to those reported in previous real-world studies and clinical trial results, validating the workflow's reliability and accuracy [20,21]. Subgroup analysis revealed the impact of prior and other concomitant medications on median rwPFS. For instance, the PALOMA-2 trial reported a median progression-free survival (PFS) of 24.8 months (95% CI 22.1-inf), which is comparable to the real-world observation in the study subcohort (N=260) of patients who received palbociclib and letrozole in the first-line metastatic setting (patients with no other prior or concomitant drugs), which was 23.00 months [22]. A matched comparison between the study cohort and other real-world cohorts or clinical trials could further establish the concordance between the survival estimates. Integrating progression events from both radiology reports and routine clinical or oncology notes standardizes the identification of disease progression, mitigating biases and overestimation that can arise from relying exclusively on a single data source. Ablation analysis also revealed the futility of using the subject sentiment analysis model in the workflow, as physicians are unlikely to describe the progression status of a family member or a blood relative in the patient's notes. While this model is useful for extracting other concepts using the clinical NLP engine, it has shown no benefit in its usage for progression capture.

The external validation further demonstrated the robustness and generalizability of the progression capture workflow across health systems. Manual validation on this dataset also achieves high accuracy at the sentence level (92.5%) and at capturing the first progression event (90.2%). Sensitivity analysis confirmed that rwPFS estimates were stable, regardless of whether death was treated as censorship or an event, with overlapping CIs observed across both scenarios. Sensitivity analysis confirmed that rwPFS estimates were stable across varying levels of missing data and event definitions, with slight increases in median rwPFS and wider CIs under data incompleteness and overlapping intervals when treating death as censorship or an event. Furthermore, integration of PHQ-8 outcomes revealed significant associations between patient-reported mental health and progression status,

XSL•FO
RenderX

highlighting the potential of PROs to provide complementary insights.

Comparison to Prior Work

The study also highlights the importance of source data used for determining rwPFS. Relying solely on radiology reports overestimated the median rwPFS compared to estimates derived from both clinical notes and radiology reports combined. The median rwPFS from the pool of free-text data excluding radiology reports (23 months) was closer to the median survival of the overall study cohort with all available pooled free-text data (20 months) when compared to the median rwPFS computed from free-text data exclusively from radiology reports (30 months). This discrepancy can be explained by the observation that patients can undergo radiological evaluations outside the EHR data network, with their findings being documented by treating physicians within the EHR network in patients' routine clinical notes. Similar findings were observed in a previous study that analyzed the impact of source data on real-world survival estimates [6]. Additionally, relying solely on structured data like drug records (time to discontinuation or time to next treatment) as a surrogate for rwPFS has been shown to underestimate the median rwPFS substantially in a prior study [23]. PROs provide direct insight into a patient's symptoms and quality of life and have been linked to progression-free and overall survival in prior studies. Although direct comparisons with alternative workflows were not performed, our method demonstrates performance metrics that are in line with those reported in previous studies, warranting further comparative analyses in future work.

Among other computational techniques for characterizing cancer response in real-world data (RWD), the use of LLMs has also shown promise. A prior study evaluating this has shown GatorTron to be the best-performing model, achieving an accuracy of 89% at the radiology report level upon fine-tuning [24]. However, applying LLMs across a broader patient corpus needs further investigation to fully ascertain their validity and generalizability. PROs provide direct insight into a patient's symptoms and quality of life and have been linked to progression-free and overall survival in prior studies [25-27]. We have observed significant associations between the decline in PHQ-8 scores and the patient's progression status.

Limitations

There are, however, limitations to this study. First, the reliance on clinician-reported events means that the accuracy of the workflow is reliant on the quality and completeness of clinical documentation. Incomplete or inconsistent documentation could lead to underestimation or overestimation of progression events. To mitigate this, careful validation of extraction patterns and data completeness checks were implemented. Second, although the semiautomated workflow reduces the resource-intensive nature of manual abstraction, it requires initial manual rule definition and configuration, which could introduce biases based on the selected rules and criteria. Representative evaluation samples were curated across the breast cancer cohorts to reduce the biases. Third, sensitivity analyses were limited primarily to variations in clinical text sources and censoring definitions. Expanding sensitivity analyses to include demographic factors, alternative definitions of progression, and data-source reliability could further strengthen the robustness of the findings. Fourth, augmenting the mortality data with commercial and federal death registries could enhance the accuracy of survival estimates. This was not feasible in the present analysis but represents an important area for future improvement. Fifth, integration of PROs could provide a more comprehensive understanding of patient well-being in relation to progression events. However, demonstrating this in RWD was challenging due to the limited availability of patient-reported records. Finally, the ensemble deep learning engine's performance was evaluated within a specific cohort of mBC patients; thus, further validation across more diverse external datasets and different cancer types is necessary to truly establish the generalizability of the workflow.

Future Directions

These findings align with the growing body of research advocating for integrating artificial intelligence and machine learning in health care data analysis, as these technologies can substantially enhance the speed, accuracy, and breadth of data processing capabilities. Future work will explore more advanced text data analysis and extraction methods, such as adaptive machine learning techniques and LLMs, to minimize manual import and enhance scalability. Furthermore, by using federated learning, insights and patterns from diverse populations across various institutions can be pooled securely, enriching the model's generalizability and performance across different health care settings. The successful implementation of this automated workflow demonstrates its potential to streamline the data extraction process from EHRs from various health systems. It also paves the way for its application in other oncological studies, where similar challenges in data abstraction exist.

Conclusions

Developing a practical and scalable method for capturing real-world progression from EHR data is crucial to improving oncological research and patient care. Overall, this technology represents a step forward in realizing the full potential of EHR data in oncology. Our findings establish a workflow for automated data capture to provide a more efficient and scalable method than traditional manual processes, particularly in handling complex, unstructured EHR data. Although the principles of progression capture remain the same across other cancer types, further research across other types of solid tumors is needed to ascertain the generalizability of the workflow.

Acknowledgments

We thank the peer reviewers for their thoughtful reviews and feedback, which greatly improved the quality of the final manuscript.

Data Availability

The deidentified patient-level EHR data that underpin the findings of this study are not publicly available due to the expert-determination process required to preserve Health Insurance Portability and Accountability Act–compliant deidentification and the terms of our data use agreement. Aggregate results and metadata supporting the conclusions are available from the corresponding author on reasonable request and subject to a data-sharing agreement. Qualified researchers may also request access via the Nference nSights Analytics Platform [15], under existing privacy and security controls. The analytic code and any training or validation datasets remain proprietary and are not publicly available.

Authors' Contributions

GV led data curation, formal analysis, visualization, writing of the original draft, review, editing, and contributed to the methodology. RKY contributed to the methodology, data curation, formal analysis, investigation, and visualization. PK was responsible for conceptualization, methodology, lead investigation, funding acquisition, lead supervision, and manuscript review and editing. BSA, SC, SKR, VK, and MM contributed to data curation and validation, with MM also involved in investigation. KP contributed to data curation, methodology, and investigation. AvA developed the clinical NLP engine software for NLP model inference. SJ developed the NLP models and software. AkA contributed to software development and provided feedback. RB and VT provided feedback, project administration, with VT also providing resources. PL and SAS contributed to validation, feedback, and writing review and editing; SAS also provided resources. VS provided supervision. All authors read and approved the final manuscript.

Conflicts of Interest

GV, PK, KP, SC, AvA, MM, SJ, AkA, RB, VT, PL, and VS are current employees of Nference, inc and hold a minority stake in the company. RKY, BSA, and VK are past employees of Nference. SAS is affiliated with Mayo Clinic, Rochester. The authors declare no further competing interests in the findings of the study.

Abstract

Background: Diagnosing and managing follicular thyroid neoplasms (FTNs) remains a significant challenge, as the malignancy risk cannot be determined until after diagnostic surgery.

Objective: We aimed to use interpretable machine learning to predict the malignancy risk of FTNs preoperatively in a real-world setting.

Methods: We conducted a retrospective cohort study at the Peking University Third Hospital in Beijing, China. Patients with postoperative pathological diagnoses of follicular thyroid adenoma (FTA) or follicular thyroid carcinoma (FTC) were included, excluding those without preoperative thyroid ultrasonography. We used 22 predictors involving demographic characteristics, thyroid sonography, and hormones to train 5 machine learning models: logistic regression, least absolute shrinkage and selection operator regression, random forest, extreme gradient boosting, and support vector machine. The optimal model was selected based on discrimination, calibration, interpretability, and parsimony. To address the highly imbalanced data (FTA:FTC ratio>5:1), model discrimination was assessed using both the area under the receiver operating characteristic curve and the area under the precision-recall curve (AUPRC). To interpret the model, we used Shapley Additive Explanations values and partial dependence and individual conditional expectation plots. Additionally, a systematic review was performed to synthesize existing evidence and validate the discrimination ability of the previously developed Thyroid Imaging Reporting and Data System for Follicular Neoplasm scoring criteria to differentiate between benign and malignant FTNs using our data.

Results: The cohort included 1539 patients (mean age 47.98, SD 14.15 years; female: n=1126, 73.16%) with 1672 FTN tumors (FTA: n=1414; FTC: n=258; FTA:FTC ratio=5.5). The random forest model emerged as optimal, identifying mean thyroid-stimulating hormone (TSH) score, mean tumor diameter, mean TSH, TSH instability, and TSH measurement levels as the top 5 predictors in discriminating FTA from FTC, with the area under the receiver operating characteristic curve of 0.79 (95% CI 0.77 - 0.81) and AUPRC of 0.40 (95% CI 0.37-0.44). Malignancy risk increased nonlinearly with larger tumor diameters and

XSL•FO
RenderX

higher TSH instability but decreased nonlinearly with higher mean TSH scores or mean TSH levels. FTCs with small sizes (mean diameter 2.88, SD 1.38 cm) were more likely to be misclassified as FTAs compared to larger ones (mean diameter 3.71, SD 1.36 cm). The systematic review of the 7 included studies revealed that (1) the FTA:FTC ratio varied from 0.6 to 4.0, lower than the natural distribution of 5.0; (2) no studies assessed prediction performance using AUPRC in unbalanced datasets; and (3) external validations of Thyroid Imaging Reporting and Data System for Follicular Neoplasm scoring criteria underperformed relative to the original study.

Conclusions: Tumor size and TSH measurements were important in screening FTN malignancy risk preoperatively, but accurately predicting the risk of small-sized FTNs remains challenging. Future research should address the limitations posed by the extreme imbalance in FTA and FTC distributions in real-world data.

KEYWORDS

follicular thyroid neoplasm; machine learning; prediction model; malignancy; unbalanced data; literature review

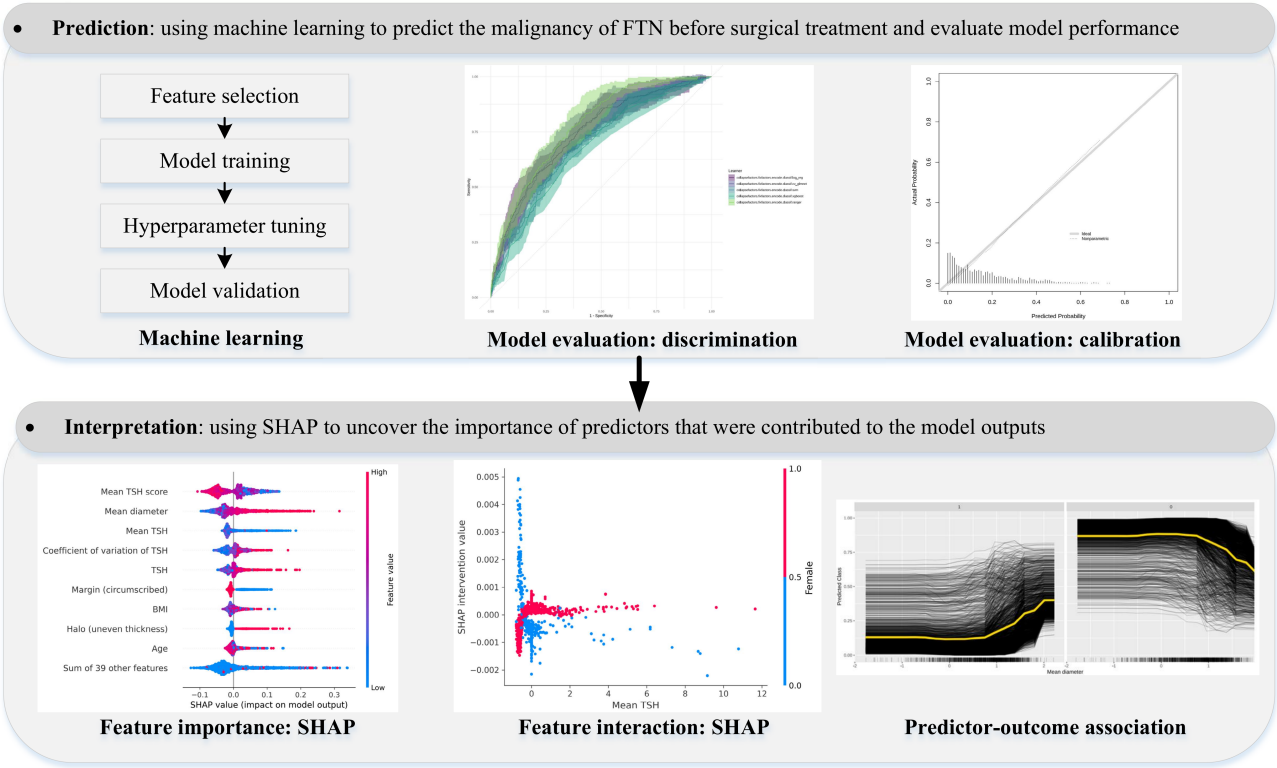
Introduction

Globally, thyroid neoplasms are becoming increasingly prevalent [1]. Among them, follicular thyroid neoplasms (FTNs) represent a major type but have garnered significantly less attention compared to papillary thyroid carcinoma. A key challenge is that over 95% of FTN cases cannot be reliably distinguished as benign (follicular thyroid adenoma [FTA]) or malignant (follicular thyroid carcinoma [FTC]) until diagnostic surgery [2]. This uncertainty often leads to both over- and undertreatment of patients with FTN. On one hand, it is estimated that over 80% of patients who undergo thyroidectomy might ultimately be diagnosed as benign FTN based on postoperative pathology [3]. On the other hand, those with malignant FTN may have already developed distant metastases to the lungs, bones, or other organs by the time they receive surgical treatment.

Several guidelines advocate for enhanced screening, accurate diagnosis, and appropriate treatment for patients with FTN [4,5]. One crucial solution is to develop prediction models to aid clinical decision-making for these patients. To date, machine learning has been proven effective in constructing predictive models for various cancers such as oral, gastrointestinal, and breast cancers [6-8]. Our literature review also indicated that machine learning technology excels at capturing complex, nonlinear relationships and high-dimensional intercorrelations among predictors [9-12].

However, our literature review revealed several limitations among most of the existing studies, mainly including (1) small sample sizes ranging from 18 to 888 participants [13-19], (2) the ratio of FTA to FTC deviating from the real population distributions, (3) reliance on simple linear models unable to capture the complex nonlinearity or interactions underlying predictor-outcome relationships [14,18], (4) using inappropriate metrics to evaluate model performance for the unbalanced data [13-19], (5) lack of assessing the extent to which a predictor influences the model's prediction (ie, model interpretability) [13,16,19], (6) not evaluating whether the predicted probabilities were consistent with actual outcomes (ie, model calibration) in the development and validation of clinical prediction models [20], and (7) predictors are predominantly confined to sonographic features with limited consideration of other factors such as the presence of Hashimoto thyroiditis (an autoimmune disease that may increase the risk for differentiated thyroid cancer [21]).

To address these limitations, our study has united a multidisciplinary treatment team for thyroid neoplasms and accumulated a cohort of over 1500 patients with FTN over the past decade [22]. This provided us a unique opportunity to develop and validate clinical prediction models to bridge the current research gaps in the field of FTN. Specifically, we aimed to individualize the clinical decision-making for patients with FTN by using interpretable machine learning to not only predict the malignancy risk of FTN but also identify the important predictors that might contribute to the prediction.



Methods

Study Design

This retrospective cohort study followed the suggestions of the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) statement [23]. Figure 1 shows the framework of our study.

XSL•FO
RenderX

Figure 1. Study framework of the machine learning–based modeling to facilitate the clinical decision-making for patients of FTN. FTN: follicular thyroid neoplasm; SHAP: Shapley Additive Explanations; TSH: thyroid-stimulating hormone.

Study Population

Our multidisciplinary research team included experts in the fields of epidemiology, surgery, pathology, ultrasound, and endocrinology. We conducted a retrospective cohort study at Peking University Third Hospital in Beijing, China, from January 2012 to September 2023. Eligible patients were those who underwent surgery and were pathologically diagnosed with FTA or FTC following the procedure. Patients were excluded if they did not undergo ultrasound examinations prior to surgery or if they had nodules classified as follicular tumors of uncertain malignant potential (UMPs). This exclusion was based on two considerations: (1) accurate diagnosis of FTNs required both an experienced pathologist and a complete biopsy sample. The key to distinguishing between benign and malignant FTNs was determining whether the tumor invaded the capsule. Tumors that invaded the capsule or blood vessels were classified as FTC, while those that did not were considered FTA. If the pathologist struggled to assess capsule invasion due to inexperience, or if the sample was inadequately collected during surgery, leading to capsule damage, the tumor might not have been accurately classified as either FTA or FTC. In such cases, it could have been labeled as a UMP. (2) Through a literature review, we found that all previous research had excluded UMPs [13-19]. Therefore, our study also excluded UMPs, enhancing comparability with prior research. We paid close attention to the accuracy of the pathological diagnosis of FTN due to its high professional requirements, which include not only complete sampling but also a thorough examination of all areas of the tumor margin. To ensure this, we invited pathologists with expertise in thyroid tumors to double-check all the postoperational pathological diagnoses in the study population, based on the most recent 2022, 5th edition WHO Classification of Thyroid Neoplasms [24].

It is important to note that our study population reflected the natural distribution of FTNs (ie, the ratio of FTA and FTC), resulting in imbalanced data, with 84.57% (n=1414) of cases was FTA. Specifically, we did not restrict the ratio of FTA to FTC to 1:1 or any other fixed ratio in the main analyses. This approach allowed the results from the developed prediction model to be more readily applicable to external populations with a similar natural distribution.

Data Sources and Processing

The data for this study were sourced from the electronic health records, extracted by professional information management personnel from the hospital's electronic information system. For critical data sources like thyroid pathology and neck ultrasound reports, a tailored data extraction form was designed using EpiData (EpiData Association), aligning with the study's research questions. The form was iteratively refined through discussions among researchers, surgeons, ultrasound specialists, and pathologists, followed by trial entries and revisions until finalized. Trained clinical doctors and medical students performed manual data entry, with researchers conducting 2 rounds of random checks to ensure accuracy and consistency. Senior doctors performed a final review to verify data quality. Missing values were imputed using the mean for continuous variables and the mode for categorical variables.

Predictors

We selected the predictors to develop the machine learning–based model based on our systematic review [17,18], domain knowledge [25-27], and data available. The predictors

XSL•FO
RenderX

included sonographic features, patients' age, sex, BMI, whether or not diagnosed as Hashimoto thyroiditis (an autoimmune disease that destroys thyroid cells by cell and antibody-mediated immune processes [28]), and measurements of thyroid hormones. Specifically, the sonographic features included mean diameter, composition (solid, predominantly solid, predominantly cystic, or cystic), echogenicity (hyperechoic, isoechoic, hypoechoic, or anechoic), taller-than-wide (the length in the vertical direction is greater than the width in the horizontal direction: absent or present), margin (circumscribed, ill-defined, irregular, or lobulated), calcifications (microcalcifications, macrocalcifications, peripheral calcifications, punctate echogenic foci of undetermined significance, microcalcifications with comet-tail artifacts, or no echogenic foci), halo (absent halo, even thickness halo, uneven thickness halo, or present halo without evenness of thickness reported), internal blood flow (absent or present), vascularity (mainly central vascularity, mainly peripheral vascularity, mixed vascularity, or avascularity), trabecular formation (typically appears as elongated, band-like, or fibrous echogenicity, arranged in a reticular or cord-like pattern: absent or present), and nodule-in-nodule appearance (a smaller nodule or an area with different echogenic characteristics is present within a larger thyroid nodule: absent or present); the measurements at the latest examination of thyroid hormones included thyroid-stimulating hormone (TSH), free triiodothyronine, and free thyroxine; additionally, TSH-related features derived from all examinations included mean TSH score (interval-adjusted detailed TSH score) [29], time-adjusted root mean square of successive differences of TSH [30], mean TSH (mean value of preoperative TSH), and coefficient of variation of TSH (the ratio of SD of preoperative TSH to mean value of preoperative TSH), and detailed definitions were introduced in previous publication [31]. All selected predictors were carefully checked by both clinicians and researchers to ensure the accuracy and reliability of the study results.

Development and Validation of Machine Learning–Based Models

We established the machine learning–based model as shown in Figure 1. We selected features, trained models, tuned hyperparameters, and validated models, as briefly described below. We used the mlr3 [32] ecosystem in R (version 4.3.3; R Foundation for Statistical Computing), scikit-learn [33], and Shapley Additive Explanations (SHAP) [34] in Python (version 3.11.1; Python Software Foundation) to conduct machine learning.

Feature selection, which aims to reduce the number of features, offers several benefits including minimizing overfitting, enhancing model robustness, and accelerating predictions. Notably, it is particularly advantageous for datasets with a high feature-to-sample ratio, where the number of features exceeds the limited size of data points. To identify a core set of predictors that could effectively predict the outcome without redundancy, we used a novel information-gain approach for feature selection [35]. To finalize the optimal model, we also compared model performance between that with full predictors and that with selected predictors.

We trained 5 classification models including logistic regression, least absolute shrinkage and selection operator (LASSO) regression, random forest, extreme gradient boosting, and support vector machine. We comprehensively considered and weighed (trade-off) the performance, calibration, parsimony, and interpretability of models and selected the most appropriate one as our prediction model.

The random search and cross-validation were combined to select model hyperparameters when training the machine learning model. We performed a random search over more than 45,000 hyperparameter combinations to select the best hyperparameter combination and trained the final classifiers. Additionally, to address the issue of imbalance, both oversampling (increasing the amount of minority class samples with producing new samples or repeating some samples) and undersampling (decreasing the amount of majority class samples) techniques were applied [36].

Evaluation of Model Performance

We evaluated the performance of the developed model in terms of discrimination (the ability of the model to distinguish between those with and without the outcome) and calibration (the consistency or agreement between the observed outcomes and predicted risks from the model). For discrimination, we first showed the confusion matrix including the numbers and percentages of true positive, true negative, false positive, and false negative. We then calculated both the threshold-free and threshold-sensitive metrics. Threshold-free metrics included the area under the receiver operating characteristic curve (AUROC) and the area under the precision-recall curve (AUPRC). While AUROC was a common performance metric for discrimination, AUPRC was considered more useful and informative for handling the unbalanced data in this study [37]. Threshold-sensitive metrics included sensitivity, precision, specificity, and accuracy. For calibration, we first plotted predicted risks (x-axis) against observed outcomes (y-axis) using a smoothed flexible calibration curve based on individual data. We also quantitatively assessed calibration using the calibration slope and calibration-in-the-large.

Interpretation of Model Prediction Results

First, we evaluated the feature importance (ie, the extent of the model depended on the feature) and the feature interaction by using the SHAP summary plot and SHAP interaction value dependence plot (see details in Multimedia Appendix 1) [34]. Second, we figured the partial dependence plots to visualize the direction of predictor-outcome associations, illustrate whether the risk of the outcome increased with a rise or decline in the predictor values, and assess whether this relationship is linear. Third, we plotted individual conditional expectations curves to explore potential modifiers that could influence predictor-outcome associations. Finally, we separated FTC into 2 groups based on whether they were correctly predicted and compared their characteristics. The significance of differences between the groups was tested using the Mann-Whitney *U* test, as the data did not follow to a normal distribution.

XSL•FO
RenderX

A Systematic Review of the Previous Studies

We conducted a systematic review of previous studies addressing similar topics. According to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [38] (see details in Checklist 1), we searched PubMed, Web of Science, Embase, and IEEE Xplore using the terms “follicular thyroid cancer” and “predict” for papers published up to October 1, 2023 (see details in Multimedia Appendix 2). Eligible studies included those that established prediction models to distinguish FTC from FTA before operation with various preoperative predictors. We included studies with either deep learning models, machine learning models, traditional statistical models, or other relevant methodologies. Studies were excluded if fewer than 50% of patients had FTN or if the papers were not written in English.

We evaluated the Thyroid Imaging Reporting and Data System for Follicular Neoplasm (F-TIRADS) scoring criteria developed by Li et al [18] to differentiate between benign and malignant cases in our dataset. These criteria are based on 6 key features: mean diameter, composition, echogenicity, margin, calcifications, and trabecular formation. Each specific characteristic of these features is assigned a corresponding point value, and the total points across the 6 features indicate the risk level of FTC. For instance, a total score of 12 points or higher suggests an FTC risk exceeding 90% (refer to Figure S1 in Multimedia Appendix 1).

Ethical Considerations

This study was classified as human participant research and was reviewed and approved by the medical research ethics committee of Peking University Third Hospital (IRB00006761-M2023168). As a retrospective analysis, the study was granted a waiver for additional informed consent. During the data extraction process, strict confidentiality measures were implemented to ensure patient privacy and data security. All extracted data were anonymized, with any information that could directly identify patients being removed.

Results

Characteristics of the Study Population

Altogether, we included 1539 patients, 1409 of whom had solitary tumors, and 130 had more than 1 tumor. Thus, a total of 1672 tumors were included and divided into 2 pathological types: FTA (n=1414) and FTC (n=258). The characteristics of the included tumors are listed in Table 1, and the characteristics of the study population are listed in Table 2. The age of the included population was 47.98 (SD 14.15) years (n=1530; missing value=9), the mean BMI was 24.18 (SD 3.66) kg/m^2 (n=1475; missing value=64), and the female population made up 73.16% (n=1126; male: n=342; missing value=71) of all patients.

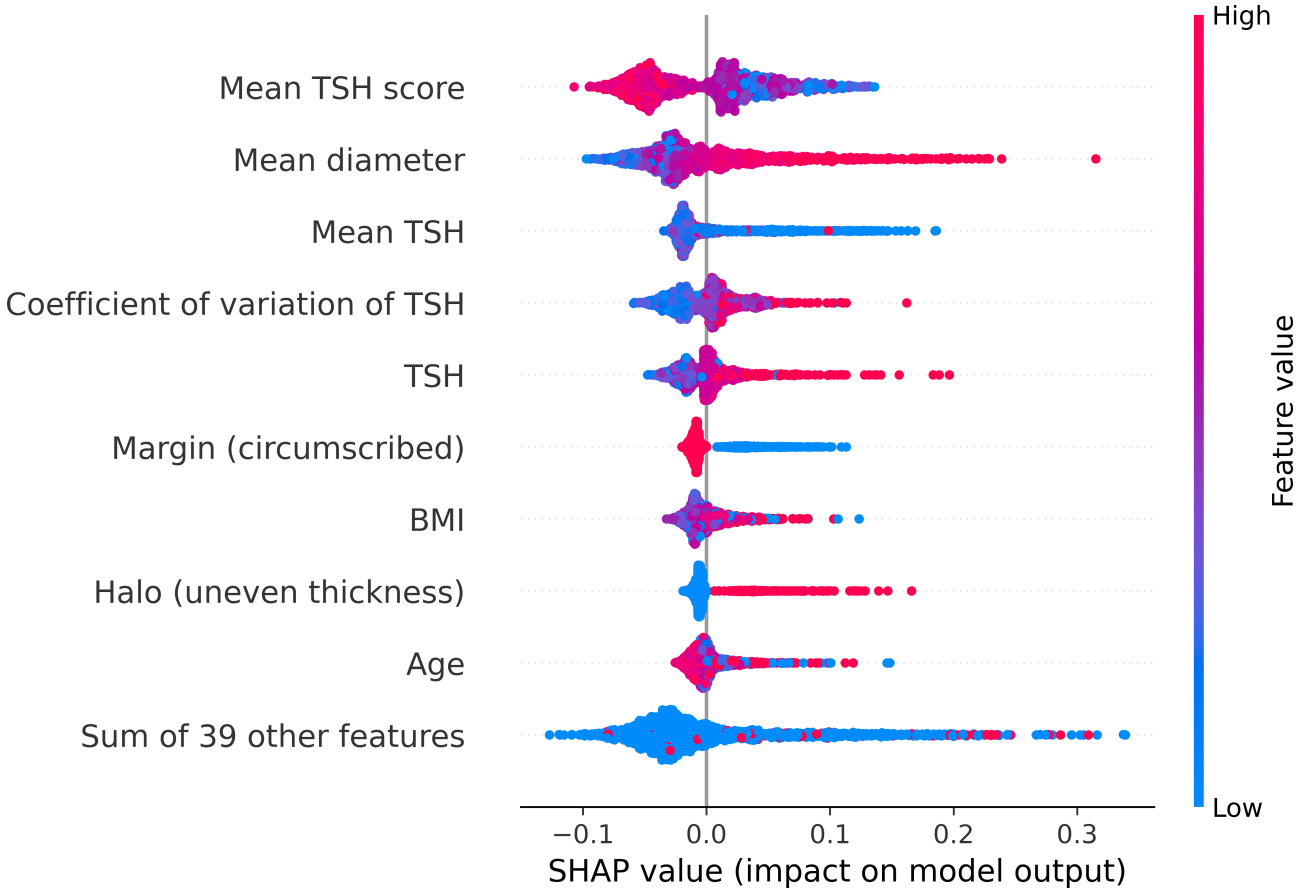
Model Performance in Discrimination and Calibration

We compared performance among 5 models (logistic regression, LASSO regression, random forest, extreme gradient boosting, and support vector machine) using the AUROC and AUPRC. As shown in Multimedia Appendices 3 and 4, the random forest model performed better in both AUROC and AUPRC than the other 4 models. With comprehensive consideration of the discrimination, calibration, parsimony, and interpretability of models, we selected the random forest model as the optimal.

We developed a random forest model with a total of 22 features: age, sex, BMI, Hashimoto thyroiditis, thyroid hormones (TSH, free triiodothyronine, and free thyroxine), ultrasonic predictors (mean diameter, composition, echogenicity, taller-than-wide, margin, calcifications, halo, internal blood flow, vascularity, trabecular formation, and nodule-in-nodule appearance), and TSH-related variables (mean TSH score, time-adjusted root mean square of successive differences of TSH, mean TSH, and coefficient of variation of TSH). After 5-fold cross-validation, the AUROC of the prediction model was 0.79 (95% CI 0.77-0.81) and the AUPRC was 0.40 (95% CI 0.37-0.44). When the threshold is gradually lowered from 50%, 40%, 30%, 20%, and finally to 10%, the accuracy, specificity, and precision decreased step by step while the sensitivity increased progressively (Multimedia Appendix 5). The calibration slope and calibration-in-the-large were 1.16 and 0.13, respectively (Multimedia Appendix 6).

In addition, we implemented both oversampling and undersampling techniques to handle the imbalance in our models. However, following oversampling, the AUROC and AUPRC were 0.76 and 0.37, respectively, while after undersampling, the AUROC and AUPRC were 0.77 and 0.39, respectively. Notably, the model performed better before applying these sampling methods, with an AUROC of 0.79 and an AUPRC of 0.40.



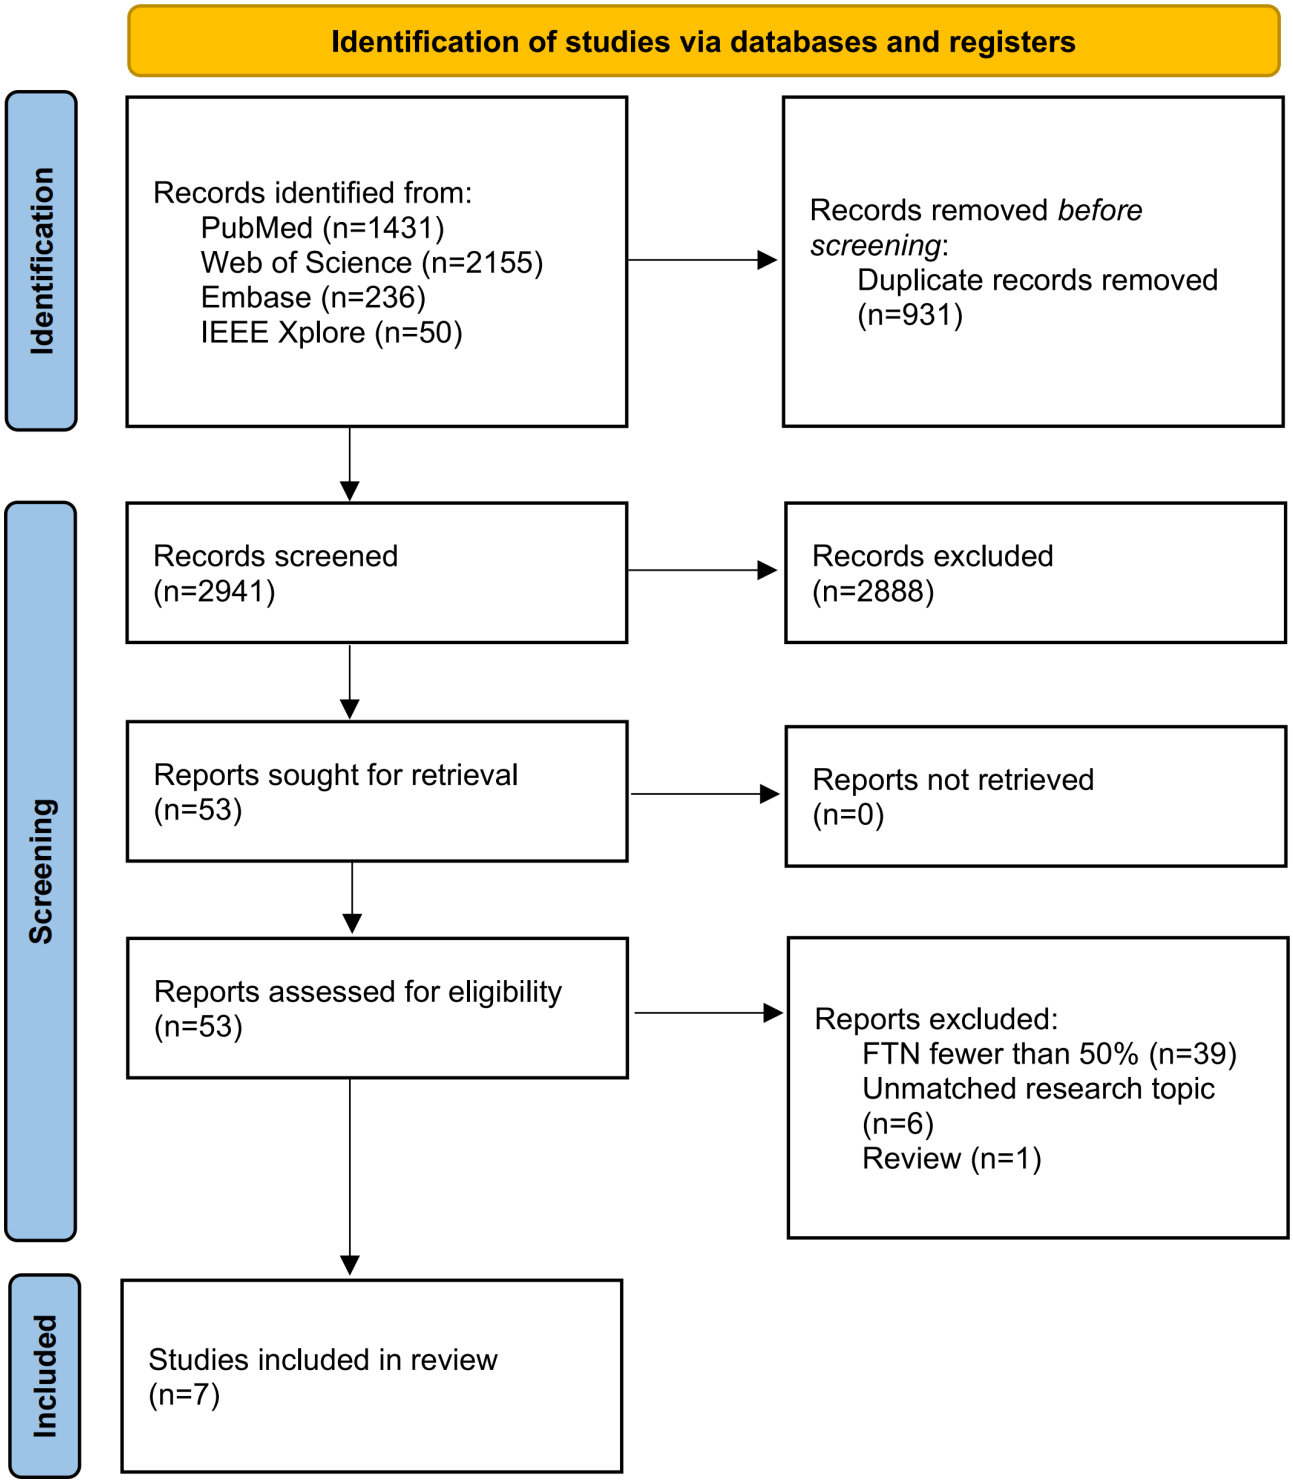
Model Performance in Interpretation

The top 5 predictors were the mean TSH score, mean tumor diameter, mean TSH, coefficient of variation of TSH, and TSH level (Figure 2). The 5 top predictors did not show explicit

XSL•FO
RenderX

interactions with the sex or other predictors (Multimedia Appendix 7). Due to the strong correlation between TSH level and mean TSH score (correlation coefficient>0.6), we only plotted the partial dependence and individual conditional expectation plots for the top 4 features, excluding the TSH level. The associations between those 4 top continuous features and prediction probability were nonlinear (Multimedia Appendix 8). In general, the risk of malignancy tended to rise as the mean tumor diameter or the coefficient of variation of TSH increased, and the risk of malignancy tended to decrease as the mean TSH score or the mean TSH increased.

Figure 2. SHAP summary plot. SHAP: Shapley Additive Explanations; TSH: thyroid-stimulating hormone.



Moreover, we compared the characteristics of FTC groups with incorrect and correct predictions. FTC predicted as FTA by the model was classified into the incorrect-predicted group, while FTC predicted as malignant correctly by the model was then classified into the correct group. The mean diameter of the tumor was smaller in the incorrect-predicted group compared to the correct-predicted group (incorrect vs correct mean 2.88, SD cm 1.38 vs mean 3.71, SD 1.36 cm; mean diameter W=1474.5; P=.02).

A Systematic Review of the Previous Studies

After screening citations, we eventually included 7 studies in this systematic review (refer to Figure 3). The characteristics of the included studies are presented in Table 3. The sample sizes of the studies ranged from 18 to 888 patients [13-19]. The ratio of FTA to FTC in previous studies varied from 0.64 to 4.00 [13-19], which was much smaller than the ratio observed in our study (5.50) and in the real population, where the ratio of FTA to FTC can be as high as 5:1 [3]. In total, 3 studies even set the ratio close to 1 to address the imbalance [15,17,19]. As for the model selection, 4 studies developed deep learning models [13,16,17,19], 1 study used a random forest model [15], and the other 2 studies only established linear regression models [14,18], without concerning nonlinear associations or complicated interactions. Previous studies did not use gene mutations and other biomarkers as predictive variables. Except for 1 study from South Korea, which reported an AUROC of just 0.612 [13], the AUROC of the models in the other studies ranged from 0.75 to 0.96. However, none of them used AUPRC as a metric to assess discrimination. As for the interpretation of the models, Lin et al [15] assessed the feature importance, Tang et al [14] drew a nomogram, Li et al [18] developed F-TIRADS scoring criteria, and Yang et al [17] drew a heat map to visualize the importance of pixel regions, but the other 3 studies did not further explore interpretability, including feature importance, or the linear and nonlinear associations and interactions between features and targets.

[i]F-TIRADS: Thyroid Imaging Reporting and Data System for Follicular Neoplasm.

Additionally, we tested the F-TIRADS scoring criteria developed by Li et al [18] with our dataset. The criteria specify 6 key features for scoring. After filtering our data to include only cases with complete information for these 6 features, we selected 1025 tumors from 993 patients as an external test set. When applying the F-TIRADS scoring criteria, the predictive performance was suboptimal. With a threshold for FTC risk set at >90%, the model achieved an accuracy of 0.82, sensitivity of 0.04, specificity of 0.99, and precision of 0.53. When using a >50% FTC risk threshold, the sensitivity increased to 0.27, while accuracy, specificity, and precision decreased to 0.79, 0.91, and 0.39, respectively. For threshold-independent metrics, the AUROC and AUPRC for the F-TIRADS scoring criteria were 0.47 and 0.59, respectively, in our external test set.

Discussion

Principal Findings

This study systematically established the interpretable machine learning–based model to address the challenge of clinical decision-making for the FTN before surgery. We developed a model using 22 readily available predictors with a preferable AUROC (0.79, 95% CI 0.77 - 0.81). Additionally, the model demonstrated excellent interpretability, identifying the mean TSH score, mean tumor diameter, mean TSH, coefficient of variation of TSH, and TSH level as the most important predictors. After comparing groups of incorrect-predicted and correct-predicted FTC, we found that smaller FTCs were more likely to be misclassified as FTA.

Comparison to Prior Work

It is crucial to evaluate the performance of clinical prediction models comprehensively, that is, the models should be well performed in discrimination and calibration. Concerning the discrimination, our developed model was comparable to that of previous studies aimed at predicting the malignancy risk of FTN before surgical treatment. For example, according to Li et al [18], the AUROC reached 0.76 in the LASSO regression model consisting of ultrasound features (the ratio of FTA to FTC: training set: 2.74 and validation set: 3.70); also, in the LASSO regression model, the AUROC reached 0.913 in discriminating FTA from FTC on selected clinical parameters, computed tomography signs, and radiomic features referring to Tang et al [14] (the ratio of FTA to FTC: 4.00). However, neither study used AUPRC as the evaluation metric. We also acknowledge that the model was derived from extremely imbalanced data (the ratio of FTA to FTC: 5.50), and in this context, the AUPRC metric for assessing model performance is more informative and intuitive than the AUROC [37]. For example, the prediction model might perform relatively well when measured by AUROC but may perform unsatisfactorily when measured by AUPRC, in the scenario of imbalanced data. Furthermore, to address the imbalance in our models, we applied oversampling and undersampling techniques, but both failed to improve performance. Our findings were in line with the previous research, which found that oversampling and undersampling generally did not enhance prediction models in large observational health datasets [39]. The possible reasons might be as follows: (1) oversampling and undersampling would modify the outcome proportions in the training data, leading to miscalibration, such as overestimated risks [39]; (2) the synthetic data generated by oversampling may not accurately represent

XSL•FO
RenderX

the original distribution of minority class, potentially affecting classification performance [40]; and (3) undersampling reduced the number of majority class samples, limiting the model's ability to fully use the features of the majority class during training [41].

As one previous systematic review indicated, calibration was commonly overlooked during the development and validation of clinical prediction models [20]. However, calibration metrics are also important to assess the size of the gap between the predicted risk probability and the true risk probability. For instance, grouping can be manipulated to obscure the evaluation of miscalibration in a particular range without a calibration curve and its numerical quantification [42]. In general, our model had relatively good calibration, as the calibration slope was close to 1 and the calibration-in-the-large close to 0.

Based on the results of our systematic review, most of the previous studies show relatively satisfying AUROC, but none of them reported AUPRC. Although Li et al [18] reported a handy score-risking tool for clinicians to assess the malignancy risk of FTN at the diagnosis stage, this tool seemed to not perform ideally in the practice of our data (AUROC 0.47; AUPRC 0.59; sensitivity 0.04 [threshold 90%] and 0.27 [threshold 50%]).

Limitations and Strengths

We should interpret the study findings cautiously. As with other single-center studies, the results from this study were limited in generalizability to patients and clinical settings with distinct characteristics. However, the pathological diagnosis of FTC was highly heterogeneous across different clinical settings due to its challenge in sufficient sampling and accurate diagnosis. Therefore, we advocated for the standardization of FTC diagnosis before the conduction of a multicenter study soon. Additionally, the prediction performance of models, comparable to the previous work with similar predictors, had room to further improve. The clinical utility of the screening stage was also less than ideal. Building on the experiences and lessons learned from this study, we are conducting a prospective cohort study to further optimize the model performance through collecting other costly multidimensional predictors including genomics, ultrasound images, and videos. Besides, our study was retrospective in nature, which may introduce selection bias. Furthermore, we excluded patients with nodules of UMPs, potentially limiting the model's accuracy in identifying borderline follicular tumors. Moreover, our models did not incorporate other potential predictors, such as genetic markers (eg, BRAF, TRET, and RAS mutations), computed tomography or magnetic resonance imaging characteristics, or family history, due to constraints in data availability.

Our study had several strengths. Our models were advantageous in the large sample size for the present topic, the clinically easy-accessible and clinician-validated predictors, and the comprehensive evaluation with the metrics appropriate for the nature of the data (imbalanced data) [43]. Furthermore, the disease distribution of FTA and FTC in the study population was fully consistent with that of patients with FTN in real-world settings, that is, we did not deliberately over- or undersample patients with any type of disease in the model development, as commonly seen in previous studies [17,18]. As such, findings from our study had theoretically better fidelity and generalizability in real-world settings. In addition, we conducted a systematic review to synthesize findings from previous studies, comprehensively integrate the evidence, and identify research gaps.

Future Directions

Our study paved the way for future research in terms of predictors, models, and targets. Concerning predictors and models, further studies might consider taking advantage of the rapidly developing deep learning models and fully using high-dimension predictors such as ultrasound images and genomics. In terms of targets, it is important to standardize the pathological diagnosis of FTC across multiple centers before conducting a future multicenter study.

Our study is also important for future clinical practice. First, findings from the interpretation of our models indicate that clinicians should comprehensively consider patients' variables such as thyroid hormones in addition to the ultrasound results. Second, in a natural distribution population with severely unbalanced data (FTA is far more than FTC), preoperative prediction of FTA and FTC by thyroid hormone and ultrasound features alone may face challenges, especially for relatively small-sized FTCs, which are easy to miss detection.

Conclusions

In clinical practice, it remained challenging to sensitively screen, precisely diagnose, and appropriately treat patients with FTN. Interpretation of our developed machine learning–based model suggests that clinicians should also pay attention to patients' variables such as TSH along with tumor size. However, it may be hard to correctly predict FTNs preoperatively with thyroid hormone and ultrasound features alone, especially for FTCs with small sizes. The findings of our study bridged the gaps of previous work and paved the way for connecting machine learning to interpretation in the field of FTN research. We call for subsequent studies to further examine the generalizability to other contexts.

Acknowledgments

This work used the data of the Peking University Third Hospital. The authors sincerely thank the research team of Thyroid Tumor Multi-Disciplinary Treatment. Abstract

Background: Next-generation sequencing (NGS) has become a cornerstone of treatment for lung cancer and is recommended in current treatment guidelines for patients with advanced or metastatic disease.

Objective: This study was designed to use machine learning methods to determine demographic and clinical characteristics of patients with advanced or metastatic non–small cell lung cancer (NSCLC) that may predict likelihood of receiving NGS-based testing (ever vs never NGS-tested) as well as likelihood of timing of testing (early vs late NGS-tested).

Methods: Deidentified patient-level data were analyzed in this study from a real-world cohort of patients with advanced or metastatic NSCLC in the United States. Patients with nonsquamous disease, who received systemic therapy for NSCLC, and had at least 3 months of follow-up data for analysis were included in this study. Three strategies, logistic regression models, penalized logistic regression using least absolute shrinkage and selection operator penalty, and extreme gradient boosting with classification trees as base learners, were used to identify predictors of ever versus never and early versus late NGS testing. Data were split into D1 (training+validation; 80%) and D2 (testing; 20%) sets; the 3 strategies were evaluated by comparing their performance on multiple m=1000 splits in the training (70%) and validation data (30%) within the D1 set. The final model was selected by evaluating performance using the area under the receiver operating curve while taking into account considerations of simplicity and clinical interpretability. Performance was re-estimated using the test data D2.

Results: A total of 13,425 met the criteria for the ever NGS-tested, and 17,982 were included in the never NGS-tested group. Performance metrics showed the area under the receiver operating curve evaluated from validation data was similar across all models (77%-84%). Among those in the ever NGS-tested group, 84.08% (n=11,289) were early NGS-tested, and 15.91% (n=2136) late NGS-tested. Factors associated with both ever having NGS testing as well as early NGS testing included later year of NSCLC diagnosis, no smoking history, and evidence of programmed death ligand 1 testing (all P<.05). Factors associated with a greater chance of never receiving NGS testing included older age, lower performance status, Black race, higher number of single-gene tests, public insurance, and treatment in a geography with Molecular Diagnostics Services Program adoption (all P<.05).

Conclusions: Predictors of ever versus never as well as early versus late NGS testing in the setting of advanced or metastatic NSCLC were consistent across machine learning methods in this study, demonstrating the ability of these models to identify factors that may predict NGS-based testing. There is a need to ensure that patients regardless of age, race, insurance status, and geography (factors associated with lower odds of receiving NGS testing in this study) are provided with equitable access to NGS-based testing.

Introduction

The care of patients with non–small cell lung cancer (NSCLC) has changed dramatically since the early 2010s, from a chemotherapy-based approach that was tailored only to the disease histology (squamous or nonsquamous tumors) to becoming a disease with multiple actionable biomarkers that can identify targeted therapies associated with superior outcomes based on individual patient genomic characteristics [1,2]. This has led to the adoption of next-generation sequencing (NGS) recommendations included in treatment guidelines for patients with NSCLC [3].

Unfortunately, despite these recommendations, multiple studies have shown that NGS-based testing is not being used for all patients with advanced or metastatic NSCLC, and only about half of all patients in some studies receive comprehensive biomarker testing [4-6]. The reasons for the lack of testing are unclear but may include barriers to ordering tests, insufficient tissue, clinical deterioration, or a crisis that requires immediate care [6]. More recent studies have also demonstrated a racial disparity in receipt of biomarker testing; patients who are Black are significantly less likely than those who are White to receive NGS-based testing in the United States [7].

Studies evaluating the barriers to testing have typically taken a specific hypothesis-driven a priori categorization of potential barriers to investigate the lack of testing [6,7]. While certainly this approach is critical to investigate specific issues such as racial disparities, this falls short when trying to evaluate the complexity of care and the multiple and potentially interacting factors. Clinical prediction models are an alternative approach to using patient-level evidence to help inform health care decision makers about patient care. These models have been used for decades by health care professionals [8]. Traditionally, prediction models combine patient demographic, clinical, and treatment characteristics in the form of a statistical or mathematical model, usually regression, classification, or neural networks, but deal with a limited number of predictor variables (usually below 25). Flexible machine learning methods can be used, by which the researcher does not force the model to evaluate a limited set of covariates, but rather the models themselves learn by trial and error from the data to make predictions, without having a predefined set of rules for decision-making. Simply, machine learning can be better understood as “learning from data” [9]. The setting of biomarker testing provides an opportunity to apply these methods to more thoroughly explore the factors that are associated with the lack of recommended biomarker testing.

While machine learning methods have been more commonly used for biomarker identification and treatment selection, there is little evidence of these methods applied to the prediction of biomarker testing itself. To date, the investigations surrounding the gaps in biomarker testing have remained largely limited to descriptive research and opinion pieces [10-13]. Therefore, this study was designed to fill this gap in evidence by applying machine learning methods to the question of biomarker testing for patients with advanced or metastatic nonsquamous NSCLC to determine demographic and clinical characteristics that may predict receipt of NGS-based testing. A second objective was to further determine the characteristics that predict receipt of NGS-based testing (early testing) in accordance with clinical guidelines that can inform first-line therapy (vs those who receive NGS-based testing after the first-line therapy is underway). These objectives were pursued to better understand factors associated with experiencing barriers to recommended testing and the timing of such testing to inform future intervention strategies.

Methods

Data Source

This study used the Advanced NSCLC Analytic Cohort from the nationwide Flatiron Health electronic health record–derived longitudinal database, comprising deidentified patient-level structured and unstructured data, curated via technology-enabled abstraction [14,15]. The data are deidentified and subject to obligations to prevent reidentification and protect patient confidentiality and are not considered human participants in accordance with the US Code of Federal Regulations [16]. These deidentified data originate from approximately 280 cancer clinics (~800 sites of care) in the United States. Patients in this database are those who have lung cancer *ICD* (*International Classification of Diseases*) codes 162.x (*ICD-9* [*International Classification of Diseases, Ninth Revision*]), C34x, or C39.9 (*ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*]) on at least 2 documented clinical visits on different days occurring on or after January 1, 2011. Longitudinal patient-level data were available through November 2021. Patients must further have had pathology consistent with NSCLC and have advanced or metastatic disease (diagnosed with stage IIIB, IIIC, IVA, or IVB disease or diagnosed with early-stage NSCLC and subsequently developed recurrent or progressive disease).

Definitions of NGS Testing Cohorts

Patients were included in this analysis if they were in the Flatiron Health Advanced NSCLC Analytic Cohort, had nonsquamous NSCLC, evidence of receipt of systemic therapy, and at least 3 months of follow-up in the database. Receipt of testing by NGS is a field recorded in the electronic medical record database by the health care provider that was used for testing identification in this study. The method of NGS testing (tissue or circulating tumor) is not specified. Patients were excluded who had evidence of NGS-based testing more than 20 days prior to initial NSCLC diagnosis. Patients meeting the

XSL•FO
RenderX

inclusion criteria for this study were categorized into 2 groups. The ever NGS-tested group included patients with at least 1 NGS test recorded in the database. All remaining patients were included in the never NGS-tested group, as this group was comprised of patients with no evidence of any NGS test recorded in the database. Among those in the ever NGS-tested group, individuals were further subgrouped by the timing of NGS-based testing. Each patient in the ever NGS-tested group was either included in the early NGS-tested subgroup, including patients whose first or only NGS-based test occurred prior to the start of first-line therapy through day 7 of first-line therapy, or the late NGS-tested subgroup, all remaining patients whose first NGS-based test occurred 8 days or later after the start of first-line therapy. The date of advanced or metastatic diagnosis was considered the index diagnosis date.

Candidate Predictors

Candidate predictors for receipt and timing of NGS-based testing were prespecified based on published literature, analyses of real-world data, and expert input from the field of cancer diagnostics [4,7,17]. These variables included patient age at advanced or metastatic diagnosis date (years), sex (male or female), race (Asian, Black, White, and other), insurance type (public, private, or other), Eastern Cooperative Oncology Group (ECOG) performance status (0-4), smoking history (ever vs never smoker), body weight (kilograms), BMI (kg/m^2), practice setting (academic or community), practice volume (the average number of those with NSCLC receiving care at the site where the included patient received care by index year over the period 2011 to 2021), biomarker result (positive, not positive, and not tested) by each available biomarker (anaplastic lymphoma kinase [ALK]; epidermal growth factor receptor [EGFR]; V-Raf murine sarcoma viral oncogene homolog B [BRAF]; Kirsten rat sarcoma virus [KRAS]; c-ros oncogene 1 [ROS1]; mesenchymal epithelial transition [MET]; neurotrophic tyrosine receptor kinase [NTRK]; rearranged during transfection [RET]; and programmed death ligand 1 [PD-L1]), stage of disease at initial diagnosis (0-IV), laboratory value (low, normal, high, or not tested) by blood test (alkaline phosphatase, alanine transaminase, aspartate transferase, bilirubin, creatinine, lymphocyte count, red blood cell count, hematocrit, platelet count, white blood cell count, and hemoglobin), number of non-NGS biomarker tests received (total number of fluorescence in situ hybridization, immunohistochemistry, polymerase chain reaction, or other non-NGS–based tests), as well as 2 variables to identify periods of environmental changes. The first of these variables categorized the status of National Comprehensive Cancer Network (NCCN) Clinical Guidelines: prior to 2016, before NGS was recommended in the guidelines; 2016-2019, when broad-based testing was recommended; and 2020 and later, when NGS-based testing was recommended [18]. The second variable evaluated the timing of US Food and Drug Administration approval of drugs that targeted the available biomarkers: period (1) January 1, 2011-August 25, 2011 (EGFR drugs only); period (2) August 26, 2011-March 10, 2016 (EGFR+ALK); period (3) March 11, 2016-June 21, 2017 (EGFR+ALK+ROS1); period (4) June 22, 2017-November 25, 2018 (EGFR+ALK+ROS1+BRAF); period (5) November 26, 2018-May 5, 2020 (EGFR+ALK+ROS1+BRAF+NTRK); period (6) May 6, 2020-May 26, 2021 (EGFR+ALK+ROS1+BRAF+NTRK+MET+RET); and period (7) May 27, 2021, and later (EGFR+ALK+ROS1+BRAF+MET+NTRK+RET+KRAS) [19]. Additionally, candidate predictors of Medicare Administrative Contractor (MAC) region [20] and Molecular Diagnostics Services (MolDX) Program adoption (yes or no) [21] were included. These variables explored the policies in place at the geography in which the patient received care. MACs are private companies that process claims for Medicare beneficiaries. These companies are geographically distinct and identifiable by unique alphanumeric designations (eg, J8=jurisdiction 8) and by private company names (eg, Noridian and Palmetto) [22]. The MolDX Program determines the coverage of diagnostic testing in 4 MACs across 28 states [20,21]. Importantly, all candidate predictor variables were required to be recorded prior to the end of the early NGS testing period to ensure that no covariates were recorded after the measurement of the NGS testing outcome.

The following interactions were deemed to be clinically relevant and forced into the models for evaluation: smoking and sex, smoking and NCCN guideline periods, race and insurance type, age and ECOG performance status, MAC region and public insurance, and MolDX region and public insurance. The estimates of the expected direction of these relationships were defined in the study protocol and are summarized in Table 1.

XSL•FO
RenderX

Table 1. Expected direction of candidate predictors for next-generation sequencing (NGS) testing.

Candidate predictor variable	Expected direction
Year of advanced or metastatic diagnosis	As year increases, NGS testing is more likely.
Smoking status (yes vs no)	Smoking=no, NGS testing is more likely.
Sex (male vs female)	Sex=female, NGS testing is more likely.
Race (Asian, Black, White, other)	Race=Asian or White, NGS testing is more likely.
Practice volume (continuous)	As practice volume increases, NGS testing is more likely.
BMI (using WHO[a] categories)	BMI=underweight, NGS testing is less likely.
ECOG[b] performance status (0, 1, 2, 3, or 4)	As ECOG performance status increases, NGS testing is less likely.
Body weight (continuous, in kilograms)	As weight increases, NGS testing is more likely.
Stage at initial diagnosis (0-I, II, III, or IV)	Stage 0-II=NGS is more likely than stage III; stage IV=NGS is more likely than stage III.
EGFR[c] (not tested, positive, not positive) by non-NGS test	EGFR=positive, NGS less likely.
ROS1[d] (not tested, positive, not positive) by non-NGS test	ROS1=positive, NGS less likely.
ALK[e] (not tested, positive, not positive) by non-NGS test	ALK=positive, NGS less likely.
BRAF[f] (not tested, positive, not positive) by non-NGS test	BRAF=positive, NGS less likely.
KRAS[g] (not tested, positive, not positive) by non-NGS test	KRAS=positive, NGS less likely.
PD-L1[h] (not tested, positive, not positive)	PD-L1=positive, NGS less likely.
Number of single-gene tests (continuous)	As the number of single-gene tests increase, NGS less likely.
Practice setting (academic, community)	Practice setting=academic, NGS more likely.
Insurance status (public, private, other)	This relationship is unknown. It is possible that insurance status=public, NGS less likely; however, it is possible that in some cases, insurance status=private only, NGS could be less likely.
MAC[i] region	No direction is known.
MolDX[j]	While this only applies to Medicare, states may adopt broader policies, and the relationship is uncertain. MolDX may make NGS more likely, but it is largely unknown.
NCCN[k] guidelines (pre, broad, or NGS)	NCCN guidelines=NGS, NGS more likely.
Drug approval periods (1, 2, 3, 4, 5, 6, 7)	As drug approval periods increase, NGS more likely.
Laboratory values (high, normal, low, not tested) for alkaline phosphatase, alanine transaminase, aspartate transferase, bilirubin, creatine, lymphocyte count, red blood cell count, hematocrit, platelet count, white blood cell count, hemoglobin	The direction of a single laboratory value is unknown. However, generally one would expect multiple out-of-range values to reflect poor health and may make NGS less likely, but the a priori assumed direction is unknown.

[a]WHO: World Health Organization.

[b]ECOG: Eastern Cooperative Oncology Group.

[c]EGFR: epidermal growth factor receptor.

[d]ROS1: c-ros oncogene 1.

[e]ALK: anaplastic lymphoma kinase.

[h]PD-L1: programmed death ligand 1.

[i]MAC: Medicare Administrative Contractor.

[j]MolDX: Molecular Diagnostics Services.

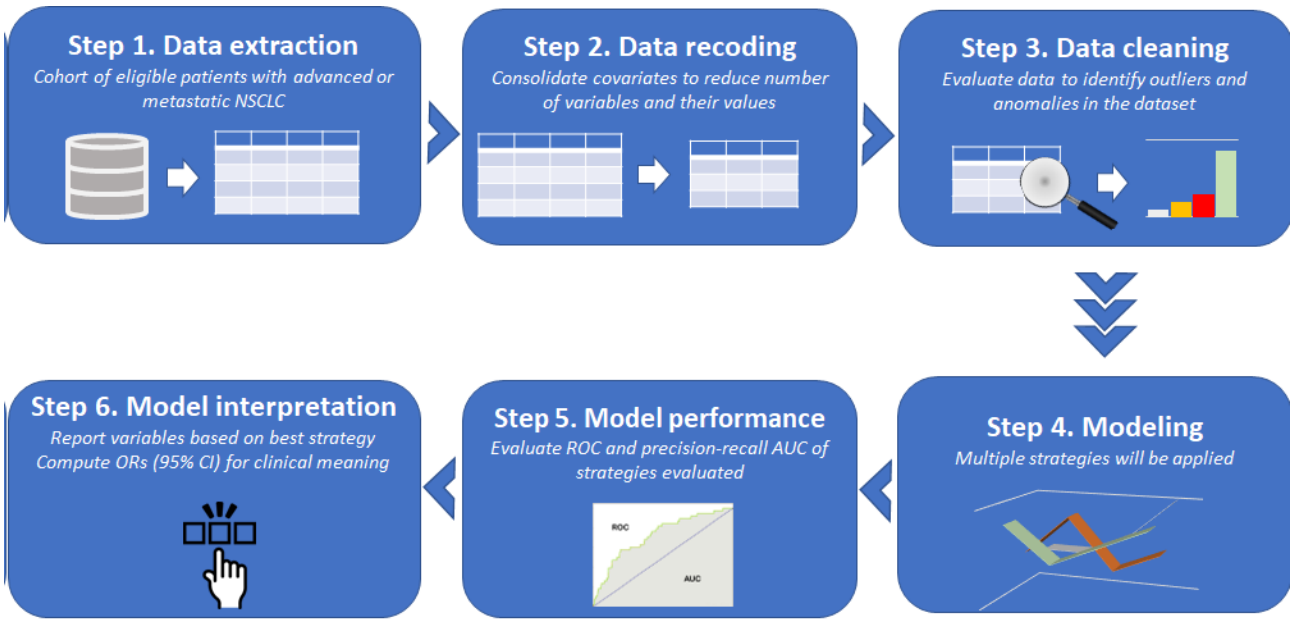
[k]NCCN: National Comprehensive Cancer Network.

Statistical Analysis

Descriptive analyses were conducted to summarize available data and to understand the extent of missingness in the database. Categorical variables were assessed using a 1-sided chi-square test or Fisher exact test and continuous variables using a 2-sided *t* test. Missing values were imputed using the random forest

XSL•FO
RenderX

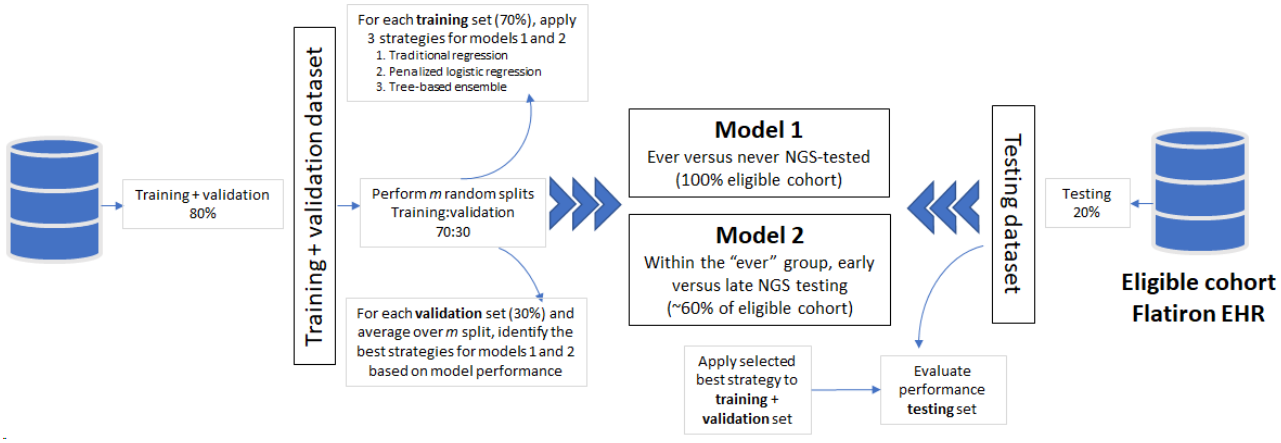
missing data algorithm (impute.rfsrc function in R package *randomForestSRC*) [23].



Three modeling strategies were used to identify potential predictors of NGS-based testing with 2 sets of outcomes for ever versus never NGS-tested (model 1) and early versus late NGS-tested (model 2). The 3 modeling strategies included logistic regression (LR) models, penalized logistic regression (PLR) using least absolute shrinkage and selection operator (LASSO) penalty, and extreme gradient boosting (XGBoost) with trees as base learners. LR was implemented using forward selection on the main effects and predefined interactions (listed earlier), starting with the predefined variables and adding the most significant terms to the model. PLR was implemented using sparse group LASSO on the main effects and predefined interactions, forcing some predefined variables into the model with the penalty selected using 5-fold cross-validation. XGBoost is a decision tree–based machine learning algorithm [24]. The model matrix for XGBoost was built using main effects and predefined interactions. Hyperparameters were selected based on 5-fold cross-validation over a grid search, and hyperparameters included the shrinkage (learning rate), the number of trees, and tree depth. Table S1 in Multimedia Appendix 1 contains the full list of hyperparameters used in this study. The data extraction approach and modeling process is summarized in Figure 1.

In step 1, data were extracted based on the prespecified inclusion and exclusion criteria. Step 2 involved variable recoding, which included transforming all categorical variables with missing information by creating an additional level to represent missing data. Step 3 was a data quality method used to identify any unusual observations that needed to be excluded or recoded in addition to any imputation that was required. Steps 4 to 6 outline the implementation of models, evaluation of the performance of these models, and interpretation of the final features selected using LR. Figure 2 provides an overview of the model strategy evaluation process for the 2 outcomes mentioned in step 4 of Figure 1.

First, the data were split into D1 (training+validation; 80%) and D2 (testing; 20%) sets. Then, the 3 strategies were evaluated by comparing their performance on multiple m=1000 splits in the training (70%) and validation data (30%) within the D1 set. Specifically, for each split, all 3 strategies were fit to training data, and performance measures (eg, area under the receiver operating curve) were computed on the validation data. Modeling was done using R packages, sparsegl was used for LASSO, XGBoost for gradient boosting, and PRROC, which computes the areas under the precision-recall and ROC curve, for performance measures. PLR and XGBoost involved hyperparameters that were fine-tuned using 5-fold cross-validation nested within training datasets. Prediction models were developed on 2 different groups: ever versus never and early versus late NGS-tested groups. In total, 146 features (including all levels of all variables) were entered into both the XGBoost and LASSO models, with only 36 features (main effects and interactions) being used in the LR model. Preselection of features consisted of excluding variables that have little to no association with the outcomes of interest.



The final model was selected by evaluating performance as described earlier (area under the receiver operating curve from validation data) and by considering the simplicity and clinical interpretability. Model performance was re-estimated using the test data D2. For the final model choice, the features with nonzero coefficients selected by PLR were run on the D1 data. These variables were fitted to an LR model within the test data D2 to calculate model estimates (odds ratios, 95% CIs, and P values). Odds ratios for main effects in the presence of interaction terms were calculated using the analytical formula presented in Multimedia Appendix 2. All analyses were conducted using SAS (version 9.4; SAS Institute Inc) and R (version 4.0.3; R Foundation for Statistical Computing).

Figure 1. Data extraction and modeling flow. AUC: area under the curve; CI: confidence interval; NSCLC: non–small cell lung cancer; OR: odds ratio; ROC: receiver operating curve.

Ethical Considerations

The data used for this study are deidentified and subject to obligations to prevent reidentification and protect patient confidentiality, and as such are not considered human subjects research and are exempt from review in accordance with the US Code of Federal Regulations [16].

Results

A total of 74,211 patient records were available in the Flatiron Health NSCLC dataset for this analysis. After applying eligibility criteria, a total of 31,407 patients were included in this analysis. Of all patients, 42.75% (n=13,425) were included in the ever NGS-tested group and 57.25% (n=17,982) were included in the never NGS-tested group. Among those in the ever NGS-tested group, 84.08% (n=11,289) were early NGS-tested, and 15.91% (n=2136) late NGS-tested. Characteristics of these groups and subgroups used as features in the machine learning models are listed in Tables 2-11.

Most features were significantly different between both the ever and never NGS-tested as well as the early NGS versus late NGS-tested groups. Of note, smoking rates and testing conducted during the NCCN prerecommendations period were lower for the ever NGS-tested group (n=10,589, 78.88% vs n=14,987, 83.34% and n=2663, 19.84% vs n=10,734, 59.69%, respectively), and ECOG status of 0 (n=4410, 32.85% vs n=4665, 25.94%) was higher for the ever NGS-tested group versus those who were never tested. Similarly, for the early versus late NGS-tested groups, there was a higher proportion of patients with a history of smoking (n=9025, 79.95% vs n=1564, 73.22%) and a lower proportion of testing conducted during the NCCN prerecommendations period (n=1746, 15.47% vs n=917, 42.93%) as well as a lower proportion of ECOG status of 0 (n=3606, 31.94% vs n=804, 37.64%) for the early tested group.

Comparison of performance metrics for each model showed that the percent AUC was similar across models (80%-84% and 77%-80%) and marginally better when the models were fit on the ever versus never NGS-tested groups. In addition, other metrics were also comparable (Table S2 in Multimedia Appendix 1). The final model chosen was the LASSO model, as it was able to identify important features including interactions (those with nonzero coefficients after shrinkage) and the metrics for each model were highly comparable (Table S2 in Multimedia Appendix 1). Figures S1 and S2 in Multimedia Appendix 1 show the feature importance plots for both groups. The most important factors associated with ever versus never testing included year of diagnosis, observation of a PD-L1 test, Black or African American race, and number of single-gene tests observed. The most important factors associated with early versus late testing included the observation of a PD-L1 test, a positive single-gene test result, the year of diagnosis, and the geographical region of care. Later year of diagnosis, evidence of PD-L1 testing, patient race, positive single-gene test results, and region were among the top 5 predictors of NGS testing for both ever versus never as well as early versus late NGS testing.

[a]NGS: next-generation sequencing.

[b]Patients in the ever NGS-tested group whose first or only NGS-based test occurred prior to the start of first-line therapy through day 7 of first-line therapy.

[c]Patients in the ever NGS-tested group whose first NGS-based test occurred 8 days or later after the start of first-line therapy.

[d]Two-sided *t* test for continuous variables; chi-square or Fisher exact test (where expected cell size <5) for categorical variables.

[e]ALP: alkaline phosphatase.

[f]ALT: alanine transaminase.

[g]AST: aspartate aminotransferase.

Over the 1000 bootstrap samples over the training data D1, an average of 135 and 89 features were identified by the LASSO models for the ever versus never and early versus late NGS-tested groups, respectively. These variables were then entered into an LR model using the testing set. The final model was established after removing any nonsignificant interaction terms, as explained earlier in the study methods. Details of the model fit statistics are shown in Table S3 in Multimedia Appendix 1. All main effects identified from the modeling for each group are shown in Figures 3-9.

There were lower odds of ever receiving NGS testing among patients with later age at initial diagnosis, bilirubin not tested, worse ECOG performance status, treated in geographies under the MolDX Program, a total higher number of genetic tests received, had only public insurance, and who were of Black or African American race as compared with those who were never tested. Patients who were obese, had a later year of initial NSCLC diagnosis, were from larger practices, had evidence of PD-L1 testing, no results for platelet testing, no history of smoking, had stage II disease, and were treated in a MAC region other than JH Novitas or J6 NGS had higher odds of ever receiving NGS-based testing.

For early versus late NGS testing (Figures 10-17), there were greater odds of receiving early NGS-based testing among patients with a later year of initial NSCLC diagnosis, who had no history of smoking, who were in later drug period approval periods, had a PD-L1 test, treated in the MAC J8 WPS, and who had no other biomarker tests or inconclusive testing.

Discussion

Overview

This study applied machine learning methods and traditional statistical tools that identified several factors that were significantly associated with not only receiving NGS-based testing but also receiving the testing early when there is a potential for early intervention with targeted therapies. Factors associated with both ever having NGS testing as well as early NGS testing included later year of NSCLC diagnosis, no history of smoking, and evidence of PD-L1 testing. These factors were consistent with the hypothesized direction of candidate variables, as NGS-based testing has been increasing over time, and it was not unexpected that the rate of testing has increased in recent years [4,25]. In addition, consistent with the hypothesized direction of these relationships, patients without a smoking history were more likely to undergo NGS-based testing. The lack of environmental causal factors would lead one to seek other explanations for the onset of lung cancer, including certain genomic abnormalities, which are frequently observed among nonsmokers with lung cancer [26]. PD-L1 testing is generally conducted alongside the NGS test and was only available in later years, so the observation of these relationships was also not unexpected.

Principal Findings

Factors associated with a greater chance of never receiving NGS testing included older age, lower ECOG performance status, Black race, higher number of single-gene tests, public insurance, and treatment in a geography associated with MolDX Program adoption. Patient age and public insurance are factors that are closely related. Patients aged 65 years and older generally have Medicare coverage, whereas younger patients will have private insurance. The median age of lung cancer diagnosis is 71 years [27], and it is highly likely that a younger patient presenting with NSCLC could raise questions about the genomic aspects of the disease that should be investigated as a result be associated with a higher likelihood of receiving early NGS-based testing as noted in the published literature [28]. Importantly, patient race, similar to prior research [7], remains a significant factor that continues to demonstrate the lack of equity in receipt of NGS-based testing. Of all factors evaluated in this study, racial inequity cannot be explained by any reasonable clinical factors and requires immediate attention by the health care community.

Several factors that did not have a clear association with NGS-based testing were those that also did not have a hypothesized direction associated with a potential relationship. While blood test results may have captured some aspect of well-being, there was no consistent relationship identified. Similarly, while patients with better performance status were more likely to receive NGS-based testing, this relationship was not strong, and the factor was not among those with the highest importance scores observed in this study. Therefore, this study suggests that these factors are likely not largely factored into a decision to receive NGS-based testing and could be why little data were observed in the published literature related to these factors.

The roles of the MolDX program and the MAC region are unclear. The emergence of MAC region J8 WPS as a predictive factor for greater odds of receiving early NGS testing and both JH Novitas and J6 NGS at lower odds of receiving any NGS testing could be an artifact of a large dataset with multiple subgroups or could reflect underlying factors related to this region that could not be explored, given the available data in the electronic data used for this study. Additionally, the timing of MolDX program adoption was not taken into account, so the patients in these regions could have had the decision made at a time that was unrelated to this variable (“yes” or “no”). Other geographic factors such as distance to a clinic, access to testing resources, and site of care could certainly have played a role as well; therefore, the relationship with MolDX should not be overinterpreted. Additionally, not all patients in these regions had Medicare coverage, so there is a great deal of uncertainty in these variables. A study with more comprehensive variables related to patient care in these regions would be needed to come to any clear conclusion about these relationships.

Limitations

First, this study is based on real-world data. The Flatiron Health deidentified data, as with most other electronic health record–based datasets, do not contain all potentially relevant variables to investigate all aspects of the complex question of NGS-based testing. Factors such as tissue availability, tissue quality, a patient crisis requiring immediate care, and other health care system–related factors were not recorded and may be additional factors that could impact access and receipt of NGS-based testing. The availability of these data, however, would not invalidate the factors that were observed in this study. Second, there were some patients who could have received NGS-based testing at an early stage diagnosis who were not included in this study due to our eligibility criteria, requiring testing within the time frame of advanced or metastatic diagnosis. Therefore, this study may not be generalizable to those diagnosed and tested at earlier stages of the disease. Third, as with all real-world data sources, missingness is a potential issue. However, the rates of NGS-based testing in this study are very similar to other estimates from different data sources, which provides confidence in the outcome variable assessed within the database used for this study [10]. Finally, when evaluating predictive models, a cutoff of 0.5 was applied to the predicted probability of events. While this may result in a suboptimal trade-off of specificity versus sensitivity for certain models (eg, for modeling “early vs late” NGS testing, it resulted in low specificities of ~20% and very high sensitivity of ~98%; Table S2 in Multimedia Appendix 1), the objective of this study was to identify predictors of NGS testing rather than optimizing predictive rules. The probability cutoffs could be further calibrated to strike a desired balance between false positives and negatives.

Conclusions

Despite the limitations of these data, this study reinforces the need to assure equity in access to NGS-based testing that has been observed in prior research. Black race is consistently associated with lower biomarker testing rates [7]. Other factors may be more associated with disease trajectory (eg, age, lower

XSL•FO
RenderX

ECOG performance status, and single-gene tests), emphasizing the flexibility needed in testing for those patients who may not be well enough for systemic therapy or who have an actionable biomarker previously identified. While efforts must be made to ensure all patients diagnosed with NSCLC have equal access to NGS-based testing early in the trajectory of the disease, there may be consideration for the specific patient needs in these cases.

Abstract

Despite growing evidence that narrative expertise may benefit cancer care professionals and the field, few hematology-oncology trainees pursue graduate degrees in the humanities. For those trainees with a particular interest in humanism in medicine, we advocate for integration of a Master of Fine Arts (MFA) degree concurrent with fellowship training. This pathway enables trainees to gain advanced skills in narrative competence, informing research and scholarly activities during fellowship and building a foundation for future careers that promote humanism in the field of hematology-oncology across clinical practice, education, research, and advocacy. Narrative competence describes the ability to create space for and elevate the voices of patients, families, and clinicians, which includes active listening, reflecting, sharing, and being moved by stories. In this paper, we review evidence suggesting that frequent exposure to suffering can threaten career longevity for cancer care clinicians, and we highlight narrative competence as an approach to mitigate moral distress, improve well-being, and bolster resilience for our workforce. The influence of narrative competence extends beyond patient care, with meaningful ramifications for advancing research, education, and advocacy efforts across the field. We encourage institutions with hematology-oncology fellowship programs that have capacity to support graduate studies to include the MFA as an option for trainees who aim to become thought leaders and experts in narrative competence. The MFA serves as a strategic mechanism to invest in growing the next generation of hematologist-oncologists with expertise in narrative competence to advance the field.

Background

Hematology-oncology fellowship aims to prepare the next generation of physicians committed to excellence in clinical practice, research, education, advocacy, and policy to advance cancer care. Medical and pediatric oncology training traditionally comprises one clinically-focused year followed by two years of dedicated research. Often, trainees pursue graduate degrees concurrent with their research years [1], such as a Doctor of Philosophy (PhD) for basic scientists or a Master of Public Health for clinical researchers. Increasingly, nontraditional degrees in business, health care administration, health policy, ethics, and medical education are integrated within fellowship [1]. Graduate degrees in the humanities, however, remain uncommon, despite growing evidence that expertise in narrative competence may benefit oncology professionals and the field [2,3].

Narrative competence refers to the ability to create space for and elevate the voices of patients, families, and clinicians through active listening, reflecting, sharing, finding meaning in, and being moved by stories [2,4-6]. Through narrative competence, clinicians can deepen compassion and bolster therapeutic relationships in the context of stressful encounters [7]. Frequent exposure to suffering increases burnout and threatens career longevity for oncology clinicians [5], and narrative competence offers a humanistic approach to mitigate

XSL•FO
RenderX

moral distress, improve wellbeing, and bolster resilience for our workforce [8-11].

Rationale for Supporting Narrative Competence in Oncology Training

The influence of narrative competence extends beyond patient care, with meaningful ramifications for advancing research, education, and advocacy [12,13]. For example, narrative elicitation in research can elevate voices from patients and families, and effective storytelling can strengthen grant applications and streamline dissemination of findings to promote scientific discovery, collaboration, and activism [14]. Clinician narratives about cancer can educate the public about cutting-edge preventative, therapeutic, and supportive care strategies [12,14]. Storytelling exercises in educational curricula fostered solidarity among trainees and increased reported preparedness to navigate work-life balance [9]. Strategic marketing through storytelling propels advocacy to mitigate health disparities, as seen in communications by the Global Initiative for Childhood Cancer [13]. Narratives can function as a lobbying tool for policy design and implementation and for gaining public support to improve cancer care [15].

The importance of how we tell stories about cancer and how these stories can catalyze change begs the question: how can we promote expertise in narrative-based practice for oncology professionals? Currently, few fellowships offer formal instruction in writing or other forms of narrative-based practice, limiting skill development during training. Growing the next generation of oncology clinicians with narrative expertise could have far-reaching implications for advancing the field. Here, we describe a novel track for graduate-level education in creative writing concurrent with medical subspecialty training to promote narrative competence among physicians and advance the field of narrative in oncology.

Creative Writing as a Flexible Graduate Degree Option for Oncologists

For hematology-oncology trainees with a particular interest in humanism in medicine, we advocate for integration of a Master of Fine Arts (MFA) degree concurrent with fellowship training. The MFA in Creative Writing is a graduate degree that offers students the opportunity to hone their writing craft and lifelong careers as writers with guidance and personalized feedback from expert writing instructors and published authors as faculty. This pathway can equip trainees with advanced skills in narrative competence, informing research and other scholarly activities during fellowship and building a foundation for a future career that promotes humanism in clinical care, education, research, and advocacy.

While traditional MFAs comprise two to three years of in-person education, ‘low-residency’ MFA programs offer two-year part-time graduate degrees that can be completed alongside full-time training. Presently, 52 low-residency MFA programs exist in the United States, offering a hybrid model of virtual asynchronous learning combined with in-person didactics [16]. Most MFA programs include tracks in nonfiction that can be tailored to the academic goals of oncology trainees and professionals. Formal training through an MFA provides infrastructure to develop advanced skills in narrative competence and writing through experiential learning, practical skill development, and personalized one-on-one feedback from renowned writers and scholars. While opportunities to enhance narrative skills exist outside of the MFA through nonaccredited classes and online writing communities, graduate-level training provides a comprehensive foundation in narrative techniques with longitudinal mentorship tailored to the student’s content area of interest. Additionally, each degree culminates in a full-length manuscript through a master’s thesis, readily translatable into scholarly writing for scientific or lay communities to advance the field.

Pursuit of an MFA Degree During Oncology Training

To our knowledge, St. Jude Children’s Research Hospital is the first institution in the United States to offer a formal track for fellows to integrate an MFA into their training, combining protected research time with pursuit of this degree (Figure 1). Recognizing that common barriers to pursuit of an MFA include time and cost, our institution subsidized the MFA similar to other graduate degrees. Our first trainee to complete an MFA through the integrated narrative oncology track demonstrated unique achievements in scholarly productivity across research, clinical care, education, and advocacy domains, supporting the feasibility of completing an MFA within the fellowship period. The trainee received targeted education and feedback to enhance her narrative competence and writing skills, resulting in publication of numerous essays in impactful journals including the Journal of the American Medical Association [17]. With research mentorship through fellowship and writing techniques learned through the MFA, the trainee also designed, implemented, and rigorously studied a narrative writing intervention for adolescents and young adults with cancer that was found to be feasible, acceptable, and impactful. The trainee further conducted a comprehensive systematic review of the literature, synthesizing the benefits of narrative-based interventions for cancer care professionals. During her MFA, the trainee also developed and implemented narrative-based educational programming for interdisciplinary fellows across multiple hospitals, including integration of narrative approaches into longitudinal curricula, workshops, and bedside rounding. Additionally, the trainee taught narrative competence to undergraduate, medical, and healthcare students, as well as connected with multidisciplinary cancer care professionals nationally and internationally to foster community and collaboration related to narrative competence across the field. Currently, the trainee is orchestrating efforts to create a national consortium to leverage narrative hematology-oncology expertise and consolidate resources in a shared central location to advance research in narrative-based practice. From a scholarship perspective, the MFA promoted prolific scientific and narrative writing within the 24 month period of the MFA, including four original research manuscripts [4,18,19,20], two narrative essays in peer-reviewed medical journals [17, 21], an essay in a book

XSL•FO
RenderX

[22], and three lay publications raising awareness about narrative writing in cancer care [23-25].

Figure 1. An embedded training model for pursuit of a Master in Fine Arts (MFA) degree in creative writing during Hematology/Oncology Fellowship. During the first year of hematology-oncology fellowship, trainees should engage in conversations about graduate-level funding with their institution. Each semester of a low-residency MFA begins with a full-time residency, comprising 7 - 10 days of in-person instruction. Students participate in a total of 5 residencies over the 4 semesters, with the fifth and final residency occurring after submission of a thesis. Joint pursuit of the MFA during hematology-oncology fellowship can promote narrative skills that can inform a trainee's scholarly activities in research, education, and advocacy. MFA: Master of Fine Arts.

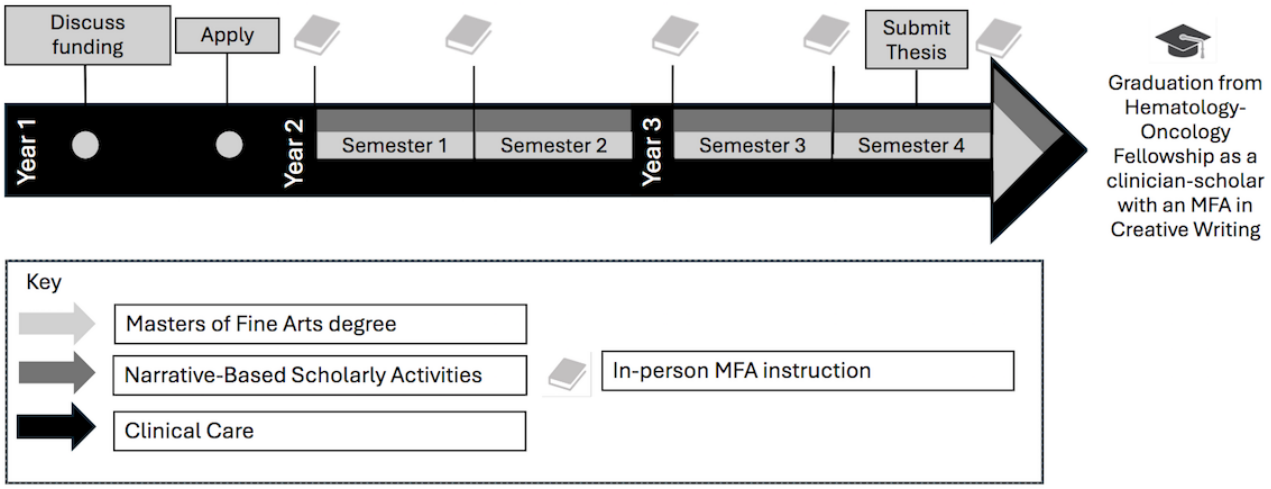

Figure 1 describes a novel training pathway for hematology-oncology fellows with a targeted interest in developing expertise in narrative competence. Hematology-oncology fellowship traditionally includes one year of clinical medicine followed by two years of protected scholarship time. MFA applications typically are due in the spring and consist of a personal statement, letters of recommendation, and a 20-page writing sample. The embedded training model described in Figure 1 enables pursuit of graduate-level training to hone expertise in narrative competence with concurrent impact in clinical practice and scholarly activities during training and beyond.

Positioning trainees to be thought leaders in narrative oncology as faculty members can advance narrative-based clinical care, education, research, and advocacy in cancer care in alignment with individual trainee interests. Further quantitative and qualitative data are needed to evaluate how participation in an MFA in creative writing during fellowship may impact metrics like trainee wellness, career development, and patient-centered outcomes. Measurable deliverables might include frequency and extent of didactics and experiential learning opportunities related to narrative oncology, volume of students with exposure to the field and access to mentorship in this area, and growth of narrative-based research studies conducted by graduates of the narrative oncology track.

We believe that institutions with fellowship programs that have capacity to support graduate studies should include the MFA as an option for hematology-oncology fellows who aim to be thought leaders in narrative medicine. We also encourage institutions to anticipate logistical aspects to streamline this process. As with other graduate programs in the United States, incoming trainees should apply during the spring of their first year to align coursework with protected research time. Trainees accepted into an MFA program may need to proactively arrange their call schedules to accommodate 1 - 2 weeks spent at in-person residencies each semester. Barriers for trainees to receive support for the MFA across diverse fellowship settings may include limitations in clinical scheduling flexibility, lack of institutional precedent, lack of institutional awareness about the value of narrative expertise in oncology, or cost. For programs that subsidize the cost of graduate training for fellows, overall costs for an MFA are typically less than those for other master programs. Including costs for transportation and accommodations during in-person residencies, the cost of a low residency MFA generally ranges from US $30,000 to US $80,000, compared to traditional costs for other graduate degrees that often fall in the US $60,000 - US $100,000 range. Potential return on investment from the MFA in creative writing may include advancement of the nascent field of narrative oncology at a national level; increased opportunities for networking, mentorship, career development, collaboration, and community-building in narrative oncology; and improvements in job satisfaction and trainee or faculty wellbeing. Growing awareness of narrative oncology and mentorship across institutions may help facilitate increased implementation of this training pathway across diverse fellowship settings.

In summary, the MFA serves as a strategic mechanism to invest in growing the next generation of oncologists with expertise in narrative competence. Storytelling is integral to advancing the field of oncology [2], and we encourage institutions to explore approaches to implementing this innovative track for trainees and faculty to gain the requisite skills to harness narrative-based practice as a powerful tool to advance the field through clinical care, research, education, and advocacy.

Abstract

While patient-reported outcome measures are regularly incorporated into phase 3 clinical trials, they have been infrequently used in early phase trials. However, the patient's perspective is vital to fully understanding dose toxicity and selecting an optimal dose. This viewpoint paper reviews the rationale for and practical approach to collecting patient-reported outcome data in early phase oncology drug development and the rationale for electronic collection.

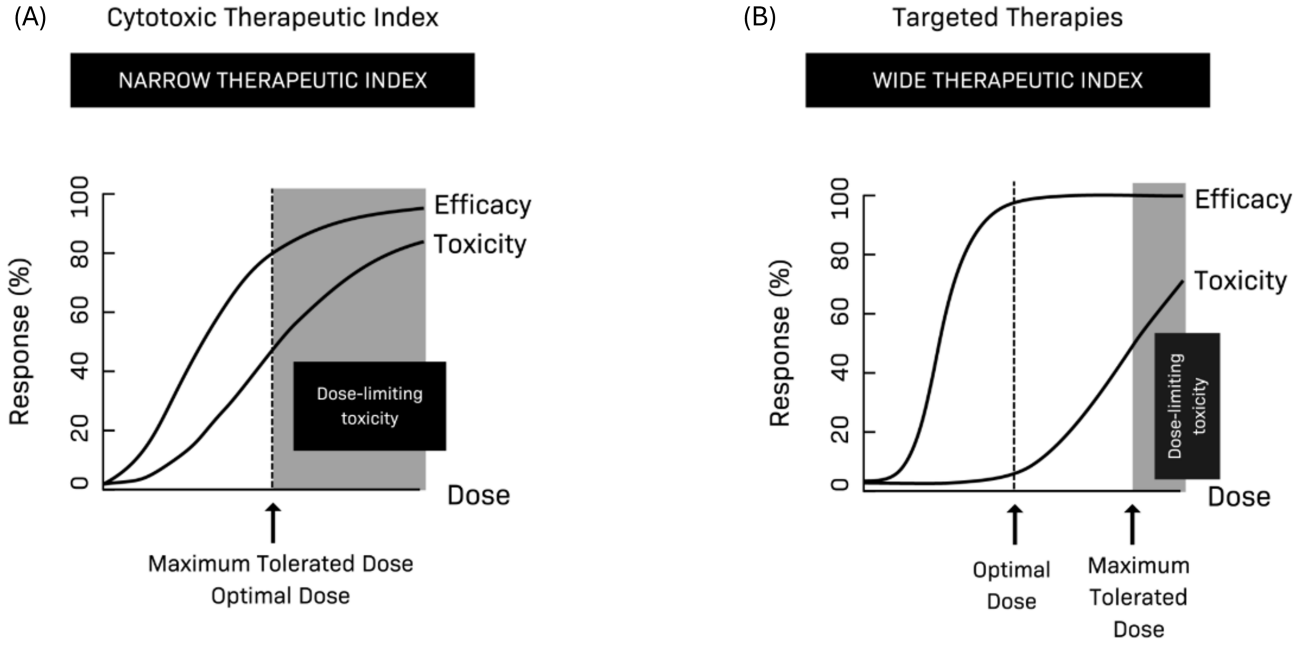
clinical trials; early phase; dose finding; patient-reported outcome; PRO; electronic patient-reported outcome; ePRO; PRO-CTCAE; adverse events; tolerability; optimal dose; cancer trials; dose toxicity; oncology; drug development; electronic collection; dose level; pharmacodynamic; cytotoxic chemotherapy drugs; cytotoxic; chemotherapy drug; life-threatening disease; Common Terminology Criteria for Adverse Events

Dose Finding in Oncology Drug Development

Traditional dose findings in oncology clinical drug development have focused on determining the maximum tolerated dose, assuming that the efficacy-dose relationship follows a steep monotonic increasing curve. By this assumption, the recommended dose is defined as the highest dose in which dose-limiting toxicity is not observed. Typical early phase programs (Figure 1) often use a 3 + 3 dose escalation design in which subsequent cohorts of 3 patients are studied, each receiving a higher dose than the last. Dose levels often follow a modified Fibonacci sequence whereby dose increments become smaller as the dose increases [1]. When dose-limiting toxicity is observed in at least one patient, the dose level is repeated in a further cohort of 3 patients, and if dose-limiting toxicity is observed again, further escalation stops, identifying the previous dose as the recommended maximum tolerated dose to take forward. Further study of the recommended dose is achieved, often using a seamless phase 1-2 design, by recruiting an additional larger group of patients into a dose expansion study. The primary end point in an expansion cohort is usually to determine efficacy, most frequently according to the radiological response rate. Additionally, further safety data is gathered, and pharmacodynamic markers may also be developed.



XSL•FO
RenderX

Figure 1. Traditional early phase oncology dose-finding studies. RECIST: Response Evaluation Criteria in Solid Tumors.

This approach has been acceptable for cytotoxic chemotherapy drugs due to their steep dose-response relationships, their limited drug target specificity, and the willingness of patients to trade off substantial toxicity to treat serious, life-threatening diseases [2]. However, it may lead to the recommendation of higher doses and a suboptimal tolerability profile when used in dose finding for modern, more targeted oncology drugs such as kinase inhibitors and monoclonal antibodies (Figure 2). In these cases, the wider therapeutic index means that a range of doses may show relevant efficacy, and doses below the maximum tolerated dose may have similar efficacy with reduced toxicity [3]. This can be particularly important because targeted therapies are often taken for much longer periods, during which lower grade, persistent symptomatic toxicities can present a greater challenge to patients [2]. Dose finding limitations have been illustrated in 26% of Food and Drug Administration (FDA)–approved kinase inhibitors (2001‐2015) requiring postmarketing requirements/commitments to study alternative doses [4].

Figure 2. Dose-response relationships and optimal dose selection for cytotoxic chemotherapy drugs and targeted therapies.

Better characterizing dose response to optimize dose finding has been underlined by the FDA's Project Optimus, which aims to reform how doses are selected in oncology clinical trials, with a particular focus on maximizing efficacy and optimizing safety and tolerability [5]. This led to their subsequent guidance on dose optimization for new cancer treatments [2]. Studying more dose levels in the dose expansion study may be one approach to enable this and may better enable characterization of the dose-response relationship, albeit qualitatively given the likely small cohort sizes.

Understanding Tolerability

Tolerability is defined in good clinical practice as "the degree to which overt adverse effects can be tolerated by the subject" [6]. In oncology, assessment of tolerability typically comprises clinician-reported treatment-related adverse events (AEs) using, for example, the Common Terminology Criteria for Adverse Events (CTCAE) [7], along with other data such as dose modifications, discontinuations and interruptions, safety biomarkers, hospitalization, and death [8]. However, these tools and data fail to fully account for the patient's perspective or to

XSL•FO
RenderX

fully measure the impact of AEs on the patient's activities and quality of life. Many studies comparing physician and patient reports of treatment-related AEs have consistently shown underreporting and reduced severity rating in physician interpretations compared to patient reports [9-16]. This represents a challenge for drug developers in accurately quantifying the dose-toxicity relationship and limits the ability to define optimal doses, leading to a greater risk of exposing greater numbers of patients to doses that are too high, potentially resulting in increased discontinuation and a less favorable safety profile.

For example, measuring the frequency of individual AEs reported by early phase patients using the full Patient-Reported Outcomes version of the CTCAE (PRO-CTCAE) item bank [17], Veitch and colleagues [9] evaluated the associated frequency of reporting of the same AEs by physicians using the CTCAE. They found that all 50 AEs reported by at least 10% of patients undergoing cancer treatment (n=243) were consistently underreported by physicians using the CTCAE, in some cases markedly. For example, 9 AEs were identified at least 50 times less frequently by physicians: decreased libido (31.4% vs 0.1%), palpitations (14.7% vs 0.1%), wheezing (14.5% vs 0.2%), voice alteration (14.1% vs 0.2%), hiccups (13.9% vs 0.1%), hyperhidrosis (23.9% vs 0.4%), vaginal dryness (11.0% vs 0.1%), nail ridging (10.0% vs 0.2%), and urinary incontinence (10.0% vs 0.2%). Further, 19 CTCAE items were reported 1% or less of the time by physicians, compared to 10%-31.4% by patients.

A further study in 1933 patients with a variety of oncology conditions treated in various routine care settings reported an underestimation of AE severity by clinicians in comparison to patient reports [10]. The frequency of symptoms assessed as moderate or severe by patients and physicians, respectively, were pain (67% vs 47%), fatigue (71% vs 54%), generalized weakness (65% vs 47%), anorexia (47% vs 25%), depression (31% vs 17%), constipation (45% vs 30%), poor sleep (32% vs 21%), dyspnea (30% vs 16%), nausea (27% vs 14%), vomiting (14% vs 6%), and diarrhea (14 vs 6%). While this study was not conducted in an early phase setting, it is likely that the discordance in clinician and patient assessments, consistent with Veitch et al [9], would be similarly reflected in early phase research.

These examples demonstrate that physician assessment of patient AEs may be both incomplete and underestimated in comparison to the patient perspective. Reasons for this may include patient difficulties in spontaneously raising or describing AEs, patient fears of delay or discontinuation of treatment options in which they have high expectations of positive results, introduction of clinician subjectivity, and time constraints and practical limitations with current physician tools.

While valuable in addressing the underreporting and lower scoring of AE severity by physicians, the PRO-CTCAE alone fails to assess the cumulative impact of the AE profile and the effects on functioning and quality of life. The cumulative impact may be especially important in newer treatments taken for sustained periods, where multiple, concurrent, low-grade but persistent AEs may together represent an intolerable burden for the patient. As we describe later, supplementing the rating of individual AEs with an overall single-item measure of the cumulative impact of AEs (eg, using the Functional Assessment of Cancer Therapy–Item GP5 [FACT GP5] [18] or item 168 from the European Organisation for Research and Treatment of Cancer [EORTC] item library [19]) and the adverse impact on patient physical function and role function (eg, measured using the associated subscales of the EORTC Quality of Life Questionnaire—Core Questionnaire [EORTC QLQ-C30] [20]) provides a valuable assessment of the impact of the AE profile experienced.

Using Patient-Reported Outcomes in Early Phase Oncology Trials

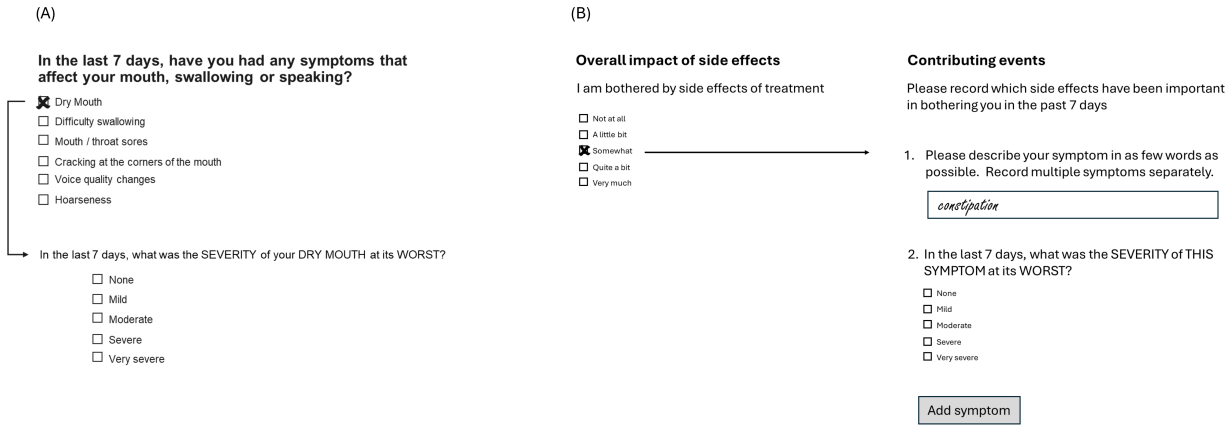
Overview

While the use of patient-reported outcome measures (PROMs) is increasingly incorporated into phase 3 clinical trials, and regulatory recommendations on measurement strategy have been recently published by the FDA [21], there is little use of PROMs in early phase trials [22]. Barriers to adoption in early phase oncology studies include a lack of guidance regarding PROM selection, concerns relating to dealing with missing patient-reported outcome (PRO) data, overburdening site staff and patients, handling patient and data queries [23], and low power associated with small sample sizes. Nonetheless, the patient perspective is a vital element of fully understanding dose toxicity and selecting an optimal dose for later phase development.

Adverse Events

In later phase trials, there is typically enough understanding of the AE profile of the investigational treatment to enable a reliable preselection of items for measurement (eg, using a small subset of PRO-CTCAE items). The same is not true for first in human and other early phase trials. Preclinical data may provide some signals to drive thinking, but these are unlikely to be robust and comprehensive, and while the AE evidence from other drugs with the same mechanism of action may be available and relevant, this is not always the case. The full PRO-CTCAE instrument contains 124 items across 78 distinct terms [17], and this is impractical to use in a full list format for regular ongoing measurement.

Janse van Rensburg and colleagues [24] used a statistical approach to develop a reduced list of PRO-CTCAE items considered most likely to occur in a phase 1 population using the same dataset reported by Veitch et al [9]. Using that dataset, they eliminated AEs recorded less than 5% of the time; those recorded as "mild" severity by at least 75% of patients; and AEs associated with interference scores of "not at all," frequency scores of "never," or amount scores of "not at all" by at least 80% of patients. Finally, terms with the lowest internal reliability within each organ system domain, as measured using Cronbach α, were also eliminated. With further refinements from physician perspectives, this led to a tailored PRO-CTCAE survey consisting of 58 items assessing 30 terms. While a useful and interesting approach, the generalizability of this reduced survey may be limited by the relatively small sample size, the limited



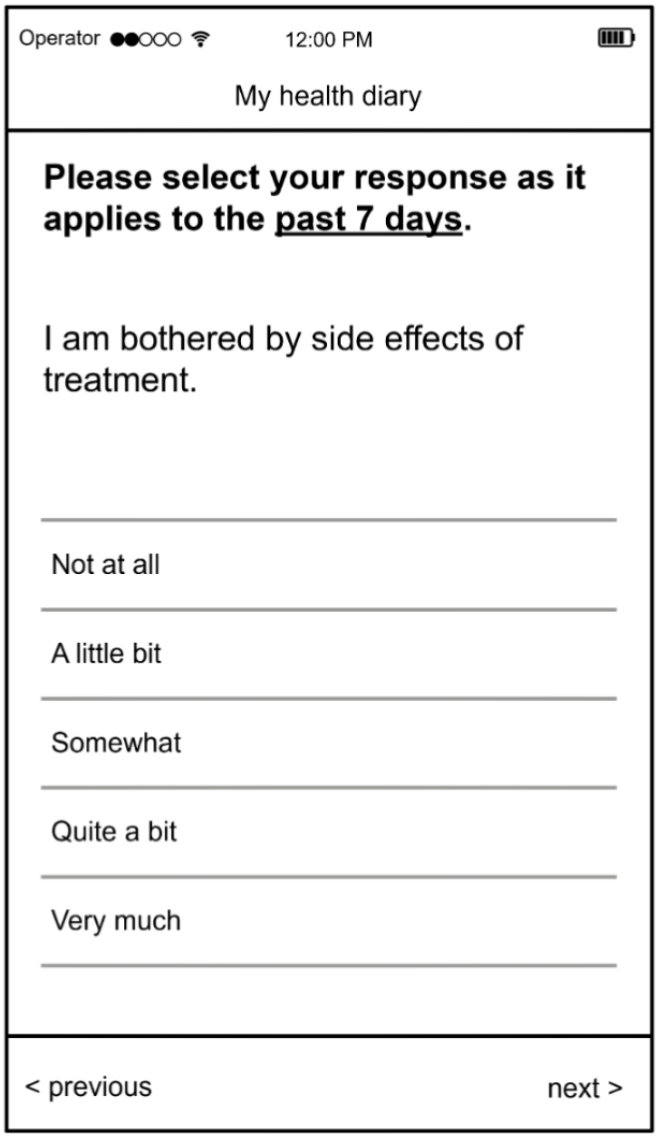
XSL•FO
RenderX

set of treatments and tumor types represented, and the risk that using historical data may miss important aspects of tolerability for new targeted therapies.

When selecting a reduced set of predefined items, it is helpful, as PRO-CTCAE recommends and allows, to include a free-text item to capture other important AEs not listed [25] and to use this information to allow the item list to adapt with the emerging understanding gained through continued study.

Because the PRO-CTCAE items are grouped by organ system domains, it is possible to optimize the completion of the full item list compared to an individual symptom-by-symptom approach (Figure 3A). Alternatively, a free-text approach asking patients to list and rate the AEs that contribute most to their overall impact rating (scored using the FACT GP5 item, for example) might provide a less burdensome approach (Figure 3B). Leveraging an electronic PRO (ePRO) solution, using a smartphone app, for example, would enable free-text symptom text to be resurfaced as a list of existing AEs to be easily rescored at future time points.

Figure 3. Approaches to simplify adverse event capture and scoring (A) using organ system grouping and (B) collecting the most bothersome adverse events associated with overall impact score.



Collecting the most bothersome AEs (Figure 3B) has similarities to some existing PROMs that measure the most bothersome symptoms (MBSs). For example, MBS has been shown to be a useful patient-centric measure of migraine symptoms [26,27] and is referred to in the patient-focused drug development guidance published by the FDA [28]. Challenges with collecting an MBS include how to pool data in the statistical analysis and different symptoms becoming the most bothersome over time. However, these challenges may be less relevant when collecting the set of most bothersome AEs to understand the dose-toxicity relationship in early phase cancer trials.

Other Recommended PROMs

The Friends of Cancer white paper [8] and FDA guidance on PROs in cancer trials [21] both recommend that in addition to the collection and scoring of individual AEs, an overall measure of the AE impact is included, along with measures to assess the impact of treatment on physical function and role function, although the FDA guidance is more focused toward use in confirmatory trials. A single item to score the overall impact of AEs, such as the FACT GP5 [18] (Figure 4) or Q168 of the EORTC item bank [19], is important as it enables the patient to account for the impact of any AEs not covered by PRO-CTCAE administration and to attach greater importance to the combined impact of multiple low-level AEs. This understanding may be particularly important in assessing the impact of newer treatments taken over longer periods. The FDA has identified measures of physical function and role function they consider suitable, including the EORTC QLQ-C30 physical function and role function subscales [20] and the Patient-Reported Outcomes Measurement Information System (PROMIS) physical function scale [29].

Mitigating Barriers to PROM Adoption in Early Phase Trials

As described earlier, barriers to the adoption of PROMs in early phase cancer trials include a lack of guidance regarding PROM selection, concerns relating to dealing with missing PRO data, overburdening site staff and patients, handling patient and data queries [23], and low power associated with small cohorts. We address PROM selection in the discussion above. Dealing with missing data is always an important consideration in clinical research, as different missing data approaches rely on assumptions that, if violated, can lead to biased estimates. Although researchers in early phase trials may use less formal approaches to interpreting the data and determining the optimal dose, it will remain important to consider the impact of missing data using a variety of sensitivity evaluations.

In terms of patient burden, the UK National Cancer Research Institute Consumer Forum survey indicated that most patients and carers affected by cancer and involved in research activities (n=57) were willing to spend up to 15 minutes per day completing PROMs [23]. This time duration seems high for frequent collection but perhaps reflects the value that patients see in communicating this data to their treating physician. The measures we have discussed above typically use a 7-day recall period, and it is, therefore, most likely that a weekly completion schedule would be recommended. Recall bias using the weekly recall periods associated with these validated measures is unlikely to be a concern, but ensuring completion times do not overburden patients with the debilitating effects of the disease and treatment is an important consideration. Median per-item completion rates of PROMs commonly used in oncology trials have been reported as 6 - 14 seconds [30], which suggests that a weekly PROM assessment of, for example, the PRO-CTCAE implemented using the approach outlined in Figure 3A, an overall AE impact item, and the physical function and role function subscales of the QLQ-C30 (items 5 and 2, respectively) might translate to an average completion time of less than 5 minutes per week. This seems to be a feasible assessment strategy, and ensuring a flexible completion window across more than 1 day may drive higher completion rates.

XSL•FO
RenderX

The remaining barriers cited may be mitigated by electronic collection of PRO data, for example, by using an ePROs smartphone app. The burden on site staff and patients during busy clinic visits can be mitigated by enabling at-home completion, and electronic tools can eliminate data queries by prohibiting ambiguous or invalid entries. The easy implementation of longer lists of items using branching logic to speed completion is only practical using an electronic approach. Further, the use of ePRO solutions can also lead to reduced missing data through alarms, reminders, and remote monitoring to drive on-time completion.

Electronic collection of PRO data may be perceived as a significant additional cost relative to the smaller numbers of patients involved in early phase studies, but this should be considered in the context of the value of the data. The more frequent assessment schedules and the nature of the measures implemented drive the use of electronic solutions. In the context of the increased expense of studying more patients in early phase trials due to the need to better characterize dose response, the use of ePROs to drive more accurate, reliable data may lead to accurate decision-making using relatively smaller sample sizes and offset the cost of ePROs many times over.

Smaller sample sizes associated with early phase studies may limit the robust characterization of the dose-response relationship, but this limitation is not unique to PRO data and also applies to other measures of efficacy and tolerability that inform dose selection. A thoughtful approach is required to balance the cost of increased sample size with the statistical robustness of dose-response characterization. Supplementary qualitative data collected using in-trial patient interviews may be a valuable addition to understanding the AEs experienced by the patients and aid the interpretation of PROM data when limited by small sample sizes.

Conclusion

There is growing interest in more completely quantifying the dose-response relationship to inform optimal dose determination for new oncological treatments. PROs play a vital role in understanding dose tolerability profiles, especially as treatment-related AEs tend to be underreported and underscored by physicians. While AE profiles are less understood in early phase drug development, this should not prevent the capturing of this data to inform dose selection decisions as early as the first in human study using some of the approaches discussed in this paper.

Of course, we lack experience in interpreting PRO tolerability data from such early studies and need to remember that we may not have adequately defined the patient population at this early stage, and so the clinical interpretation of dose-response relationships associated with the PROs and other efficacy and tolerability data needs to be interpreted with this in mind.

With newer targeted therapeutics, there is a need to learn much more about safety and tolerability across a wide range of doses, and the current dose-finding models focusing on a single “optimal” dose may no longer work. A fundamental element of the decision-making process for determining safety and tolerability currently missing is the patient experience. It has been assumed that the physician, through patient interaction and AE reporting, can provide a sufficient reflection of the patient experience, but the evidence demonstrates that this is not reliable. Some important symptoms for patients are missed completely. The severity of other symptoms is underreported. Further, with newer targeted agents, AEs may accumulate over time, and the chronic nature or combination of events may make a dose become intolerable for the patient later. If the patient’s perspective is not considered, there is a risk of selecting dose groups that are too high, leading to reduced compliance. It is, therefore, necessary to build a PROM assessment strategy for early phase trials that combines elements of well-established scales to assess safety and tolerability in a package that is practical and not burdensome, yielding vital data to support decision-making as the trial progresses. Maximizing the value of the early patient experience is ethically appropriate and feasible, and drives efficiency in development programs and patient exposure.

Authors' Contributions

Abstract

As patients with cancer increasingly seek guidance from online sources, the patient-clinician relationship is at risk of being displaced by fragmented, often unreliable information. One of the primary drivers of this trend is the insufficient time available for in-depth, relational consultation with health care providers (HCPs). We argue that the current clinical routine, constrained by documentation and administrative demands, fails to allow adequate time for supporting the informational, emotional, and relational needs of patients navigating complex decisions. This shortfall undermines HCPs' ability to engage patients in shared decision-making and weakens the foundation of trust between patient and HCP. For some patients, this can result in selecting less-effective treatments or turning away from evidence-based care toward unproven online alternatives. While policy reforms to reduce administrative burdens and free up time for patient education and counseling are essential, they are slow to materialize, making immediate, actionable steps at the clinician level more urgent. We propose a set of practical, evidence-informed strategies that clinicians can adopt today to help meet patients' informational and emotional needs, strengthen patient-HCP relationships, and ensure that patients' health care decisions fit their preferences and are supported by scientific evidence.

Introduction

One of the most pressing challenges in cancer care is insufficient time available for patient visits and patient-centered conversations [1]. While not the only factor, time constraints play a pivotal role in motivating patients with cancer to seek information from nonclinical sources, particularly those that they can find online [2-6]. Available at the fingertips of many patients and their caregivers, online cancer-related content is often either incomplete, unreliable, or dangerously inaccurate [7-10]. In this Viewpoint, focusing on the US health care system, we illustrate how limited time with health care providers (HCPs) contributes to patients' reliance on nonclinical sources of information and increases their risk of making poorly informed, value-discordant decisions. Figure 1 shows a potential pathway to these decisions. While needed policy changes to rebalance HCPs' time from administrative tasks and paperwork to patient counseling are yet to come, we identify and propose practical, actionable strategies to help HCPs mitigate the migration of patient trust to online sources.

Figure 1. A pathway from limited clinical time for patient consultation to misinformed decisions by the patient.

Time Barriers in Patient-Clinician Communication

A cancer diagnosis immerses patients into an emotionally charged and cognitively demanding landscape, where they must navigate complex clinical information, often under intense psychological stress. When people need to find cancer-related information, about 55% of them will reach a physician first, according to the Health Information National Trends Survey conducted in 2020 [11]. Patients place immense trust in their clinicians, seeking guidance in navigating complex treatment decisions. According to the National Trend Survey and Pew Research Center, more than half of patients believe they can consistently rely on their physicians to carry out care duties effectively, demonstrate care for patients' interests, and offer accurate information [12,13]. However, when it comes to delivering cancer information to those who are looking for it, both patients and HCPs encounter a critical barrier—time availability for patient counseling.

Before 2012 [14], the average duration of an oncology outpatient encounter ranged from 17 to 23 minutes. While average visit length has remained relatively stable over time [15], the complexity of these visits has increased dramatically [16]. With the development of new treatments, the number of pages in practice guidelines for oncology has almost doubled over the same period [17]. Today, HCPs must not only assimilate a substantially greater volume of medical knowledge but also convey a share of that knowledge to patients in a clear and understandable manner within a similar time limit as 13 years ago. In addition to a dramatic increase in knowledge, systemic drivers play a role in the time pressures on clinicians. HCPs have to dedicate clinical time to managing referrals and orders, extensively documenting visits, seeking insurance preauthorizations, and navigating business-driven financial pressures to see more patients (eg, relative value unit–based reimbursement). These factors ultimately reduce HCPs' availability for spending time with patients. Despite clinicians' best efforts, the constraints of a typical clinical routine leave little room to fully address the range of informational needs regarding diagnoses, tests, and treatments, as well as physical and psychosocial burdens.

Unmet Information Needs

Many newly diagnosed patients leave their medical appointments without a clear understanding of their treatment options [18], and they have unmet information needs related to supportive care, including information about psychological and physical adjustment to daily living and information about managing symptoms and side effects [19,20]. Although limited time is not the only factor contributing to patients' unmet informational needs, it exacerbates other well-documented challenges, such as limited health literacy [21], delays in access to HCPs [22], and gaps in HCP communication skills [23]. Limited time with clinicians remains one of the key barriers to meeting patients' information needs and exacerbates the other issues [24].

Time constraints make it difficult for patients to voice their preferences, ask clarifying questions, or request further explanation—all of which are essential to meaningful shared decision-making [25]. Limited time for shared decision-making is especially concerning, given that many cancer-directed treatments place a significant burden on patients, often involving life-altering side effects that patients must self-manage outside of clinical settings. If patients have unmet information needs

XSL•FO
RenderX

or misunderstand their treatment options and potential consequences, they may be poorly prepared to adhere to their treatment, manage their side effects, and, thus, miss the opportunity to have a better quality of life and treatment outcomes [26-28]. Therefore, time for collaborative shared decision-making is critical not only for maintaining trusting relationships but also for optimal patient outcomes that are concordant with their goals.

From Informational Needs to Anxiety

Unmet information needs increase uncertainty and, consequently, anxiety among patients with cancer. Patients who reported being unsatisfied with the information provided also reported higher levels of anxiety and depression, as well as a lower quality of life [29]. Further, among women with breast cancer, those with unmet information needs at baseline had increases in anxiety over time [30]. Notably, unmet informational needs that contribute to heightened anxiety can create a vicious cycle of negative experiences. Higher levels of anxiety correlate with patients' ability to recall information from clinical encounters [31]. Furthermore, compared to patients with lower anxiety, those with higher anxiety report feeling less comfortable asking clinicians questions and trusting HCPs' opinions [32]. In turn, clinicians may be less likely to initiate difficult conversations with anxious patients, leading to further disconnects in trusting patient-clinician relationships [33]. Although not the sole solution, allocating additional time to address patients' informational needs is a critical component, especially during periods such as initial diagnosis or significant changes in disease status (eg, progression or recurrence). Investing time into informational needs is a time-efficient strategy: when patients' needs are not met and collaborative, shared decision-making is not established, patients feel disconnected from their HCPs, and more time is required to rebuild trust.

Information Search Online

As patient-centered communication weakens and uncertainty or anxiety builds, patients tend to invest more effort in seeking cancer information outside of clinical sources [2]. Although more than half of patients with cancer search for health-related information online, those who are dissatisfied with their care use online information significantly more [34]. In general, online information could be helpful and support patients' education, preparing them for health-related conversations with their HCPs [35] and for self-management [36]. At the same time, patients use various sources of information, and the information provided is not always accurate. For instance, a recent study showed that up to 65% of people affected by cancer were willing to use social media to make medical decisions [37]. Another study indicated that 1 in 10 patients with cancer has based their medical decisions on the recommendations they identified on social media [38]. The quality of health information online, particularly on social media, remains questionable, with studies showing that up to 30% of posts related to cancer may be inaccurate, potentially leading patients toward harmful or suboptimal outcomes [7,39]. When evaluating the quality of online information, individuals tend to rely on observable factors, such as navigability, aesthetics, and ease of understanding, rather than on elements that truly reflect the information's quality [40]. Thus, without proper consultation with health care experts, patients who search for information online are at risk of making misinformed decisions. The more patients rely on potentially unreliable sources, the more they become disconnected from their clinicians (ie, evidence-based sources), and the more time clinicians must spend later correcting misconceptions. Proactively addressing patients' informational needs can help prevent misunderstandings and reduce the time required to correct patients' knowledge in future visits.

Risk of Misinformed Decisions

When patients cannot meet their informational needs or verify information with their trusted HCP, they face a risk of making suboptimal decisions that lead to poor clinical outcomes. For example, patients who use prescribed medication and rely on digital sources were 18% more likely to report low adherence than those who relied on health professionals (62% vs 44%) [41]. Similarly, use and trust in information from mass media and social media platforms undermined patient understanding of health-related information and reduced adherence to medical recommendations in different contexts [42,43]. In the cancer context, inaccurate and unreliable information often appears in the form of overly optimistic claims about complementary or alternative therapies. While some complementary therapies may offer great benefits for patients with cancer (particularly for managing symptoms) [44], if used without health care expert guidance, complementary medicine may lead to harmful outcomes. For instance, patients with cancer who use complementary medicine relying on inaccurate information tend to delay or report nonadherence to evidence-based treatments [45-47]. Furthermore, those patients who delayed evidence-based cancer-directed therapy and relied solely on complementary approaches had a 2-fold greater risk of death compared to those who did not delay standard therapy [48].

Time as a main barrier for discussing complementary medicine and other patient-identified information from nonclinical sources has long been recognized [49]. Yet, despite significant changes in the informational landscape in the last decade, where patients with cancer now have greater access to medical advice of varying quality through web sources and social media, this barrier remains unaddressed [50].

Importantly, dedicating more time to a discussion might not be enough for patients who are relying on nonclinical sources of information. Without proper training, patient-clinician communication may fall short. Currently, up to 37% of patients with cancer reported having negative experiences when bringing to HCPs information they found on their own [39]. Compared to those with positive experiences, these patients express significantly lower trust in information provided by HCPs [39]. This evidence suggests that discussion of patient-identified information likely requires not only a time commitment during a visit but also requires HCPs to invest time in receiving training for improving communication skills. Thus, supporting patients

XSL•FO
RenderX

at the time of diagnosis and across the cancer continuum by addressing their informational needs, helping them access reliable sources, and validating their findings may not only lead to better outcomes but also help maintain trust and make clinical consultations more time-efficient and impactful.

Action Plan for Insufficient Time With Patients

As patients increasingly turn to the internet and social media for answers to questions that could not be addressed in their visits—often at great personal cost—there is an urgent, unaddressed crisis at hand. As illustrated above, unmet informational and emotional needs frequently drive patients to seek support elsewhere and rely on nonclinical, potentially unreliable recommendations. While not the sole factor, limited time with HCPs remains a significant contributor to this concerning pattern. Increasing meaningful interactions and optimizing available time with the health care team can help patients better meet these needs and make informed, evidence-based decisions. Importantly, critical adjustments do not always require extensive effort. How can HCPs meet patient needs when more time is not an option? We summarize in Table 1 several strategies to optimize interactions with patients and provide examples from prior literature.

Table 1. Time-saving strategies for patient education in a digital information era.

Identified issue and recommendations	Implementation	Examples of using the recommended approach
No time to address patients' questions		
Set a collaborative agenda at the beginning of a visit	Ask the patient about their agenda, establish the number of concerns that can be addressed, and collaborate on a plan for any remaining issues.	Collaborative agenda-setting did not increase visit length, but reduced the amount of "oh by the way" concerns that surfaced at the end of the visit [51].
Assess patients' concerns and questions preemptively, prior to the visit	Assessing patients' concerns could be completed either in paper-and-pencil format in a waiting room or via electronic check-in with artificial intelligence–powered chatbots and electronic visit planners.	Patients who used a visit planner in the waiting room were more prepared and began the visit by communicating their top concerns [52].
Diversify modes of communication	Telehealth visits, e-visits, or communication via a patient portal could be helpful to meet patients' remaining needs after clinical encounters.	Asynchronous e-visits through a patient portal provided clinical outcomes that were comparable to those provided by in-person care [53].
No time to ensure patient understanding of clinical information		
Educational sessions	Use follow-up visits or education in small groups to clarify diagnosis and treatment options.	A group session saved 111 hours of clinical time, with 92% of patients increasing confidence regarding critical concepts in oncology care [54].
Use educational materials about evidence-based treatment	Use standardized printed materials.	Patients who received printed chemotherapy information had almost 3 times greater odds of understanding their goals of care [18].
No time to verify information that patients find on their own		
Direct patients to reliable digital resources	Preemptively advise patients on where to find high-quality resources for self-education, considering patients' literacy, e-literacy, cultural background, and access to digital resources.	An example from a qualitative research, in which clinicians share their recommendations on how to help patients to stay informed: "...maybe suggest some more sites that will...have... more reputable information...direct them that way" [55].
Contribute to increasing patients' digital literacy	Share tips with patients on how to identify reliable information and direct patients to resources that might help them learn about finding reliable information, including educational materials and workshops.	The National Cancer Institute provides resources for patients on how to identify reliable information online [56].
Engage other health care team members	Patients may address questions about information they find on their own to nurses, medical assistants, nutritionists, integrative specialists, physical therapists, and other experts in the health care system.	Nurse practitioners tend to adopt a patient-centered communication style while communicating about patients' online health information–seeking [57].

One approach is to set a collaborative agenda at the start of the visit, allowing patients to identify their top concerns and helping HCPs prioritize what can be addressed while planning follow-up for unresolved issues. Previsit assessments, via paper forms or electronic tools such as check-in platforms and visit planners, can further streamline care. Artificial intelligence–powered chatbots may assist patients with lower digital literacy by helping them formulate and prioritize questions to prepare for clinical conversations. If visit time remains insufficient, we would like to underscore practices that many clinics currently strive to implement, such as follow-up through video, phone, or secure messaging. Additionally, to improve patient understanding of diagnoses and treatment options, structured educational sessions outside the primary visit, such as follow-up appointments or discussions in small groups, can provide deeper engagement. Further, offering standardized, evidence-based

XSL•FO
RenderX

printed materials reinforces key clinical information and gives patients accessible, reliable resources to review on their own. In Table 1, you will find examples of how these strategies were implemented by clinical teams in different clinical contexts.

Recognizing that some patients will continue to seek information online, clinicians and support staff can preemptively guide patients to trustworthy sources that match their literacy levels, cultural backgrounds, and access to technology. Sharing strategies for evaluating information and offering digital literacy resources, such as educational tools or workshops, can further support this process. Finally, encouraging patients to consult other team members, such as nurses, medical assistants, nutritionists, or physical therapists, helps distribute the time needed for validating patient-identified information and ensures timely, accurate guidance.

While we focused this review on the US health care system, the challenge resonates globally, with multiple studies from other regions reporting issues related to insufficient clinical time between patients and HCPs [58-60]. In today's landscape of highly complex and accessible public health information, which can be both helpful and potentially misleading, it is critical to test and implement strategies that counter time-limited oncology visits and help preserve patient trust while supporting their informed decision-making.

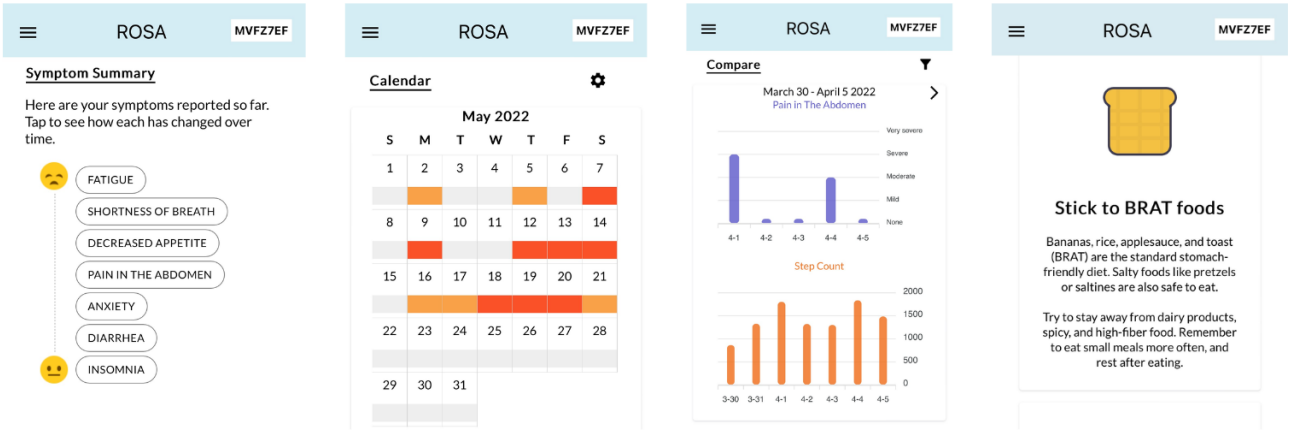
Abstract

This study describes patients' interaction with a personalized web-based visualization displaying daily electronic patient-reported outcomes and wearable device data during outpatient chemotherapy.

(JMIR Cancer 2025;11:e62711) doi:10.2196/62711

KEYWORDS



oncology; cancer; data visualization; remote monitoring; mobile technology; patients; outpatient; chemotherapy; symptoms; side effects; cancer treatment; electronic patient-reported outcome; online; monitoring; self-management

Introduction

Chemotherapy can cause significant symptoms that impact the quality of life [1]. Although electronic patient-reported outcome (ePRO) systems for collecting symptom ratings from patients have become increasingly common in cancer care, most of these are designed for clinicians, and fewer than half share data visualizations with the patients [2,3]. Visualization of ePRO and other data (eg, wearable device data) may help patients undergoing cancer treatment find patterns that help them to prepare for future treatment cycles, manage side effects, and have productive conversations with clinicians [4,5].

As part of a prospective longitudinal National Cancer Institute–funded study to develop a remote symptom monitoring system during chemotherapy [6], we created mobile-friendly web visualizations of each patient's daily symptom ratings and wearable device data (Figure 1). The aim of this paper is to describe patterns of use of these novel visualizations.

Figure 1. Visualizations of daily symptom ratings and wearable data with self-care resources.

Methods

Recruitment and Study Design

Participants undergoing chemotherapy for any solid tumor and who owned smartphones were recruited from oncology clinics at a single academic center in Pittsburgh, Pennsylvania. During the study, the participants wore a Fitbit device (Inspire; Google LLC) and reported 16 symptoms commonly experienced during chemotherapy (eg, nausea, fatigue) daily, using the patient-reported version of the Common Terminology Criteria for Adverse Events [7]. The website also included

XSL•FO
RenderX

evidence-based symptom self-management resources as described by Donovan et al [8].

At the time of enrollment, we provided each patient with a personalized link to their real-time visualizations; however, no instructions about viewing frequency for the visualizations or usage reminders were given during the study. At the end of the 3-month study, 141 patients completed an electronic- or paper-based 11-question survey (mean completion time was 5 min) to assess whether they used the visualizations, frequency of use, helpful information, and suggestions for improvement. Data were collected between February 2022 and April 2024.

Ethical Considerations

The University of Pittsburgh's Institutional Review Board approved all study activities (19070011). At the time of enrollment, all participants provided informed written consent. All data were stored in secure locations and identified only by anonymized study ID numbers. Participants received US $100 and could keep the Fitbit device (estimated value $100).

Results

Characteristics of the participants can be found in Table 1. Survey respondents were heterogeneous in age (mean 61, SD 12; range 29-92 years), race (113/141, 80% White; 28/141, 20% other races), and cancer stage (75/135, 56% stage IV). Approximately half (76/141, 54%) of the participants accessed the link to their data visualizations. Participants with non-binary gender (n=1, 0.7%) and unknown cancer stage (n=6, 4.3%) were excluded from χ^2 analysis while comparing participants who accessed their visualizations. There were no significant differences between the participants who clicked on the link and those who did not during the study in terms of mean age (P=.74), gender (P=.66), race (P=.50), or cancer stage (P=.31). Of those who accessed the platform, most (54%, 41/76) viewed it a few times (ie, less than monthly), while 13% (10/76) used it daily. The 10 daily users were within 3 months of starting chemotherapy for the first time. Most participants (58/75, 77%) found the visualizations *somewhat* or *very helpful/informative*. Few participants shared their data with family members or friends (11/141, 8%) and with others (2/141, 1%); none shared data with their providers or other patients. Participant–suggested improvements included reminders to view graphs and the ability to enter treatment and surgery dates.

Table . Participant characteristics.

Characteristics	Overall (N=141)	Did not click the link (n=65)	Clicked the link (n=76)	Test statistic (*df*)[a]	*P* value
Age (years), mean (SD)	61 (12)	61 (13)	60 (11)	t (130.1)=0.68	.74
Gender, n (%)				$\chi^2(1)=0.2$	.66[b]
Female	94 (66.7)	45 (69.2)	49 (64.5)		
Male	45 (31.9)	19 (29.2)	26 (34.2)		
Non-binary	1 (0.7)	0 (0)	1 (1.3)		
Unknown	1 (0.7)	1 (1.5)	0 (0)		
Race, n (%)				$\chi^2(1)=0.45$	.5
White	113 (80.1)	50 (76.9)	63 (82.9)		
Others[c]	28 (19.8)	15 (23.1)	13 (17.1)		
Stage IV cancer, n (%)				$\chi^2(1)=1.04$	.31[d]
Yes	75 (53.2)	39 (60.0)	36 (47.4)		
No	60 (42.5)	25 (38.5)	35 (46.0)		
Unknown	6 (4.3)	1 (1.5)	5 (6.6)		

[a]Welch two sample *t*-test and Pearson's χ^2 test were used, as appropriate; degrees of freedom (*df*) are provided in parentheses.

[b]Participants with non-binary or unknown gender were excluded from this test.

[c]Other race category included Black or African-American (n=24), Asian (n=2), and more than one race (n=2).

[d]Participants with unknown cancer stage were excluded from this test.

Discussion

Overview

Providing real-time visualizations of ePRO and activity data throughout chemotherapy may help patients anticipate and manage symptoms effectively and potentially identify patterns between activity or other sensor data and symptoms. These preliminary findings suggest that patients are motivated to view their data, and these visualizations were accessible to patients of different ages, races, and cancer stages. Daily users, who were mostly new to chemotherapy, may have higher levels of

XSL•FO
RenderX

anxiety and a greater need for health information [9]. Future studies should investigate the potential benefits of patient-facing visualizations for patients beginning chemotherapy.

Limitations

The visualizations and other website content were developed as part of an ancillary project in an ongoing study, and participants received no instructions or reminders regarding website usage. Survey respondents represented a subset (141/158, 89%) of participants, who received personalized visualizations, and the results may be influenced by selection, response, and recall biases.

Conclusion

This study describes initial efforts to share real-time ePRO and wearable device data visualizations with patients undergoing chemotherapy. Further research is needed to improve the usability of data visualizations and evaluate their impact on symptom management, self-efficacy, and other outcomes.

Conflicts of Interest

None declared.

Abstract

Electronic prospective surveillance models (ePSMs) have the potential to improve the management of cancer-related impairments by systematically screening patients using electronic patient-reported outcomes during and after treatment, and linking them to tailored self-management resources and rehabilitation programs. However, their successful implementation into routine care requires careful consideration of patient and provider needs and must align with clinical workflows, which may vary across settings and require adaptation to the local context. The aim of this paper is to describe the development of REACH, a web-based ePSM designed to remotely screen for physical cancer–related impairments and direct patients to rehabilitation resources based on need. The development of REACH followed an integrated knowledge translation (iKT) approach, engaging key knowledge users including patients, clinicians, administrators, and information technology specialists. The development process involved collaboration across 5 working groups. The system content and logic group selected the impairments to be screened, measures used, frequency of screening, and resources recommended based on results of a survey with oncology providers and researchers, patient feedback, a literature review, and an environmental scan. The machine learning group explored predictive modeling approaches to optimize the assessment frequency using retrospective patient data. The implementation group identified features from existing systems that could be built to promote assessment completion and integration into clinical workflows through a scoping review, interviews with clinic staff, and focus groups with patients. The design group conducted co-design workshops and usability testing with patients to iteratively refine the interface and develop a prototype. Finally, the software development group converted the prototype to a web-based application and conducted privacy and security assessments and quality assurance. The integration of key knowledge users through an iKT approach played a critical role in determining the design and functionality of REACH. REACH allows patients to remotely complete assessments tailored to their cancer type and treatment status on any electronic device. The system generates automated advice based on the assessment responses, including links to educational

XSL•FO
RenderX

resources for self-management, suggestions for community programs to register for, and recommendations to contact their oncology team for further assessment and possible referral to rehabilitation services. These recommended resources are stored in the patient's personalized library, organized by type and severity of cancer-related impairments reported, and are updated following each new electronic patient-reported outcomes assessment completed. Additional key system features include a patient-driven and structured process for managing high impairment scores, usability enhancements to improve navigation, and safeguards to ensure data security. The development of REACH demonstrates how an iKT approach can be used to design an ePSM that is user-friendly, clinically relevant, and aligned with implementation considerations. The system has been implemented at 4 Canadian cancer centers, and its implementation is being evaluated to inform future refinements.

Introduction

People living with and beyond cancer are at risk of experiencing treatment-related adverse effects that can lead to impairment and disability [1]. It is estimated that 37% of individuals affected by cancer report significant challenges with basic activities of daily living and about 55% report challenges with instrumental activities of daily living along the cancer pathway (eg, diagnosis, adjuvant therapy, and follow-up surveillance) [2]. However, treatment-related adverse effects often go underreported and undetected [3,4], leading to the low uptake of cancer rehabilitation services [5,6].

An electronic prospective surveillance model (ePSM) is an evidence-based digital solution that aims to enable the proactive identification of impairments to promote early self-management, through access to education, as well as facilitate timely referrals to programs and rehabilitation services [7,8]. An ePSM uses electronic patient-reported outcomes (ePROs) to systematically screen and identify rehabilitation needs throughout cancer treatment and follow-up surveillance and provides patients with tailored self-management advice and alerts to clinicians to support the management of identified impairments [7,8]. Studies evaluating ePSMs in cancer care have demonstrated the clinical use of these systems [9], improvements in important patient outcomes such as symptom management and quality of life [10,11], and improvements in health service outcomes such as reductions in emergency department presentations [12]. However, there are noteworthy challenges to their development and implementation, including the need to develop a system that meets the needs of a heterogeneous patient population (eg, cancer types, treatment options, and types of impairments) that can be integrated into diverse clinical settings (eg, availability of rehabilitation resources, variability in workflows, current use of digital solutions, and the use of different electronic medical record systems) [13-15].

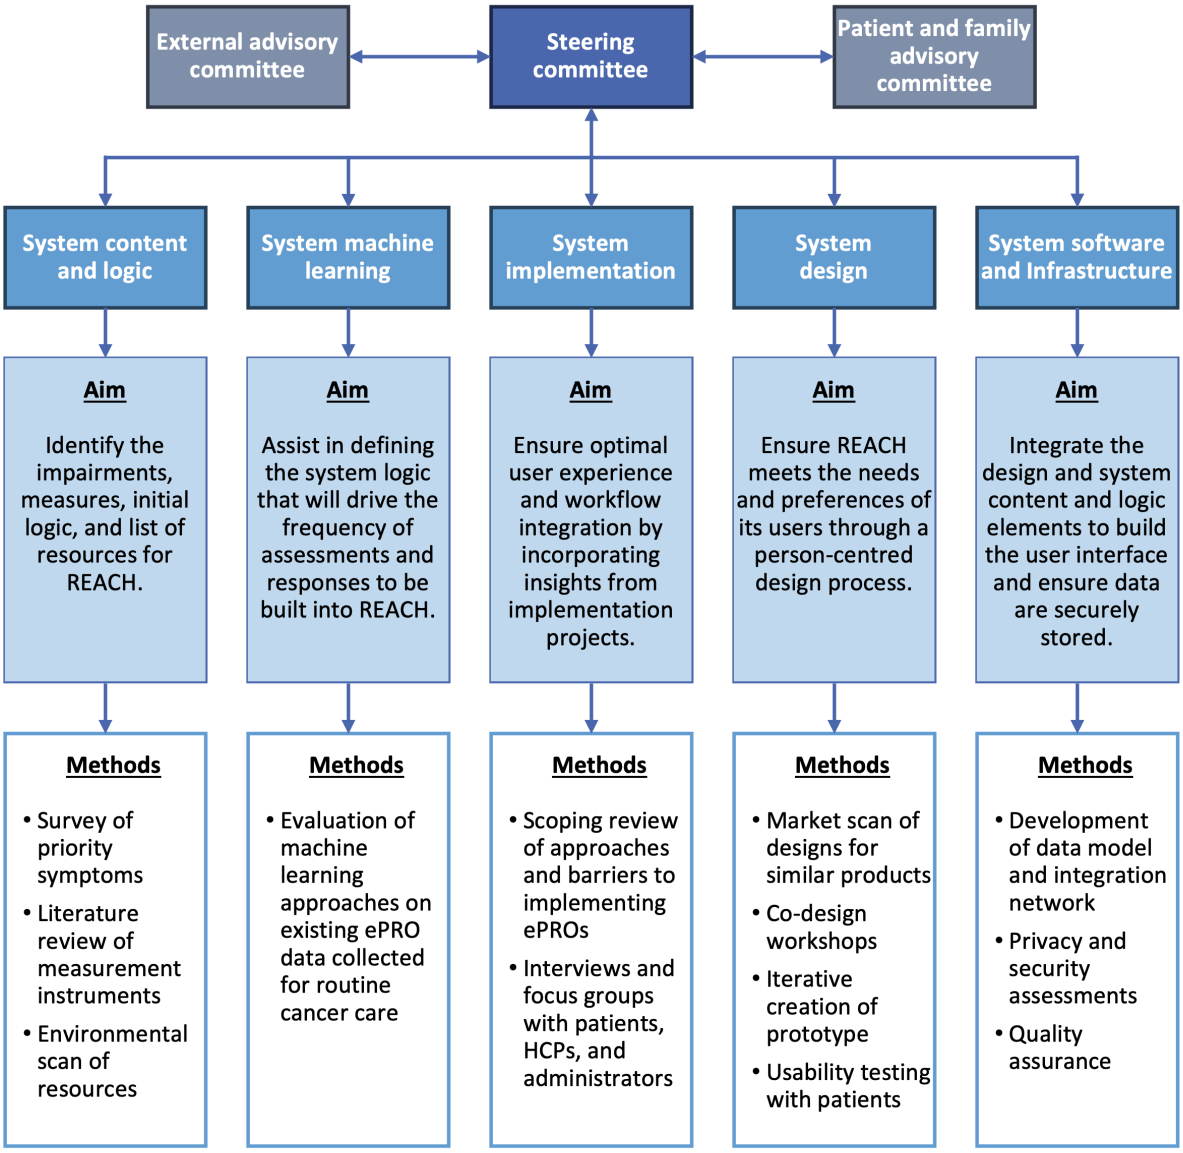
An integrated knowledge translation (iKT) approach can help address key development and implementation challenges of ePSMs. iKT involves the partnership between researchers and knowledge users throughout the research and implementation process [16]. In the context of an ePSM, an iKT approach ensures that key knowledge users (eg, patients, health care providers, administrators) play an active role in shaping the system's design and implementation. This step is critical as it may promote local uptake of an ePSM through a sense of increased ownership by key knowledge users. Furthermore, engaging knowledge users early and throughout the process helps to align an innovation with their needs, values, and workflows, which may enhance an innovation's clinical use, adoption, and sustainability [17].

Despite the growing use of ePSMs, there remains a need for detailed descriptions of their development to provide insights into the processes and decision-making involved, which can help guide others looking to design and implement similar systems. This paper describes the iKT approach taken to develop an ePSM called REACH prior to its implementation within 4 centers in Canada and 4 disease sites (breast, colorectal, head and neck, and lymphoma). These populations were selected due to their high prevalence and high potential for impact given the documented symptom burden within each disease site. The aim was to ensure the REACH system was tailored to these clinical settings and populations to facilitate its subsequent implementation into routine care.

Project Team and Governance Structure

The Canadian Cancer Rehabilitation (CanRehab) team comprises a multidisciplinary group of researchers, clinicians, and patients with cancer across Canada. CanRehab operates within a team-based organizational structure that includes a steering committee (ie, study principal investigators, implementation science lead, and training program lead), a patient and family advisory committee (PFAC), and an external advisory committee. The PFAC comprised 13 representatives across Canada, and the external advisory committee comprised 3 international experts in cancer rehabilitation.

REACH System Development Plan



Overview

To ensure local needs were considered in the development of the REACH system, we used an iKT approach. Throughout the development of REACH, we engaged patients through the PFAC, as well as oncology health care providers, administrators, and information technology staff within the settings where REACH will be implemented. The development of REACH also involved the collaboration between 5 working groups, each reporting to the CanRehab steering committee and contributing

XSL•FO
RenderX

specialized expertise. These working groups focused on: (1) system content and logic; (2) system machine learning (ML); (3) system implementation; (4) system design; and (5) system software and infrastructure. Each group's responsibilities, methods, and deliverables are described in detail in the following sections and summarized in Figure 1.

Figure 1. Canadian Cancer Rehabilitation (CanRehab) team organizational structure and process for the development of the REACH system. ePRO: electronic patient-reported outcome; HCP: health care professional.

System Content and Logic

The system content and logic working group was led by team members with expertise in cancer survivorship and physical medicine and rehabilitation (JMJ, KLC, and DML). The development of the initial logic and content of REACH included the completion of three main system components: (1) impairments to screen for each disease site; (2) measurement instruments, cut-offs, and frequency of assessments; and (3) self-management and rehabilitation resources offered to patients.

To determine the impairments that would be monitored for each disease site, the working group conducted a web-based survey. Members of the CanRehab team who were invited to complete the survey included oncologists from all disciplines (eg, medical, radiation, hematology, and surgical oncology) and disease sites that were the focus of the initial implementation of REACH (breast, colorectal, head and neck, and lymphoma), as well as researchers with expertise in patient-reported outcomes, cancer rehabilitation and survivorship, and cancer education. The survey was delivered via SurveyMonkey [18], and all responses were anonymous. Survey participants were provided with 5 lists of approximately 10 impairments (1 list for each of the 4 disease sites and 1 general list). Participants were asked to rank these impairments based on their perceived importance, relevance, and feasibility for assessment and surveillance. Each list had an option to add additional impairments. This activity was issued a formal waiver exempting it from the requirement for research ethics board approval at the University Health Network, as it

XSL•FO
RenderX

was determined not to constitute research as described by the Tri-Council Policy Statement [19].

A total of 29 surveys were completed by members within the CanRehab team. To select the final list of impairments for each disease site, this working group synthesized the survey responses and aimed to select the top 5 ranked impairments. Further consideration was given to the availability of resources to offer patients to manage a specific impairment. The final list of impairments selected for each disease site is displayed in Table 1. Briefly, each cancer type includes an assessment for falls and balance, fatigue, pain, and activities of daily living, in addition to impairments specific to each site. Examples include screening for dysphagia and trismus (head and neck cancer), lymphedema (breast cancer), and sexual function (breast and colorectal cancer).

Table . Impairments and measures selected for REACH.

Impairment	Cancer type	Measures adapted
Fatigue	Breast, colorectal, head and neck, lymphoma	FSI[a]
Pain	Breast, colorectal, head and neck, lymphoma	ESAS[b] pain and BPI[c]
Activities of daily living	Breast, colorectal, head and neck, lymphoma	PRFS[d] and FSQ[e]
Falls and balance	Breast, colorectal, head and neck, lymphoma	STEADI[f]
Return to work	Breast, colorectal, head and neck	None
Shoulder and neck dysfunction	Breast, head, and neck	QuickDASH[g], Neck Dissection Impairment Index
Sexual dysfunction	Breast, colorectal	BSSC-M and F[h]
Lymphedema	Breast	Lymphedema Symptom Report
Dysphagia	Head and neck	4QT[j]
Trismus	Head and neck	EORTC QLQ[i]-H&N35
Speech	Head and neck	UW[k] Head and Neck Questionnaire
Xerostomia	Head and neck	EORTC QLQ-H&N35

[a]FSI: Fatigue Symptom Inventory.

[b]ESAS: Edmonton Symptom Assessment System.

[c]BPI: Brief Pain Inventory.

[d]PRFS: patient-reported functional status.

[e]FSQ: Functional Status Questionnaire.

[f]STEADI: Stopping Elderly Accident, Deaths, and Injuries.

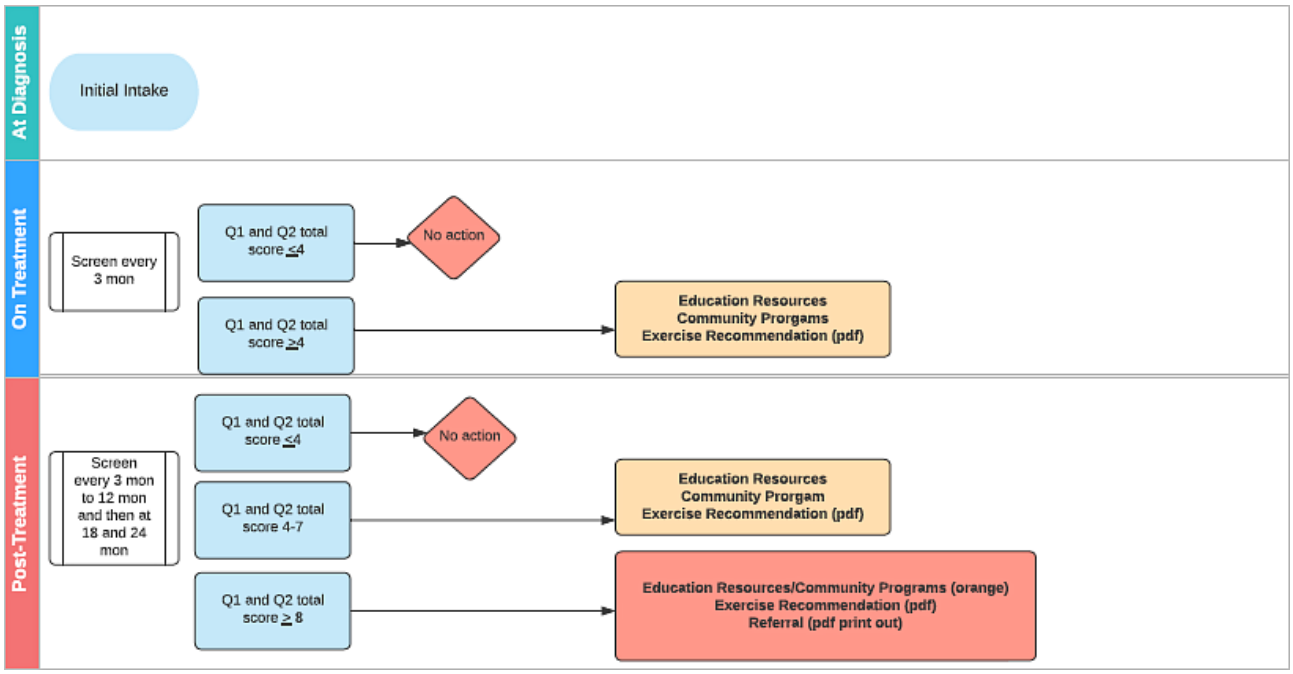
[i]EORTC QLQ-H&N35: European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Head and Neck Module.

[j]4QT: 4-Point Questionnaire Test.

[k]UW: University of Washington.

Next, the system content and logic working group conducted a literature review of measurement instruments for the impairments selected. The working group aimed to use the findings from the literature review to select patient outcome measures for the impairments selected that had been validated and had clear cut-offs. In cases where a validated measure was not identified (ie, screening for difficulties with return to work), the system content and logic working group developed a brief question about the impairment. The proposed questions were presented to the CanRehab external advisory committee, steering committee, and the PFAC, and the questions were refined based on feedback from these groups. Notable feedback included adding a question for each impairment, where if a patient breached the threshold for being referred to a program or service, the system would ask the patient if they had already received a referral and were already being seen by a health care provider for that impairment. The final list of measurement instruments is displayed in Table 1.

The system content and logic working group then conducted site-specific and national environmental scans to identify all self-management and rehabilitation resources (eg, patient education resources, hospital- and community-based programs, and rehabilitation professionals) that may be included as resource options in the system. These were categorized into three types: (1) education, (2) programs, and (3) referrals. “Education” included websites, videos, and online pamphlets that provided information to enable patients to self-manage impairments. “Programs” included online and in-person classes, workshops, and programs delivered by trained professionals in the community. “Referrals” included specialized services associated with or delivered in the cancer center. These resources were mapped to each geographical site, cancer type,



XSL•FO
RenderX

and impairment where appropriate. All links to resources (websites, videos, programs, and clinics) were validated by a member of the CanRehab team. Furthermore, all community- and hospital-based programs were contacted to inquire about referral processes (eg, physician referral or self-referral) and patient eligibility criteria to ensure the recommended resources to patients on the system were appropriate.

The environmental scan of resources resulted in a total of 98 resources that were included in the REACH system. Most of the resources were categorized as education (61/98, 62%) compared to programs (16/98, 16%), and referrals (21/98, 21%). Of the 61 (62%) education resources, most were websites (29/61, 48%) and links to online pamphlets (22/61, 36%), followed by videos (8/61, 13%) and e-modules (3/61, 5%). Of the 16 (16%) programs, over half can be delivered either in-person or virtually to patients receiving care at a specific center (9/16, 56%), with the remaining programs being delivered virtually to all patients across all 4 centers (7/16, 44%). Of the 21 services within the referral category, services included outpatient physiotherapy (4/21, 19%), occupational therapy (1/21, 5%), speech-language pathology (4/21, 19%), dietetics (3/21, 14%), lymphedema programs and specialized staff (5/21, 24%), pain management clinics (2/21, 10%), and outpatient rehabilitation programs offering a variety of these services with a multidisciplinary team (2/21, 10%).

Finally, the system content working group held internal meetings dedicated to each impairment being monitored by REACH. These meetings aimed to establish the algorithms and pathways for each impairment, which were developed using Lucidchart (Lucid Software Inc). These pathways were then presented to the steering committee and the PFAC for their feedback and refinement. A figure of the final logic for each impairment selected (ie, the frequency of assessment during and after treatment, and the type of resource provided based on the patient's response and clinical characteristics) was created to facilitate the translation of the logic to the REACH system during system software development (see Figure 2 for example for fatigue).

Figure 2. System logic for fatigue. mon: months.

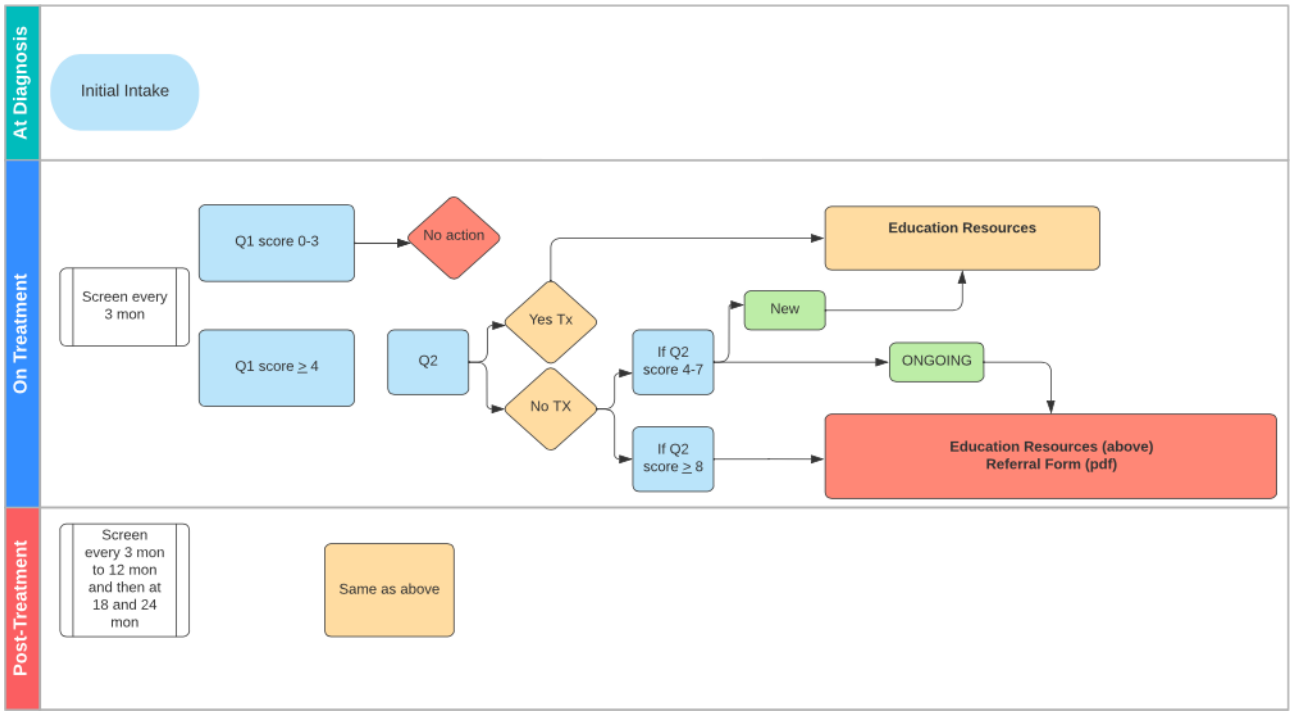
System ML

This working group was led by a team member with expertise in ML for health-related applications (AD). The purpose of this working group was to evaluate the potential use of ML for predicting impairment levels that would inform the need for a follow-up assessment (or not), thereby assisting the system content and logic working group in defining the system logic for REACH (ie, tailoring the assessment frequency based on a patient's previous assessment and level of impairment, as well as cut-offs for impairments screened). To achieve this goal, the working group conducted analyses using ML approaches on existing ePRO data collected from one of the centers where REACH would be implemented. The data analyzed were from patients with breast, colorectal, head and neck, and lymphoma collected as part of distress screening at the Princess Margaret Cancer Center (N=36,574 patients with >1 assessment). The analysis focused on 2 impairments, namely pain and fatigue, and extracted the distribution of records over impairment levels (0-10, with 0=lowest symptoms). Full details on the methods and results of this work are reported elsewhere [20]. The ML pipeline relied on light gradient boosting machine [21], an interpretable and efficient classifier based on decision trees, combined with the synthetic minority oversampling technique for handling data imbalance [22]. The working group simulated the training and use phases of the ML pipeline by splitting the data into 2 parts. The working group used 5-fold cross-validation for model selection during training. In evaluation, the ML pipeline was used to predict all impairment level records appearing in the deployment (test) set, and its performance was quantified using the mean average error per class (impairment level) and overall using the weighted mean average error. In a

XSL•FO
RenderX

first evaluation setting, the working group assumed that the previous level of impairment would always be available for predicting the next one (as usually performed in ML evaluations). The working group then conducted another evaluation setting (closer to reality) where the ML pipeline would only have access to the previous level of impairment if the patient had been previously selected for a follow-up assessment (ie, based on the predictions of the previous impairment levels).

This evaluation revealed that it would not be appropriate to rely on an ML model to determine the frequency of follow-up assessments based on a patient's previous level of impairment reported on the REACH system. Specifically, we found that the amount of available data decreased as the impairment level increased, leading to greater prediction errors at higher impairment levels. This imbalance in the data significantly impacted the ML model's ability to learn and accurately predict across all levels of impairment. In addition, our evaluations suggested that if the frequency of follow-up assessments depends on an ML model, there is a risk that prediction errors would start accumulating over time and prevent the observation of signals that the ML model would require for correcting its future predictions (which are based on the current levels). This was supported by a Shapley Additive Explanations analysis of the ML model, which revealed that the prediction for the current impairment level is mostly based on the previous observed level and the gradient between the 2 previous observed levels. Finally, we observed that using an ML model for deciding when to ask patients to complete a follow-up assessment rapidly translates into a decrease in performance, even if the observation is set to a low value. Given these challenges, we determined that an ML-driven approach to tailoring assessment frequency would not be appropriate for REACH at this point. Further investigations would be required for a safe integration of this technology.



System Implementation

The system implementation working group was led by individuals with training and expertise in implementation science (CJL, SNS, and JMJ) with additional support from individuals with expertise in implementing digital health interventions within clinical care practices (GS and JB). The design of the implementation plan for the REACH system was conducted in parallel to its development. The working group led a scoping review of the approach to implementing ePSM systems in cancer care and a qualitative study with patients, oncology health care providers, and clinic leadership to identify barriers and facilitators prior to implementing REACH at each of the 4 implementation settings. Details of the methods and results of both studies have been published [13,23]. While the primary aims of these studies were to inform the development of the implementation plan for REACH, the findings from both studies acted as an additional point of consideration during discussions regarding the system's features to improve user experience and facilitate the integration with clinical workflows.

Findings from the scoping review helped support the system content and logic group's work on defining the initial frequency of assessments on REACH. The scoping review found that most systems did not have a defined assessment schedule for patients and, of those that did, the frequency of assessments and duration of surveillance varied widely. For instance, the frequency of assessments ranged from daily to every 3 months, and the duration of surveillance ranged from one month to 5 years after the completion of treatment. Furthermore, this depended on many factors including where patients were along the cancer pathway, the impairments being screened, and the goal of the assessment (eg, whether the assessment was conducted as part of a clinical visit). These results were integrated into discussions during the internal meetings dedicated to each selected impairment to be monitored by REACH, as well as presentations to the steering committee and PFAC. The team decided on initial frequencies of 2 - 3 months during treatment and 3 - 6 months after treatment, depending on the impairment being screened (see Figure 3 for example for pain). Several considerations led to this decision, including the system's purpose of identifying persistent cancer-related impairments rather than acute toxicities, and the importance of minimizing patient burden, particularly during treatment, when patients face competing demands such as intensive treatment schedules and frequent clinic visits. The scoping review also synthesized common features of ePSM systems and found that many systems used various methods to display a patient's ePRO scores longitudinally (eg, graphs and reports). This was also recommended by patients interviewed in our qualitative study. As such, we developed a feature in the REACH system that allows a patient to view their responses from the most recent assessment. Patients can access this at any time but are also presented with the option to view their previous assessment scores if they log into REACH before their next scheduled assessment.

XSL•FO
RenderX

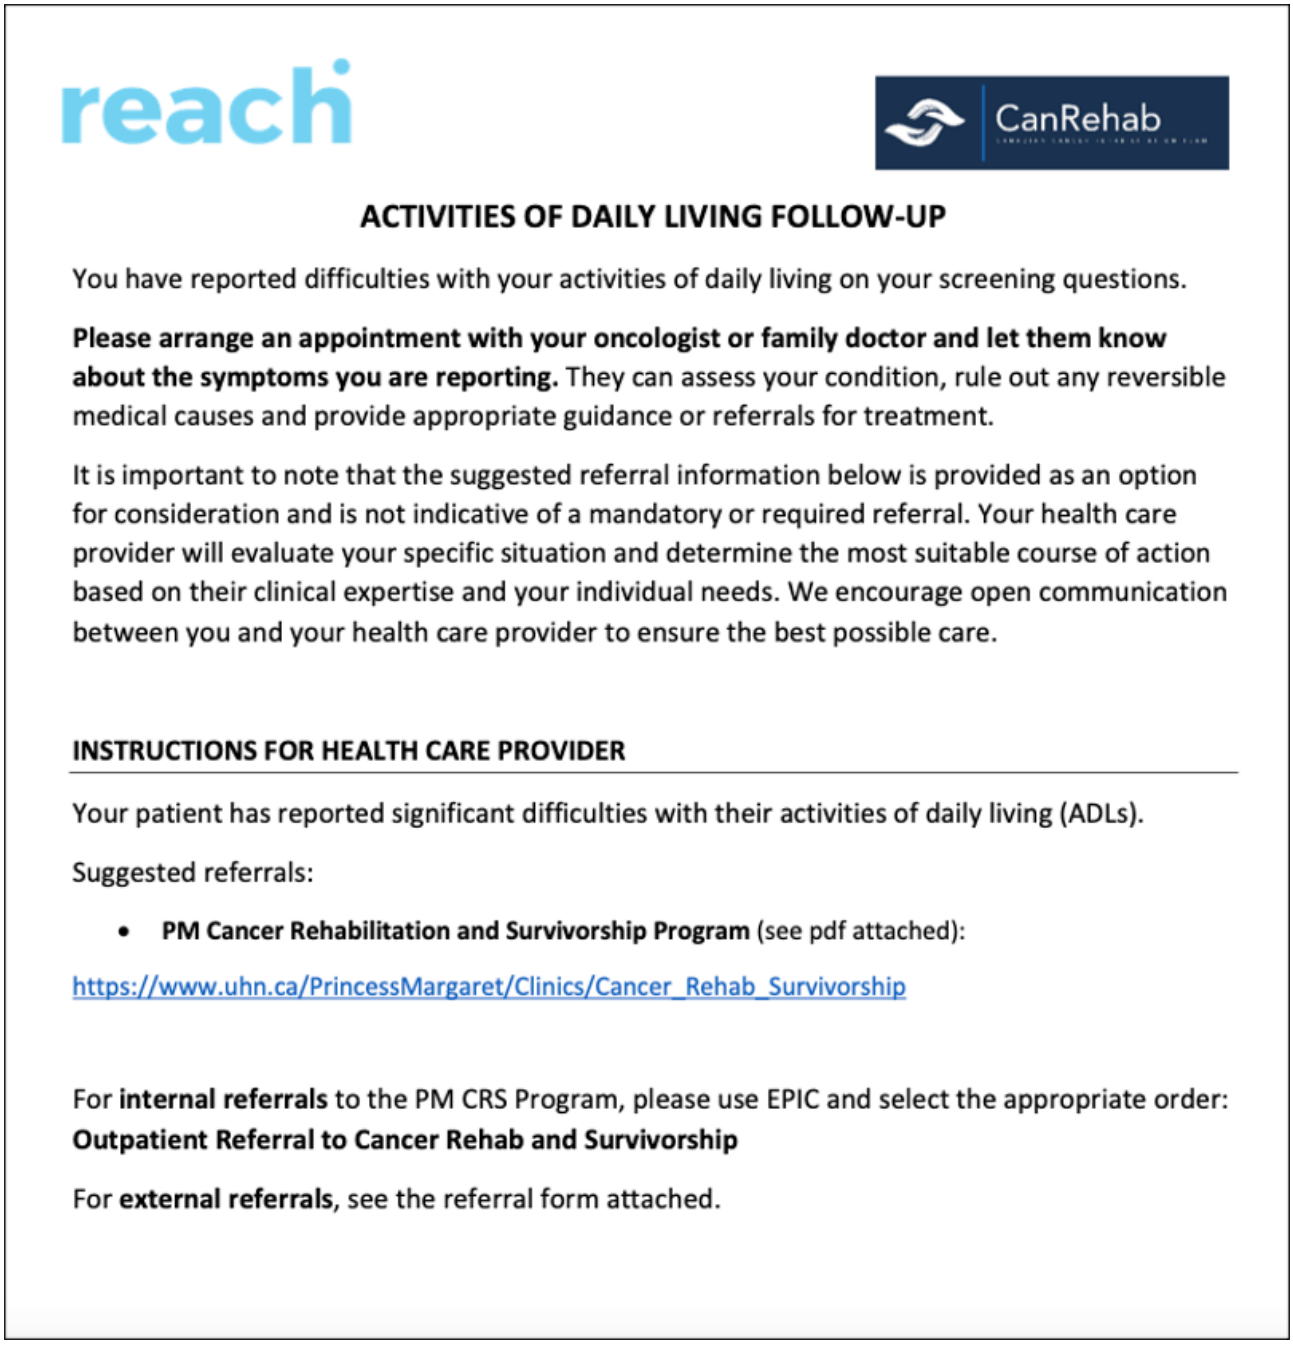


Figure 3. System logic for pain. mon: months; Tx: treatment.

Findings from the scoping review and the qualitative study also informed the development of a process to manage high scores reported by patients and facilitate referrals to rehabilitation services. Some systems in the scoping review included a method of alerting patients that they should contact their clinical team for further screening, and in certain contexts, that their scores were not being monitored by a provider in real-time. Systems also typically included alerts to the clinical team for patients who breached specific thresholds that require attention, as well as recommended clinical actions and suggested referrals to manage identified impairments. In our qualitative study, interviews with health care providers revealed that certain rehabilitation services that are in the REACH library may require a referral from a physician; however, providers also noted that it would not be feasible for the clinical team to receive alerts related to the REACH system. Therefore, we developed a process on REACH where patients who (1) breach specific clinical thresholds for various impairments assessed and (2) are not currently receiving care for the identified impairment are recommended to schedule a visit with their family physician or oncologist for further screening. Patients are also provided with a printout to bring to their appointment which includes a brief background of the assessment and suggested referrals for the physician to consider (see Figure 4 for example for activities of daily living).

reach

CanRehab

ACTIVITIES OF DAILY LIVING FOLLOW-UP

You have reported difficulties with your activities of daily living on your screening questions.

Please arrange an appointment with your oncologist or family doctor and let them know about the symptoms you are reporting. They can assess your condition, rule out any reversible medical causes and provide appropriate guidance or referrals for treatment.

It is important to note that the suggested referral information below is provided as an option for consideration and is not indicative of a mandatory or required referral. Your health care provider will evaluate your specific situation and determine the most suitable course of action based on their clinical expertise and your individual needs. We encourage open communication between you and your health care provider to ensure the best possible care.

INSTRUCTIONS FOR HEALTH CARE PROVIDER

Your patient has reported significant difficulties with their activities of daily living (ADLs).

Suggested referrals:

- **PM Cancer Rehabilitation and Survivorship Program** (see pdf attached):

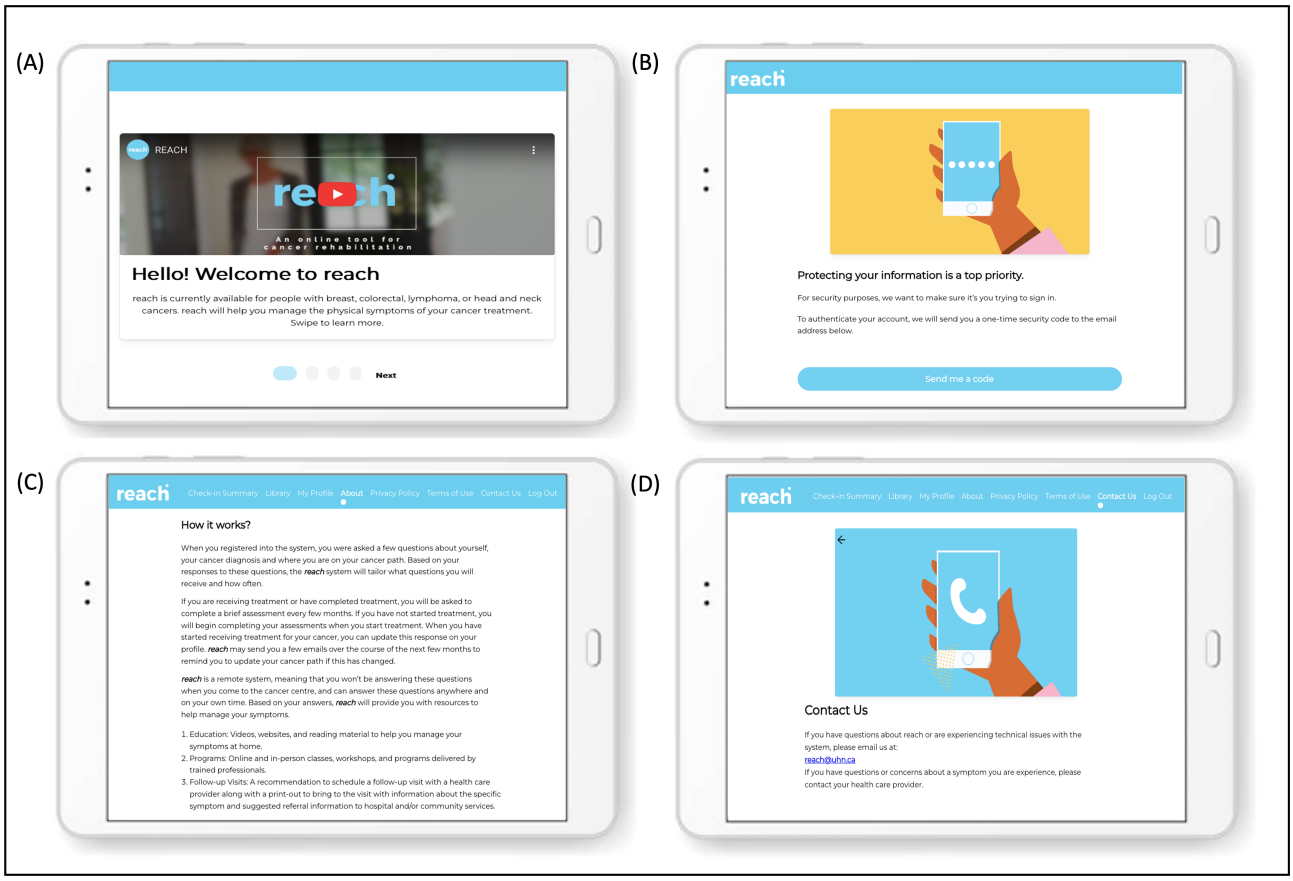
https://www.uhn.ca/PrincessMargaret/Clinics/Cancer_Rehab_Survivorship

For **internal referrals** to the PM CRS Program, please use EPIC and select the appropriate order: **Outpatient Referral to Cancer Rehab and Survivorship**

For **external referrals**, see the referral form attached.

System Design

The system design working group was led by individuals from the Healthcare Human Factors team (HHF) at the University Health Network. HHF team members included the Director of Design and Strategy (JR) and designers (PN and LP), who supervised and administered a human-centered design approach. The first phase (immerse and understand) involved conducting a market scan for analogous products in other diseases and industries to review successful schematics for providing tailored online recommendations to users. This scan served as a source of inspiration for the end-product, enabling its design to ultimately be both engaging and relevant. A document immersion was also conducted to situate the product within the context of the cancer journey and align it with the overarching system goals. In the second phase (concept design), a unique set of product concepts was generated and brought to 2 virtual co-design workshops with the PFAC to elicit feedback on how to best deliver REACH. During these 3-hour workshops, facilitators from the HHF team led participants through a series of activities to define the value proposition for REACH, identify the rehabilitation resources they relied on throughout the cancer pathway, validate design concepts, and explore how they would come to life in the next phase.



Next, the HHF team began the third phase (design and test) in which they iteratively created the interface and experience of using the system, incorporating feedback along the way. The needs and journeys of the people that the solution aims to serve were captured through a series of user stories that enabled

XSL•FO
RenderX

designers to create REACH's information architecture. From there, a set of wireframes was produced, structured around key patient workflows and later converted into a refined prototype, ready for feedback from end users. In the final step of the third phase, the HHF team conducted usability testing with 9 members of the PFAC. Goals of this usability testing included assessing the user-friendliness of the product and gaining insight into whether the features successfully met the user needs previously identified. Prior to each session, participants were provided with a brief introduction to the testing environment and test materials. During the testing session, participants were asked to perform representative tasks with the application, while test administrators monitored the proceedings for any usability issues that may be indicative of user-safety or usability problems.

The HHF team then created the final designs of the REACH system, aiming to deliver a user-friendly, visually engaging, and easy-to-navigate platform for patients. Key design elements include an onboarding page that contains brief and accessible information on the purpose of REACH and the steps required to create a user profile (Figure 5). A video demonstration of the process for creating a user profile on the system is provided in Multimedia Appendix 1. Upon logging into the system, patients are provided with a screen displaying the date of their next assessment and a list of resources that were recommended to them during their previous assessment. During an assessment, patients are presented with all the questions for a given impairment on a single page, allowing them to easily navigate between different impairments. Questions that use a scale are accompanied by definitions for each end point (eg, 0=no pain; 10=worst possible pain) to ensure clarity in responses. The resource library is organized by impairment (eg, fatigue, lymphedema, and pain) and resource type (education, programs, and follow-ups), enabling patients to easily locate resources that best match their needs and preferences. In addition, patients have access to various pages, including a "Contact Us" section that provides an email address for inquiries related to REACH or technical issues (Figure 5). A video demonstration of the assessment process and resource library navigation is provided in Multimedia Appendix 2.

Figure 5. Example screens of key design elements for REACH. (A) Onboarding page outlining the system's purpose and target population. (B) Multifactor authentication screen for secure login. (C) "About REACH" page providing details on assessments and types of resources offered in the library. (D) Contact information for support with technical issues.

System Software and Infrastructure

Following completion of the final designs, the design and software and infrastructure teams worked closely together to convert the prototype into a web-based application. The system software and infrastructure working group was led by individuals from the Techna team at the University Health Network. The Techna project manager (TT) and a senior analyst (YG) supervised and managed the development work with additional support from a system architect, software developer, and quality assurance specialist. This working group followed a structured software development life cycle process. The team worked together to build a robust and scalable data model, design the integration network, and finalize technical specifications. Furthermore, the system software and infrastructure working group developed the user interface

XSL•FO
RenderX

according to the designs developed by the design team, set up the application on a secure web server, and performed quality assurance prior to production. Finally, the team worked with the University Health Network's privacy, security, and legal teams to conduct a medical device assessment and develop the system's Terms of Use and privacy policy and embed this into the REACH platform.

Collectively, this work resulted in the development of a secure login process, secure storage of user data, embedded algorithms to support tailored assessments and recommended resources for patients, automated email notifications to patients (registration, password reset, and assessment reminders), and the generation of system logs to support quality improvements. To set up an account on REACH, patients use their own email and password, and multifactor authentication was implemented to support secure user access (Figure 5). Password resets are managed by the system, where patients may submit a forgot password form using their email address. The system stores a unique temporary token for that patient and sends an email to the patient with a link that contains the specific token. Notably, the REACH system consists of a lightweight progressive web application with centralized data storage in a secure data center at the University Health Network. As such, REACH can be accessed on any electronic device and only uses browser local storage to determine if the patient has been prompted to install REACH and if the patient has previously visited the site. No personal health information or identifiable data is stored on the patient's device. The data are encrypted at rest and in transit. Passwords are salted and hashed using SHA256. The operating system that is used for REACH is Linux/Red Hat EL7 (application) and Oracle Linux v7.9 (database). The application programming interface of REACH has logging and auditing capabilities.

Discussion

Overview of the REACH ePSM System

There is a need to develop ePSM systems that meet the needs and preferences of patients, consider the fit with clinical settings, and address potential implementation barriers. The successful implementation of these systems has the potential to address the low reporting and detection of cancer-related impairments during and after treatment and facilitate patient uptake of self-management and rehabilitation resources. This paper describes the process of using an iKT approach to develop an ePSM system, called REACH.

REACH is a web-based application that systematically screens for common cancer-related impairments and provides patients with tailored rehabilitation resources based on their reported needs. Registered patients create a user profile by providing their sex, age, cancer type, treatment status, and institution receiving care. The system then personalizes the type and schedule of assessments accordingly. Patients receive automated email notifications when assessments are due and are provided with tailored resources based on their responses. These resources, including links to education resources for self-management, community programs to register for, and recommendations to follow-up with their physician with suggested referrals, are stored in each patient's personalized resource library, which remains accessible for viewing and use at any time.

REACH was intentionally designed as a patient-driven system in which patients self-enroll and complete assessments independently, outside of clinical encounters. As such, integration with the electronic medical record was not prioritized, since the tool is intended primarily to support self-management rather than to inform real-time clinical decision-making. In addition, the 4 implementation sites used different electronic medical record systems, making technical integration complex and resource-intensive. To facilitate uptake while maintaining feasibility, REACH was instead designed to align with existing clinical workflows by being introduced through standard patient education processes. These include presurgical classes, systemic therapy and radiation therapy teaching sessions, and inclusion in educational packages distributed to patients. Strategies to promote awareness and uptake, such as handouts, posters, videos, and point-of-care staff introductions, were tailored to each site and are detailed in a separate publication describing the REACH implementation strategies [24].

The integration of diverse knowledge users through an iKT approach played a critical role in shaping the final design and functionality of the REACH system. Several key system features were directly influenced by input from patients, clinicians, administrators, and information technology staff, highlighting the importance of ongoing engagement in system development. For instance, in response to health care provider concerns about feasibility, a structured process was developed for managing high impairment scores, recommending patients to bring a printout to their physician instead of generating automated alerts to clinicians. Furthermore, to ensure resources are directed to those in need, a follow-up question was added for each impairment (ie, asking whether a patient had already been referred and was receiving care for that impairment) based on feedback from the PFAC and external advisory committee. This addition enhances the appropriateness of the system's recommendation for patients to schedule a visit with their oncology team for further assessment and possible referral to a rehabilitation service. Usability feedback led to design choices that improved navigation, including the addition of definitions accompanying question scales to ensure clarity in responses, and structuring the resource library by impairment and resource type to enable patients to easily locate resources that best match their needs and preferences. Finally, to address privacy and accessibility concerns, REACH was designed to function across multiple devices without storing personal health information locally. These iterative refinements underscore the value of continuous knowledge user engagement during system development.

Alignment With Best Practices and Recommendations

Our iKT approach used multiple strategies to engage knowledge users, including regular meetings, working groups, surveys, and workshops, to facilitate decision-making for the design of the REACH system for its target populations and clinical settings. These strategies were facilitated through dedicated resources and funding to support these collaborative activities. Our

XSL•FO
RenderX

approach is consistent with the findings of a scoping review on iKT approaches in health care, which identified a variety of iKT approaches used such as committees and working groups, meetings and presentations, and consultation and deliberative dialogue [25]. In addition, our iKT approach to developing REACH is consistent with national and international recommendations for the development of ePRO systems for clinical practice. The International Society for Quality of Life Research PRO Implementation Guide and the National Comprehensive Cancer Network Electronic Health Record Oncology Advisory Group outline several considerations for the development of ePRO systems, such as the selection of measures used, frequency of assessments, methods for scoring, interpreting, and displaying assessment results, and approaches to minimize patient and clinician burden and maximize action in response to ePRO completion [26,27]. The Canadian PROs Position Statement recommends that ePRO systems are co-designed with patients and families and that patient data is used in real-time to enhance care and address unmet needs [28]. Finally, priority recommendations developed by Mazariego et al [29] for the implementation of PROs into routine cancer care include the development of strong partnerships with key knowledge users (ie, patients, family members, clinicians, and system developers). Aligned with these recommendations, the development of REACH followed a structured approach to integrate best practices for ePRO system design to ensure the ePROs in REACH are clinically relevant, meaningful, and easy to complete, and that ePRO data is used in real-time to present resources directly to patients to support self-management.

Limitations and Design Considerations

While our iKT approach ensured that key knowledge users played an active role in shaping the system, there are limitations to this approach that warrant consideration. Despite efforts to incorporate diverse perspectives, it is likely that PFAC members had a greater interest in the use of eHealth interventions for cancer care, which may not fully represent the design perspectives and needs of patients with lower digital or health literacy. In addition, differences in priorities across knowledge user groups may have influenced key design decisions. For instance, while health care providers emphasized minimizing clinical burden and maintaining a patient-driven approach, some patients may benefit from more direct clinical involvement. The PFAC's motivation and interest, combined with providers' preference to rely on patients to act on REACH's prompt to schedule a visit with their oncology team, may limit the system's feasibility and acceptability for patient subgroups known to have lower engagement with ePRO systems. Similarly, although psychosocial concerns such as distress, anxiety, and fear of recurrence are highly prevalent and overlap with many physical symptoms, these domains were not included in the initial version of REACH. This decision reflected an intentional effort to maintain a narrow scope during the system's first iteration, focused on persistent physical impairments, in order to keep both the system development and implementation process feasible. In addition, some participating centers had existing distress screening processes in place. However, this design choice may limit the system's responsiveness to broader patient needs. We are currently assessing the feasibility and acceptability of REACH when implemented into routine care at 4 centers in Canada, and the results of the evaluation will inform refinements to the system, including the potential expansion of symptom domains.

Conclusions

iKT can serve as a model for developing ePRO-based systems, ensuring they are user-friendly, clinically relevant, and effectively integrated into routine cancer care. This paper describes the use of an iKT approach to develop an ePSM called REACH. By integrating best practices for ePRO system design and actively engaging key knowledge users throughout development, REACH was designed to include ePROs that are clinically relevant, meaningful, and easy to complete, and supported by features that enhance system navigation and patient self-management by linking patients to tailored resources in real-time. REACH has been implemented into routine cancer care at four Canadian centers for 4 disease sites (breast, colorectal, lymphoma, and head and neck), and its implementation is being evaluated to inform system refinements to support patient uptake, feasibility, and acceptability [30].

Acknowledgments

The authors would like to thank the members of the project's patient and family advisory committee, the health care providers, and the developers and designers who contributed to this project.

Abstract

Background: Cutting-edge oncology care often depends on patients' ability to use rapidly evolving health technology. Digital health literacy (DHL; the capacity to understand health-related information with electronic media) is an emerging, yet underexplored social determinant of health in patients with cancer.

Objective: We aimed to characterize sociodemographic and clinical factors associated with DHL in patients with cancer and explore whether a single-item screener could be derived from a widely-used DHL questionnaire to detect low DHL.

Methods: Patients (N=105) who received systemic treatment in the past year for colorectal carcinoma (CRC) or non-Hodgkin lymphoma (NHL) were recruited through collaborating clinics. Participants self-reported DHL using the eHealth Literacy Scale (eHEALS). They also reported general health literacy and sociodemographic and clinical characteristics. Correlations and group comparisons (independent sample *t* tests and χ^2 tests, as appropriate) were used to evaluate links between DHL and sociodemographic and clinical characteristics. Receiver operating characteristic (ROC) curve analysis was used to determine whether a single eHEALS item could effectively screen for low DHL (eHEALS score ≤20).

Results: Patients with a lower education level (Spearman ρ=0.29; *P*=.004) and lower general health literacy (r=0.25; *P*=.009) had lower DHL. Patients with NHL reported lower DHL than those with CRC (t_{103}=2.72; *P*=.008). Additionally, the subset of patients who reported participation in a clinical trial (n=10) exhibited lower DHL than nonparticipants (t_{100}=3.08; *P*=.003). Other sociodemographic and clinical characteristics were not significantly associated with DHL (all *P*>.21). The ROC curve analysis showed that eHEALS item 4 ("I know where to find helpful health resources on the Internet") was a strong predictor of high versus low DHL (area under the curve=0.975, 95% CI 0.949 - 1.00; *P*<.001).

Conclusions: In this convenience sample, DHL varied based on cancer type, education level, general health literacy, and clinical trial participation. Furthermore, we found that a single item from the eHEALS has strong potential for identifying those with low DHL. These findings may inform which patients have higher need for or may benefit from DHL interventions and suggest avenues for detecting low DHL in oncology clinics.

KEYWORDS

digital health literacy; eHealth; screener; screening; colorectal carcinoma; non-Hodgkin lymphoma

Introduction

Physicians, caregivers, and cancer survivors increasingly use technology as part of cancer care [1,2]. Engagement with health technologies (eg, telemedicine and patient portals) confers substantial benefits [3-5]; they facilitate access to care, increase patient engagement, and help patients manage, coordinate, and learn about their health [6-8]. However, accelerating health technology availability has increased the "digital divide"

XSL•FO
RenderX

between patients who adopt health technology as part of their care and those who do not [9-11].

Digital health literacy (DHL; the capacity to find and understand health-related information with electronic media) is an emerging social determinant of health (SDOH) [12,13]. Lower DHL is associated with health risks and may impede uptake of cutting-edge patient-centered technologies aimed to optimize cancer care [14,15]. In a recent retrospective study of patients with cancer, those with higher DHL showed better overall survival than those with lower DHL [16].

Promoting equitable cancer outcomes across DHL levels calls for new methods to quickly identify low DHL among patients with cancer [17]. Accordingly, we investigated how sociodemographic and clinical factors were related to patients' reported DHL using data from a multicenter cross-sectional study of patients with non-Hodgkin lymphoma (NHL) or colorectal carcinoma (CRC). We also examined whether a single-item screener could be derived from a widely used DHL questionnaire to maximize screening opportunities in the oncology clinic and inform future studies.

Methods

Study Procedures

Patients (N=105) who received systemic therapy (eg, chemotherapy or immunotherapy) within the last year for NHL or CRC were recruited between November 2022 and April 2023 from 3 clinics at MedStar Georgetown University Hospital, MedStar Washington Hospital Center, and John Theurer Cancer Center as part of a larger cross-sectional study about cancer survivorship experiences. The study's methods were previously published, and the current analysis represents a secondary analysis of these data [18]. NHL and CRC were selected to represent both solid and hematological cancers and due to their high prevalence at collaborating clinics, frequent use of systemic therapies, and prevalence across age and gender groups (versus, eg, breast or prostate cancer) [19]. Participants reported DHL on the validated eHealth Literacy Scale (eHEALS) by rating their ability or confidence to complete digital health tasks on 8 Likert-scale items (score range: 8-40) [20,21]. Scores ≤20 indicate low DHL [22-24]. Cronbach α was 0.96 in this sample. Participants reported their age, gender, race, ethnicity, education, general health literacy (with the 3-item Health Literacy Screening questionnaire [25]), and disease- and treatment history–related clinical factors. Surveys were mailed or emailed to the patient and were completed on paper, online, or over the phone.

Statistical Analysis

Statistical analysis used RStudio (version 2023.12.0+369) and GraphPad-Prism (version 10.3.1). We computed descriptive statistics, then used independent-sample *t* tests, χ^2 tests, and correlations (as appropriate) to test associations between sociodemographic or clinical factors and DHL, with a 2-tailed α level of .05. We used simultaneous multiple linear regression to evaluate whether associations between clinical factors and DHL remained when adjusting for covariates (age, education level, and general health literacy; these were selected according to prior work or significant relationships with DHL in this dataset at $P<.05$) [13,15,26,27].

To identify how single items performed to identify low DHL, we generated receiver operating characteristic (ROC) curves for each eHEALS item using a previously described approach [28,29]. We examined the area under the curve (AUC) for each ROC curve to compare the overall performance of each item for predicting low DHL.

Ethical Considerations

The Georgetown-MedStar Joint Oncology Institutional Review Board (STUDY00005586) approved the study. All participants provided informed consent. Study procedures included standard practices to prioritize participants' privacy and confidentiality, including labeling surveys with participant IDs rather than identifiers, secure data storage, deidentification prior to analysis, and aggregate reporting. A US $20 gift card was offered to all participants.

Results

Participant Characteristics

Among the 105 participants (Table 1), 50 (48%) had NHL and 55 (52%) had CRC. Participants were primarily middle-aged to older (mean age 60, SD 13.2, range 22 - 84 years), male (n=57, 54%), identified as White (n=65, 62%), and had a college-level education or higher (n=57, 54%). The mean eHEALS score was 26.9 (SD 8.24, range 8 - 40), and 24% (n=25) had low DHL (score ≤20).

[a]eHEALS: eHealth Literacy Scale.

[b]Participants could select more than one option for race/ethnicity.

Sociodemographic and Clinical Factors Associated With DHL

Those with lower education levels and lower general health literacy had lower DHL (Spearman ρ=0.29; *P*=.004 and *r*=0.25; *P*=.009, respectively). DHL did not vary by age, gender, race/ethnicity, or household income (all *P*>.21).

Patients with NHL reported lower DHL than patients with CRC (t_{103}=2.72; *P*=.008; Figure 1A). This pattern persisted when controlling for age, education, and general health literacy (unstandardized b coefficient=−3.07, SE=1.65; *P*=.07). The patient subset who participated in a clinical trial (n=10) as part of their cancer treatment had lower DHL than patients who did not participate in a trial (t_{100}=3.08; *P*=.003; Figure 1B). In the adjusted model, patients reporting trial participation still showed lower DHL when controlling for age, education, general health literacy, or disease type (b=−10.45; SE=3.20; *P*=.002; Table 2). DHL did not vary by time since diagnosis or treatment type (all *P*>.23).

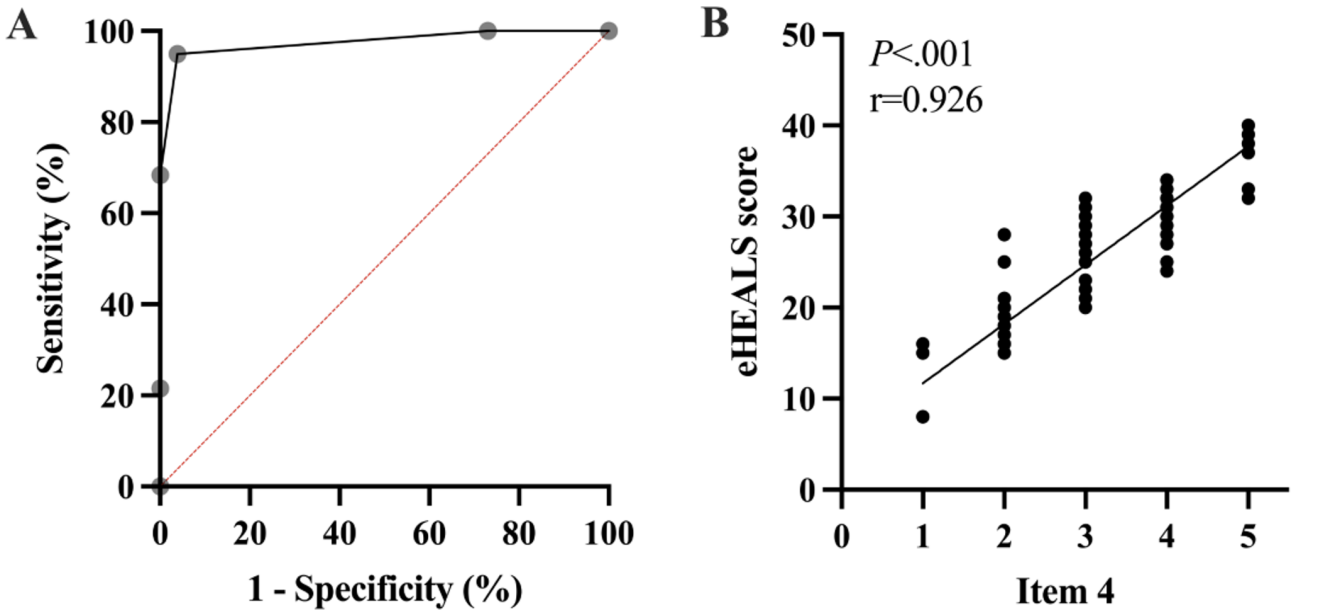
General health literacy	0.69	0.34	.046

[a]CRC: colorectal carcinoma.

Single-Item Screener for Low DHL



In an ROC analysis predicting low DHL (eHEALs ≤20), individual items' AUC values ranged from 0.895 to 0.975 (Table 3, Figure S1 in Multimedia Appendix 1). eHEALS item 4, "I know where to find helpful health resources on the Internet," had the highest AUC (0.975, 95% CI 0.949 - 1.00; *P*<.001; Figure 2A). Responses to item 4 were strongly correlated to overall eHEALS scores (*r*=0.926; *P*<.001; Figure 2B). We determined the optimal threshold score for this item to predict high versus low DHL based on accuracy (Table S1 in Multimedia Appendix 1). Using the Likert-scale options (ranging 1-5), a score less than 3 predicted low DHL with an accuracy of 96.2%, a sensitivity of 94.94% (95% CI 87.69 - 98.01) and a specificity of 96.15% (95% CI 81.11 - 99.80).

XSL•FO
RenderX

Table . eHealth Literacy Scale (eHEALS) items' area under the curve (AUC) values, calculated with receiver operating characteristic curve analysis. The items come from the eHEALS, developed by Norman and Skinner [20].

Item	Definition	AUC (95% CI)	*P* value
1	I know how to find helpful health resources on the Internet	0.901 (0.828 - 0.974)	<.001
2	I know how to use the Internet to answer my health questions	0.939 (0.882 - 0.996)	<.001
3	I know what health resources are available on the Internet	0.953 (0.904 - 1.00)	<.001
4	I know where to find helpful health resources on the Internet	0.975 (0.949 - 1.00)	<.001
5	I know how to use the health information I find on the Internet to help me	0.935 (0.873 - 0.996)	<.001
6	I have the skills I need to evaluate the health resources I find on the Internet	0.940 (0.890 - 0.990)	<.001
7	I can tell high quality from low quality health resources on the Internet	0.949 (0.910 - 0.988)	<.001
8	I feel confident in using information from the Internet to make health decisions	0.895 (0.831 - 0.959)	<.001

Figure 2. (A) Receiver operator characteristic curve for eHealth Literacy Scale (eHEALS) item 4 detects high and low digital health literacy with high sensitivity and specificity (P<.001). (B) Correlation between eHEALS item 4 and participants' overall eHEALS scores (P<.001).

Discussion

Principal Findings

DHL allows patients to benefit from technological advances in oncology care. However, little is known about which patients with cancer are more likely to experience low DHL, and clinically feasible ways to identify patients with low DHL are limited. Here, we examined sociodemographic and clinical factors associated with DHL and explored whether single items could identify patients with low DHL. Patients with a lower education level and general health literacy had lower DHL. Patients with NHL also had lower DHL than those with CRC. Interestingly, those who reported participating in a clinical trial had lower DHL than those who did not. ROC analysis showed that agreement with a single item from the widely used eHEALS ("I know where to find helpful health resources on the Internet") was strongly predictive of low DHL; this may be a brief yet sensitive way to screen for low DHL.

Links between DHL and sociodemographic factors have previously been reported [13,15,26,27], but clinical correlates have been less frequently explored. We observed notable differences in DHL between patients with CRC and NHL that

XSL•FO
RenderX

remained after adjusting for covariates. Future studies should identify drivers of DHL differences by cancer type in larger samples. We observed a novel, unexpected association between lower DHL and clinical trial participation, contrasting with prior findings that clinical trial participants used the internet first, before physicians, for clinical trial information [30]. On the other hand, it is possible that patients with worse DHL have poorer outcomes, thus necessitating later lines of therapy and enrollment in clinical trials, which could help to explain our findings. The complex relationship between clinical trial participation and DHL requires further investigation in prospective studies with electronic medical record–documented trial participation.

Rapidly and effectively identifying those with low DHL is critical to advancing this research area. Short-form screeners are well-suited for time-limited oncology clinics [29,31]. Our findings indicate that disagreeing or strongly disagreeing with the statement "I know where to find helpful health resources on the Internet" is a candidate screening criterion for low DHL. If validated in larger samples and other cancers, the item could be included in previsit paperwork, and identified patients with low DHL could receive additional support (eg, for telehealth and patient portals) or alternative modalities (eg, print resources). Future studies could also use this item to quickly screen for digital health needs in study candidates.

Limitations

This study's small convenience sample may limit its statistical power to identify associations and may restrict generalizability. Although we included people with solid and hematological cancers, correlates and best screening items for DHL may differ across other cancer types. Nonetheless, the observed links to sociodemographic factors are consistent with prior literature, and the full range of possible eHEALS scores (8-40) was represented in our sample. Future studies should include larger samples, more clinical trial participants, and more diverse sociodemographic and cancer groups. Additionally, future studies should include family members and other care partners, who have an important role in helping patients with lower DHL navigate their care.

Conclusions

DHL is an emerging and actionable SDOH impacting health outcomes for people with cancer. These results provide insight into how DHL varies across cancer patients and suggest a highly predictive single-item screener that may be used to identify patients with low DHL. Using this item, if it is further validated, could increase opportunities for clinical support and developing DHL interventions better suited to patient needs.

Abstract

Background: Cancer is the second leading cause of death in the United States. Compelling evidence shows screening detects colorectal cancer (CRC) at earlier stages and prevents the development of CRC through the removal of precancerous polyps. The Healthy People 2030 goal for CRC screening is 68.3%, but only 36.5% of Missouri federally qualified health center patients aged 50 - 75 years are up-to-date on CRC screening. For average risk patients, there are three commonly used screening tests in the United States—two types of stool tests collected at home (fecal immunochemical test [FIT]–immunochemical fecal occult blood test [FOBT] and FIT-DNA, such as Cologuard) and colonoscopies completed at procedural centers.

Objective: This study aims to examine variation by month for the three types of CRC testing to evaluate consistent patient care by clinical staff.

Methods: Data from 31 federally qualified health center clinics in Missouri from 2011 to 2023 were analyzed. A sample of 34,124 unique eligible "average risk" patients defined as persons not having a personal history of CRC or certain types of polyps, family history of CRC, personal history of inflammatory bowel disease, and personal history of receiving radiation to the abdomen or pelvic to treat a previous cancer or confirmed or suspected hereditary CRC syndrome. Another eligibility criterion is that patients need to be seen at least once at the clinic to be included in the denominator for the screening rate calculation. Descriptive statistics characterize the sample, while bivariate analyses assess differences in screening types by month.

Results: Completion of CRC screening yielded statistically significant differences for patients completing the different types of CRC screening by month. October-January had the highest proportions of patients (644-680 per month, 8.5% - 10.2%) receiving a colonoscopy, while February-April had the lowest (509-578 per month, 6.9% - 7.8%), with 614 being the average monthly number of colonoscopies. For FIT-FOBT, June-August had the higher proportions of patients receiving this test (563-613 per month, 8.9% - 9.6%), whereas December-February had the lowest (453-495 per month, 7.1% - 8%), with 541 being the average monthly number of FIT-FOBT kits used. For FIT-DNA, March was the most popular month with 11.3% (n=261 per month) of patients using the Cologuard test, followed by April, May, and November (207-220 per month, 8.7% - 9.4%), and January and June (168-171 per month, 7.2%-7.3%) had the lowest proportion of patients using Cologuard, with 193 being the average monthly number of FIT-DNA kits used. Combining all tests, February had the fewest CRC tests completed (1153/16,173, 7.1%).

Conclusions: Home-based tests are becoming popular, replacing the gold standard colonoscopy, but need to be repeated more frequently. Monthly variation of screening over the course of a year suggests that CRC screening efforts and patient care may be less than ideal. Months with lower rates of screening for each type of CRC test represent opportunities for improving CRC screening.

Introduction

Colorectal cancer (CRC) is the third most common cancer in the United States and the second leading cause of cancer deaths [1]. Evidence shows that screening detects CRC at earlier stages, and its development can be prevented by removing precancerous polyps. For average risk patients, there are three common screening tests—two types of stool tests collected at home (fecal immunochemical test [FIT]–immunochemical fecal occult blood test [FOBT] and FIT-DNA, like Cologuard) and colonoscopies

XSL•FO
RenderX

completed at procedural centers. The revised Healthy People 2030 goal for CRC screening among people aged 45 - 75 years changed from 74.4% to 68.3% [2]. Federally qualified health centers (FQHCs) provide low-cost care for approximately 30 million people, and 90% of FQHCs' patient population (n=17,562,189) have an income less than 200% of the federal poverty level [3,4]. The CRC screening rate of patients using FQHCs in Missouri (n=95,191) is 36.5% compared to 74.1% for patients not using FQHCs (n=1,657,026) [5].

Colonoscopy is considered the gold standard of CRC screening since precancerous polyps can be removed at the time of the test, preventing cancer. However, numerous patient and health system barriers to colonoscopies have been identified [6]. Home-based testing is becoming more common, and FIT-DNA use has increased post COVID-19 [7]. The increased FIT-DNA use may reflect patient preference for home-based testing that does not incur being wait-listed for months to get a colonoscopy [8]. Additionally, the manufacturer of FIT-DNA provides a full service in facilitating patients' completion of the test. This service includes a patient follow-up to encourage returning the kits and results sent directly to the patient's electronic medical record. For the FIT tests, a clinic is responsible for patient follow-ups regarding stool collection and sending the kit in for analysis [9].

Since screening opportunities take place at patients' routine visits to health centers, determining screening variation by month can assist health care systems adjust outreach efforts, targeting low use months to establish consistently high CRC screening opportunities throughout the year.

Objective

This quality improvement project aims to determine if there is variation in the 3 types of CRC testing by month. Identifying variations by month can support targeted attention. The global aim of the quality improvement project was to support FQHCs' in providing CRC screening opportunities with consistent screening rates each month.

Methods

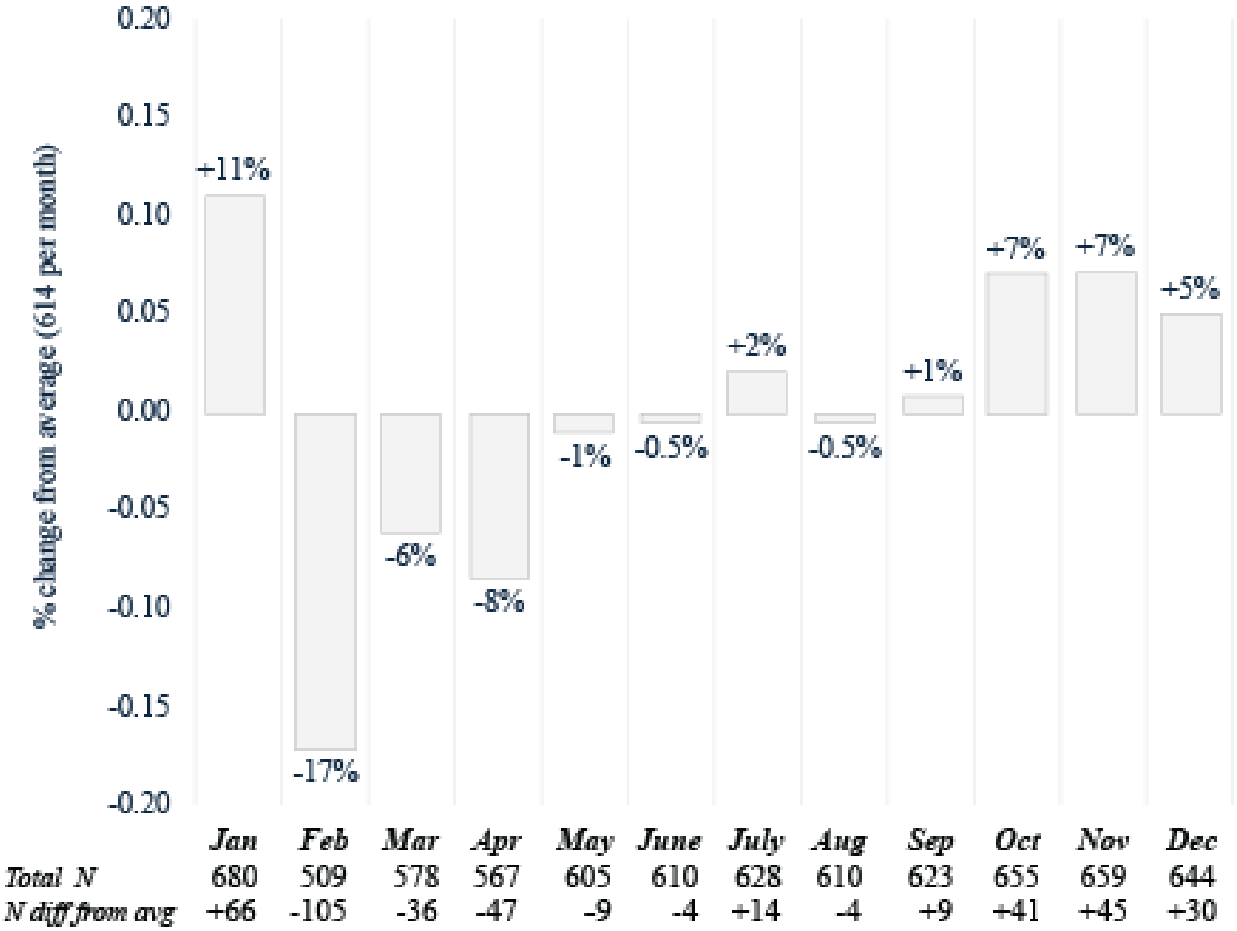
Overview

Starting in 2020 as part of a 5-year Centers for Disease Control and Prevention–funded quality improvement program, our project supported eight health care systems' initiation or enhancement of four evidence-based interventions to increase CRC screening rates of age-eligible patients using a practice facilitator model. As part of this quality improvement program, up to 4 years of annual data on CRC screening by type and date of completed CRC test for the eligible patient population in the selected health care system were available. Patient characteristics including age, race/ethnicity, primary language, and sex were gathered. Screening compliance was defined as a colonoscopy recommended every 10 years, FIT-FOBT every year, and FIT-DNA every 3 years. Screened for CRC was defined as having a medical record of being up-to-date on one of the three types of tests. For this analysis, eligible patients were aged 50 - 75 years with no prior diagnosis of CRC, adenomatous polyps, or inflammatory bowel disease, and no personal diagnosis or family history of known genetic disorders that predispose them to a high lifetime risk of CRC such as Lynch syndrome or familial adenomatous polyposis [10]. Descriptive statistics characterize the sample, while bivariate analyses assess differences in screening types by month. While examining monthly CRC screening rates, data were limited to exclude years where fewer than 10 screenings occurred for any given month. Monthly totals were first calculated, and the average number of tests across all months was used to calculate the average percentage change (increase or decrease) month to month. A χ^2 test for equal proportions of the CRC screening tests by month among the 3 types of CRC tests was then examined. Month was chosen as the unit of analysis since it is easily understood, helping plan and implement activities. A weekly analysis has fewer observations leading to less stable numbers, and holidays influence the days in any week. SAS 9.4 (SAS Institute) was used for the analysis.

Ethical Considerations

This project was approved by University of Missouri's Institutional Review Board (IRB 2034264), which allowed analysis of clinical data extracted from electronic medical records without additional consent for the secondary analysis. The data were deidentified for the analysis. All data were transmitted and stored in a Health Insurance Portability and Accountability Act (HIPAA)–compliant secure system (REDCap) [11].

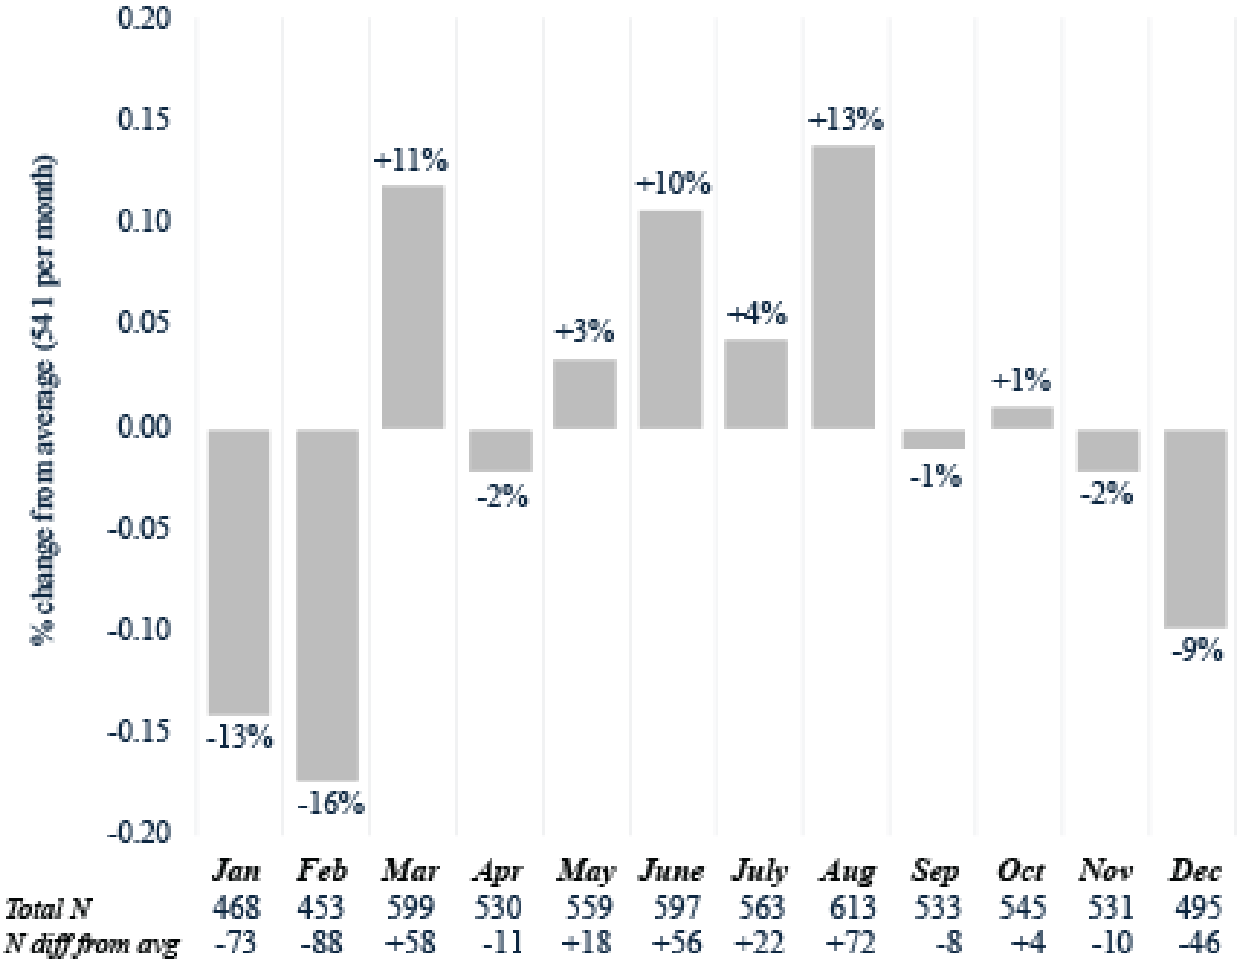
Results



A total of 31 clinics servicing predominately rural residents yielded 34,124 unique eligible patients from 2011 to 2023. Among these, 6238 (18.3%) were up to date on their CRC screening, another 5170 (15.2%) had received a CRC screening at some time in the past but were not up to date, and the remaining 22,716 (66.6%) patients had no record of being screened for CRC. Most participants were 50 - 64 years old (n=24,014, 70.4%), were female (n=19,229, 56.4%), used English as their primary language (n=31,686, 92.9%), and were White (n=27,677, 81.1%; Table S1 in Multimedia Appendix 1). Fewer participants younger than 65 years were up to date on their CRC screening than those 65 years and older. Patients with the highest proportion of ever being screened were Hispanic (837/2032, 41.2%), compared to White (9391/27,677, 33.9%) and Black (533/1385, 38.5%), but fewer Hispanic participants (n=260, 12.8%) were up to date compared to White (n=5386, 19.5%) and Black (n=268, 19.4%) participants (Table S1 in Multimedia Appendix 1). The FQHC systems in this analysis served 87% of patients who were at or below 200% of the federal poverty guidelines. Most clinics (n=28, 90.3%) were located in rural areas of Missouri. Among the clinics, the 2023 annual CRC screening rates ranged from 13.7% to 63.1% (62/451 and 238/377 eligible patients, respectively).

Table S2 in Multimedia Appendix 1 breaks down the descriptive statistics on monthly CRC screenings. There were 7368 patients who were up to date on CRC screening by colonoscopy with an average of 614 screenings per month from 2014 to 2023. A χ^2 test for equal proportions found significant differences across

XSL•FO
RenderX



monthly colonoscopy screenings (χ^2_{11}=38.9; *P*<.001). January was the highest month for colonoscopy screenings (n=680, 11% higher than the average), while February was the lowest (n=509, 17% lower than the average; Figure 1). For FIT-FOBT (n=6486), there were an average of 540.5 screenings per month from 2017 to 2023. A χ^2 test for equal proportions found significant differences across monthly FIT-FOBT screenings (χ^2_{11}=51.7; *P*<.001). August was the highest month for FIT-FOBT screenings (n=613, 13% higher than the average) compared to January (n=468, 14% lower than the average) and February (n=453, 16% lower than the average; Figure 2). There were 2319 FIT-DNA screenings, with an average of 193.3 per month from 2020 to 2023. A χ^2 test for equal proportions found significant differences across monthly FIT-FOBT screenings (χ^2_{11}=49.2; *P*<.001). March was the highest month (n=261, 35% higher than the average) while January (n=168, 13% lower than the average) and August (n=153, 21% lower than the average) were the lowest months for FIT-DNA testing (Figure 3).

Discussion

Principal Findings

Among the 3 types of CRC screening for average risk patients seen at our FQHCs in the United States, no test was completed consistently by month, and each test had different peak months of completion. We were not able to find any research that compared variation by month in CRC screening test types of colonoscopy, FIT-FOBT, and FIT-DNA. To our knowledge, this is the first study that provides results of CRC screening type by month.

As reflected in our screening choices by patients seen at FQHC clinics, home-based CRC screening increased during the COVID-19 pandemic's closures of specialty care including elective procedures (eg, colonoscopies) [7]. This change in CRC screening options allowed for testing at the discretion of the patient rather than appointment availability.

Strengths and Limitation

One strength of this study was evaluating patients over 12 years from several FQHCs. These data were snapshots of each year's CRC screening behavior by the health care systems. This also captured screening behavior before and after the pandemic.

One limitation of this study was our inability to explain the variability by month of the different screening tests. For example, FIT-DNA and FIT-FOBT tests peaked in CRC awareness month in March but not colonoscopies. Additionally, while the results are informative, only a simple analysis of screening variability was performed, which excluded an examination of temporal changes over time.

The preferences of clinicians on which CRC screening test is recommended and their patient care style were not captured. For example, some clinicians only recommend colonoscopy [12-14]; however, some patients who decline a colonoscopy [15] would be willing to complete a home-based CRC screening test if offered. Further reasons for CRC screening refusal of any test were also not captured. These could be a factor in the CRC test variation by month.

Future Direction

Among the selected participant characteristics, attention is needed on those younger than 65 years to encourage CRC screening. Similarly, while 41.2% of Hispanic participants showed a positive attitude toward CRC screening, only 12.8% were up to date with their screening. This suggests that tailored campaigns and outreach programs could encourage greater participation in CRC screening. For all populations, screening matters since the variance in testing over a year can impact the

XSL•FO
RenderX

health care system's capacity for timely preventive patient care. Gastroenterologist availability to complete colonoscopies may be limited in some regions of the country, but home-based tests can be completed each month [8]. Undoubtedly, individual-level barriers influence CRC screening rates, such as transportation, medical mistrust, financial issues, and low health literacy [16]. However, organizational factors, including monitoring and feedback, have been identified as implementation facilitators [16]. Rockwell and colleagues [6] described health system barriers, especially for colonoscopies, as sludge, "frictions or administrative burdens that make it difficult for people to attain what they want or need." Providing clinical staff information on completed CRC screening rates by month for each test type may facilitate addressing these "sludge" issues and increase CRC screening [8,17].

Abstract

Background: Generative artificial intelligence (AI) chatbots may be useful tools for supporting shared prostate cancer (PrCA) screening decisions, but the information produced by these tools sometimes lack quality or credibility. "Prostate Cancer Info" is a custom GPT chatbot developed to provide plain-language PrCA information only from websites of key authorities on cancer and peer-reviewed literature.

Objective: The objective of this paper was to evaluate the accuracy, completeness, and readability of Prostate Cancer Info's responses to frequently asked PrCA screening questions.

Methods: A total of 23 frequently asked PrCA questions were individually input into Prostate Cancer Info. Responses were recorded in Microsoft Word and reviewed by 2 raters for their accuracy and completeness. Readability of content was determined by pasting responses into a web-based Flesch Kincaid Reading Ease Scores calculator.

Results: Responses to all questions were accurate and culturally appropriate. In total, 17 of the 23 questions (74%) had complete responses. The average readability of responses was 64.5 (SD 8.7; written at an 8th-grade level).

Conclusions: Generative AI chatbots, such as Prostate Cancer Info, are great starting places for learning about PrCA screening and preparing men to engage in shared decision-making but should not be used as independent sources of PrCA information because key information may be omitted. Men are encouraged to use these tools to complement information received from a health care provider.

(JMIR Cancer 2025;11:e72522) doi:10.2196/72522

KEYWORDS

generative artificial intelligence; chatbot; chatGPT; prostate cancer; cancer screening; shared decision making; artificial intelligence

Introduction

Generative artificial intelligence (AI) chatbots such as ChatGPT, Google Gemini, and Microsoft Copilot have become highly publicized for enhancing work efficiency and effectively responding to diverse queries. These sophisticated programs leverage large language models, machine learning, and natural language processing to understand and respond to a query with publicly available or third-party information [1]. Over the past 2 years, researchers have demonstrated a growing interest in evaluating generative AI chatbots for providing quality health and cancer information [2-4]. While the performance of generative AI chatbots has varied depending on the disease queried, complexity of the query, and brand of chatbot used, these tools show promise for being reliable health information resources in the future [3,5,6].

In terms of prostate cancer (PrCA), the second leading cause of cancer mortality among men in the United States [7], the American Cancer Society (ACS) [8], American Urological Association (AUA) [9,10], and the United States Preventive Services Task Force (USPSTF) [11] recommend that men make shared PrCA screening decisions with their health care providers. To prepare for this important decision, men need access to credible, readable, and culturally-appropriate (eg, African Americans have a higher mortality risk [12]) PrCA screening information [13]. Multiple studies have investigated the quality of PrCA information generated by AI chatbots [14-22]. Overall, these studies show that PrCA information produced by chatbots can be accurate, reliable, and moderately comprehensive, but readability and credibility are often compromised. In a recent study by the authors, Owens and Leonard [23] discovered that soliciting plain-language responses from chatbots to PrCA screening inquiries significantly enhanced the response's readability. Conversely, credibility was difficult to ascertain because generative AI chatbots do not consistently reference authoritative information sources [23]. To create a reliable and credible plain-language resource for

XSL•FO
RenderX

PrCA screening information, we have developed "Prostate Cancer Info" (PCI), a generative AI chatbot using Open AI's custom GPT platform [24]. PCI is unique because it only responds to inquiries from credible, PrCA expert-curated websites (like the ACS). This method is different from current generative AI chatbots, which search the entire web and produce responses from a variety of expert-vetted and non-vetted sources. In addition, we have programmed PCI to always provide a source for responses, which is uncommon for current generative AI chatbots. Finally, we have programmed PCI to provide responses that do not exceed 6th to 8th grade readability as recommended by the American Medical Association [25]. The study's purpose is to evaluate the accuracy, completeness, and readability of PCI responses to 23 frequently asked PrCA screening questions. The study will contribute insight into the safety and efficacy of using AI chatbots for shared PrCA screening decision-making and the usefulness of developing customized AI chatbots for PrCA decision-making.

Methods

Intervention Development

Author MSL developed PCI using a multistep process. Websites published by the ACS, AUA, USPSTF, and Centers for Disease Control and Prevention (CDC) were programmed into the GPT builder [24]. The rationale for limiting our search to these websites is that these organizations are globally recognized for providing timely, evidence-based PrCA screening education and recommendations. In particular, the PrCA screening recommendations from the ACS, AUA, and USPSTF are the most widely recognized in US PrCA research and clinical practice. PCI was then directed to draw responses exclusively from these websites in the order listed. Therefore, PCI relied on the ACS website as a primary source unless the information was unavailable or was requested from a non-ACS source. Strict directives were given to PCI to (1) only retrieve information from websites provided, (2) respond with language at or below 8th grade readability, (3) ignore non-PrCA queries, and (4) provide sources for responses. PCI was pretested to confirm its adherence to these directives.

PCI answers user questions through a well-defined process: first, it limits itself to information from preapproved websites. Then, it indexes these sites, reading and organizing their content. When a user asks a question, PCI searches its indexed data for relevant details, analyzes the information to understand the context, and creates a concise, accurate answer from approved sources. This ensures consistent and trustworthy answers.

Study Protocol

A total of 23 frequently asked PrCA questions were adopted from previous studies by Zhu et al [15] and Owens and Leonard [23]. One author entered questions into PCI. Responses were saved in a document for rating by both authors. The authors used a coding form containing questions with key points and answers from ACS and CDC education resources[26,27], along with screening recommendations from the ACS, AUA, and USPSTF [8-11], and checkboxes to evaluate whether a response was accurate (contained correct statements) and complete (presented all salient facts without significant omissions). For example, a response to "What is the prostate?" would be considered accurate if it stated that the prostate is a gland that is a part of the male reproductive system. However, to be considered complete, the response would also need to include information on the size of the prostate, its location, and its purpose. If any parts of the response were not correct, they were rated as inaccurate. Table 1 shows the key points used to determine accuracy and completeness. Each of these key points is critical to a shared PrCA decision because a patient must consider factors such as the risks, benefits, and uncertainties of screening; their age, race, family history; and their personal values and preferences. Our chatbot responses have been included in Multimedia Appendix 1. Additional space was allotted on the coding form to record details about inaccuracies or omissions. The authors had 100% interrater agreement. The readability of responses was determined via a web-based Flesch Kincaid Reading Ease Scores calculator. Each response was copied and pasted into the calculator, excluding the reference website. The Flesch Kincaid Reading Ease Score uses total words, sentences, and syllables in an excerpt of text to calculate a score between 0 and 100, which corresponds to grade-level readability. Scores of 60 to 100 are considered easy to read by someone possessing an education at or below 8th to 9th grade. Scores of 50 to 60 require a 10th to 12th grade education (ie, fairly difficult) and scores below 50 require a college education (ie, very difficult) to comprehend.

XSL•FO
RenderX

Table . Key points for determining accuracy and completeness[a].

Questions	Key points
Basic Questions	
What is the prostate?	• Male reproductive organ. • The size of the prostate increases with age but is walnut-sized in younger men. • Located below the bladder and in front of the rectum. • Produces some of the fluid in semen.
How common is prostate cancer?	• About 313,780 new cases of prostate cancer (1 in 8 men). • About 35,770 deaths from prostate cancer (1 in 44 men).
What are the risks for prostate cancer?	• Risk increases with age. • More common among African-American men. • More prevalent in North America, northwestern Europe, Australia, and the Caribbean islands. • Risk is doubled if a man has a first-degree relative (eg, father, brother, or son) with prostate cancer gene mutations can increase the risk for prostate cancer. • Less common risk factors are diet, obesity, smoking, chemical exposure, inflammation of the prostate, STIs[b], and vasectomy.
When and how often should a man be screened for prostate cancer?	• ACS[c]: ages 50 years (average risk), 45 years (high risk), and 40 years (very high risk). • AUA[d]: ages 45 to 50 years (average risk) and age 40 years (high risk). • USPSTF[e]: age 55 to 69 years (average risk).
What are the symptoms of prostate cancer?	• Can have no symptoms in early stages. • Urinary problems. • Blood in urine or semen. • Erectile dysfunction. • Pain in hips, back, chest, or other areas. • Weakness or numbness in legs or feet. • Loss of bladder or bowel control.
What are the types of screenings for prostate cancer?	• DRE[f] and gloved finger test are not 100% accurate. • PSA[g], a blood test, is not 100% accurate and can produce false positives and false negatives.
What are the benefits and harms of prostate cancer screening?	• Benefit: can find cancer early. • Harms: tests, especially PSA can produce false positives or negatives, which can lead to unnecessary tests or treatments, which carry risks.
How is prostate cancer diagnosed?	• Biopsy: tissue samples from the prostate.
What are the risks of a prostate biopsy?	• Pain, blood in the semen, or infection.
How long can I live if I have prostate cancer?	• The 5-year relative survival rate is 97% on average, but depends on how far the cancer has spread.
Difficult Questions	
Is the PSA or DRE more effective for finding prostate cancer?	• PSA is more effective.
My father had prostate cancer. Will I have prostate cancer too?	• Having a father or brother with prostate cancer can more than double a man's risk of prostate cancer.
I have a high PSA level. Do I have prostate cancer?	• The probability of having prostate cancer increases with PSA level but there is no set PSA level that can definitively indicate the presence of prostate cancer.
What does a PSA level of 4 mean?	• Men with a PSA level between 4 and 10 have about a 1 in 4 chance of having prostate cancer.

XSL•FO
RenderX

Questions	Key points
What does a PSA level of 10 mean?	• The chance of having prostate cancer is 50% with a PSA of 10 or more.
What does a PSA level of 20 mean?	• The chance of having prostate cancer is more than 50% with a PSA of 20 or more.
What newer tests for prostate cancer may be more accurate than the PSA test?	• The prostate health index (PHI). • 4Kscore test. • IsoPSA test. • Urine-based tests.
If my biopsy sample is positive for cancer, should I receive genetic testing?	• Some men who have a strong family history or certain inherited genes, prior cancer diagnosis, or cancer that has spread to other parts of the body, should speak to their health care provider about this option.
If my biopsy sample is positive for cancer, how soon should I start treatment?	Will depend on the stage and grade of the cancer and their: • Age and expected lifespan. • Other serious health conditions. • Feelings about treatment. • The likelihood of a cure and doctor's opinion. • Feelings about treatment side effects.
Are there any cons to taking an at-home PSA test?	• At home PSA tests do not give a man an opportunity to make a shared decision with their health care provider about the risks, benefits, and uncertainties of the PSA test.
I am an African-American male, aged 40, with a family history of prostate cancer, at what age should I begin receiving prostate cancer screening?	• Screening should begin at age 40 based on both the ACS and AUA screening guidelines.
I am an African-American male, aged 40, with a family history of prostate cancer, can you provide me with all of the information I need to know to make a shared decision about prostate cancer screening?	Response should include all key points such as: • Prostate cancer incidence and mortality statistics. • Prostate cancer risks for African-American men. • Symptoms for prostate cancer. • Screenings for prostate cancer for African-American men. • Risks and uncertainties of prostate cancer screening. • Meaning of PSA results. • Biopsy for diagnosis. • Risk of biopsy. • Steps after a positive biopsy.
What are the differences in screening recommendations between major health organizations?	• ACS: ages 50 years (average risk), 45 years (high risk), and 40 years (very high risk). • AUA: age 45 to 50 years (average risk) and age 40 years (high risk). • USPSTF: age 55 to 69 years (average risk).

[a]Key points developed from web sources produced by ACS, CDC, AUA, and UPSTF.

[b]STI: sexually transmitted infection.

[c]ACS: American Cancer Society.

[d]AUA: American Urological Association.

[e]USPSTF: United States Preventive Services Task Force.

[f]DRE:digital rectal exam.

[g]PSA: prostate specific antigen test.

Data Analysis

Data was transferred from coding forms to Microsoft Excel spreadsheets for analysis. Descriptive statistics were calculated to determine the percentage of questions answered accurately and completely. An average mean readability score was also calculated.

Results

Accuracy and Completeness

Responses to all questions were accurate. In total, 17 of 23 questions (74%) were answered completely. Of the 6 questions with less complete responses, one lacked information about geography as a risk for PrCA and the higher prevalence of PrCA in North America. Of note is that this response recognized that

XSL•FO
RenderX

African Americans may be at greater risk for the disease, but statistics were not provided in any responses that substantiated the burden of incidence and mortality among African-American men. A total of 3 questions related to the meanings of PSAs of 4, 10, and 20 lacked statistics about the probability of PrCA, but did state men's greater chance of being diagnosed with PrCA at PSAs higher than 4. A fifth question about how soon a man should start treatment after a positive biopsy lacked information about how age, expected life span, comorbidities, and patient feelings about side effects factor into treatment decisions. Finally, a sixth question about what information an African-American male, aged 40 years with a family history of PrCA needs to know to make a shared screening decision yielded an answer that lacked information about what PSA results mean or the purpose and risks of a prostate biopsy.

Readability

The average readability was 64.5 (SD 8.7), which indicates most responses were written at an 8th-grade level or below. However, 5 of 23 responses (22%) were written at a 10th to 12th grade reading level and 1 response was written at a college level. In addition, 3 of the 5 responses addressed difficult questions. Scores ranged from 48.6 to 81.3. The lowest readability score (ie, 48.6) was in response to a basic question about symptoms of PrCA (see Table 2).

Discussion

Principal Findings

PCI had pristine accuracy and average completeness and readability. On average, completeness and readability were higher on responses to basic questions as compared to difficult questions. Specifically, 9 of 10 (90%) of the responses to basic and 8 of 13 (62%) of the responses to difficult questions were complete. In addition, 8 of 10 or (80%) and 9 of 13 (69%) of readability scores for basic and difficult questions, respectively, were below an 8th to 9th grade level. Difficult questions often contained longer and more complex responses, which likely affected readability. Furthermore, 4 of the 6 incomplete responses only lacked 1 key point which did not significantly dilute these responses. For example, 3 responses on PSA levels at 4, 10, and 20 did not effectively highlight differences in cancer likelihood (eg, over 50% chance), but each response indicated a greater chance of prostate cancer. Therefore, men would be informed that a PSA over 4 is concerning and warrants counsel from a provider. Key points missed in responses about when to start treatment for any man and about shared decision-making for African-American men are more concerning as the omitted information (eg, biopsy as a diagnosis tool) is focal to a PrCA screening decision. Not possessing this knowledge could lead to a PrCA screening decision that is not ideally informed and may not truly be shared between the patient and their healthcare provider. Specifically, knowing that the biopsy, not the PSA, is the only definitive means to diagnose PrCA may somewhat lessen the fear of an increased PSA score because another diagnostic step exists. Being informed about the biopsy could also prompt shared discussion about the relevance of a biopsy for the patient's circumstance. In addition, providing African-American men with all the information necessary to share a PrCA screening decision based on their demographic profile could be exceptionally useful for those men who may lack access to a question list, and not have time to ask multiple questions to an AI chatbot, or simply want a more tailored answer to their given circumstance. This tailored information can also facilitate a shared PrCA screening decision that is more patient-centered.

Limitations

The 23 questions we used may not reflect the full breadth of inquiries someone may have about PrCA screening. PCI was programmed to seek information from a finite set of websites from key medical authorities, but several equally credible websites were not included (eg, Mayo Clinic), which may have slightly improved PCI's performance. While much of the general information about PrCA on these additional websites (eg, signs, symptoms, and prostate anatomy) would likely be similar, there may be cutting-edge research on new PrCA screenings that may not yet be publicized on ACS or similar websites but could provide additional context for more difficult questions like those related to newer tests for PrCA. Finally, although rigorous research methods, such as interrater reliability, were used to mitigate any study bias, we acknowledge that as the developers of PCI, we may be susceptible to unconscious biases that could have affected our ratings. For transparency, we have included all PCI responses in Multimedia Appendix 1. Future studies to evaluate PCI and similar chatbots should include external raters and user feedback.

Comparison With Previous Work

Similar to our previous research [23] and research by others [15-19,21,22], generative AI chatbots like PCI can be highly accurate when responding to PrCA and PrCA screening inquiries. The completeness and readability of Prostate Info's responses to PrCA screening questions varied. PCI generally performed better than Lombardo et al [20] and comparable with Geantă et al [20-22], both of whom investigated chatbot performance on non-US PrCA guidelines. As compared with studies using US PrCA guidelines, PCI performed better than ChatGPT-3.5 (OpenAI), ChatGPT-4 (OpenAI), Microsoft Co-Pilot, Google Gemini, and Google Gemini Advanced, but equal to Microsoft Copilot on completeness of responses to basic PrCA screening queries posed in our previous comparative study, which solicited both standard and plain-language (ie low

XSL•FO
RenderX

literacy) responses [23]. However, the average readability on basic questions was lower than all, but one (ie, Microsoft Co-Pilot) generative AI chatbot when considering plain language responses only [23]. Otherwise, PCI outperformed all, but one (ie, Google Gemini Advanced) chatbot when we asked it to provide a standard response [23]. Compared to Zhu et al [15], who evaluated multiple generative AI chatbots' performance on a similar combination of basic and difficult questions to our study, PCI did not perform nearly as well as ChatGPT and ChatGPT Plus (earlier versions of ChatGPT) on completeness. PCI outperformed all other chatbots evaluated by Zhu et al [15] including Perplexity (by Perplexity AI), YouChat (by You.com), Chatsonic (by Writesonic), and NeevaAI (by Neeva). However, PCI's average readability may have been (but not definitively) lower than all generative AI chatbots evaluated in Zhu and colleagues' [15] study. It is important to note that Zhu et al [15] used a slightly different method for calculating completeness and readability than this study or the study by Owens and Leonard [23]. Zhu et al [15] determined the percentage of comprehensiveness using a Likert approach as opposed to indicating whether a response was simply complete or not complete. Numbers listed in Table 3 for Zhu et al [15] represent the percentage of questions that were "very comprehensive" (ie, fully complete). Readability was rated by reviewers as opposed to using a validated readability measure. Percentages reported in Table 3 for Zhu et al [15], represent that percentage of total responses that were "very easy to read." SDs for Zhu et al [15] were not reported.

XSL•FO

Table . Comparison of completeness and readability of chatbot responses on US prostate cancer screening guidelines.

Study	Chatbot name	Completeness, n/N (%)	Average readability score	
			mean (SD)	%, mean (SD)
This study	PCI[a]	17/23 (74)	64.5 (8.7)	—[b]
Zhu et al [15]	ChatGPT	21/22 (95)[c]	—	100 (NR[d])
Zhu et al [15]	ChatGPT Plus	20.3/22 (92)[c]	—	100 (NR)
Zhu et al [15]	ChatSonic	14.3/22 (65)	—	95 (NR)
Zhu et al [15]	YouChat	10.34/22 (47)	—	98 (NR)
Zhu et al [15]	Neeva AI	8.8/22 (40)	—	84 (NR)
Zhu et al [15]	Perplexity Detailed	6.6/22 (30)	—	95 (NR)
Zhu et al [15]	Perplexity Concise	6.6/22 (30)	—	95 (NR)
Owens et al [23]	ChatGPT 3.5 standard response	6/11 (54)	38.0 (7.6)	—
Owens et al [23]	ChatGPT 3.5 low literacy response	4/11 (34)	70.3 (7.2)[e]	—
Owens et al [23]	ChatGPT 4.0 standard response	7/11 (63)	43.1 (9.2)	—
Owens et al [23]	ChatGPT 4.0 low literacy response	7/11 (63)	74.1 (9.9)[e]	—
Owens et al [23]	Google Gemini standard response	6/11 (54)	55.7 (10.4)	—
Owens et al [23]	Google Gemini low literacy response	5/11 (45)	81.0 (3.6)[e]	—
Owens et al [23]	Google Gemini Advanced standard response	6/11 (54)	66.3 (9.4)[e]	—
Owens et al [23]	Google Gemini Advanced low literacy response	6/11 (54)	79.4 (5.1)[e]	—
Owens et al [23]	Microsoft Copilot standard response	8/11 (72)	50.8 (9.3)	—
Owens et al [23]	Microsoft Copilot low literacy response	6/11 (54)	65.1 (6.6)[e]	—
Owens et al [23]	Microsoft Copilot Pro standard response	7/11 (63)	61.2 (9.5)	—
Owens et al [23]	Microsoft Copilot Pro low literacy response	6/1 (54)	78.8 (4.7)[e]	—

[a]PCI: Prostate Cancer Info.

[b]Not applicable.

[c]Chatbot had a higher completeness score than PCI.

[d]NR: not reported.

[e]Chatbot had definitively higher readability scores than PCI based on the Flesch-Kincaid readability. Other scores may also be higher but were not based on a validated measure.

We expected PCI to outperform most other commercially available generative AI chatbots on completeness because of its development using the latest ChatGPT-4.0 technology and its directive to secure information from specific websites, but PCI underperformed earlier versions of ChatGPT. Therefore, additional training of the large language model that undergirds ChatGPT-4.0 will be needed for this niche area. In addition, unexpected was the lower average readability of responses from PCI, especially compared to our previous work, which solicited plain-language responses from multiple chatbots including ChatGPT-3.5 and ChatGPT-4. Nonetheless, the average readability of PCI is suitable for an audience with a middle school education.

Conclusions and Future Directions

Generative AI chatbots, such as PCI, are great starting places for learning about PrCA screening and preparing for shared decision-making but should not yet be used as sole sources of PrCA information because of their periodic omission of key information. Nevertheless, with further testing and validation,

XSL•FO
RenderX

model training, and refinement of the source selection process, we hope PCI can be a publicly available resource for credible, evidence-based, and culturally appropriate information for PrCA screening decisions. In the future, PCI could be integrated into the decision-making workflow by prompting patients to use PCI before their medical visit via an emailed link or a 1-page hard copy with a QR code. This same email or document could contain multiple frequently asked questions about PrCA. Men should be encouraged to pose as many of these questions as possible, but especially those on our list that are more complex (eg, Is the PSA or DRE more effective for finding prostate cancer?) PCI questions and responses could then be saved on their mobile device or printed, notated to indicate areas of concern or need for clarity, and then taken to their appointment to be used to guide the shared PrCA screening discussion. During this discussion, the health care provider should ensure that men understand their personal PrCA risk; screening options; and risks, benefits, and uncertainties of PrCA screening. The discussion should then shift to focus on men's questions and their screening preferences. Using this method of generative AI integration into the shared decision process could fortify men's PrCA knowledge and identify patient values and preferences.

To improve the overall performance of PCI in the future, it will be necessary to iteratively fine-tune our model which will include expanding the sources from which PCI retrieves data, which could include the most current peer-reviewed journal articles in addition to websites of major research hospitals and international health organizations. All sources will be curated by a PrCA expert who will review each data source to ensure it contains quality information. Equally important will be soliciting routine feedback from health care providers and patients through an embedded satisfaction survey that can enable them to comment on the quality of questions developed by the research team, potential questions that should be added to the database, and the quality of the responses generated by the PCI. Additional model training will come from tracking common follow-up questions from users to incorporate them into the initial responses. Based on these continuous feedback loops, PCI's performance could be improved significantly and always remain up-to-date. Future research should focus on the clinical deployment of PCI and testing to assess its acceptability, ease of use in a clinical workflow, and usefulness in the shared PrCA screening decision process.

Conflicts of Interest

None declared.

Correction of: https://cancer.jmir.org/2025/1/e54154

(JMIR Cancer 2025;11:e71958) doi:10.2196/71958

In "Benefits of Remote-Based Mindfulness on Physical Symptom Outcomes in Cancer Survivors: Systematic Review and Meta-Analysis" (JMIR Cancer 2025;11:e54154) an error was noted.

Reference 46 was previously a duplicate of reference 26, as follows:

Nissen ER, O'Connor M, Kaldo V, et al. Internet-delivered mindfulness-based cognitive therapy for anxiety and depression in cancer survivors: A randomized controlled trial. Psychooncol. Jan 2020;29(1):68-75.

All in-text citations to reference 46 have been changed to 26, the repeated reference information removed, and all subsequent references renumbered accordingly.

The correction will appear in the online version of the paper on the JMIR Publications website on February 13, 2025, together with the publication of this correction notice. Because this was made after submission to PubMed.

Submitted 30.01.25; this is a non–peer-reviewed article;accepted 31.01.25; published 13.02.25.

Abstract

(JMIR Cancer 2025;11:e86071) doi:10.2196/86071

In “Narrative Expertise in Oncology: An Integrated Training Model to Advance the Field” [1], the authors noted three errors.

The corresponding author’s email address has been changed to the following:

trisha_k_paul@urmc.rochester.edu

In addition, reference 23 has been changed from:

23. Paul TK. Why share your childhood cancer story. Together Blog: Jude Children’s Research Hospital. Mar 19, 2024.

The reference now appears as:

23. Paul TK. Why share your childhood cancer story. Together Blog: St. Jude Children’s Research Hospital. Mar 19, 2024.

Finally, reference 22 has been changed from:

22. Paul TK. Goldstein MA, Tran KM, editors. Work on Professionalism” Becoming a Better Physician: Insightful and Inspirational Stories from Attending Physicians, Residents, and Medical Students. Springer; 2024:8-11. ISBN: 3031694120

The reference now appears as:

22. Paul TK. Goldstein MA, Tran KM, editors. “Work on Professionalism” Becoming a Better Physician: Insightful and Inspirational Stories from Attending Physicians, Residents, and Medical Students. Springer; 2024:8-11. ISBN: 3031694120

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Retraction: "Designing Positive Psychology Interventions for Social Media: Cross-Sectional Web-Based Experiment With Young Adults With Cancer"

JMIR Editorial Office

JMIR Publications, 130 Queens Quay E, Suite 1100, Toronto, ON, Canada

Corresponding Author:
JMIR Publications, 130 Queens Quay E, Suite 1100, Toronto, ON, Canada

Related Article:

https://cancer.jmir.org/2024/1/e48627

Abstract

(JMIR Cancer 2025;11:e82724) doi:10.2196/82724

Following a request by the authors, the JMIR Publications Editorial Office is retracting the article "Designing Positive Psychology Interventions for Social Media: Cross-Sectional Web-Based Experiment With Young Adults With Cancer" by Lazard et al [1] due to concerns regarding the integrity and reliability of the survey data collected by an external contractor, which underpinned this article. As a result, the JMIR Publications Editorial Office, the editor in chief of the journal, and the authors have lost confidence in the results and conclusions of the published article.

Author Statement

Lazard et al [1] used an external contractor for data collection in December 2021. In June 2025, the authors became aware of legal concerns about alleged fraudulent practices by the external contractor used to collect the survey data the article wholly relied on. The authors can no longer confidently verify how these data were collected nor confirm their legitimacy. Consequently, the authors believe that retraction of the article is the most responsible course to maintain the integrity of the scientific record due to a loss of confidence in the findings.

All authors agreed with the retraction of the article.
