Abstract

Background: The rising number of cancer survivors and the shortage of health care professionals challenge the accessibility of cancer care. Health technologies are necessary for sustaining optimal patient journeys. To understand individuals' daily lives during their patient journey, qualitative studies are crucial. However, not all patients wish to share their stories with researchers.

Objective: This study aims to identify and assess patient experiences on a large scale using a novel machine learning–supported approach, leveraging data from patient forums.

Methods: Forum posts of patients with colorectal cancer (CRC) from the Cancer Survivors Network USA were used as the data source. Topic modeling, as a part of machine learning, was used to recognize the topic patterns in the posts. Researchers read the most relevant 50 posts on each topic, dividing them into "home" or "hospital" contexts. A patient community journey map, derived from patients stories, was developed to visually illustrate our findings. CRC medical doctors and a quality-of-life expert evaluated the identified topics of patient experience and the map.

Results: Based on 212,107 posts, 37 topics and 10 upper clusters were produced. Dominant clusters included "Daily activities while living with CRC" (38,782, 18.3%) and "Understanding treatment including alternatives and adjuvant therapy" (31,577, 14.9%). Topics related to the home context had more emotional content compared with the hospital context. The patient community journey map was constructed based on these findings.

Conclusions: Our study highlighted the diverse concerns and experiences of patients with CRC. The more emotional content in home context discussions underscores the personal impact of CRC beyond clinical settings. Based on our study, we found that a machine learning-supported approach is a promising solution to analyze patients' experiences. The innovative application of patient community journey mapping provides a unique perspective into the challenges in patients' daily lives, which is essential for delivering appropriate support at the right moment.

Introduction

Colorectal cancer (CRC), the third most common cancer in the Netherlands significantly impacts the health of individuals [1]. Supportive care involves adopting a person-centered care approach, intending to offer individuals affected by cancer the essential services required to address their informational, emotional, social, and physical needs and concerns throughout the entire patient journey [2,3]. Understanding the needs and concerns of those affected by this disease during their patient journey is crucial for improving patient outcomes and quality of care [4]. Several survey and qualitative studies involving

CRC survivors offer valuable information about the needs and perceptions of patients [4-7]. However, these survey- and qualitative studies are limited by sample size, labor-intensive processes, and could lead to socially desirable answers [8]. Efforts were made to include vulnerable populations who may not be accessible through focus groups, ensuring a more comprehensive understanding of diverse patient perspectives [9]. In the last decade, patient web forums have emerged as valuable platforms for individuals to openly share their experiences and thoughts related to CRC, providing unique insights into the social, physical, and emotional aspects of their patient journey [10,11]. These forums offer different opinions compared with traditional patient experience data collection methods, such as questionnaires and interviews.

While patient community forums contain a wealth of information, the analysis of the extensive unstructured data within these forums poses a considerable challenge [12]. Traditional manual qualitative analysis by human experts is time-consuming, labor-intensive, and lacks scalability, making it impractical to analyze the sheer volume of patient-generated unstructured content. Machine learning techniques offer a potential solution to address this challenge. This enables the automated processing and analysis of textual data, allowing for the efficient extraction and interpretation of large amounts of patient forum posts [13,14].

Our primary objective is to assess patient experiences using a novel machine learning–supported approach and data from patient forums. To achieve this, we used patient community journey mapping to better understand the experiences throughout the patient journey [15]. This is a machine learning-driven approach, that uses web-based patient forums as input data and is processed through topic modeling. By gaining insights into these patient experiences, we can shape future patient journeys such as remote monitoring systems to be aligned with current patients' needs.

Methods

Ethical Considerations

Ethical approval was given by the human research ethics committee of the Delft University of Technology (ID 2596). Informed consent was not required since the data used in this study were sourced from publicly available forums, in accordance with institutional guidelines. The data were accessed and analyzed in accordance with the terms of service and privacy policies outlined by the platform hosting the data. As the ethics committee suggested, all data used in this study were anonymized by removing all direct and indirect identifiers (eg, names, location, and user ID) to prevent potential privacy issues within our data set. Confidentiality was strictly maintained during data collection, analysis, and reporting to ensure that no identifiable information was disclosed.

In order to assess patient experiences using machine learning–driven analysis, this study used systematic data collection, advanced topic modeling techniqu and cocreation sessions with domain experts to interpret and validate identified clusters. The Consolidated Reporting Guidelines for prognostic and diagnostic machine learning modeling studies checklist can be found in Multimedia Appendix 1.

Data Source

To enable research, we used forum posts of patients with CRC scraped from the Cancer Survivors Network USA, an open-source patient community platform. The web-based platform provides support, education, and advocacy for patients affected by CRC that includes current patients, former patients, families, and caregivers. The posts are written with the intention of asking questions to peers and health care providers, as well as forsharing experiences among peers [16]. The initial CRC discussion thread (ie, main posts, comments, and replies) has remained active on the public platform since the year 2000. No distinctions were made between main thread posts and replies to posts.

The data collection involves 2 main steps: first involves using Selenium WebDriver to gather the URLs of discussion pages, and second, using BeautifulSoup to extract data from the HTML elements while keeping sensitive information secure.

Data Analysis (Topic Modeling)

Information about the personal (health) status of patients, which could be directly or indirectly identifiable, was excluded from the analysis. Topic modeling, a machine learning algorithm was used to recognize patterns in the platform data. Nonnegative matrix factorization (NMF) was used as a topic modeling technique to analyze the data set and identify topics with weighted keywords [17,18]. The number of topics was determined by evaluating topic coherence scores and model stability [19,20]. Model stability was assessed using Jaccard similarity to reduce the overlap of topics. Human evaluation was used to ensure that the output contains diverse and distinctive topics, without topics unrelated to patient experiences. This evaluation was conducted by 4 researchers to select the number of topics that yield the most diverse and distinctive clusters.

Interpretation of Data Analysis (Qualitative Analysis)

To comprehend each topic, researchers meticulously read and analyzed the top 50 most relevant posts and top 20 related keywords. The most relevant posts and keywords had the highest dominant topic score identified by the algorithm, indicating they were most closely associated with the topic. The algorithm efficiently identified the most relevant posts and keywords within each topic by using Term Frequency–Inverse Document Frequency to calculate the importance of each term in relation to each document [21].

Clusters

The identified topics were grouped into clusters for topics that revolved around similar concerns. Irrelevant topics (eg, those related to platform-specific issues) were excluded. The frequency of discussions on each topic was recorded by counting the number of posts associated with each topic.

Creation of Patient Community Journey Map

This study uses patient community journey mapping to visually present the identified patient experience topics. The creation of

the patient community journey map began with the conduction of 2 interviews with CRC medical doctors to outline the patient journey and its distinct phases such as diagnosis and follow-up of a patient with CRC.

The results of the interpreted topics were deliberated in an in-person cocreation session involving domain experts [22]. The cocreation session took place in the Erasmus Medical Centre in March 2023 and lasted 3 hours. The interdisciplinary team of domain experts reviewed and discussed the outputs comprehensively. The team comprised 2 oncological surgeons, 2 surgical oncology PhD candidates (MD), and an epidemiologist with an interest in oncological research. A total of 3 out of 5 participants have over 20 years of work experience, indicating a high level of expertise. During the cocreation session, clusters from the NMF results were interpreted, and feedback was provided on the generated interpretations. This process ensured a thorough examination and validation of the identified clusters within a clinically relevant context. During this session, the same domain experts also reviewed the patient community journey map. The identified topics were positioned on the journey map, with allocation to specific phases of the patient journey. Distinctions were made regarding whether each topic was taking place at a “hospital” or “home”setting.

Results

Data

A total of 294,166 posts were extracted from the patient forums of the Cancer Survivors Network USA. The posts on the website were created between the year 2000 and 2022. However, 212,107 posts were analyzed, as the remaining 82,059 posts were excluded through topic modeling.

Topic Modeling

Using NMF topic modeling, the topic coherence score, and model stability did not provide clear insights as the coherence score consistently declined. Therefore, human evaluation was required. Initially, 40 and 50 topics were considered the best amount of topics. Subsequently, the cut-off of 45 topics was also reviewed. Ultimately, 50 topics were chosen as the number that provided the most diverse and distinctive topics. This was confirmed by examining keywords and the most relevant posts for each cluster. Additionally, one topic bin identified 82,059 posts as unclassifiable," which could not be categorized into any of the 50 topics.

Identified Patient Experience Topics and Patient Community Journey Map

A total of 50 topics were identified with the use of NMF topic modeling. Thirteen topics were excluded as they were unrelated to patient experiences, such as platform use and expressions of gratitude. The data export of the relevant topics is shown in Table 1. These are the key patient experiences found in our study.

A total of 10 clusters were derived from 37 topics. The patient community journey map, shown in Figure 1, serves as a visual guide to navigate through the nuanced dynamics of patient experiences.

The topics in the home context have a more emotional content, as emotionally charged keywords such as “confused,” “bad,”and “worried” are more often discussed. Conversely, the hospital context is marked by the clinical terminologies “drug” and “node.” This reflects the distinct atmospheres characterizing discussions in different contexts.

The clusters commanding the highest share of posts are “Daily activities while living with CRC” (38,782, 18.3%) and, “Understanding treatment including alternatives and adjuvant therapy” (31,577, 14.9%) underscoring their important role in shaping the experiences of CRC survivors. Patients expressed significant concerns about test results, as indicated by the 14.1% of posts within cluster 4. As shown in Figure 1, “Understanding treatment including alternatives and adjuvant therapy” is a cluster that goes through almost the entire journey, while the “Daily activities while living with colorectal cancer,” is more in the home context and starts later in the follow-up.

Table . Overview of the clusters derived from the topics and their keywords.

Clusters and topics, (n, %)[a] (N=212,107)	Top 20 keywords	Number of posts[b], n
Cluster 1: Experience around medical professionals' opinion (9756, 4.6%)		
Doubts about treatment options from medical professionals	'doctor', 'oncologist', 'surgeon', 'told', 'patient', 'system', 'cell', 'wrong', 'reason', 'medical', 'asked', 'office', 'immune', 'trust', 'kill', 'testing', 'medicine', 'appointment', 'clinic', 'recommend'	5043

Discussion

Principal Findings

This study delves into the daily experiences of patients using data from a web-based platform, applying topic modeling as a tool to efficiently analyze and interpret large volumes of patient-driven daily life experience data. We analyze patient experiences (eg, struggles, tips, and coping strategies) reported on a platform to better understand patient needs. This understanding of patients' needs has positive potential for future care path development such as information provision or psychosocial support in remote patient monitoring. The use of machine learning techniques in analyzing qualitative data holds significant promise to improve various aspects of health care. This includes optimizing patient care, by using advanced methods such as using symptom checkers to guide patients to the most suitable care journeys and support disease diagnosis. This approach will ultimately lead to patient-centered care to support and empower patients.

The identified clusters in this study align with findings from previous qualitative and survey research, emphasizing the potential to optimize the use of machine learning in qualitative studies of health care in the years to come [4,23]. Based on our analysis, it becomes evident that patients exhibit a notable interest in actively participating in discussions with other CRC survivors to exchange experiences regarding the daily challenges of living with CRC. This underscores the crucial role of social support and the dissemination of pragmatic, day-to-day coping strategies within the broader patient community. This theme aligns with observations from a systematic review detailing the experiences of CRC survivors, where the significance of coping and addressing functional limitations emerged as a central theme [23].

The cluster with the highest share of posts (cluster 10; 38,782, 18.3%) revolves around the challenges associated with resuming daily activities while living with CRC. This substantial volume of posts highlights the significant impact of this particular aspect on the experiences of CRC survivors, as well as the needed change in patients' mindset (cluster 8; 26,379/212,1087, 12.4%). The systematic review of survivorship experiences further supports these findings [23]. The alignment between these dominant themes in the posts and the insights from the qualitative literature underscores the robustness of our findings [24]. These findings emphasize the importance of integrating

comprehensive support mechanisms to facilitate the successful reintegration of patients into their daily lives.

On the platform, patients frequently engage in discussions centered around understanding treatment options (cluster 2; 31,577, 14.9%), highlighting its significance as a key topic. This observation aligns with the qualitative study conducted by van Deursen et al [4], where participants similarly emphasized the need for more information regarding their treatment. It is noteworthy that patients on the platform also frequently express concerns regarding test results (cluster 4; 29,984, 14.1%). This anxiety and fear of recurrence are recognized as common concerns among cancer survivors [25], highlighting the potential to offer valuable support in addressing this. Additionally, the positive outcomes associated with the interaction with family, as reported in the systematic review [23], further underscore the importance of familial support within the context of patient experiences in our findings [26].

A novel finding from our analysis was the open expression of patients' sentiments regarding the opinions of medical professionals (cluster 1; 9756, 4.6%). Not completely surprising as this is possibly due to the reluctance of patients to express negative feelings in a setting where researchers are present, such as focus groups or interviews. Furthermore, qualitative studies primarily concentrate on the follow-up phase, excluding discussions on the experiences of surgery and the subsequent recovery phase. These aspects might provide valuable insights into the comprehensive journey of patients.

The Added Value of Machine Learning to Support the Understanding of Patient Experiences

To reflect on our approach, topic modeling allows extraction from a vast pool of large-scale patient data. The alignment of our study with existing literature is indeed promising. Additionally, topic modeling offers a novel approach by sparing patients the burden of active participation in qualitative studies. Rather than focusing on a single aspect, as is often the case in conventional studies, this method presents a broader spectrum of patient experiences beyond specific questions from researchers. Notably, topic modeling relies on patient-driven data, in contrast to a physician-driven approach. This method's replicability allows seamless comparisons between various medical conditions. This not only contributes to a more extensive comprehension of diverse experiences but also facilitates the identification of commonalities and distinctions of different medical conditions. For example, we explored the present method with patients with pulmonary fibrosis and found comparable experiences to those with CRC, their increased focus on treatment options highlights the distinctive challenges inherent to their specific condition (unpublished data). Given the large data sets on forums, we can quantify patients' experiences with the implementation of topic modeling. This complements the challenges of focus groups and interviews, where the ability to quantify and prioritize findings is limited. As patients' experiences change throughout their journey, the simplicity of using topic modeling remains a flexible and efficient approach for understanding patients' experiences and priorities in the era of remote monitoring [27]. It offers a convenient and adaptable method, without burdening patients [28].

Limitations

Using stories from patients who prefer to share their experiences on a digital platform introduces a risk of selection bias. It is essential to address the potential overexpression of emotion in our findings as the platform primarily captures narratives from individuals who are willing to share their experiences on the web. However, it should be recognized that these individuals represent the intended user group for new care path developments such as remote monitoring support approaches. Patients who are not feeling well, patients who do not have access to the internet, or reserved patients may be less inclined to engage in web-based discussions and might be underrepresented [29]. To complement this, in previous research, we conducted interviews with vulnerable patient populations to ensure their perspectives were included in our understanding of patient experiences [9]. Similar themes such as the need for information provision, concerns about test results, and challenges in reintegrating into daily life were found in this study. Additionally, our approach demands a significant investment of human labor and time to interpret the meaning of topics after generating groups of topics. Thus, exploring another artificial intelligence technique to interpret patient experiences is a promising direction. As an example, a large language model, a pretrained model, can be used to interpret and summarize large quantity textual data [30]. The use of machine learning, even in the part where we used human experts' knowledge, is a promising area to labor-effectively understand the patients' experience while having the least safeguarding support of human validation. Another limitation is the lack of direct involvement of patients with CRC in the co-design or review of the map. We plan to address this in the future as this can provide valuable insights. However, the primary purpose of this method is to enhance the methodology while minimizing the burden on patients. To overcome this limitation, we sought input from highly experienced medical professionals' perspectives. Three of these experts possessed more than 20 years of medical and research experience, specifically with patients with CRC.

In future research, efforts should be directed towards further refining machine learning techniques with the ultimate aim of minimizing or eliminating the need for human involvement, as this will enable more frequent monitoring of patient experiences and thereby facilitate responsiveness to those experiences. Addressing the nuanced interpretation of emotions in patients remains a challenge for artificial intelligence systems. A promising direction is the automatic interpretation of patient-reported outcome measures using machine learning and NLP. Patient-reported outcome measures offer structured data that can improve AI's ability to understand emotional nuances. This approach aims to improve remote patient monitoring, reduce the burden on health care professionals, and identify those who face psychosocial challenges [31]. This approach not only empowers patients in managing their health but also leads to a proactive and personalized approach.

In conclusion, topic modeling and the use of patient forum data offer a robust and efficient approach to understanding patients' experiences in their daily lives. This approach reveals the challenges patients encounter in their daily life such as getting back to daily activities and the need for understanding their treatment. This study not only provides a comprehensive overview of patient experiences through web-based platforms but also highlights the potential for improving patient monitoring systems. This machine learning technique of identifying patient experiences contributes to a more efficient way of building value-based health care. By integrating these insights into the development of remote monitoring solutions, a patient-centered approach can be created that not only addresses medical concerns but also caters to the broader spectrum of challenges individuals face in their daily lives.

Acknowledgments

We extend our gratitude to all the individuals who shared their experiences on the Cancer Survivors Network USA, an open-source patient community platform. This provided valuable insights for this study. Generative artificial intelligence was not used in the writing process.

Abstract

Background: Survivorship care plans (SCPs), ie, personalized health care plans for cancer survivors, can be used to support the growing group of melanoma survivors throughout their disease trajectory. However, implementation and effectiveness of SCPs are suboptimal and could benefit from the involvement of stakeholders in developing a user-centered design.

Objective: The aim of this study was to identify the ideal SCP for patients with melanoma in terms of functions and features to be included according to different stakeholders and to explore their underlying motives.

Methods: In total, 3 cocreation sessions were organized with mixed samples of stakeholders, ie, patients with (a history of) melanoma (n=4), health care providers (HCPs) active in melanoma care (n=3), and IT specialists active in hospital IT departments (n=6). They were invited to compose their ideal melanoma SCP based on potential functions and features identified from prior qualitative research. These functions and features belonged to one of the four main categories of survivorship care (SSC): (1) information and education, (2) identification and treatment, (3) oncological follow-up, and (4) coordination. Participants were invited to explain their motives for including functions and features. Ideas were shared between stakeholders, and interaction was promoted. Descriptive statistics were used to determine the ideal SCP per stakeholder group. To analyze underlying motives, all cocreation sessions were audio-taped, transcribed verbatim, and analyzed in a thematic content analysis.

Results: With regard to their ideal SCPs, all stakeholders added functions from all 4 SSC categories. Patients assembled a rather compact SCP with category 2 on *identification and treatment* being most important. Both HCPs and IT professionals constructed a somewhat larger SCP, with category 3 on *oncological follow-up* being the most important aspect and HCPs also focusing on category 4 on *coordination*. As for the motives behind their ideal SCP compositions, patients predominantly added functions based on their personal experiences or experiences from fellow patients, whereas both HCPS and IT professionals based their compositions primarily on their respective areas of expertise: HCPs related their additions to their roles as medical practitioners; for example, in providing a complete treatment plan and obtaining informed consent, while IT professionals' contributions were mainly influenced by feasibility and privacy concerns.

Conclusions: This cocreation study provides insights into stakeholders' ideal melanoma SCP and the motivations behind them. Considering the diversity in both the preferences and underlying motives regarding SCP composition between patients, HCPs, and IT specialists, it is crucial to develop a broad SCP that extends beyond traditional SCP content, emphasizing personalization. In addition to continued stakeholder involvement, efforts should be focused on addressing potential feasibility and privacy issues to ensure the SCP meets both patients' and HCPs' needs.

cocreation; survivorship care; psycho-oncology; supportive care; motives; melanoma; cancer survivor; melanoma care

Introduction

In recent years, the prognosis of melanoma, one of the most aggressive forms of skin cancer, has significantly improved due to advancements in innovative treatments such as immunotherapy and targeted therapy [1]. With an estimated worldwide total of 325,000 new cases in 2022, increasing to an expected total of 510,000 new cases in 2040 [2], this results in an expanding cohort of melanoma survivors, ie, individuals living with or beyond melanoma [3]. To ensure that patients get the necessary support throughout their treatment trajectory and assist them in resuming life thereafter, it is important to provide them with effective survivorship care (SSC) [4].

SSC can be divided into four main categories [4,5], namely (1) information and education, (2) identification and treatment, (3) oncological follow-up, and (4) coordination (Textbox 1 [4,5]). Survivorship care plans (SCPs), personalized health care plans for cancer survivors, have an important role in the delivery of SSC, traditionally mainly regarding categories 1 and 3 of SSC (Textbox 1) [4]. However, notwithstanding their potential benefit for both patients and health care providers (HCPs) and the recommendation of their use in clinical guidelines, the present implementation and effectiveness of SCPs seem to be suboptimal [6-8]. Until now, most SCPs have been static, paper-based documents, while patients have shown a preference for dynamic, electronically accessible formats that permit alterations and accessibility for all stakeholders [8]. Personalization, an essential element of SCPs, has often been overlooked, despite evidence emphasizing the importance of tailoring SCPs to accommodate the diverse information needs among patients [9]. However, these findings are mostly based on evaluations of the SCP subsequent to its implementation and based on the feedback of 1 single type of stakeholder. Indeed, while stakeholder engagement seems critical for effective implementation [10], involvement of key stakeholders like patients and HCPs during SCP development has been limited until present [8,11]. The specific needs of patients with melanoma and their HCPs regarding the content of melanoma SCPs have been explored previously [12], which showed that while both stressed the importance of adequate information throughout the disease trajectory and personal oncological follow-up, different opinions existed regarding psychosocial support and coordination of care. However, the reasons why they consider these elements important and why their opinions differ remain unknown. Thus far, only the needs of users have been investigated, with developers' perspectives yet to be examined, even though this could provide valuable insights into the feasibility of desired content.

An approach to integrating the diverse perspectives of all stakeholder groups, ie, patients, HCPs, *and* IT professionals (future developers), is to engage them in a cocreation process [13,14] that encourages their direct involvement in SCP development. Cocreation allows stakeholders to be active partners in the development of innovations, as opposed to objects of study, resulting in products and services that people want and need [15,16]. Therefore, the objective of this study is to investigate the ideal SCP in terms of functions and features to be included per stakeholder group and to explore the motivations behind these preferences through a cocreation process. The findings of this study will serve as a basis to design a user-centered, practically feasible SCP that is tailored to the needs of stakeholders and thereby more easily integrated in clinical practice.

Textbox 1. The 4 main categories of survivorship care.

- *Information and education* about the disease, its treatment, and the possible early and late effects.
- *Identification and treatment* of the disease and therapy effects on all possible domains (ie, physical and psychosocial, including work- and insurance-related).
- *Oncologic follow-up* with surveillance for cancer progression, recurrences or second cancers.
- *Coordination* between all health care providers involved in the care process, to make sure the survivor's health needs are met.

Methods

Setting

This study was part of a regional project in which a digital and personalized melanoma SCP will be developed that will be linked to the patients' electronic health record and provided to patients from diagnosis onwards to help them deal with all disease and treatment-related impacts [17,18]. This project takes place in the region Rijnmond, the Netherlands, and forms a collaboration between 1 academic (Erasmus Medical Center) and 3 non-academic hospitals (Albert Schweitzer Hospital, Francicus Gasthuis & Vlietland, and Maasstad Hospital), in which, like internationally [7], SCPs are not yet routinely provided [6]. The project consists of multiple phases—from needs assessment to implementation—in which cocreation is used to develop an SCP that is adapted to all stakeholders' needs [13].

Study Design

In this study, qualitative research methods in terms of cocreation sessions were used to gain an in-depth understanding of the preferences of all stakeholders involved [19]. Conducting cocreation sessions allows both the end users, ie, patients and HCPs and developers, ie, IT specialists, to collaborate in the SCP design process to reduce the gap between research and implementation [13,14].

The COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines [20] were used in reporting this qualitative study.

Participants and Recruitment

Eligible participants were patients with (a history of) cutaneous stage I-IV melanoma; HCPs involved in both primary, secondary, and tertiary melanoma care such as dermatologists, oncologists, surgeons, general practitioners, and nurse practitioners; and hospital-based IT professionals, for example, those working in organizational aspects of IT in health care and eHealth (future developers of the SCP). We aimed to recruit an equal number of patients, HCPs, and IT professionals to ensure a balanced cocreation session in terms of perspectives to be included and to explore the motives in these perspectives. All patients had to be treated in and therefore under follow-up in, and both HCPs and IT professionals had to be affiliated with one of the 4 participating hospitals. To select participants, first patients and HCPs that participated in prior qualitative research and/or had given consent to be contacted (again) for participation in a follow-up study were invited to participate. IT professionals as well as the remaining patients and HCPs were approached through the professional networks of the researchers. All potential participants received information about the study by email or by phone. Our aim was to recruit ±15 participants, in which we follow prior research (eg, Vandekerckhove et al [21]). In the end, 19 participants signed up, and based on their availability and eventual willingness to participate, a total of 3 mixed cocreation sessions with 4-5 participants were organized, with a total of 4 patients, 3 HCPs, and 6 IT specialists. No financial compensation was given for participation.

Cocreation Sessions

Input for the cocreation sessions was based on prior in-depth qualitative research, in which SSC needs of a total of 50 patients with stage I-IV melanoma and 24 HCPs were explored [6,17,18]. In total, 23 interview- and 8 focus group transcripts were re-analyzed for the purpose of this study using Nvivo version 12/R1, to identify potential functions and features of a melanoma SCP. *Functions* represent the overarching areas in which support can be provided, while *features* are tools to deliver that support. First, all transcripts were coded to identify patients' and HCPs' needs regarding SSC (including SCPs) by 2 researchers (JB, a female medical master student and a female health care management master student), which was then checked and complemented by 2 other researchers (NK, a female medical doctor, and KT, a female academic researcher in health care innovation and cocreation). The resulting SSC needs were reformulated as 44 potential features of an SCP by the research team (first reformulation by JB and a female health management student, under supervision of NK and KT, which was then discussed in the multidisciplinary research team including NK, ML, JB, KT, and a medical student until consensus was reached). Subsequently, an exploratory literature review was conducted to assess completeness, which did not reveal any new features. Subsequently, the features were structured according to the 4 main categories of SSC [4,5], as presented in Textbox 1, and further divided into 14 potential functions. Using this classification, the 44 potential features of a melanoma SCP were presented to the participants of the cocreation sessions (see Multimedia Appendix 1).

As a result of the national restrictions placed in response to the COVID-19 crisis, the 3 cocreation sessions were held online via Zoom in May 2021. All sessions took approximately 90 minutes and were moderated by JB and NK (experienced in moderating group discussions) and a health care management student, who were all not directly involved in melanoma care.

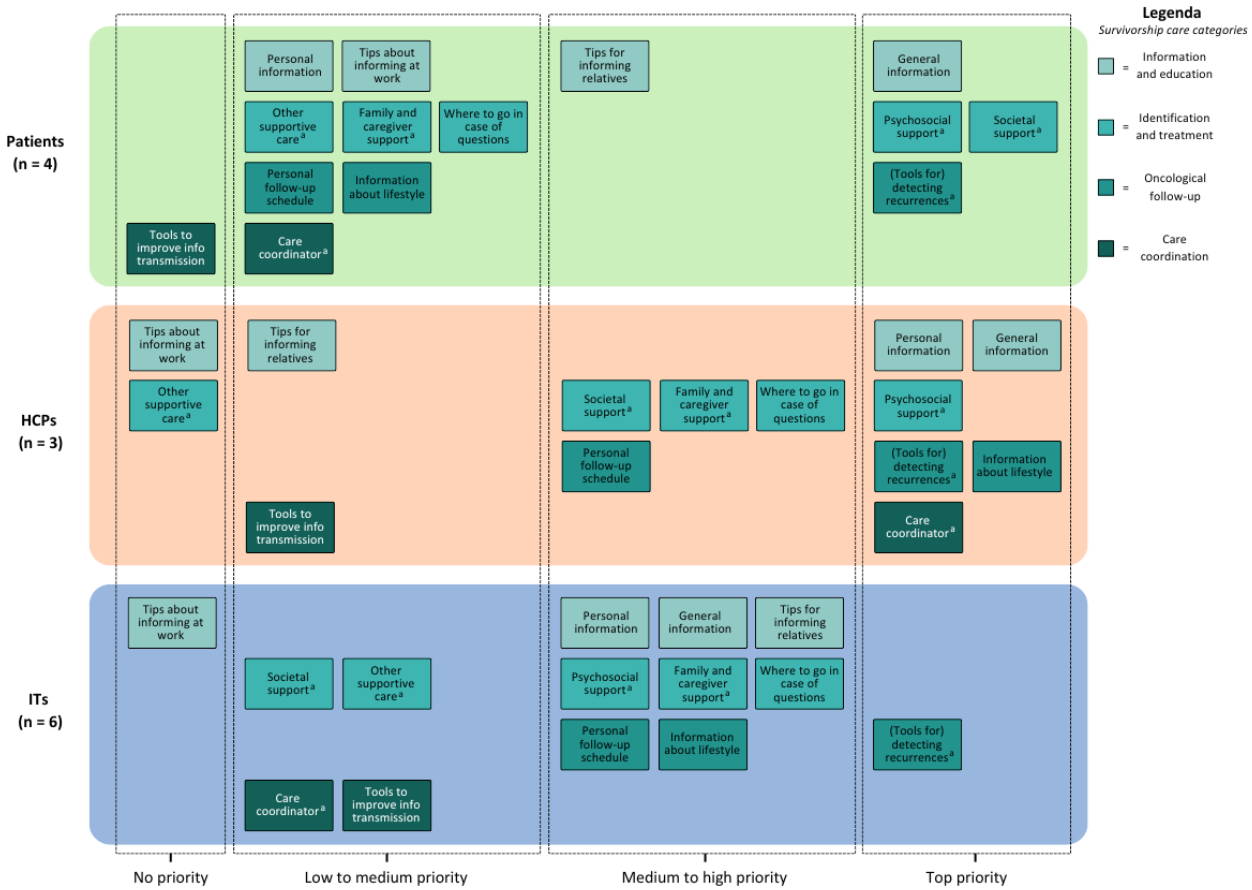
During the cocreation sessions, a PowerPoint presentation was used to present potential functions and features, and participants were invited to individually create their "ideal SCP" by placing their preferred features in a box. Subsequently, participants had a plenary, semistructured discussion in which they were encouraged to share their ideas about the ideal SCPs by sharing their screens. They were invited to elaborate on their motives for (not) including certain functions and features, and discussions arose. At the end of the sessions, the moderators questioned the participants about under-discussed features. All cocreation sessions were audio-taped, and participants were invited to hand in their filled-in sheets.

Data Analysis

All 3 audio-recordings were transcribed verbatim in anonymized form and were analyzed using Nvivo version 12/R1. Descriptive analyses were used, using Microsoft Excel, to determine the ideal SCPs of the different stakeholder groups based on the filled-in PowerPoint sheets and on comments they made during the sessions. For each function and feature, it was determined by how many percent of the participants they were included. Subsequently, all functions were categorized into "top," "medium to high," "low to medium," or "no priority" based on the following criteria: 100% of respondents adding the function to their ideal SCP was defined as "top priority," 50%-99% as "medium to high priority," 1%-49% as "low to medium priority," and 0% of respondents adding the function to their ideal SCP was defined as "no priority"; see also Figure 1. Based on this figure, we then described the ideal SCP par stakeholder group and the similarities and differences between them.

Second, underlying motivations of all participants for including functions and features in their ideal melanoma SCPs were analyzed in a thematic content analysis [22]. As a first step of the analysis, all transcripts were coded based on the functions and features within the 4 main categories of SSC, as previously mentioned (Textbox 1), by 2 researchers (JB and a health care management master student). This was checked and complemented by a third researcher (medical master student). Next, within these categories, underlying motives for composing the ideal SCPs were explored. Motives of each stakeholder group to include (or exclude) a specific function or feature in the SCP were openly coded by one researcher (JB), which was checked and complemented by a second researcher (NK). The next phase of analysis consisted of axial coding, in which the open codes were clustered in concept motives and links between motives and stakeholder groups were made in order to investigate the differences and resemblances between the ideal SCPs for patients, HCPs, and IT specialists. The resulting overview was discussed within the multidisciplinary research team until consensus was reached (JB, NK, ML, and KT).

Figure 1. Overview of composed ideal SCP per stakeholder group in terms of functions added per main category of SSC. For an overview of all functions, including their corresponding features, see Multimedia Appendix 1. [a]Information about and referral to reliable and up-to-date information and tools regarding this topic. HCP: health care provider; SCP: survivorship care plan; SSC: survivorship care.



Ethical Considerations

This cocreation study was part of a larger project, of which the study protocol was submitted to, and approved by, the Medical Ethics Committee Erasmus MC. After reviewing the protocol, the committee concluded that the Medical Research Involving Human Subjects Act (Dutch abbreviation: WMO) did not apply to this study (MEC-2020-0197). Written informed consent was obtained from all participants involved in the cocreation sessions and they were informed that they could withdraw at any point during the study. Participants did not receive any compensation for participation in this study.

Results

Participant Characteristics

The characteristics of the 13 participants in the cocreation sessions as well as the compositions of all 3 sessions can be found in Table 1.

Table 1. Characteristics of participants per cocreation session.

Participant	Gender	Stakeholder	Experience or expertise	Care setting
Session 1				
1	Female	Patient	Melanoma stage IV	Secondary or tertiary care
2	Female	IT professional	Assistant professor in organizing aspects of IT in health care	Tertiary care
3	Male	IT professional	Information management and IT advisor	Tertiary care
4	Female	IT professional	Clinical informatician and data protection officer[a]	Secondary care
Session 2				
5	Male	Health care professional	General practitioner	Primary care
6	Female	IT professional	Information manager in research and innovation	Secondary care
7	Female	IT professional	Clinical informatician: information advisor and architect, (application) implementation lead	Secondary care
8	Male	Patient	Melanoma stage I/II	Secondary care
Session 3				
9	Female	Health care professional	Oncological surgeon	Tertiary care
10	Female	Health care professional	Oncological nurse practitioner	Secondary care
11	Female	IT professional	Information manager	Tertiary care
12	Male	Patient	Melanoma stage IV	Secondary or tertiary care
13	Male	Patient	Melanoma stage IV	Secondary or tertiary care

[a]Having a partner with melanoma.

Ideal SCPs and Underlying Motives

In Figure 1, an overview is provided of the composed ideal SCPs per stakeholder group, followed by an in-depth description of their underlying motives for (not) including certain functions and features. All results are discussed per category of SSC (Textbox 1), and all motives are provided from the participants' perspectives.

Ideal SCPs

Overall, patients assembled the smallest SCP; for them, fewer functions were of medium to high, or top priority compared to the other 2 stakeholder groups. For patients, category 2 focusing on identification and treatment was most important. They primarily included general information and support for themselves, tips on how to inform their relatives, and information about (tools for) detecting recurrences. On the other hand, both HCPs and IT professionals constructed a somewhat larger SCP with more functions being of medium to high, or top priority, with category 3 focusing on oncological follow-up being the most important aspect. HCPs added more information about (personal) follow-up for the patient, including (tools for) detecting recurrences. Furthermore, they added both general and personal information, as well as support for both the patient and their family and caregivers. Additionally, they included information about a care coordinator. IT professionals, on the other hand, considered (tools for) detecting recurrences particularly important to add, and they included extensive information about the patient's (personal) follow-up, both personal and general information, along with support for the patient and their family and caregivers.

Underlying Motives Per Stakeholder Group

For each stakeholder group, motives for (not) including certain functions and features are discussed below per main category of SSC and can be found in Table 2. For readability, results are provided on the function level, which are **bold**. Submotives are in *italics.*

Table 2. Overview of motives for (not) including functions and features from the 4 main categories of SSC in the ideal SCP, per stakeholder group.

Motives and submotives	PT[a]	HCP[a]	IT[a]
Motives for including functions and features			
Informing patients			
To meet patients' information needs	1, 3	1, 2, 3	1, 2, 3
To provide understandable information	1	1	1
To provide reliable information	1	2	1
To help remember provided information	1	1	
To obtain informed consent		1	
Helping patients deal with psychosocial issues			
To identify psychosocial issues		2	
To alleviate patients' concerns	3	3, 4	3
To provide support for or treat psychosocial issues	2	2	2
To help patients deal with lack of understanding of others	1		1[b]
Improving patient empowerment			
To improve patients' self-management skills	3	3	1, 2, 3
To support patients in decision-making		4	
Preparing and providing structure for patients			
To prepare for or raise awareness about what to expect	1	1	
To prevent unnecessary consultations	3	2, 3	1
To provide structure for patients		3	
Empathizing with patients and their situation			
To empathize with (other) patients' needs	2, 3	2	1, 2, 3
To take the patient's context into account		1, 2, 4	
Meeting the relatives' needs			
To meet relatives' information needs		1, 2, 3	1
To meet relatives' support needs			2
Improving health and outcomes			
To improve melanoma outcomes		3	3
To improve health in general		3	
Providing integrated care			
To improve communication and collaboration between HCPs		4	4
To provide a complete treatment plan		2, 3	2
To provide an accessible contact point	2, 3, 4	2, 3, 4	2, 3, 4
Relating to experiences and expertise			
Based on own experiences	1, 2, 3, 4		1, 2, 3, 4[b]
Based on experiences of others	2, 3		1, 2[b]
Based on expertise		1, 2, 3	1, 2, 3, 4
Taking feasibility and privacy into account			
Function is feasible			1, 2, 3, 4
Function is important and this exceeds potential privacy issues			2, 3
Motives for not including functions and features			
Preventing patient distress			

Motives and submotives	PT[a]	HCP[a]	IT[a]
To prevent (irrelevant) information overload		1, 3	3
To prevent taking away hope	1		1[b]
Preventing unnecessary development			
SCP is not the right medium		2	4
Similar tools already exist	3	3	3
Function is applicable in general, not for melanoma specifically			1, 3
Lack patient need for function	3		
Taking feasibility and privacy into account			
Function is unfeasible			2, 3, 4
Privacy issues are more severe than the importance of including the function and its relevance for patients			3

[a]The numbers correspond with the main category of SSC to which the functions belonged and for which submotives were provided, namely (1) information and education, (2) identification and treatment, (3) oncological follow-up, and (4) coordination.

[b]Submotives for (not) including functions provided solely by an IT professional with a partner with melanoma.

Motives of Patients

The most important category for patients was category 2 (identification and treatment). Patients included **psychosocial support**, **societal support**, and **where to go in case of questions** because it would *help them* in *dealing with psychosocial issues*. Furthermore, they indicated that the SCP should contain information about and referral to (reliable and up-to-date information about) **psychosocial** and **societal support** because patients recognized the existence of such issues *based on their personal experiences* and because they *empathized with other patients' (diverse) needs.*

> *Of course it's all very individual.. One person might struggle with their mortgage, while another might not have financial issues due to their illness. […] And chatting with fellow patients for example, peer support, can be helpful for many people, although I personally don't have the need for it.* [Patient, male]

Patients included **general information** and **tips for informing relatives** from the second most important category, namely category 1 (information and education), because they valued being *informed* and *prepared* and to help them *deal with their psychosocial issues*. They indicated that the ideal SCP should provide **general information** that is *reliable* and *understandable* since much of what is currently included in, for example, the patient portal is too medical and written in "doctor's language." According to them, providing this information within the SCP could potentially prevent both patients and their relatives from searching for (incorrect) information on websites.

> *I did a lot of googling myself during the years I was under treatment, and at some point, you end up on really unpleasant websites where you're practically told that you'd be better off not living, and five years later, here I am. I found that very distressing, and it always made me very sad. So, I would like people to know how to find their way to the right information.* [Patient, female]

Tips or **information about informing relatives** could also *help them deal with psychosocial issues*, for example *with the (lack of) understanding of others.* A reason considered for not including functions from this category in their ideal SCP, such as specific parts of **general information**, was to *prevent getting distressed*; they emphasized not to add specific information, such as treatment effectiveness, because, *in their experience*, it *took away their hope.*

Being informed, prepared, and empowered were important motives to include **(tools for) detecting recurrences**, a **personal follow-up schedule**, and **information about a healthy lifestyle** from the third category (oncological follow-up), as was *dealing with their psychosocial issues*, which they did when *empathizing with other patients' needs*. Furthermore, patients stressed that adding information regarding **(tools for) detecting recurrences** could *improve their self-management skills, alleviate their concerns*, and (thereby) *prevent unnecessary consultations*. Motives not to include functions from this category (eg, **information about a healthy lifestyle**) were that similar functions or tools already exist so that *unnecessary development could be prevented*.

Functions in the fourth and last category (coordination), like information regarding a **care coordinator**, although less important in their ideal SCP, were added *based on their own experiences* since they missed an *easily accessible contact point* during their disease trajectory.

Motives of Health Care Providers

HCPs added functions from category 3 (oncological follow-up) to *inform*, *prepare*, and *empower patients*. More specifically, they indicated that the ideal SCP should include information about/referral to **(tools for) detecting recurrences** to *meet patients'* as well as *relatives' information needs*, *improve patients' self-management*, and *alleviate their concerns.* Altogether, this could *prevent unnecessary consultations. Meeting patients' information needs* and also *improving their melanoma outcomes and health in general* were reasons for adding **information about a healthy lifestyle**. Furthermore,

HCPs indicated that offering this information is needed in order *to provide* patients with *a complete treatment plan*, which they did *based on their expertise*. However, others mentioned that *similar tools already exist* and therefore did not add this function to the SCP. A **personal follow-up schedule** including background information was added by HCPs to *meet patients' information needs* and *to provide structure for them.* On the other hand, a reason for not including this background information was also mentioned, namely *to prevent (irrelevant) information overload.*

Identifying and providing support for or treating psychosocial issues were motives mentioned by HCPs for adding **psychosocial support** from category 2 (identification and treatment) to their ideal SCP. They did this *based on their expertise* and when *empathizing with patients' needs*. Other reasons mentioned for adding this function were to *provide reliable information* (preferably by linking it to existing trustworthy resources) that is up-to-date and to *provide an accessible contact point* for patients. Furthermore, HCPs indicated that information regarding and/or referral to **societal support** should be added to meet patients' *information needs* since questions regarding financial and work-related issues arise from diagnosis onwards. **Family and caregiver support** was added by the HCPs to *provide a complete treatment plan* for the patient and their loved ones and to *meet the relatives' information needs*, the latter being important as heredity is a topic that elicits many questions. HCPs indicated that by better informing relatives, *unnecessary consultations* could be *prevented*. Lastly, **where to go in case of questions** was added by HCPs to *provide structure for patients* and to help them find the right person to turn to among the many HCPs involved in their illness and treatment journey.

> *That the patient actually has some idea of where to go for which question, so they don't get lost in the maze of various professionals.* [Health care professional, male]

Similarly, regarding category 4 (coordination), they added information regarding a **care coordinator** to *provide an accessible contact point* for patients and their relatives. They also did this *to alleviate patients' concerns*, which is something that such a contact point could do. In addition, they considered this information important to ensure that the patient had a sense of having somewhere (or someone) to turn to for questions and uncertainties.

Functions from the first category (information and education) that were added to the ideal SCP of HCPs were both **personal** and **general information**, and they included them to *meet the patients' information needs, to provide understandable information, to help patients remember provided information,* and *to support them in (treatment) decision-making.* They mentioned that patients often forget important **personal information** about their received diagnosis and treatment options, but also **general information regarding** what certain treatments (effects) entail, and they considered it important to assist them in retaining this information. In general, HCPs *based this on their expertise* and indicated they should provide this information in order *to obtain informed consent.*

> *You're supposed to tell them what you're going to do, what the side effects are, what the chances are that it will work; make it clear what the patient can choose. Only then can they give informed consent. So, whether you're going to perform surgery or provide immunotherapy, this is the information you must share.* [Health care professional, female]

Motives of IT Professionals

Category 3 (oncological follow-up) was the most important category in the ideal SCP of IT professionals. They added information regarding **(tools for) detecting recurrences** based *on their own experiences* and when *empathizing with patients' needs.* Furthermore, *to improve patients' self-management skills, to alleviate their concerns*, and *to provide an accessible contact point* were also mentioned as motives for including this function. IT professionals indicated that they thought patients could have worries and uncertainties around potential recurrences and that support regarding these worries, which is also *feasible*, should be provided to them. While *empathizing with patients' needs,* they indicated that a **personal follow-up schedule** including background information should be added *to meet patients' information needs*. However, *taking feasibility and privacy into account,* they mentioned that while they considered adding background information feasible, they foresaw several *privacy issues* for including a **personal follow-up schedule** that *were more severe than the importance of including and the relevance of* this information.

> *For privacy regulations, I deliberately left those things out because otherwise, it makes it quite challenging when it comes to an appointment calendar or something similar. If you manage it yourself, it's fine, but if it has to come through the hospital information system, then you have to integrate with that, and it becomes really tricky from an IT and privacy standpoint.* [IT professional, female]

They added **information about a healthy lifestyle** for patients with melanoma when *empathizing with* and *to meet their needs*, as well as *to improve melanoma outcomes*. Reasons for not including this information were that *having a healthy lifestyle is applicable in general, to prevent (irrelevant) information overload* and because *similar tools already exist*.

IT professionals added functions belonging to category 2 (identification and treatment) *based on their expertise* and, more specifically, because they considered them *feasible.* In addition, they added **psychosocial support** to *provide support for or treat psychosocial issues* and *to improve patients' self-management*, which they *based on their own and others' experiences.* They added **family and caregiver support** to *meet patients' and relatives' information and support needs* and *to provide a complete treatment plan*. Some included information about **where to go in case of questions** to provide clarity for patients; although some of them questioned its feasibility, they thought *its importance and relevance for patients outweighed the potential privacy issues.*

> *I think that if you can have patients fill in information like, 'I have this general practitioner, I go to that hospital with that specialist, and these are the other health care providers involved,' and alongside that, a general guide saying, 'For these kinds of questions, contact your GP,' I think that can provide more value. But when you want to retrieve that information automatically, it becomes challenging.* [IT professional, female]

For others, these *potential issues* made them consider this function *unfeasible*, and they did not add this to their ideal SCP.

Informing, *preparing*, and *empoweringpatients* were reasons mentioned by IT professionals to include functions like **personal** and **general information** from category 1 (information and education). They added them *to meet* both *patients' and relatives' information needs, to provide understandable* as well as *reliable information*, and to, at the same time, *help patients deal with the lack of understanding of others*. **Tips to inform relatives** were added by the IT professionals to *meet relatives' information needs* and to *help patients deal with a lack of understanding of others*, which they did *based on the experiences* they gained *from others*. They considered adding these functions (**personal** and **general information** and **tips to inform relatives**) *feasible* as *based on their own expertise* and when *empathizing with patients' needs*. Reasons for not adding functions like **general information** included considering them *not applicable to melanoma specifically* and to prevent this general information from *taking away hope*.

IT professionals considered category 4 (coordination) least important. Nevertheless, they added functions (**care coordinator** and **tools to improve information transmission**) from this category *based on their own and others' experiences* and based on *their expertise*. They also provided motives for not including functions from this category; they indicated that according to them, the *SCP is not the right medium* to include **tools to improve the information transmission between HCPs**, a function that they also considered *unfeasible* to realize.

Discussion

Principal Findings and Comparison With Prior Work

The aim of this study was to gain insight into the ideal SCPs according to relevant stakeholder groups and to explore their motivations behind adding them. Patients composed a rather compact SCP, mainly focusing on category 2 on identification and treatment, including both information and support for themselves, with their motives being primarily based on their personal experiences and needs. HCPs and IT professionals constructed more comprehensive SCPs, with category 3 on oncological follow-up being the most important one, and HCPs additionally focusing on category 4 on *coordination*. When looking at their underlying motives, they all aligned with their respective areas of expertise: HCPs related their additions mainly to their roles as medical practitioners, such as providing a complete treatment plan and obtaining informed consent, while IT professionals' contributions were mostly influenced by feasibility and privacy concerns.

In light of our findings and prior research focusing on other types of cancer (eg, colorectal and gynecological [23-25]) than melanoma, it is evident that patients place considerable emphasis on *identification and treatment of disease and therapy effects* (category 2), perceiving the SCP mainly as an informational and supportive tool. Thereby, patients' unmet needs are related to their commonly faced challenges such as psychological distress, anxiety, depression, long-term and late effects, as well as the fear of recurrence. As a result, they express a need for a more comprehensive supportive care approach that includes nonmedical information, like peer support, financial guidance, return-to-work strategies, and psychological resource information [17,26-28]. Moreover, the emphasis on category 2 in our results underscores the importance of broadening traditional, current SCP content, which predominantly targets categories 1 and 3 on *information and education* and *oncological follow-up* [4]. Patients agreed that functions from category 2 (eg, psychosocial and societal support) are indeed essential for effective SSC, as it would both help them deal with certain issues and prevent searching for incorrect information online and related distress. Integrating (referrals to) this information in the SCP also allows all to be centralized in one place, instead of spread over paper-based information and web-based resources given to them by various HCPs. Despite patients' agreement on category 2, their opinions differed on other functions. For example, some accentuated the need for general information (category 1, information and education) and more specifically on treatment effectiveness, but others felt that knowing this might negatively influence their hope toward a positive outcome. A reason for this may be found in patients' motives for the composition of their ideal SCP, which were predominantly based on their personal, specific experiences with the disease and the knowledge they gained when they were affected and treated [29]. In addition, our findings align with previous research showing that providing certain information might be beneficial for some patients but can trigger fear among others [8,9], and thereby further underscore the importance of personalizing the SCP's content [30,31]. To adequately tailor the SCP to each patient's individual needs, future research should investigate ways for SCP tailoring, possibly through patient profile definition or integrating artificial intelligence (AI) methodologies. In addition, further quantitative research should follow to investigate the actual impact of our results on both SCPs' implementation and effectiveness in clinical practice, for example, through a classic randomized controlled trial or partially randomized patient preference trial, the latter incorporating patient preferences in the process of randomization [32].

HCPs and IT professionals, in contrast, mainly based their ideal SCP preferences on their professional expertise. HCPs primarily related their choices to their clinical knowledge and roles as medical professionals and indicated what is needed to provide patients with a complete treatment plan and in order to obtain informed consent. IT experts offered more practical reasons, predominantly concerning feasibility and privacy issues, thereby including perspectives the end users may have insufficient knowledge about [29,33]. Both HCPs and IT professionals regarded *oncological follow-up (category 3)* as most important. Within this category, information about (tools for) detecting

recurrences was added unanimously. This corresponds with previous literature that identified fear of recurrence as a prevalent psychological concern among melanoma survivors [6,17,34], and offering information and support concerning this has been shown to alleviate the intensity of such fears [35]. In the context of the ongoing digital health transformation and the workforce challenges in health care [36,37], AI offers promising solutions. AI could help in assessing skin abnormalities and thereby detecting recurrences in the future [38]. Although physicians have concerns about AI tools' accuracy and potential health inequality risks, it could lead to fewer unnecessary consultations, cost reductions, and improved care pathways [39]. As a result, improving SSC practices regarding *oncological follow-up* could also facilitate advancements in category 4 on *care coordination*, a topic that HCPs in our study also deemed important. This suggests that the HCPs viewed the SCP as a care coordination tool, which could potentially address areas for improvement that were stressed in previous literature [40].

The feasibility and privacy concerns highlighted by IT professionals were particularly related to functions deemed vital to end users, ie, patients and HCPs, such as an overview of where to go (category 2), a personal follow-up schedule (category 3), and tools to improve information transmission between HCPs (category 4). Although legitimate, particularly given the patients' unmet needs, it is important to investigate how to adequately address these issues. Suggestions put forth to mitigate some of these concerns included providing only the patients' specialist's name rather than their comprehensive contact information and linking the SCP to the electronic patient portal instead of incorporating a personal follow-up schedule directly within the SCP. However, since the use by HCPs in clinical practice and thereby the SCP's implementation could be facilitated by linking it directly to the electronic health record [6], which has been shown feasible before [41], it should be investigated how to overcome these privacy concerns.

The above discussion suggests that HCPs, patients, and IT professionals attribute different but complementary roles to SCPs. Whereas HCPs view SCPs primarily as a coordination tool, patients stress their informational and supportive roles, and IT professionals see them as a data-sharing tool that must function in a safe and reliable manner. These differing perspectives can be explained by the organizational structure of melanoma care, including SSC, which is organized in networks with centralization of administration of systemic treatments across the Netherlands. In the Rijnmond Region, it operates from a "shared-care model" [42], where HCPs lead the network and its coordination while patients are positioned at the receiving end of care, thus receiving care, information, and support. From this point of view, the role of IT professionals in relation to SCPs is to ensure that coordination, information sharing, and support are conducted in a reliable manner.

Recommendations for Future SCP Developers

The future SCP that we envision based on our results should address all the above roles, functioning both as a comprehensive information tool—facilitating the safe and reliable linking and sharing of information of multiple stakeholders through its digital aspect and connection with the patient's electronic health record—and as a means to improve the coordination of melanoma care. Being better informed and supported will likely enhance patient empowerment, allowing them to take a more active role in managing their disease and treatment coordination and thereby facilitating shared decision-making [43,44], rather than merely being passive recipients of care. Thus, future developers should create SCPs that contain functions and features with both personal and general information, information about/referral to reliable information on psychosocial and societal support for patients, as well as information on lifestyle and tools for detecting recurrences, and with functions and features that facilitate care coordination. This SCP can and should be further personalized, depending on patients' and HCPs preferences, by adding additional functions and features such as a personal follow-up schedule, information on where to go in case of questions [12], tips for informing relatives, and support for them.

Strengths and Limitations

The main strength of this study is its inclusive approach to cocreation. Unlike many other cocreation studies that often engage only 1 stakeholder group, typically patients [45,46], or more recent at most 2 (patients and HCPs [47,48]), our study uniquely incorporated IT professionals. Whilst they are not the primary users of SCPs [4], their involvement proved invaluable as they offered crucial insights into the development process, particularly highlighting feasibility and privacy concerns. Moreover, we actively engaged all stakeholders from the inception of the SCP development rather than limiting their participation to its evaluation, as seen in, and of which the importance was stressed in, previous literature [7,33]. Furthermore, this cocreation approach aligns with the current shift toward value-based health care, endorsing the principles of patient partnership and shared decision-making [49]. Such an approach empowers the target audience and other stakeholders to shape the outcome actively, ensuring that the final SCP aligns closely with their needs and preferences. Moreover, the composition of our sessions with mixed groups fostered mutual learning and encouraged interactive discussions [13,14,50]. These elements collectively enhance the likelihood of the tool being widely accepted, facilitating more effective implementation and practical effectiveness.

A limitation of our study was its regional sample, which raises questions about the transferability of our findings. However, since melanoma care is uniformly organized in networks throughout the Netherlands, we expect that our results will be applicable outside our region and possibly to other countries if melanoma care is similarly organized. However, to reach an optimal, inclusive SCP, perspectives and needs of patients with varying levels of (health) literacy, socio-economic status, and backgrounds should also be investigated and incorporated. Another aspect warranting attention is the inclusion of an IT professional being a relative of a patient with melanoma. Even though we believe their experiences did not greatly affect the composition of IT professionals' ideal SCP, it could be interesting to further investigate relatives' perspectives on ideal SCPs and their underlying motivations for it. Based on previous literature, we know that relatives of cancer survivors can encounter significant challenges and have unmet needs

throughout the patients' disease trajectory [17,51,52] and are therefore sometimes even included in the definition of a cancer survivor [3]. Lastly, our participant pool only included patients who had finished their treatment for some time. Since retrospective experiences might differ from those of patients currently undergoing treatment, it is important to focus on this latter group in future research, ensuring a complete understanding of patients' SSC needs throughout the whole disease trajectory.

Conclusions

This cocreation study provides insights into stakeholders' ideal melanoma SCP and the motivations behind them. Considering the diversity in both preferences and underlying motives regarding SCP composition between patients, HCPs, and IT specialists, it is crucial to develop a broad SCP that extends beyond traditional SCP content, emphasizing personalization. By understanding the motives and considerations of patients and HCPs in shaping their ideal SCPs, which we were able to elicit through the interaction and discussion between different stakeholders, thoughtful design can optimize patient care and support throughout the survivorship journey. At the same time, keeping the practical requirements of IT professionals in terms of feasibility and privacy in mind is important to ensure the ideal SCPs can be realized. In addition to continued stakeholder involvement, efforts should be focused on addressing the potential feasibility and privacy issues, particularly those related to personalization, to ensure the SCP meets the needs of both patients and HCPs.

Acknowledgments

This study is part of a larger project that is multi-sponsored by Bristol Myers Squibb (BMS), Merck Sharp & Dohme (MSD), Novartis, and Pierre Fabre. However, the sponsors were not involved in the design of the study, data collection, data analysis, manuscript preparation, and/or publication decisions. The authors thank all patients, HCPs, and IT professionals for sharing their experiences and particularly for their openness during the cocreation sessions. Furthermore, the authors thank Esther Bijl for helping with the data collection and analysis.

Authors' Contributions

NK, ML, JB, and KT designed the study. NK, JB, MW, and KT performed the patient selection. NK and JB performed data analysis under supervision of ML and KT. NK, ML, JB, and KT interpreted the data. NK and KT wrote the first version of the manuscript, and all authors revised the following versions of the manuscript and approved the final version.

Conflicts of Interest

None declared.

Abstract

Background: Survivors of childhood cancer are at risk of medical, psychological, and social late effects. To screen for their risks, receipt of consistent, cancer-specific follow-up care is crucial. However, <50% of survivors attend their aftercare, and only 35% of them recognize that they could have a serious health problem. The use of mobile health (mHealth) is a promising form of intervention to educate, connect, and empower survivors of childhood cancer on the importance of follow-up care.

Objective: This study aimed to use co-design to identify the priority components to include in an mHealth intervention with young adult (aged between 18 and 39 years) survivors of childhood cancer and health care providers.

Methods: This study was conducted between January and November 2022 in Canada and used patient-oriented research methods. Participants were recruited through local or provincial long-term follow-up clinics, using convenience sampling from patient partners who assisted in recruiting survivors across geographical areas in western, central, and eastern Canada, and social media outreach (X, formally known as Twitter; Facebook; and Instagram). Qualitative descriptive data (focus group interviews) from survivors of childhood cancer and health care providers (individual interviews) were gathered. We analyzed the collected data

using reflexive thematic analysis and verified it through member checking techniques through an online community engagement event.

Results: We conducted with patient partners 5 online (Zoom) focus groups with 22 survivors of childhood cancer (mean age 29.19, SD 4.78 y). We conducted individual telephone interviews with 7 health care providers. Participants identified five priority areas to be included in an mHealth intervention: (1) connections, (2) education and information, (3) engagement, (4) personalization, and (5) resources. Results were shared with and validated by survivors of childhood cancer, their families, health care providers, and academic researchers as part of a community engagement event. Small and large group discussions were facilitated to allow participants to review and discuss the accuracy of the themes derived regarding the core components to be included in mHealth. A graphic recording artist visually captured key ideas from the event. A subset of the participants also completed a web-based satisfaction survey, and responses indicated that the community engagement event was generally well received.

Conclusions: Results from this study have provided the necessary foundation to progress in intervention development. The next step of this multiphased project is to build an innovative and accessible mHealth intervention prototype that is based on the identified core components and is grounded in an established conceptual framework for co-design of mHealth.

Introduction

Follow-Up Care for Survivors of Childhood Cancer

Due to advances in treatment and supportive care, the survival rate for pediatric cancer (age 0-19 years) now exceeds 80% [1]. In turn, the number of long-term survivors of childhood cancer has grown exponentially, with more than 45,000 survivors living in Canada today [2]. While this is encouraging, survivors of childhood cancer are at a lifelong risk of developing medical, psychological, and social late effects due to their cancer treatment [3]. By the age of 50 years, nearly 100% of survivors develop one or more chronic health conditions, many of which are disabling or life-threatening [4,5]. This prevalence suggests an important need for early screening and intervention of late effects to improve longer-term outcomes for this group considered vulnerable.

Consistent, cancer-specific follow-up care is associated with better long-term outcomes, including earlier identification of late effects or secondary cancers and minimized risk of morbidity and mortality [6-8]. However, less than 50% of survivors of childhood cancer attend long-term follow-up clinics [9,10]. Known barriers to attending follow-up care in Canada include limited knowledge of late effects and recommendations for follow-up care, treatment factors (eg, diagnosis and type of treatment), distance from cancer-specific follow-up clinics, and sociodemographic factors (eg, minority status and male sex) [7,10]. Furthermore, only 35% of survivors recognize that they could develop a serious health problem [11]. Young adults (aged between 18 and 39 years [12]) survivors of childhood cancer are especially at risk of not receiving consistent long-term follow-up care due to their unique developmental stage. Specifically, this is a critical and dynamic time during which major transitions occur, including greater autonomy, independent living, and financial independence, as well as a period of increased mental health concerns and risk-taking behaviors [13]. The transition from pediatric to adult health services is also particularly challenging and may result in diminished engagement in follow-up care [14].

Mobile Health Intervention for Survivors of Childhood Cancer

Development of innovative interventions is needed to better educate and engage survivors of childhood cancer in their follow-up care. An ideal intervention would meet survivors where they are, be accessible outside of formal follow-up care programs, account for the sociocultural context of survivors [15], and ultimately address the distinct needs and challenges of this population. Mobile health (mHealth) refers to the use of wireless technology in medical care to deliver health education. mHealth has shown potential to educate patients about preventative health care [16]. Furthermore, mHealth may serve to break down some of the geographic barriers and issues related to accessibility faced by survivors of childhood cancer residing in more remote or rural regions [17]. Given the widespread use of smartphones among young people [18], mHealth has the potential to address the unmet psychosocial and health care needs of young adult survivors of childhood cancer. Therefore, the use of mHealth is a promising new form of intervention to educate, connect, and empower survivors of childhood cancer on the importance of cancer-specific follow-up care.

mHealth interventions targeting young adult survivors of childhood cancer are in their infancy [19,20]. A systematic review of eHealth and mHealth interventions in pediatric cancer lends support for the feasibility and acceptability of technology-based approaches to improve outcomes of children with cancer. However, evidence of the effectiveness of interventions targeting specific outcomes (eg, emotional distress and health behaviors) remains mixed [19]. Limitations of existing interventions include restrictions to single-site pretest-posttest designs, a failure to consider an iterative process to intervention development, and a lack of engagement with patients as partners in the co-design of these programs, and intervention components must be guided by survivors' priorities [21]. Engaging patients as partners is a feasible and efficient way to conduct clinical research, as they are considered experts through their own lived experiences [21]. Research shows that patient engagement in health research has many benefits,

including higher participation rates, design of study protocols with more relevant outcomes, and more meaningful and accessible means of disseminating research to study participants and community members [21]. However, survivors are seldom included in the development of interventions directed at improving knowledge of the importance of long-term follow-up care. Therefore, co-designing with survivors of childhood cancer in addressing their own barriers to attending follow-up care may be a promising means to enable survivors of childhood cancer to understand and engage in their follow-up care and maximize their outcomes. There is also limited research that incorporates health care provider perspectives [22,23]. Health care providers that deliver follow-up care to survivors of childhood cancer may offer complementary insights on the mHealth intervention development in the context of Canadian health care systems.

Current Research

The overarching goal of this research was to co-design an mHealth intervention with young adult survivors of childhood cancer, as well as health care providers that deliver follow-up care to this population. In this research, we refer to co-design as a meaningful engagement with end users in the entirety of the research process [24]. In addition, our research approach adhered to the best practices outlined by the Strategy for Patient-Oriented Research (SPOR) of the Canadian Institutes of Health Research (CIHR) [25].

As a foundational step toward mHealth intervention development, we conducted a qualitative study to understand and identify the priority components to be included in an mHealth intervention that can engage, educate, and empower survivors of childhood cancer on the importance of attending their follow-up care. Subsequently, we validated the results by seeking feedback from multiple informants, including survivors, caregivers, health care providers, and researchers, through a community engagement event.

Methods

Overview

This study was conducted as part of a larger, multiphased project regarding survivors of childhood cancer and their follow-up care experiences [26,27]. We used patient-oriented research and qualitative descriptive study design. Qualitative description is a qualitative research framework that provides detailed experiences directly from participant perspectives [28]. This study design is well suited for health sciences research because it captures broad insights and helps address key clinical and health care services questions [29].

Study data were collected and managed using REDCap (Research Electronic Data Capture; Vanderbilt University) electronic data capture tools hosted at the University of Calgary. REDCap is a secure, web-based software platform designed to support data capture for research studies, providing (1) an intuitive interface for validated data capture, (2) audit trails for tracking data manipulation and export procedures, (3) automated export procedures for seamless data downloads to common statistical packages, and (4) procedures for data integration and interoperability with external sources [29,30].

Ethical Considerations

Ethics approval for this study was granted by the Health Research Ethics Board of Alberta—Cancer Committee (HREBA.CC-20-0248). As this project involved human participants, informed consent was obtained from all participants. Data collected were deidentified before data analysis. Participants were compensated for their time in the study (refer to the Procedure section for compensation details).

Patient and Public Involvement

In line with best practices of CIHR SPOR [25], we have reported the background, objectives, methods, and results of this project based on the checklist from the Guidance for Reporting Involvement of Patient and the Public Short Form [31]. Patient partners were involved as coresearchers throughout the project, including study design, recruitment, data collection, interpretation of results, and knowledge dissemination. Patient partners were compensated financially for their time.

Participants

Survivors were eligible to participate in the qualitative study if they were (1) currently aged between 18 and 39 years, (2) diagnosed with cancer before the age of 18 years, (3) at least 5 years after diagnosis and/or 2 years after treatment, and (4) currently living in Canada. Health care providers were eligible to participate in the study if they were (1) delivering clinical care to survivors of childhood cancer, (2) practicing for >5 years, and (3) currently living in Canada.

Participants were eligible to participate in the community engagement event if they were (1) survivors of childhood cancer as defined earlier, (2) parents or caregivers of survivors of childhood cancer, (3) health care providers that provide follow-up care to survivors of childhood cancer as defined earlier, or (4) researchers of childhood cancer survivorship.

Recruitment

Several strategies were used to recruit individuals from diverse sociodemographic backgrounds as part of the larger, multiphased project [26]. First, survivors and health care providers were informed about the study by their local or provincial long-term follow-up clinics, where they were given the option to complete a consent-to-contact form and subsequently invited to participate by the study team. Second, patient partners assisted in recruiting survivors across geographical areas in western, central, and eastern Canada. The practice of patients recruiting patients to integrate diverse patient perspectives is supported by the principle of inclusiveness according to the CIHR SPOR framework [25]. Third, social media outreach was used, including X (formerly known as Twitter; X Corp), Facebook (Meta Platforms), and Instagram (Meta Platforms). This strategy involved recruiting through patient and young adult cancer advocacy groups and communities by sharing study graphics (eg, Childhood Cancer Survivor Canada and #AYACSM).

Participants that completed other phases of this project were invited to participate in this qualitative study. Participants that participated in other phases of the project, as well as those who did not participated in the project, were all welcome to attend the community engagement event.

Procedure

We conducted 5 online focus groups with survivors of childhood cancer on Zoom (Zoom Communications Inc) between March and July 2022. Focus group discussions lasted approximately 90 minutes. Eligible participants were contacted and provided with a link to consent to the study on the web through REDCap. They were then provided with a Zoom link and date for the focus group. Participants were compensated with a CAD $25 (US $17.91) e-gift card for their participation. Similarly, we conducted telephone interviews with health care providers who followed the same consent process as survivor participants. Each interview lasted 15 to 20 minutes. Health care providers were also compensated with a CAD $25 (US $17.91) e-gift card for their participation.

We hosted a half-day online community engagement event via Zoom in October 2022. The event was cofacilitated by 2 academic researchers (FSMS and SHJH) and 2 patient partners (RD and IR). A collaborator from a digital technology company, Cambian, attended the event to provide input from a feasibility and usability standpoint. Cambian specializes in providing collaborative health care information services. A graphic recording artist from Fuselight Creative attended the event to visually capture central and representative ideas generated from the community event. Fuselight Creative is a visual facilitation company that specializes in the strategic use of graphic recording to enhance interactive engagement and learning in community events.

Eligible participants were asked to register for the event and provide their email address to receive the Zoom link. Registered participants provided verbal consent to partake on the day of the event on the web via Zoom. Participants were compensated with a CAD $25 (US $17.91) honorarium for their participation in the community engagement event. Likewise, patient partners (RD and IR) were compensated for their cofacilitation of the event.

Measures

Sociocultural Demographics

For the qualitative study, survivors completed an initial questionnaire regarding their sociodemographic background, including age, sex, gender, relationship status, family composition, and race and ethnicity. Survivors also completed questions regarding their clinical history, such as their diagnosis, age at diagnosis, type of treatments received, and number of years after treatment. Health care providers completed a similar questionnaire to survivors regarding their sociodemographic background, as well as questions regarding their professional experiences, including the number of years practicing and years of experience delivering care to survivors of childhood cancer.

Interview Guide

Survivors engaged in an online focus group discussion, guided by a semistructured interview guide exploring the development of an mHealth intervention for survivors of childhood cancer to optimize their engagement in follow-up care. Questions were codeveloped with patient partners and centered on the development of content (eg, “What are your thoughts on creating a platform for survivors?”), education (eg, “What type of information would you want included?”), communication (eg, “Would you want an opportunity to interact with other survivors and/or healthcare providers?”), and engagement (eg, “What are some features that could help you engage in your follow-up care?”) related to the mHealth intervention.

Health care providers engaged in an individual telephone interview. The same set of semistructured interview questions was administered, with wording modified to reflect the health care providers’ perspective on the same topic. The complete set of questions asked during the focus groups can be found in Multimedia Appendix 1.

Small and Large Group Discussions

As part of the community event, participants engaged in interactive small and large interactive group discussions. Facilitators posed semistructured questions on the accuracy, representativeness, and resonance of the themes conceptualized from the data. During small group discussions (3-4 participants per group), differences in perspectives were discussed in the presence of an observer who was a member of the research team. The observer’s role is to ensure equal participation among members and that no one individual or group’s views are dominant over others. The observer takes notes, facilitates the flow of conversation and turn-taking among participants, and shares a summary of key discussion points with members to ensure the accuracy of notes taken. Key discussion points from the small group sessions were subsequently integrated into the larger group discussion (all participants) to achieve consensus, facilitated by 2 main facilitators (SHJH and FSMS) and 2 patient partners (RD and IR). Large group discussions were facilitated using interactive media features, including a Google Jamboard, Mentimeter, and polling on Zoom.

Satisfaction Survey

Participants completed a web-based questionnaire within 1 week following the event. Questions were derived and adapted from the Public and Patient Engagement Evaluation Tool [32]. Participants were asked to rate the extent to which they agreed with statements regarding their experience at the event, using a 5-point Likert scale (1=strongly disagree and 5=strongly agree). Questions were centered on participants’ understanding of the nature of the workshop (eg, “I had a clear understanding of the purpose of this community workshop”), as well as whether the workshop met the stated objectives described herein. We also solicited feedback from participants using an open-text response format.

Analysis Plan

Sociodemographic information gathered from participants was summarized using descriptive statistics and analyzed with SPSS (version 28.0; IBM Corp). Qualitative descriptive data gathered from focus groups and interviews were audio-recorded, transcribed verbatim, and deidentified. Transcripts were subsequently analyzed using reflexive thematic analysis [33]. Reflexive thematic analysis is a theoretically flexible analytical approach used to identify patterns of meaning and conceptualize them into themes. This type of analysis is commonly used in qualitative description studies [34]. In total, 5 researchers

(SHJH, BH, RD, KM, and HW) conducted the analysis according to the steps outlined by Braun and Clarke [33]. First, researchers read the transcripts several times to familiarize themselves with the data. Next, researchers developed a preliminary coding framework and coding book. Each researcher independently coded the same transcript and met as a team to compare coding choices and ensure alignment in the interpretation of the codes. Following this, the remaining transcripts were each analyzed by 2 researchers. Theme abstraction took place iteratively among the researchers by meeting regularly to discuss and review each researcher's interpretations. Any differences in theme abstraction were reconciled through open dialogue until a consensus was reached. Data analysis was supported using NVivo (version 14; Lumivero) [35], a qualitative data management software. Multimedia Appendix 2 includes a reflexivity statement from all researchers involved in the thematic analysis.

Member checking, also known as response validation, is a validation technique used in qualitative health research and has been recognized as a method of rigor to enhance the trustworthiness of qualitative data [36]. Member checking was conducted with multiple informants, including survivors, caregivers, health care providers, and researchers, through an online community engagement event. Member checking was achieved through multiple methods, including small and large group discussions, satisfaction surveys, and graphic recording throughout the community engagement event.

Results

Participant Characteristics

In total, we conducted 5 online focus groups with 22 survivors of childhood cancer, with a range of 4 to 6 participants present per focus group. The mean age of survivors was 29.19 (SD 4.78) years. Over 95% (21/22) of survivors indicated that their assigned sex was female and likewise that their gender identity was female. Most survivors (19/22, 86%) identified as White. Survivors came from 6 provinces, most prevalently from Alberta (10/22, 46%), Ontario (5/22, 23%), and Nova Scotia (4/22, 18%). Most survivors (18/22, 82%) lived in an urban geographical region. Survivors reported a history of leukemias (11/22, 50%), lymphomas (6/22, 27%), and solid tumors (5/22, 23%) as the most common diagnoses. The average age at diagnosis was 10.59 (SD 5.45) years, and the mean time off treatment was 17.45 (SD 6.81) years.

We conducted individual telephone interviews with 7 health care providers. In total, 6 health care providers indicated that their sex assigned at birth was female and that their gender identity was female. All health care providers identified as White. Health care providers included 3 registered nurses and 4 allied health professionals. All health care providers had experience delivering care to survivors of childhood cancer; 29% (2/7) of the participants had between 1 and 5 years of experience, 43% (3/7) of the participants had between 5 and 10 years of experience, 14% (1/7) of the participants had between 10 and 15 years of experience, and 14% (1/7) of the participants had >15 years of experience. Health care providers were from Alberta (2/7, 29%), British Columbia (3/7, 43%), Manitoba (1/7, 14%), and Ontario (1/7, 14%). All health care providers reported residing in urban regions. A summary of participant demographic characteristics is provided in Table 1.

Table 1. Demographic and clinical characteristics of survivors of childhood cancer (n=22) and demographic and professional characteristics of the health care providers of survivors of childhood cancer (n=7).

Demographic and characteristics	Value

Priority Components to Be Included in an mHealth Intervention for Survivors of Childhood Cancer and Health Care Providers

Connections: Establishing Connections Is a Top Priority

Survivors' Perspective

Survivors spoke of the importance of being able to connect with other survivors because they feel validated by those who understand that the cancer journey does not end when treatment ends and that, in fact, the cancer experience is lifelong (quote 1). Survivors also felt that the ability to communicate with other survivors on mHealth would allow them to establish a sense of community through a shared experience and shared understanding of having been impacted by cancer (quotes 2 and 3). Survivors specified that such a connection could be a therapeutic process as well as an opportunity to provide peer support (quotes 4 and 5). Survivors also discussed the possibility of being able to connect with their health care provider through additional means outside of clinical care (quote 6). Finally, survivors emphasized that being able to establish these connections with other survivors of childhood cancer as well as health care providers was a means of self-empowerment and self-advocacy because they could take control of their own care and experiences (quotes 7-9).

Health Care Providers' Perspective

Health care providers also recognized the importance of connecting survivors with one another. Health care providers shared that these social connections are likely to mitigate feelings of isolation for survivors in their cancer experience and, in turn, empower them to engage in their follow-up care (quotes 10 and 11). Health care providers also expressed a desire to connect with other health care providers across Canada for the opportunity to consult and learn from one another about pertinent matters in delivering follow-up care for survivors of childhood cancer (quote 12). In addition, health care providers shared that being able to connect with survivors (eg, navigating appointments and/or scheduling), as well as with primary care providers, may be a useful feature to incorporate in mHealth to enhance the efficiency with which they deliver follow-up care (quote 13; Textbox 1).

Textbox 1. Theme, subthemes, and representative quotes from survivors (n=22) and health care providers (n=7) on the development of an mHealth intervention to enhance follow-up care. This textbox covers theme (1), "connections: establishing connections is the top priority."

Survivors' perspective

- Connecting with other survivors feels validating because not everyone understands the cancer journey and that it is lifelong.
  - Quote 1: "...I think in just hearing others communicate about their experiences to speak to the volume and importance of it's not done after, we're not done after treatment, it's a lifelong thing that we'll always re-engage in at various points in time in different ways." [S6F2]I
  - Quote 2: "...the idea of a platform is really great, especially when you think about people's readiness to engage in that kind of stuff...So having that available when people are ready to engage gives them access and gives them a sense of control about when they are actually feeling they need that support versus when you have that follow-up first talk..." [S6F2]
  - Quote 3: "And you can be surrounded with people that do care about how you're feeling and how you're doing but no one knows what it's like. So being able to connect to people that have gone through the same things as you, that can validate your feelings and all of that..." [S4F5]
- Connecting with other survivors can help create a sense of community.
  - Quote 4: "Almost kind of like meet-up where you could get a bunch of survivors together and like, all go for coffee or something and we'll just hang out and talk about our stories or like how we're moving forward with our lives or what's going on...I think it would be really cool to see something on a bigger scale that's perhaps all the way across the country or just something along that line, as well as having resources." [S4F3]
  - Quote 5: "And also, maybe an option to talk to people who have been through the same thing, but not talk about cancer at all...Build up a bigger community around it without feeling super nervous or weirded out by it." [S4F3]
- Connecting with health care providers may help ensure a shared understanding of what occurs at follow-up care and increase access to health care providers.
  - Quote 6: "When I said, 'I am anxious about ABC' or like, 'XYZ happened to me in my life,' did they hear that or did they just say, 'Worried about cancer but looks good. Goodbye,' like I want to know that they had the same thing. And it would be lovely to have some kind of ability to keep on top of that or keep track of that whether that be some variation of like there's a passport where it's just like, 'We had this conversation on this date' and then I know for future that it has been brought up or it has been talked about." [S1F4]
- Self-advocacy is integral to being a survivor of childhood cancer, and teaching people how to empower themselves through connections and knowledge is key to their health care.
  - Quote 7: "They put you kind of, you're more involved in the whole process if you have really easy access to all the information. Like [participant 3] was saying about her binder, and how she's sort of being involved in the process with keeping track. I think that just helps you feel like you're taking control of your own health. And it's like, that would help engagement." [S2F1]
  - Quote 8: "I think for some of us who are a little more like question shy when it comes to like speaking to doctors, like I know, I often find myself listening and not asking. I think maybe including information on how to like advocate for yourself as a patient would be important." [S3F3]
  - Quote 9: "I'm not 100 percent sure on how this would fit in with the platform yet, but I think that something in aftercare that is kind of missing that might be beneficial in kind of helping people to be able to advocate and engage in their care a little bit more is like—I don't know if it's the first appointment you ever have when you go to adult care or the last one or somewhere in-between." [S3F4]

Health care providers' perspective

- Health care providers recognize that connecting survivors with other survivors is a priority. These social connections can potentially help mitigate feelings of isolation and empower them to engage in their follow-up care.
  - Quote 10: "Yeah well, I agree with the idea of a platform, it helps people to move from kind of the more insular cancer experience to broadening and connecting in the community and identifying what they have in common with other people because I think that would help people and with the focus on mitigating of effects." [HP2]
  - Quote 11: "Really help them with like social opportunities because a lot of them are so isolated socially. Some of them have a really hard time making friends, because they don't like, it's not like a muscle memory they learned in high school. Like where they don't—they just have a hard time knowing how to make and maintain friendships. So that I think would be a useful sort of like, a place where people like me, across the country, could refer to get people connected socially." [HP5]
- Health care providers want to connect with other health care providers to discuss, ask questions, and share expertise.
  - Quote 12: "No. I think one interesting thing too is that we, as a long-term follow-up group, have a Canadian group that we talk about. Like we need every, say, quarterly online and discuss, you know, different issues and what are you doing here? What are you doing here? So, I think having that expertise, Canadian expertise of those groups would be good. So, you know, when this is up and running it would be great if that was presented at our group. Like, you could join our email Zoom, and you know, get everyone on the same page of engagement." [HP6]

- Health care providers indicated that navigating appointments and scheduling with survivors and communication with primary care providers may be useful features.
    - Quote 13: "So, I don't know if adding the primary care information and being able for them to amend it as it changes. I don't know if there's a functionality where when they see an update, they could forward that to their primary care provider. I mean I'm thinking really big here and I know it's nearly impossible to do but, you know, there must be a way to maybe get things together even if it means, you know, they have to physically show it to their primary care provider when they go for their next visit." [HP1]

Education and Information: Having a Cancer History Profile Can Be Useful

Survivors' Perspective

Features that provided information on and tracking survivors' cancer history were some of the most prevalent themes discussed by survivors. Specifically, survivors emphasized the importance of having their cancer treatment history summarized in the form of a cancer profile, along with information regarding the type of follow-up care they receive, a summary of their follow-up care visits, and a summary of past and current medications and treatments (quote 14). Participants highlighted several benefits of this feature in an mHealth intervention, including being able to recall their medical history during appointments with new health care providers, establishing a shared understanding between survivors and health care providers, addressing any gaps in communication, and making their follow-up care more accessible (quotes 15 and 16).

Health Care Providers' Perspective

Health care providers identified a need for a cancer profile so that information such as treatment history (eg, cumulative doses and exposures) can be summarized in 1 hub (quote 17). Furthermore, health care providers indicated that a cancer profile may serve as an effective tool to communicate with survivors about their follow-up care, including the importance of screening for late effects, provided that the cancer profile can include a summary of potential risks of late effects related to diagnosis and treatment (quote 18). Similarly, health care providers explored the possibility of linking updated survivorship guidelines to a cancer profile, which may be informative for survivors of childhood cancer (quote 19; Textbox 2).

Textbox 2. Theme, subthemes, and representative quotes from survivors (n=22) and health care providers (n=7) regarding the development of a mobile health (mHealth) platform to enhance follow-up care. This textbox covers theme (2), "education and information: creating a personalized cancer profile would be helpful."

Survivors' perspective

- A treatment summary can help with communicating with health care providers at follow-up care visits and remembering treatment history details.
    - Quote 14: "Yeah, I mean, I feel like, earlier like I was saying, I have that binder which I feel like is kind of like a one stop shop. But if that was in a digital form, I feel like that would be, that would be useful. Some sort of platform where, yeah it would have some sort of resource thing, but customized to what treatment you had, what drugs specifically you were on. Something that would have—even when you go to aftercare, a digital version of your test results as well. That way it's stored there and there's a history you can refer back to." [S3F1]
- Being able to track and view the history of follow-up care visits would make care more convenient, transparent, and accessible.
    - Quote 15: "...I guess a lot of things are getting more digital now so just being able to have access to records, maybe possible notes of previous visits you had. So, something just to refer to would be very convenient." [S1F1]
    - Quote 16: "...let's say if you want to refer back to a visit that you did a couple of years ago, have some notes that you can kind of refer to. Other than, kind of see how you've improved. And I think that would just help to refer back and then see how it's progressed, from any concerns from past follow-ups." [S1F1]

Health care providers' perspective

- A treatment summary can help health care providers consolidate information and inform treatment planning.
    - Quote 17: "I think that making sure that it has like a comprehensive treatment summary, and by that, I mean...like the significant cumulative doses, that they know what complications that they have, and then the things at risk. But I think the number one thing on the very first page after their treatment summary would be the very practical things you have to do, echoes, when's your next test due; and to also make sure that they have a primary care physician" [HP1]
- A cancer profile may help health care providers communicate the importance of understanding and screening for late effects for survivors of childhood cancer.
    - Quote 18: People have to be prepared kind of for the long haul without knowing exactly what the long haul is. But for some people we have a fairly good idea that they will like pretty significant cognitive or physical disabilities depending on what they've gone through. So, the challenge of figuring out how to help people with that process as it evolves." [HP2]
- Linking updated survivorship guidelines to a cancer profile may be informative for survivors of childhood cancer.
    - Quote 19: "I think it could be linked to the survivorship guidelines somehow but that the less we put and the most important stuff that we put in that will actually make it useful." [HP1]

Engagement: Issues Related to Accessibility and Health Equity Impact Survivors' Engagement in Their Follow-Up Care

Survivors' Perspective

Survivors discussed the challenges related to accessing their follow-up care, referring to the ease of reaching and using health care services, and how these barriers reflected issues related to health inequities that some experience. For example, survivors felt that all survivors requiring follow-up care should be able to access their follow-up care, and yet, disparities exist in this regard (quote 20). Survivors spoke about their difficulty in accessing follow-up care due to geographic barriers, especially for those that reside in more rural or remote communities (quotes 21-23). In addition, survivors shared that features such as appointment reminders, accommodation provided for transportation, and being able to ask questions to health care providers in an mHealth intervention may be ways that can help increase access to their follow-up care (quote 24).

Health Care Providers' Perspective

Health care providers recognized that health inequities exist in the current service delivery of follow-up care to survivors of childhood cancer and highlighted the need to make mHealth easily usable and accessible (quote 24). Health care providers also identified practical strategies that can help survivors engage in their follow-up care, such as displaying a list of the upcoming appointments on mHealth or outlining follow-up care in a stepwise fashion so that survivors that face cognitive effects of their treatment can be accommodated and supported in their engagement with follow-up care (quotes 25 and 26; Textbox 3).

Textbox 3. Theme, subthemes, and representative quotes from survivors (n=22) and health care providers (n=7) on the development of an mHealth intervention to enhance follow-up care. This textbox covers theme (3), "engagement: issues related to accessibility and health equity impact survivors' engagement in their follow-up care."

Survivors' perspective

- Appointment reminders, flexibility, and accommodations for transportation are ways to increase access and engagement to follow-up care.
  - Quote 20: "I would love to have an appointment at a certain time and for the appointment to be like within one hour of that time rather than that's the only thing on my day because I might be pushed four or five hours. And I understand like oncology is a field that does have emergencies and things happen and yes, like those precedent absolutely. But when I'm coming there just to get a rubber stamp that said I've done it and they've already looked at my blood work, where it definitely could've been a phone call, but I was spending my whole day in clinic instead, those are the things that would make it easier for me to engage more with my follow-up rather than treat it like a check box." [S3F1]
- Health inequities exist, and people from remote or rural communities have a harder time accessing their follow-up care. Telehealth mitigates some of these challenges but not all.
  - Quote 21: "But aside from that a lot of the more helpful things to engage with follow-up are things that unfortunately, unless you're building a city from scratch, are very hard to accomplish. I would like to be near my area, I would like more my follow-up is being happening, I would like for there to either be parking or public transport that is easy to access and get me there. All of those things." [S1F4]
  - Quote 22: "And if that's something that, like I said out here, it was shocking to live the reality that health equity is a dream, not a reality in Canada as much as we want it to be. Because like people in [city], the health care here is, it's just not accessible, it's brutal...I mean, I think Zoom and all of the telecommunication stuff will really help now, hopefully where people are more open to doing these sorts of things virtually, rather than having to drive four hours to [city], that sounds horrible." [S4F5]
  - Quote 23: "But just, if there was something that could address that for people who maybe can't access care where they live remotely, and they can actually be connected with practitioners or—yeah, I don't know. I think that's all I wanted to say about the app." [S3F5]
- Being able to communicate with the health care team and ask questions may help increase access to follow-up care.
  - Quote 24: "I also think a message feature would probably be efficient because I think of like, if I have to call the clinic sometimes that can be a little bit of a hassle with my phone tag. But if I knew that on the App, I could just send a message saying something like, 'appointment needs to be changed,' whatever. 'Can you give me a call?' Or even just being able to do it that way completely would be useful." [S3F1]

Health care providers' perspective

- Health inequities exist, and access to care can be increased by showing survivors how to navigate mHealth and making mHealth readily available.
  - Quote 24: "I think that, if I had to be very sort of realistic, I think that making sure that they have things to access is the most important. I still think that that probably would be like a big barrier to building this if we had to add that functionality [to the mHealth platform]." [HP1]
- There are practical strategies that may help survivors of childhood cancer engage in their follow-up care.
  - Quote 25: "But I think the number one thing on the very first page after their treatment summary would be the very practical things you have to do, echoes, when's your next test due." [HP1]
  - Quote 26: "Yeah, just that transition to adulthood thing of helping people see what are the normal kinds of tasks that people learn to become adults; so that's kind of more concrete for them. Perhaps break some of those tasks down into concrete steps so it's not so overwhelming." [HP2]

Resources: Providing Personalized Resources Can Help Enhance the Survivorship Experience, Psychosocial Well-Being, and Reproductive Health

Survivors' Perspective

Survivors highlighted the need for resources specific to the unique needs of cancer survivorship, highlighting that personalization helps normalize the experience of survivors of childhood cancer (quotes 27 and 28). Survivors also expressed a desire for more mental health resources. They readily endorsed the impact of diagnosis and treatment on their social, emotional, and mental well-being, especially wanting to know more about the notion of posttraumatic growth and posttraumatic stress in survivorship (quotes 29-30). Survivors also highlighted major gaps in resources dedicated to reproductive health, even though there is a negative impact of cancer treatment on fertility and family planning (quote 31). Survivors also noted that educational resources to support survivors' transition back to school are largely absent (quote 32). Finally, survivors discussed the importance of being able to access resources that are up-to-date and reflect recent advances in science and research (quote 33).

Health Care Providers' Perspective

Health care providers identified, as a priority, the need for resources dedicated to survivorship experience, financial assistance, and health care transitions (quote 34). They also identified a gap in psychosocial and educational supports (quote 35). Moreover, health care providers spoke of the need for better resourcing to help survivors understand and navigate their fertility and family planning (quote 36). Finally, health care providers discussed the importance of being able to share resources that are updated and reflect advances in research and science (quote 37; Textbox 4).

Textbox 4. Themes, subthemes, and representative quotes from survivors (n=22) and health care providers (n=7) on the development of an mHealth intervention to enhance follow-up care. This textbox covers theme (4), "resources: providing tailored resources can help enhance the survivorship experience, psychosocial well-being, and female and reproductive health."

Survivors' perspective

- Offering resources on the unique survivorship experience can help to normalize being a survivor of a childhood cancer.
  - Quote 27: "And like it would be nice to have a platform where you can exchange stories and have some of those anxieties assuaged of like this isn't a unique to you experience, it's a unique to the childhood cancer experience. Like there are other people who went through the same thing." [S1F4]
  - Quote 28: "But I think that maybe people would like to access, maybe there's testimonials from people. If it's about people feeling like it normalizes their situation." [S3F5]
- Mental health resources are lacking. Survivors are interested in better understanding the impact of diagnosis and treatment on their social, emotional, and mental well-being, including experiences of posttraumatic growth and posttraumatic stress.
  - Quote 29: "But what I was going to say was, I would say like social, emotional, mental health resources, just that larger I think important too. Or even contacts specifically connected to the aftercare clinic with relation to those. Whether it be social work, or child and youth, depending on the age, that type of thing." [S3F4]
  - Quote 30: "So, I think education maybe around mental health, what certain terms might mean like post-traumatic growths, what is that? Or post-traumatic stress disorder, or survivor's guilt, education content around what kind of complications could pop up for people that have had cancer treatment as a pediatric patient." [S7F2]
- Resources on female and reproductive health of survivors of childhood cancer is inadequate. Survivors would like to be better educated and equipped with the impact of diagnosis and treatment on their female and reproductive health.
  - Quote 31: "I was never told any—I had to ask if I was going to be able to have kids. It was never brought up to me. But I mean, I don't know, I only had chemotherapy. So, I don't know if radiation has something to do with that, but yeah, they've never brought it up." [S2F5]
- Knowing what accommodations and modifications are available to survivors of childhood cancer in their learning and education would be a helpful guide.
  - Quote 32: "I think maybe for deciding where this is for me, at home schooling. Because I know when I was going through treatment they had to—I skipped out like a year and a bit. So, yeah, I guess just resource things or places to refer to, to kind of continue that education if you're not able to be in class." [S1F1]
- Survivors would like resources that are updated and reflect advances in research and science.
  - Quote 33: "...just what's the most up to date evidence, because I think it's constantly evolving, so I think that's a huge piece of that information need and education need. I think it also helps you problem-solve, too, when things come up and you're 'is this normal?' And then you go to research and it's 'yeah, 20 percent or more end up with mental healthcare needs. OK, it's not abnormal for me to be feeling this way or for me to have this challenge.' So, I think there's a normalization element to having information that can support you in navigating follow-up care, for sure." [S6F2]

Health care providers' perspective

- Resources dedicated to the survivorship experience, financial assistance, and health care transitions are priorities.
  - Quote 34: "So, if we can figure out parking, just sort of if you think about another practical suggestion, how do you engage, if you need financial assistance with parking or travel, links to some resources that might be helpful. Not that there's not many, but just sort of how to eliminate barriers." [HP4]
- Health care providers identified a major gap in psychosocial and educational supports.
  - Quote 35: "Well, the big mental health ones I think is key, mental health, like the, I know [location] Health Services have their, has their cope, hard, coping in hard times kind of link or something, just those would be I think standard, would be helpful to have that. And even counselling specific, psychosocial counselling, counselors that are, identify, have experience in working in this area. Private ones would be helpful, although, yeah, and then just financial resources as well too, just links to that. I know, you could kind of there's a whole bunch of different ones I'm sure that you could link there, but the counselling, vocational supports." [HP4]
- Better resourcing is needed to help survivors of childhood cancer understand and navigate their fertility and family planning.
  - Quote 36: "You know some common big things that, not so much for our young patients for our adolescent and young adults, I do think that sort of resources about fertility and family planning needs to be somewhere in there because I think that that's something that some patients whether it be cultural or just personal can't openly ask, and I think that we'll agree that that's probably the most complex late effect that we deal with from a physical and mental-health perspective. I think that that—I don't know if it has to be something on its own, but I wish we could be better at telling a young person that, you know, family planning is different for everybody and that there are different ways to have families and the definition of family is changing every day. So, I don't know if that part is just—if I won $10 million I would put the money toward fertility salvage in survivors; that's what I would do." [HP1]

- Health care providers would like resources that are updated and reflect advances in research and science.
  - Quote 37: "Also, a place where they could see where there's a change in practice, like how often we do echoes or, you know, new recommendations for vaccinations, you know, like the very specific stuff that they, you know—flags or alerts I think would be helpful." [HP1]

Personalization: There Is a Need for Personalized Features on mHealth, Including Consideration of Survivors' Readiness; Emotional Impact of Accessing Follow-Up Care; Privacy; and Right to Accurate, Moderated Information

Survivors' Perspective

Survivors highlighted several important considerations to help personalize the mHealth intervention. For instance, survivors described the importance of providing options so that survivors can feel that they have a choice in when and how they wish to navigate mHealth in their cancer journey (quotes 38 and 39). Furthermore, survivors discussed the emotional impact of accessing their follow-up care, highlighting that the survivorship experience is diverse and that they want to be able to establish their own boundaries in accessing their follow-up care and cancer history through mHealth (quote 40). In addition, survivors discussed the importance of incorporating privacy features to protect their identity and health information, whether that is from their family members and/or other members of the mHealth community (quotes 41 and 42). Finally, survivors recognized that, while they would value being able to communicate with other survivors in a forum on mHealth, there is a need to modulate all communication to ensure that any information or resources shared are accurate and not to be mistaken with professional recommendations (quote 43).

Health Care Providers' Perspective

Health care providers expressed their concern for any information that survivors receive that is not communicated directly from a health care provider (quote 44). They expressed a desire to ensure that survivors receive accurate knowledge and resources to support their follow-up care (quote 44). Health care providers also shared their concern for the limited capacity of current health care providers in being able to support the growing population of survivors (quote 45; Textbox 5).

Textbox 5. Themes, subthemes, and representative quotes from survivors (n=22) and health care providers (n=7) on the development of an mHealth intervention to enhance follow-up care. This textbox covers theme (5), "personalization: there is a need to account for personalized features, including survivors' readiness; emotional impact of accessing follow-up care; privacy; and right to accurate, moderated information, in accessing mHealth."

Survivors' perspective

- Being able to choose when to access, and have control over access, mHealth is an important feature. Not all survivors feel ready or want to engage in their mHealth at all times.
  - Quote 38: "And I don't think that it should be alert based, or maybe if there's a way that you opt out of alerts, because I think that that would be probably a stressor, when you're at work, and you like, 'Ping. Have you thought about cancer today?'" [S3F5]
  - Quote 39: "...the idea of a platform is really great, especially when you think about people's readiness to engage in that kind of stuff. Oftentimes...I wasn't ready at first to engage with other youths at that time. It took some time, and it actually was, I made my closest friendships with other survivors five years post, maybe even more than that. So, it was—I was quite defended from that, but there was a readiness there, that I was ready to do that, but it came at an appropriate time. So having that available when people are ready to engage gives them access and gives them a sense of control about when they are actually feeling they need that support versus when you have that follow-up first talk, it's 'hey, here are the resources available to you, have at them when you need them,' and that can be a little intimidating." [S6F2]
- For survivors, there is an emotional impact to accessing their follow-up care. These experiences are diverse, and survivors want to be able to establish their own boundaries in accessing their follow-up care and cancer history.
  - Quote 40: "But my concern with peer support has always been that the people who tend to gravitate toward looking for support, are people who aren't doing well. And so, I don't want to go or be part of something that becomes a co-rumination." [S2F5]
- Establishing privacy features is important for survivors to protect their identity and health information from their family and others.
  - Quote 41: "And I think it's not just me that you're kind of targeting with a platform like this, it's also especially for people who might be younger and still living at home. You're now getting the whole family. Because, with iPads and phones and emails and all these things now, if folks are still living at home, their parents may also be seeing these notifications." [S4F5]
  - Quote 42: "I'd love to meet up with other individuals that have shared my experience one on one or even in a small group setting like this, whether it be like an optional pen pal thing through the platform where you could talk one on one. And, you know, if you wanted to talk to them through video that is your choice but make something so it's secure so you're not giving out personal information if you don't want to." [S4F5]
- It is important that any communication on mHealth is moderated and not to be mistaken with medical or professional advice.
  - Quote 43: "...I do kind of feel as though there might need to be some sort of like regulation on what is said. As much as like 100 percent lived experiences and what people have gone through is so important and can be relayed, but I just would also worry that things would be maybe not communicated clearly and I would just worry that like, 'Oh, someone said that high dose vitamin C treatments at this random clinic did something.' And just that is the only like little thing in my ear that's saying like just be careful is all." [S3F5]

Health care providers' perspective

- Any information shared with survivors of childhood cancer needs to be properly communicated by a health care provider.
  - Quote 44: "You know I think it's a good idea to have some sort of platform where survivors can [pause] I can't think of the right word, that they can look at and give them information. I do sometimes think I worry if they get information without back-up to discuss it and all, like you can't just tell somebody, 'You're going to be infertile' and not go through it all, you know, discuss your options and that sort of thing. That's what I'm thinking from that perspective. [HP3]
- There is a concern for the capacity of health care providers to be able to serve the growing population of survivors of childhood cancer.
  - Quote 45: "I mean, yeah, it's, like I said, the big piece is just increasing capacity and then, yeah, looking at, if we're going to continue on this trend in terms of survivorship. And if we're looking at having the seeing people indefinitely within [location], I don't know if that's the case, then what's the future hold...That's what my concern is, is that we're really, are we really providing the best service possible if we're, we have these volumes and we just don't have the staff to really provide that support, that's my main concern, I guess, where are things going and is there going to be capacity to support it." [HP4]

Validating Findings Facilitated Through Community Engagement

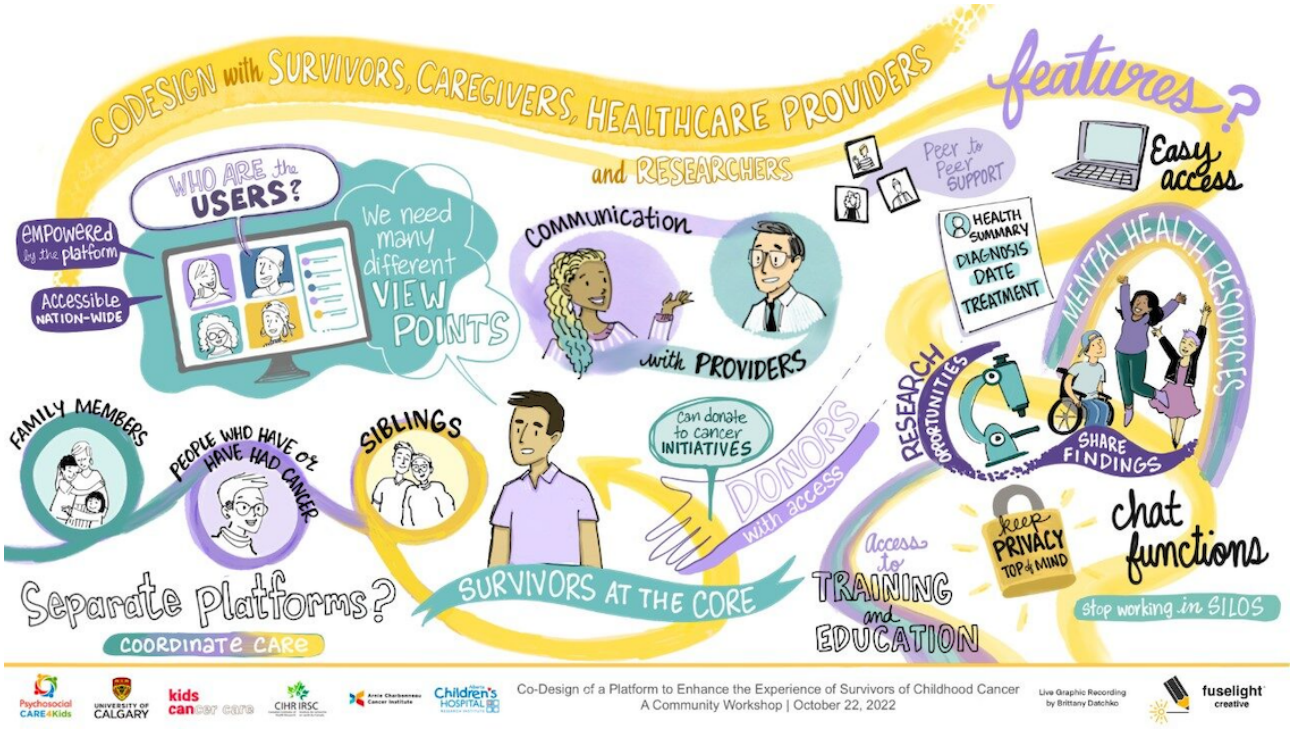
A total of 31 participants, including survivors of childhood cancer (n=10, 32%) and their caregivers (n=2, 6%), health care providers (n=6, 19%), researchers (n=11, 35%, including 2 patient partners), and collaborators (n=2, 6%) participated in the community engagement event to review and verify the qualitative results gathered.

Small and Large Group Discussions

Participants endorsed the accuracy of themes derived regarding the core components to be included in mHealth. Participants explored additional contexts in the development of an mHealth intervention, including considerations for family members (eg,

families and siblings) and the practicalities of preserving privacy and confidentiality on a technology-based intervention. Participants also reported feeling heard through the graphic recording process. The final graphic recording is shown in Figure 1.

Figure 1. Graphic recording of the community engagement event on October 22, 2022. Illustration completed by Fuselight Creative.



Satisfaction Survey

Some participants (8/22, 36%) completed a web-based questionnaire assessing participant engagement at the event. On average, participants *strongly agreed* that they felt that their views were heard (mean 5.00, SD 0.00) and that they were able to discuss their views freely (mean 4.71, SD 0.45). Participants also strongly agreed that they felt they had enough information to contribute to the topics discussed (mean 4.71, SD 0.35) and that a wide range of views on the topics were shared (mean 4.71, SD 0.45). Participants *mostly agreed* that they had a clear understanding of the purpose of the community workshop (mean 4.14, SD 0.35). In addition, participants were asked to indicate the extent to which they agreed that the community engagement event objectives (ie, to co-design mHealth, to engage with others, and to provide feedback on study results) were achieved, and their responses ranged from *mostly* to *strongly* agreed (mean scores ranging from 4.00 to 4.71, SD scores ranging from 0.45 to 0.83). Importantly, participants *strongly agreed* that they felt confident that the input provided through this event would be incorporated by the study team. A summary of participant responses is reported in Tables 2 and 3.

Table 2. Participant responses to community engagement event evaluation (n=8)[a] for section 1 (overview of the workshop)[b].

Overview of the workshop	Responses, mean (SD)
"I had a clear understanding of the purpose of this community workshop."	4.14 (0.35)
"I had enough information to contribute to the topics discussed."	4.86 (0.35)
"I was able to express my views freely."	4.71 (0.45)
"I felt that my views were heard."	5.00 (0.00)
"A wide range of views on the topics discussed were shared."	4.71 (0.45)

[a]A total of 8 attendees, including 4 survivors of childhood cancer, 1 caregiver, 2 family members, and 1 researcher, completed the evaluation.

[b]Attendees were asked to rate the extent to which they agreed with statements in this table, using a rating scale where 1=strongly disagree and 5=strongly agree.

Table 3. Participant responses to community engagement event evaluation (n=8)[a] for section 2 (workshop objectives)[b].

Workshop objectives	Responses, mean (SD)
"To describe the preliminary results from the study on improving follow-up care for survivors of childhood cancer."	4.14 (0.83)
"To co-design a platform for survivors of childhood cancer that is agreed upon within this community."	4.00 (0.76)
"To engage with other core community members (health care professionals, researchers, families, and caregivers)."	4.71 (0.45)
"I am confident that the input provided through this community workshop will be used by the CARE4Kids team at the University of Calgary."	4.71 (0.45)

[a]A total of 8 attendees, including 4 survivors of childhood cancer, 1 caregiver, 2 family members, and 1 researcher, completed the evaluation.

[b]Attendees were asked to rate the extent to which they agreed that the objectives listed in this table were achieved, using the rating scale where 1=strongly disagree and 5=strongly agree.

Discussion

Principal Findings

It is important that survivors of childhood cancer receive routine health care follow-up, yet many survivors do not understand the importance of their follow-up care or have limited knowledge on their need for follow-up care. Our study aimed to amplify the voices of young adult survivors of childhood cancer in identifying the priority components to be included in an mHealth intervention that can help educate and engage survivors in their long-term follow-up care.

Our approach was unique in using co-design and a qualitative research framework and adhering patient-oriented research principles to engage in mHealth intervention development [21,37]. We uniquely incorporated perspectives from survivors of childhood cancer and health care providers that deliver cancer-specific follow-up care. Patient partners collaborated with our team over the entirety of the research process, including study design, recruitment, data collection (ie, cofacilitation of focus groups and interviews), interpretation of results, and knowledge dissemination. Furthermore, a community engagement activity was cofacilitated with patient partners to enhance the validity of qualitative descriptive data gathered.

Limited mHealth interventions have been created *with* survivors of childhood cancer despite its rising potential to improve health [38]. Most efforts have focused on patients who are on active cancer treatment. For instance, a systematic review indicated a positive effect of mHealth interventions on improving the health-related quality of life of adult patients with cancer [38]. Other studies have explored delivering a survivorship care plan and an app for enhancing self-management for adolescents and young adults [39]. Few studies have effectively engaged in the co-design of mHealth, and even less work has been conducted with young adult survivors of childhood cancer in this regard, as well as with health care providers. Therefore, our work provides important and novel insights from the perspectives of individuals with lived experience of cancer and health care providers regarding their follow-up care experiences. Specifically, results shed light on the priority areas necessary to increase knowledge of and engagement in follow-up care for survivors of childhood cancer, establishing a critical foundation in mHealth intervention development.

In total, 5 major themes were conceptualized as the priority components of the mHealth intervention. Many of the themes are consistent with the existing literature on the unmet needs of survivors of childhood cancer. For example, survivors and health care providers from our study identified a lack of knowledge of diagnosis and treatment, as well as associated late effects, for survivors. These results are consistent with past work showing that most survivors of childhood cancer fail to recognize their risk for developing a serious health condition [11,40]. Furthermore, previous research indicates that survivors of childhood cancer need a better way to learn about and engage in their own health information [10,41]. Indeed, our findings indicate a need for advanced means to deliver follow-up care knowledge, such as the use of a mobile app or website, as well as the need for creative features to enhance the follow-up care experience, such as reminders for appointments and a cancer profile to consolidate health history information.

Another notable theme generated was the need for more education and support during health care transitions. This builds on an extensive body of literature on health care transitions for young adults impacted by cancer [42]. There are cancer-specific risks and health care needs of survivors of childhood cancer that are distinct from those with other chronic illnesses [43]. Therefore, our research lends further support for the importance of personalized care for young adult survivors during their health care transition from pediatric to adult health care, one that prioritizes educating survivors on their potential late effects related to their diagnosis and treatment, as well as the utility of engaging in consistent surveillance to promote longer-term optimal outcomes.

Survivors expressed some hesitation toward having regular access to their cancer history information and therefore discussed the importance of being able to have choice and control in how they navigate mHealth. These findings are consistent with existing work documenting experiences related to posttraumatic stress experienced by survivors [44] and the importance of prioritizing a trauma-informed approach in intervention development.

Several other themes were generated from this study that are novel and relevant to building an mHealth intervention for survivors of childhood cancer. Survivors and health care providers emphasized the importance of establishing connections with other survivors and health care providers. These results likely reflect a sense of disconnect that survivors experience and a desire to broaden opportunities for meaningful connections. Indeed, survivors spoke about the need to explore their identity beyond their cancer journey. Taken together, these

results are consistent with past work documenting that adolescents and young adults with cancer experience substantial psychosocial challenges, including peer and family relationships and personal growth stresses [45]. Likewise, health care providers echoed the importance of cultivating connections among survivors to address feelings of isolation on their cancer journey. Importantly, health care providers also highlighted a desire to connect with other health care providers that provide follow-up care across Canada, emphasizing the importance of connecting with and consulting one another to stay informed of current concerns and practices in survivorship. Few studies have addressed the unmet needs of health care providers in delivering follow-up care to survivors of childhood cancer [23]. Our study provides unique insight of both survivors and health care providers, offering a more contextualized understanding of how to improve follow-up care from multiple perspectives.

Issues related to accessibility of follow-up care and health equity were a prominent finding from our research. These outcomes contribute to our understanding of some of the geographic barriers faced by survivors from rural or remote regions, as reflected in our study sample. Developing an mHealth intervention will aim to address these barriers by connecting survivors to their follow-up care through technology. However, barriers to health care are complex and dynamic and require consideration of factors beyond the individual, including health care providers and health care systems factors, to alleviate health disparities [46]. Therefore, further work is needed to capture the complete and intersecting effects of accessibility factors, as well as other inequities faced by survivors of childhood cancer, on their receipt of high-quality health care. These are important considerations in intervention development to ensure that the burden of change is not placed solely on survivors of childhood cancer but rather recognized as a systemic problem that requires multilevel intervention.

Our research incorporated a response validation technique, member checking, to enhance the rigor of qualitative data gathered. Previous qualitative work using member checking lacked detail and discussion in the implementation of the technique. Absence of this reporting may be confounded by epistemological and methodological challenges [36]. In this research, we conducted a comprehensive assessment and report of member checking using a multiinformant, multimodal approach to strengthen the credibility and validity of data gathered. The strength of this approach is to demonstrate the true and iterative process that we took to achieve consensus among researchers and those with lived experiences in the research process. Our goal with this undertaking is to enhance the transparency, accessibility, and replicability of best practices in qualitative health research.

Limitations and Future Directions

We review several important limitations to be considered when interpreting the results of this study. A major strength of this research was leveraging technology for participation (ie, online focus groups and community engagement). This meant an increase in accessibility to those residing in remote or rural regions. However, reliance on technology also meant that participants from lower levels of income, or some individuals from geographically more remote or rural regions of Canada, may face greater barriers to participating because they are less likely to have access to technology. Future research incorporating community outreach, phone-based participation, or compensated travel to the local context can help to mitigate this challenge in research recruitment. Input on how we can account for potential technological limitations in reaching individuals from more remote or rural regions of Canada will be important as we build the intervention.

Research shows that a diversity of perspectives drives innovation [47]. Participants from our study offered important insights into accessibility issues that contribute to health inequities for survivors of childhood cancer. However, our sample nonetheless lacked representation and voice from individuals from diverse backgrounds (eg, diversity in ethnicity, gender identity, sex, language use, and geographic regions) and/or who are not engaged in their follow-up care. We recognize that a potential bias of our sample is that most of our sample reported attending their follow-up care. We are missing the voices of individuals who are not engaged in their care at this time, and future research leveraging purposive sampling of those not regularly attending their follow-up care would offer us important insights into the barriers they face in attending care. In addition, there is a notable disparity in gender representation of participants, with 86% (19/22) of participants identifying as female gender. Studies have found that female gender predicted attendance to follow-up care, such that female participants were more likely than male participants to attend follow-up care [48]. This bias in our sampling reinforces that our findings reflect the views of those who are attending their follow-up care. In addition, there are many factors that contribute to a lack of gender representation in cancer research, including researcher bias, gender stereotypes, and unequal social opportunities [49]. Importantly, a review of gender representation trends in psychosocial survivorship research showed that there is a trend toward a more balanced representation of men and women over a 15-year period (2007 and 1992) [49]. Taken together, our skewed sample indicates an important need to continue to engage with survivors from equity-deserving groups, particularly given the increasing diversity of the Canadian population.

Research shows that members of equity-deserving groups face significant barriers to accessing high-quality and accessible health care [50,51]. Without knowledge of the perspectives and experiences of these individuals, we are missing critical information that can help to address health disparities and, in turn, bring greater awareness to the importance of follow-up care surveillance and attendance for those from underrepresented and underserved communities. Implementation of safe, inclusive, and culturally responsive recruitment strategies is needed to increase representation in pediatric cancer research [52].

Finally, this study solicited feedback from participants and other important parties to enhance the credibility and validity of the results. We demonstrated rigor of data by using a multiinformant and multimodal approach to achieve consensus. However, the response rate for completing the satisfaction survey for our community event was 36%, so responses gathered on patient engagement may not be representative of feedback from most attendees. Another limitation of our community engagement

event is that we did not determine whether attendees included those who previously participated in the focus groups and interviews. Therefore, the feedback gathered at the community event may be influenced by participants' familiarity with the study. Future research establishing and implementing a comprehensive and systematic evaluation of patient and public engagement is necessary to strengthen the rigor of our evaluative framework and enhance patient engagement and research.

The next step of this multiphased project is to build an innovative and accessible mHealth intervention prototype based on the core components identified and grounded in an established conceptual framework for co-design of intervention development. Results from this study have provided the bedrock to progress in our development of an mHealth intervention for survivors of childhood cancer to enhance their knowledge of and engagement in their follow-up care.

Conclusions

In this study, we identified core components to be included in an mHealth intervention to increase the knowledge of and enhance follow-up care engagement for survivors of childhood cancer. We engaged in a rigorous and iterative co-design process with survivors of childhood cancer and health care providers. We incorporated a community engagement event to validate our findings with a broader audience of community members. Findings will inform the next phase of our multiphased, co-design project, ultimately aiming to improve follow-up care and long-term outcomes for survivors of childhood cancer.

Acknowledgments

The authors acknowledge Sharon Paulse and Annette Flanders for their support and insights on the recruitment process. This study is supported by funding from the Strategy for Patient-Oriented Research of the Canadian Institutes of Health Research Catalyst Grant, Alberta Children's Hospital Research Institute, and Kids Cancer Care. Postdoctoral fellow SHJH is funded by the Arnie Charbonneau Cancer Institute and Cumming School of Medicine at the University of Calgary Postdoctoral Fellowship Awards.

Data Availability

Data generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

FSMS secured funding acquisition. FSMS and SHJH conceptualized the study and methodology. SHJH led investigation, data curation, project administration, formal analysis, and supervision. FSMS oversaw investigation, data curation, project administration, formal analysis, and supervision. CF and BH supported project administration, data curation, and formal analysis. RD, KM, and HW contributed to portions of formal analysis. IR, PRT, HZ, MS and JD contributed to portions of data curation. EKD, CE, MST, LS, PN, MS, KG, and KR contributed to portions of investigation. SHJH prepared the original draft. FSMS, CF, BH, RD, KM, HW, IR, PRT, HZ, MS, EKD, and JD contributed to reviewing and editing the manuscript.

Conflicts of Interest

EKD owns and operates a consultancy (EmilyDrake.ca). CE is a DSMB member for CONNECT. All other authors declare no conflicts of interest.

Abstract

Background: Male breast cancer (MBC) is an uncommon disease. Few studies have discussed the prognosis of MBC due to its rarity.

Objective: This study aimed to develop a nomogram to predict the overall survival of patients with MBC and externally validate it using cases from China.

Methods: Based on the Surveillance, Epidemiology, and End Results (SEER) database, male patients who were diagnosed with breast cancer between January 2010, and December 2015, were enrolled. These patients were randomly assigned to either a training set (n=1610) or a validation set (n=713) in a 7:3 ratio. Additionally, 22 MBC cases diagnosed at the First Affiliated Hospital of Guangxi Medical University between January 2013 and June 2021 were used for external validation, with the follow-up endpoint being June 10, 2023. Cox regression analysis was performed to identify significant risk variables and construct a nomogram to predict the overall survival of patients with MBC. Information collected from the test set was applied to validate the model. The concordance index (C-index), receiver operating characteristic (ROC) curve, decision curve analysis (DCA), and a Kaplan-Meier survival curve were used to evaluate the accuracy and reliability of the model.

Results: A total of 2301 patients with MBC in the SEER database and 22 patients with MBC from the study hospital were included. The predictive model included 7 variables: age (hazard ratio [HR] 1.89, 95% CI 1.50 - 2.38), surgery (HR 0.38, 95% CI 0.29 - 0.51), marital status (HR 0.75, 95% CI 0.63 - 0.89), tumor stage (HR 1.17, 95% CI 1.05 - 1.29), clinical stage (HR 1.41, 95% CI 1.15 - 1.74), chemotherapy (HR 0.62, 95% CI 0.50 - 0.75), and HER2 status (HR 2.68, 95% CI 1.20 - 5.98). The C-index was 0.72, 0.747, and 0.981 in the training set, internal validation set, and external validation set, respectively. The nomogram showed accurate calibration, and the ROC curve confirmed the advantage of the model in clinical validity. The DCA analysis indicated that the model had good clinical applicability. Furthermore, the nomogram classification allowed for more accurate differentiation of risk subgroups, and patients with low-risk MBC demonstrated substantially improved survival outcomes compared with medium- and high-risk patients (P<.001).

Conclusions: A survival prognosis prediction nomogram with 7 variables for patients with MBC was constructed in this study. The model can predict the survival outcome of these patients and provide a scientific basis for clinical diagnosis and treatment.

Introduction

Male breast cancer (MBC) is an infrequent type of malignancy [1,2]. The incidence of MBC accounts for less than 1% of all breast cancer (BC) instances, and MBC accounts for 0.31% of all BC cases in China [3-5]. The incidence of MBC varies by region and ethnicity, with higher rates observed in Africa, North America, and Australia, and the lowest rates are observed in Asia [6]. In China, there are only 4 cases of MBC per million people, but this figure has been increasing gradually in recent

years [6]. Due to the low incidence of MBC, current research on BC primarily focuses on female patients [7]. Therefore, the current treatment for MBC is based on the guidelines for treating female BC [8]. However, MBC possesses unique tumor, molecular, and clinicopathological characteristics, and no consensus has been established regarding its diagnosis, treatment, and assessment of prognostic risk factors. A previous study revealed that the median age at diagnosis for BC in men is 67 years old, which is 5 - 10 years later than that in women [9]. Despite this, the overall survival of MBC is significantly lower than that of female BC, largely due to late diagnosis [10].

The TNM (tumor, extent of spread to the lymph nodes, and presence of metastasis) staging system is the most commonly used clinical instrument to evaluate the prognosis of individuals with cancer [11-13]. However, in MBC, the limited amount of breast tissue and the frequent involvement of the chest wall at early stages reduce the prognostic value of TNM staging [14]. Many studies have demonstrated that factors such as age, tumor type, and other factors significantly influence the prognosis of BC [15,16]. Compared to using the clinical stage alone, comprehensive multivariate models can provide numerical estimates of practice-specific risk and the accuracy of prognostic predictions for patients with cancer [17]. Therefore, various clinical medical records need to be combined to construct a prognostic model for MBC, thus enabling a more accurate judgment of the prognosis of patients and an accurate, individual evaluation of the prognosis of patients.

Current clinical approaches for constructing risk prediction models include the nomogram, a scoring system, and other methods, which can serve as a guide for clinical decision-making and individualized treatment [18-20]. The nomogram, as a straightforward and intuitive prediction tool with strong predictive ability, has the advantages of accurate predictive ability and calibration ability, and it has been widely used in prognosis research [21-23].

This study aimed to identify the prognostic indicators of patients with MBC by using the Surveillance, Epidemiology, and End Results (SEER) database; establish a predictive model on the basis of the independent predictors of overall survival; and internally and externally validate the model to guide clinical staff in evaluating the prognosis of patients more accurately and formulating more personalized diagnosis and treatment plans. We present the study in accordance with the TRIPOD reporting checklist.

Methods

Data Sources

The SEER database collects information on new cancer cases and survival rates from 18 population-based cancer registries, which currently cover approximately 30% of the US population [22]. Clinical data on male patients with pathologically confirmed BC from 2010 to 2015 were gathered using the SEER database to establish a training set and an internal validation set. Data from patients with MBC admitted to the First Affiliated Hospital of Guangxi Medical University between 2013 and 2021 were used for the external validation set of the model. Clinical data for MBC were retrospectively collected from the hospital database, and follow-up information was obtained through telephone interviews. Patients with missing follow-up data or other essential clinical information were excluded.

Patient Inclusion and Exclusion Criteria

The criteria for patient inclusion were as follows: (1) male patients; (2) an *International Classification of Diseases for Oncology, Third Revision* code; (3) breast as the primary site; and (4) complete survival data. The exclusion criteria were (1) missing clinical information, including TNM staging and tumor laterality; (2) unknown demographic characteristics, such as age at diagnosis and marital status; and (3) instances without records of follow-up (0-month survival time code). The enrolled patients were randomly assigned in a 7:3 ratio to two sets: a training set and an internal validation set. The training set was used to develop the prediction model, and the internal validation set was used for internal validation. The data obtained at the hospital were applied for external validation.

Variable Selection

The outcome variable in this study was overall survival. The selection of predictor variables was informed by previous reports in the literature. The variables collected included year of diagnosis, age, marital status, pathological grade, breast subtype, estrogen receptor, progesterone receptor, human epidermal growth factor receptor 2 (HER2), American Joint Committee on Cancer stage, chemotherapy, surgery, radiotherapy, duration of follow-up, and death.

Follow-Up of Patients

Male patients with BC were followed up by telephone in the hospital, and the follow-up ended on June 10, 2023. The index used for follow-up was overall survival time, with the outcome event being mortality.

Statistical Analysis

Data analysis was conducted using the R software version 4.1.1 (IBM Corp). Percentages were used to represent categorical variables, and the χ^2 test or Fisher exact test was used to compare the baseline characteristics of the training set, internal validation set, and external validation set. The Kaplan-Meier model was applied to describe the overall survival curve, and the log-rank test was used to evaluate the disparities in survival among various subgroups of each variable. First, variables that had a significance value of $P<.05$ in the univariate analysis were chosen to be incorporated into the multivariate Cox proportional hazard model to obtain variables affecting the survival of patients with MBC. Second, stepwise regression was performed based on the Akaike information criterion. The nomogram prediction model was constructed using R software (via the *rms* and *survival* R packages) to assess the influence of risk factors on the overall survival of patients with MBC. Predictions were made for the 1-, 3-, and 5-year overall survival rates of patients with MBC by constructing the nomogram.

The performance of the nomogram was evaluated through internal and external validations. Bootstrapping was used to perform 1000 instances of resampling to internally validate the predictive performance of the nomogram to ensure the stability

and reliability of the model's performance. The discrimination of the nomogram was assessed using the Concordance index (C-index) and receiver operating characteristic (ROC) curve. A calibration curve was created to assess the degree of calibration of the nomogram to ensure its accuracy and reliability. Furthermore, decision curve analysis (DCA) was conducted using *ggDCA* in the R package, to evaluate the clinical utility and application value of the nomogram. Finally, X-tile software (version 3.6.1, Yale University School of Medicine) was used for risk stratification on the basis of the total score of the nomogram for each individual. An α level of .05 was used.

Ethical Considerations

The data used in this study were extracted from a publicly accessible SEER database. This study was reviewed and approved by the Medical Ethics Committee of the First Affiliated Hospital of Guangxi Medical University (2023-E320-01). During the follow-up, informed consent was obtained orally from individual participants included in the study, and the investigator explained the purpose of the study to the patient or caregiver. Participants were also made aware of their right to withdraw at any time without penalty or prejudice to their future care, a principle that was strictly adhered to throughout the study period. In addition, participants who completed the survey received a complimentary disease knowledge resource as a token of appreciation and compensation for their participation, All participants' information was confidential, and each patient was assigned an ID to keep the study data and results anonymous.

Results

Patients' Baseline Characteristics

Figure 1 depicts the screening procedure in the SEER database. In accordance with the inclusion and exclusion criteria, a cohort of 2301 eligible patients with MBC was selected from the SEER database and randomly divided into a training set (n=1595) and an internal validation set (n=706). A total of 22 patients with MBC were chosen from the institution to serve as an external validation set. Significant variations in age were observed among the 3 groups in relation to demographic characteristics (P=.01). The proportion of older men in the SEER database (training set: 1180/1595, 74%; internal validation set: 505/706, 71.5%) was substantially greater than that in the external validation set (9/22, 41%). Significant differences were found in chemotherapy, lung metastasis, breast subtype, and HER2 status among the 3 groups (all P<.05). The proportion of men with breast cancer who received chemotherapy was higher in the external validation set (17/22, 77%) than in the SEER database (training set: 601/1595, 37.7%; internal validation set: 257/706, 36.4%). The incidence of lung metastasis in patients with MBC in the external validation set (3/22, 14%) was higher than that in the SEER database (training set: 49/1595, 3.1%; internal validation set: 24/706, 3.4%). There was a high prevalence of luminal A among men, with rates of 86.7% (1379/1595) and 85% (607/706) in the training set and internal validation set, respectively, as well as 41% (9/22) in the external validation set. A notable detail is that a significant portion of the total population exhibited a HER2-negative status accounting for 88.6% (1413/1595) in the training set, 87.5% (618/706) in the internal validation set, and 59% (13/22) in the external validation set. Table 1 displays the demographic and clinicopathological characteristics.

[a]Chi-square test was performed.

[b]T: tumor.

[c]Fisher precision probability test was performed.

[d]N: lymph nodes.

[e]M: metastasis.

[f]HER2: human epidermal growth factor receptor 2.

The data of 22 male patients diagnosed with BC in the study hospital were collected. Statistically significant differences were observed between the two groups in terms of age, T stage, chemotherapy, breast subtype, and HER2 status (P<.05). In the unit set, ≤60 years old, T_2 stage, receiving chemotherapy, luminal B, and HER2-positive status accounted for a greater proportion of patients with MBC. The clinicopathological characteristics of the SEER set and the unit set are provided in Multimedia Appendix 1.

Univariate and Multivariate Cox Regression Analysis

Cox regression risk analysis was applied to conduct univariate and multivariate survival analysis for the patients with MBC in the training set. The findings indicated that age (hazard ratio [HR] 1.89, 95% CI 1.50 - 2.38), marital status (HR 0.75, 95% CI 0.63 - 0.89), T stage (HR 1.17, 95% CI 1.05 - 1.29), clinical grade (HR 1.41, 95% CI 1.15 - 1.74), surgery (HR 0.38, 95% CI 0.29 - 0.51), chemotherapy (HR 0.62, 95% CI 0.50 - 0.75), and HER2 status (HR 2.68, 95% CI 1.20 - 5.98) were risk variables for the survival of patients with MBC (all $P<.05$; Table 2).

Table . Univariate and multivariate analysis of male breast cancer risk factors in the training set.

Variable	Univariate		Multivariate	
	HR[a] (95% CI)	*P* value	HR (95% CI)	*P* value
Marital status	0.71 (0.60 - 0.84)	<.001	0.75 (0.63 - 0.89)	.01
Age	1.74 (1.39 - 2.16)	<.001	1.89 (1.50 - 2.38)	<.001
T[b] stage	1.45 (1.33 - 1.58)	<.001	1.17 (1.05 - 1.29)	.04
N[c] stage	1.23 (1.12 - 1.35)	<.001	1.03 (0.90 - 1.17)	.67
M[d] stage	5.19 (4.18 - 6.45)	<.001	1.08 (0.61 - 1.91)	.81
Clinical stage	1.86 (1.70 - 2.04)	<.001	1.41 (1.15 - 1.74)	.01
Laterality	1.00 (0.85 - 1.19)	.99	—[e]	—
Surgery	0.18 (0.15 - 0.22)	<.001	0.38 (0.29 - 0.51)	<.001
Radiation	0.98 (0.82 - 1.18)	.84	—	—
Chemotherapy	0.78 (0.65 - 0.93)	.006	0.62 (0.50 - 0.75)	<.001
Bone metastasis	0.18 (0.14 - 0.24)	<.001	0.71 (0.46 - 1.10)	.12
Brain metastasis	0.21 (0.09 - 0.49)	<.001	0.53 (0.24 - 1.17)	.12
Liver metastasis	0.20 (0.10 - 0.41)	<.001	0.91 (0.47 - 1.80)	.79
Lung metastasis	0.25 (0.17 - 0.35)	<.001	0.98 (0.69 - 1.40)	.93
Breast subtype	1.16 (0.93 - 1.44)	.19	2.03 (0.95 - 4.30)	.07
Estrogen receptor status	0.44 (0.29 - 0.65)	<.001	1.86 (0.45 - 7.76)	.39
Progesterone receptor status	0.64 (0.50 - 0.83)	<.001	0.91 (0.67 - 1.24)	.56
HER2[f] status	1.31 (1.02 - 1.68)	.03	2.68 (1.20 - 5.98)	.02

[a]HR: hazard ratio.

[b]T: tumor.

[c]N: lymph node.

[d]M: metastasis.

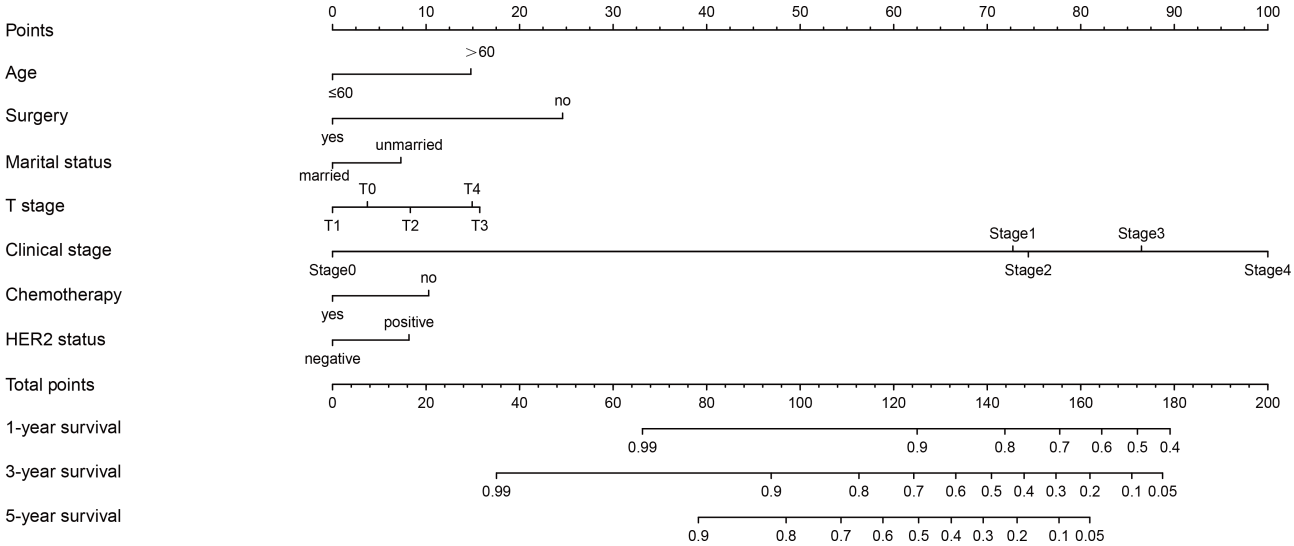
[e]Variables that were not significant in the univariate analysis do not have specific data in the multivariate analysis.

[f]HER2: human epidermal growth factor receptor 2.

Construction and Validation of Nomogram

The construction of a nomogram for the overall survival prognosis of MBC was based on the results of the Cox regression analysis conducted on the training set. This analysis identified 7 variables that were subsequently used in the development of the nomogram (Figure 2). The nomogram demonstrated that clinical stage and surgery were the primary vital risk variables that affect the survival outcomes of patients with MBC. The total score could predict the 1-, 3-, and 5-year survival rates of patients with MBC by summing the scores of each variable.

Figure 2. Nomogram for predicting 1-, 3- and 5-year overall survival in patients with male breast cancer. HER2: human epidermal growth factor receptor 2; T: tumor.



The discrimination ability of the nomogram was evaluated in this study by using the ROC curve and the C-index. The area under the curve values of the nomogram at 1-, 3-, and 5-year survival probabilities had excellent discrimination efficacy in the training set (Figure 3A-C). The area under the curve values in the internal validation set were 0.736, 0.773, and 0.765 (Figure 3D-F), and the external validation set values were 1, 0.947, and 0.825 (Figure 3G-I). The C-index of the training set was determined using the bootstrap method, and the C-index of the external validation set was 0.72, 0.747, and 0.981 for the at 1-, 3-, and 5-year survival, respectively, indicating that the nomogram exhibited a favorable discriminatory capability in the American and Chinese populations.

The calibration curves were used to evaluate the consistency of the nomogram. The findings indicated a high degree of uniformity between the predicted and observed probabilities of survival in the training set (Figure 4A-C) and internal validation set (Figure 4D-F).

The DCA curve demonstrated that the nomogram exhibited superior performance in terms of net clinical benefit and predictive accuracy for 3- and 5-year survival outcomes in the training set (Figure 5A) and internal validation set (Figure 5B).

Figure 3. Receiver operating characteristic curve of prediction of 1-, 3-, and 5-year survival in the training set (A-C), internal validation set (D-F), and external validation set (G–I). AUC: area under the curve.

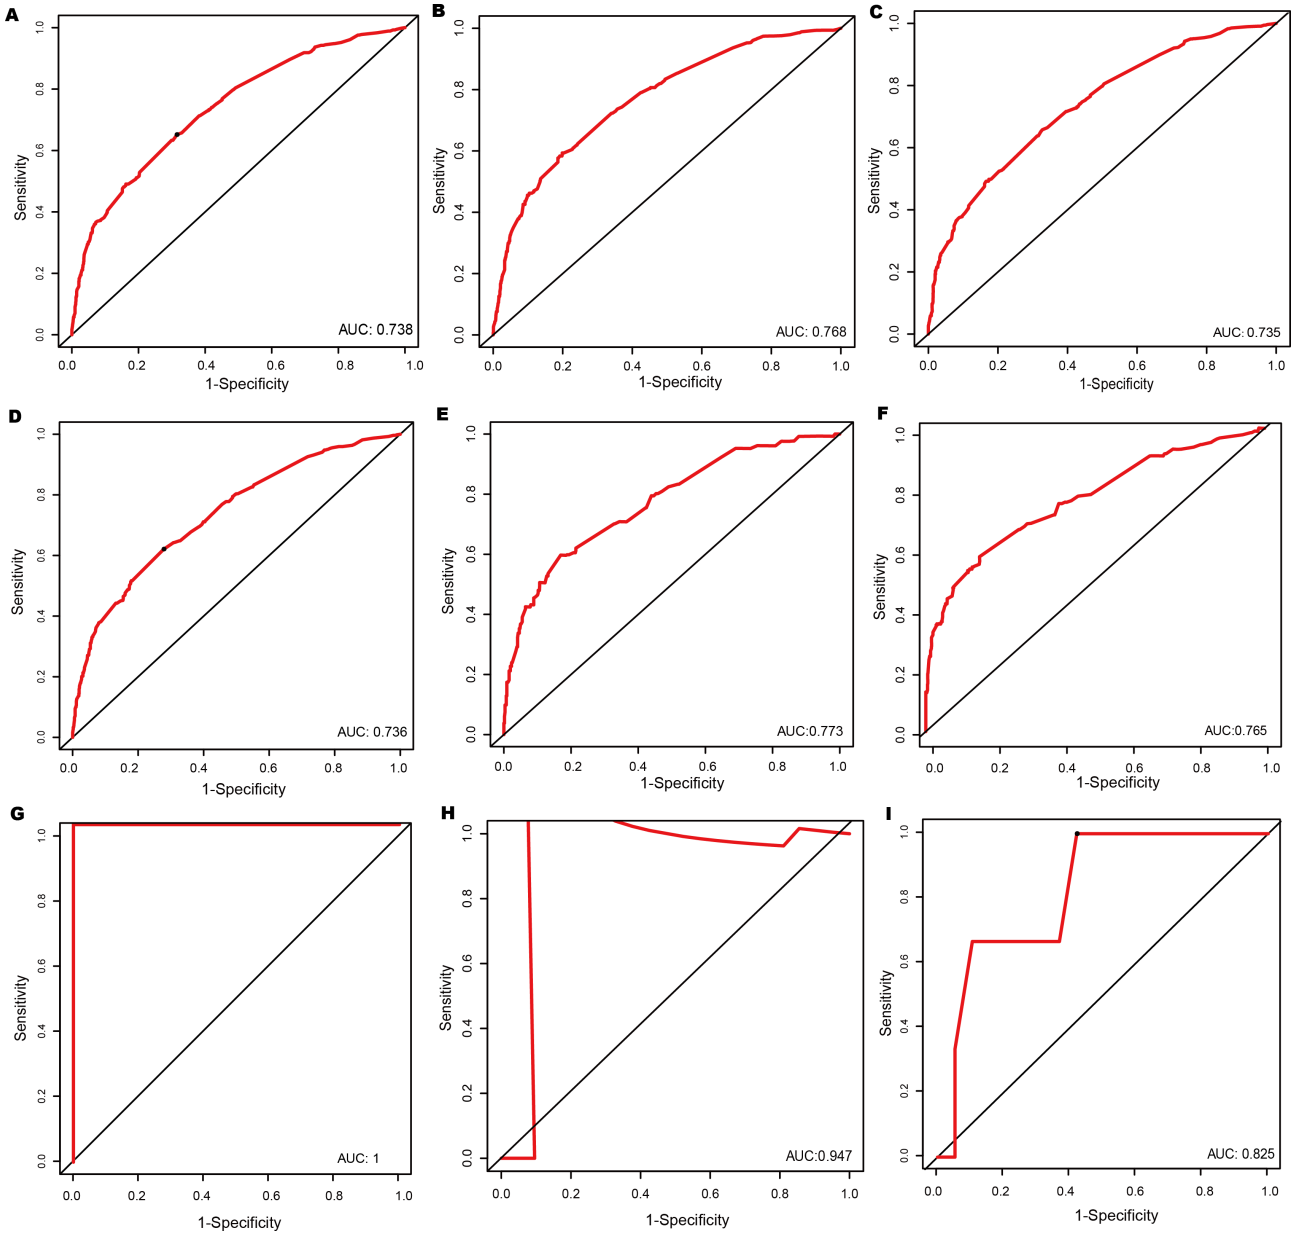


Figure 4. Calibration curve of 1-, 3-, and 5-year overall survival in the training set (A-C) and internal validation set (D-F). The errors bars represent the 95% CI of these estimates.

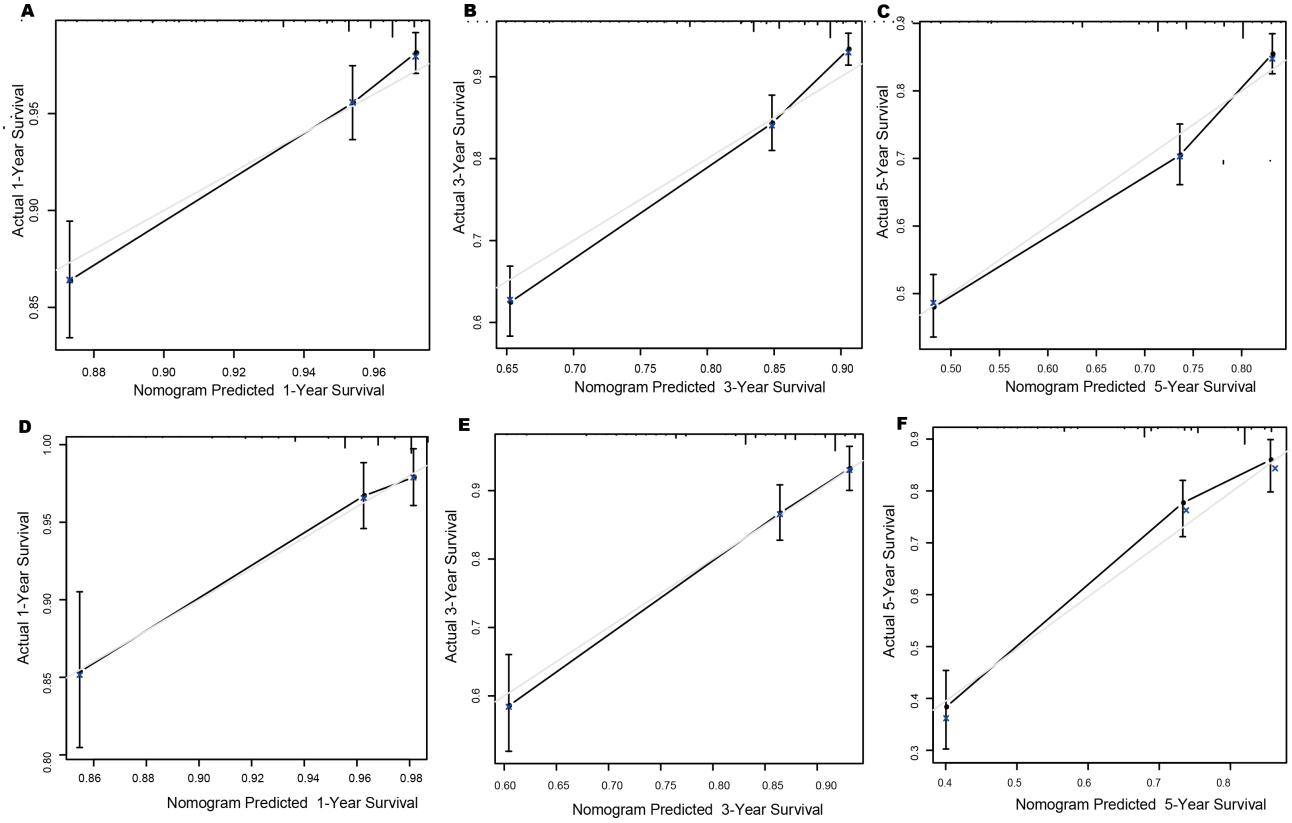

Figure 5. Decision curve analysis of 1-, 3- and 5-year survival in the training set (A) and the internal validation set (B).

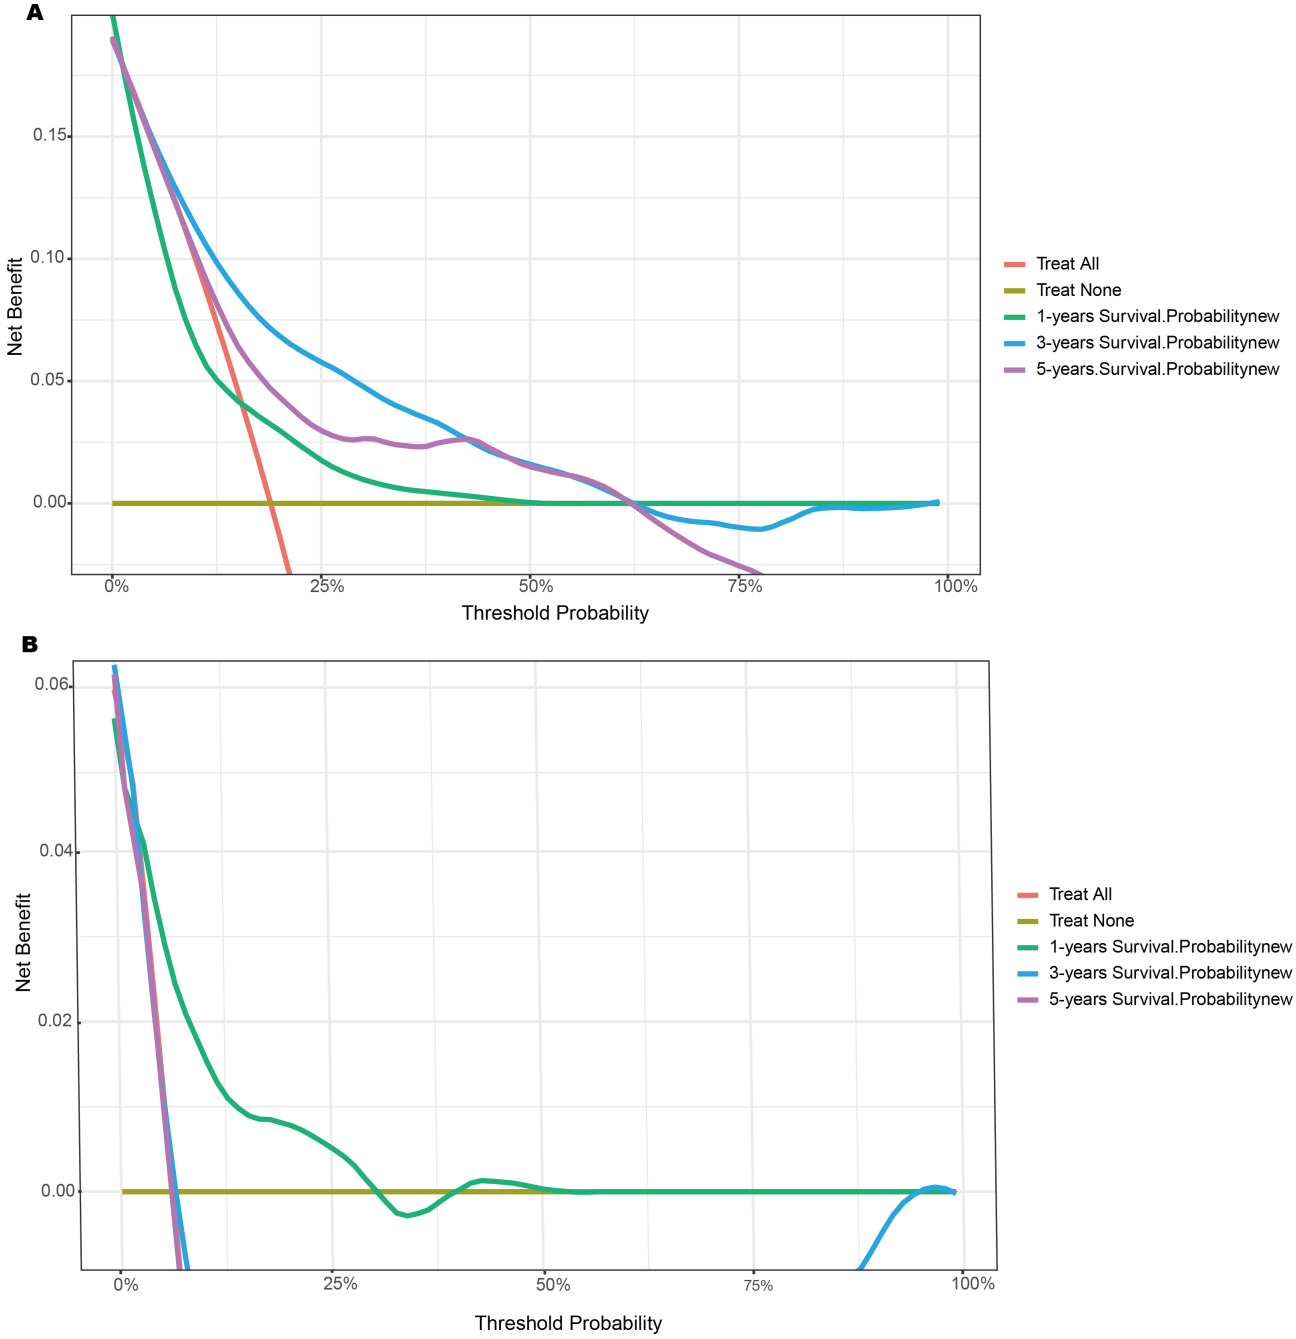

Nomogram Prediction Score Risk Stratification

Finally, risk stratification was conducted by calculating the nomogram total score of each individual in the training set (Table 3). After the cut-off values were determined using X-tile software, all patients with MBC were divided into 3 groups: low-risk group (points≤93), medium-risk group (93<points≤117), and high-risk group (points>117). The survival curves of each risk group were depicted using the Kaplan-Meier model in the training set (Figure 6A) and internal validation set (Figure 6B). A log-rank test was used to compare the differences between the groups to assess the accuracy of risk stratification on the basis of the nomogram score.

Table . Nomogram score of male breast cancer survival.

Variable	Points
Age	
≤60 years	0
>60 years	15
Surgery	
Yes	0
No	25
Marital status	
Unmarried	7
Married	0
T[a] stage	
T_0	4
T_1	0

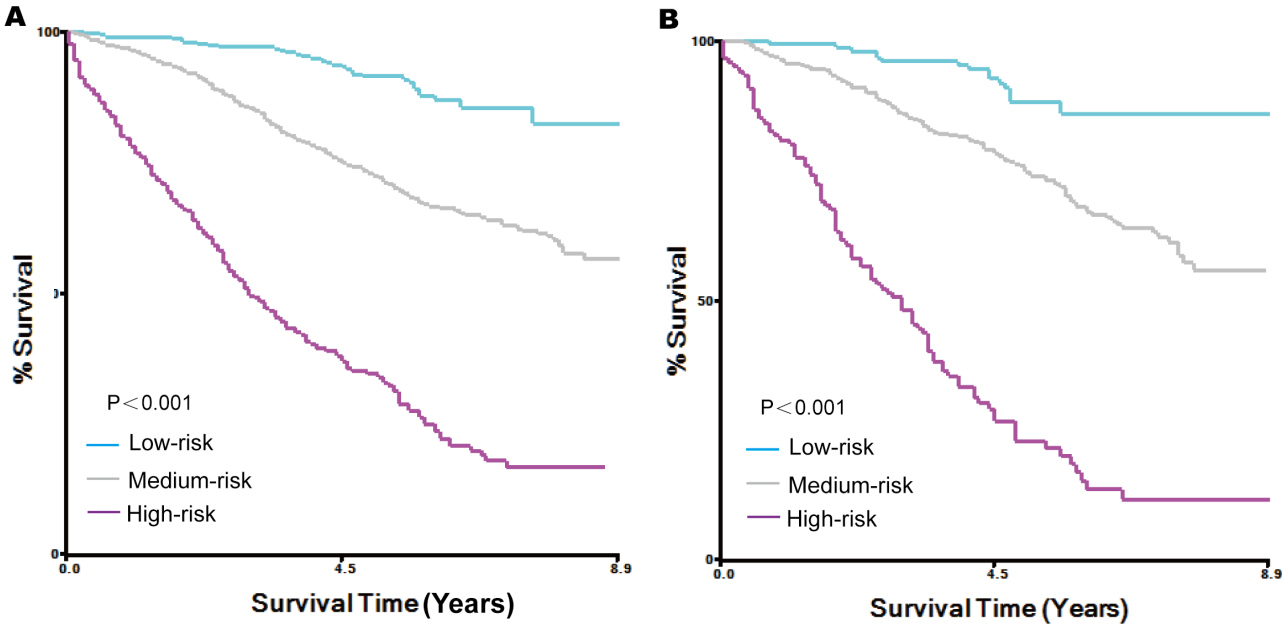
No	10
HER2[b] status	
Positive	8
Negative	0

[a]T: tumor.

[b]HER2: human epidermal growth factor receptor 2.

Figure 6. Analysis of survival based on risk stratification. Kaplan-Meier curve for patients categorized as low-risk, medium-risk, or high-risk in the training set (A) and internal validation set (B).



Discussion

Principal Findings

In this study, we developed a nomogram to predict survival in MBC based on the SEER database and validated it using both an internal validation dataset from this database and an external validation cohort from a single center. We identified 7 independent risk factors and incorporated them into the nomogram to predict the survival of patients with MBC. The results of both internal and external validation demonstrated that the nomogram exhibited good accuracy and discriminative power, confirming the robustness of the prediction model.

MBC has a low incidence and is a rare malignancy [24]. However, MBC exhibits a delayed onset, presents as a more advanced disease, and has a less unfavorable prognosis than female BC [25]. Due to its rarity, MBC is often overlooked in clinical practice. The assessment of prognosis in MBC holds considerable importance for facilitating the implementation of comprehensive treatment strategies. This study used the clinical data of 1595 patients with MBC from the SEER database to establish a nomogram for prognosticating the survival in MBC. The bootstrap method was used for internal validation, and external validation was performed in the hospital cohort. The ROC curve, C-index, and calibration curve were used to assess the discrimination and reliability of the nomogram. Additionally, the clinical benefit and application value of the nomogram were evaluated using the DCA curve. The findings demonstrated that the nomogram can accurately and individually predict the survival outcomes of patients with MBC. This predictive tool holds the potential for informing clinical decision-making and guiding the development of appropriate diagnostic and therapeutic strategies.

Previous studies analyzed the influencing factors of MBC survival by using univariate and multivariate Cox proportional hazards regression models [26,27]. Compared with traditional multivariate regression, least absolute shrinkage and selection operator (LASSO) regression is widely regarded as a superior approach for variable selection owing to its ability to mitigate model complexity, minimizing overfitting by incorporating a loss function or a penalty term into the objective function. In this study, the LASSO regression algorithm identified 7 variables (age, surgery, marital status, T stage, clinical stage, chemotherapy, and HER2 status) as factors that are associated with the prognosis of MBC. This detail has also been recognized in other studies [9,28]. Based on the aforementioned variables, a nomogram prediction model that significantly enhanced the clinical applicability within various clinical scenarios was developed. The nomogram exhibited good discrimination, consistency, and clinical validity in the training set and validation set. It may guide clinical decision-making for these patients more effectively.

Age was identified as a significant risk factor for the survival of patients with MBC in the nomogram, and individuals aged over 60 years had higher mortality, consistent with prior studies [28,29]. This finding may be related to the presence of more comorbidities in older patients [28]. Surgery and chemotherapy are essential for determining the prognosis of patients with MBC who are undergoing treatment, a finding that is similar to that of previous studies [30-32]. A recent study conducted by Wang et al [33] indicated that patients diagnosed with MBC who received surgery or chemotherapy exhibited a more favorable prognosis than individuals who did not undergo these treatments. The prognostic significance of marital status was observed, with unmarried patients exhibiting a poorer prognosis [34-36]. The reason for this result may be that unmarried patients with MBC experience more significant psychological distress, including feelings of sadness and anxiety, compared to married patients [37], and they may demonstrate greater adherence to treatment regimens [38], which could improve cancer management. Additionally, this study provided evidence to support the notion that the T stage and clinical stage are prognostic indicators for MBC [39,40]. Among the 7 parameters in the nomogram, the clinical stage showed the most significant influence on overall

survival, and patients with stages III and IV MBC had the worst prognosis. One study in Serbia showed that low initial disease stage and low tumor grade are independent predictors of a good prognosis in patients with MBC [41]. In addition, having a HER2-positive tumor is widely acknowledged as a significant prognostic factor for MBC, and this observation has been corroborated by other investigations [42-44].

In this study, the average age of onset of Chinese patients with MBC may be younger than that of patients in the SEER database, which is similar to the onset characteristics of female patients with BC [45]. In addition, the hospital exhibited a higher proportion of patients in the early T stage than the SEER database. The proportion of patients undergoing chemotherapy was significantly greater than that in the SEER database, contributing to the favorable prognosis observed in Chinese patients with MBC.

Constructing a nomogram for the survival of patients with MBC can be beneficial for medical staff to intuitively analyze the weight of risk factors and the corresponding survival probabilities of patients. These survival probabilities can be used as a basis for stratification. The patients were classified into 3 groups: low-, medium-, and high-risk. For example, a patient with MBC that is over 60 years old, is married, has undergone surgery and chemotherapy, has a T grade of T_2, has a tumor stage of II, and has a HER2-positive tumor, would have a total score of approximately 105, belonging to the medium-risk group for survival. Therefore, the medical staff should take relevant measures to timely manage and improve the prognosis of this patient. In clinical practice, the proposed model can be used to determine and evaluate the survival rate and prognosis of patients with MBC. This approach aims to provide personalized and accurate survival rate and prognosis and then develop targeted clinical decisions for patients with MBC.

Strength and Limitations

Our study has the following strengths. First, the existing prognostic models for BC have a focus on female BC, and little focus has been given to MBC. The study aims to develop a prognostic model specifically for this group. Second, the SEER database included a large and diverse cohort, ensuring robust and representative results. In addition, external validation using datasets from our own hospital further confirmed the model's accuracy and generalizability.

However, this study has some limitations. First, as a retrospective study, it is subject to selection bias. Second, important variables, such as endocrine therapy, BMI, and the cellular proliferation marker Ki-67, are not included in the SEER database, which may limit the accuracy and effectiveness of the nomogram. Finally, the external validation sample size in this study was limited, including only retrospective data from a single health care institution, and the predictive ability of the model for the Chinese population needs to be further verified using a large sample of data.

Future Directions

Future studies should consider incorporating data from multicenter cohorts to increase the sample size, thereby enhancing the accuracy and generalizability of survival prediction models for MBC. By collecting data from diverse geographic locations, researchers can ensure that the model captures a broader range of clinical variables, improving its robustness and applicability. Additionally, prospective cohort studies should be conducted to externally validate the model in real-world clinical settings and assess its practical utility in daily clinical decision-making for MBC. Furthermore, integrating additional datasets that include critical variables, such as BMI and the cellular proliferation marker Ki-67, would further strengthen the model's predictive power.

Conclusion

In summary, a nomogram was developed using 7 variables to predict the prognosis of patients with MBC, and age, surgery, marital status, T stage, clinical stage, and HER2 status were identified as independent risk factors for predicting the survival of patients with MBC. Internal and external verifications proved that the model has good accuracy and reliability. Thus, it could serve as an accurate and individualized tool that clinicians could use for decision-making.

Acknowledgments

The authors thank all the patients and institutions for participating in the study, especially for the open access to the SEER database.

Abstract

Background: Patients with cancer need coordinated care for both treatment and concurrent health conditions. This requires collaboration among specialists when using telemedicine services, emphasizing the importance of care continuity.

Objective: This study aimed to explore the effects of cross-sectorial video consultation involving oncologists, general practitioners, and patients with cancer on patients' perceived coordination of care, compared with usual care.

Methods: This study describes the primary outcomes from a 7-month follow-up of patients in the Partnership Project, a randomized clinical trial. Patients in the intervention group were randomized to receive a "partnership consultation," a shared video consultation with an oncologist, general practitioners, and the patient, in addition to their usual care. Questionnaires were completed for both groups at baseline and 7 months to assess the primary outcome, "global assessment of inter-sectorial cooperation," from the Danish questionnaire "Patients' attitude to the health care service." The questionnaire also included 2 single items and 5 index scales, examining patients' attitude toward cooperation in the health care system. Change in perceived global coordination from baseline to 7 months was compared between intention-to-treat groups using generalized estimating equations in a linear regression model.

Results: A total of 278 participants were randomized with 1:1 allocation, with 80 patients receiving the intervention. Further, 210 patients completed the questionnaire at baseline, while 118 responded at 7-month follow-up. The estimated difference in the primary outcome between usual care (−0.13, 95% CI −0.38 to 0.12) and intervention (0.11, 95% CI −0.11 to 0.34) was 0.24 (95% CI −0.09 to 0.58) and not statistically significant (*P*=.15).

Conclusions: Low rates of intervention completion and high levels of missing data compromised the interpretability of our study. While we observed a high level of global assessment of coordination, the estimated intervention effect was smaller than anticipated, with no significant difference in perceived coordination between control and intervention groups. Future studies should explore strategies like patient incentives to increase response rate and improve the evaluation of this innovative health care model.

Introduction

Health care systems increasingly use digital technology to improve quality of health care services across a spectrum of medical issues including critical conditions like cancer [1]. Notably, over the past 2 decades, there has been a growing deployment of telemedicine technologies, making a transformative shift in how health care is delivered and experienced [2].

Patients with cancer have distinctive medical requirements, including both cancer therapy and treatment of concurrent health conditions [3]. Addressing these needs involves engaging various specialties and health professionals, using specialized telemedicine care services, and ensuring continuity of care throughout and after cancer treatment. This necessitates a higher level of care coordination [4]. However, both patients and health care providers face challenges in coordinating care and communication patterns, as evidence by logistic issues such as technological problems which hinder effective telemedicine practices [5,6]. To mitigate such challenges, shared care models have been proposed as a promising approach [7]. These models allow patients to benefit from the expertise of specialists, while maintaining the care through the primary care providers. By bringing together the patients, general practitioners (GPs), and oncologist in a shared video consultation, telemedicine offers a powerful solution to improve care coordination. A recent study further supports the benefits of telemedicine as its ability to improve care coordination, and better management patients' health needs through enhanced communication [8]. Therefore, efforts to assist patients with cancer have shifted toward patient-centered communication approaches [6], so that over time, such approaches for these patients are rapidly expanding and diversifying [9]. Based on a previous study, these approaches may have varying impact on patients' outcomes and perceptions [9]. Furthermore, application of such approaches in combination with virtual consultations may have diverse effects on outcomes, as they may interact differently with each patient's unique health needs. This aligns with the health care providers' perspective, who advocate patient-centered approaches in cancer care [9]. Despite such widespread advocacy, there is limited consensus on definition and methods to achieve patient-centered care [9].

A previous meta-analysis on cancer care coordination suggests that implementation of cancer-care coordination approaches resulted in positive changes in majority of measured outcomes (eg, overall patients' experience on cancer care, quality of end-of-life care, etc). The study recommended the development of new intervention models and care coordination strategies to enhance patients' self-management [10]. Notably, none of the studies included in this meta-analysis applied a virtual intervention mode [10].

We hypothesized that virtual shared models involving specialists, primary care providers, and patients could more effectively address optimal outcomes for patients with cancer [3]. Hence, this study aims to investigate the effects of a shared video consultation including oncologists, GPs, and patients with cancer on the patients' perceived coordination of care.

Methods

Study Design

This study is a randomized controlled trial entitled "The Partnership Project' (PSP)" [11]. The protocol and details of the study have been published previously [11-13]. This paper now presents the primary outcome based on a 7-month follow-up survey on patients' participation in a shared video-based consultation.

Participants and Setting

All newly diagnosed patients with any type of cancer receiving treatment with chemotherapy for the first time at the Department of Oncology, Lillebælt Hospital, University Hospital of Southern Denmark were invited for the study. The eligibility criteria were age above 18 years, proficiency in speaking and reading Danish, and having an estimation from an oncologist indicating a survival time of more than 7 months.

Multimedia Appendix 1 provides an explanation of the initial sample size that was previously published [14]. Since patient inclusion matched the predetermined sample size, the trial was ended.

Usual Care

The control group was randomized to receive "usual care" in terms of standard information exchanging between the department of oncology and primary care. This involved sending an electronic summary letter to the GP after each visit to the department of oncology. GPs and the hospital can communicate by phone if needed. In addition, patients may reach out to their GP or a designated coordinator at the department of oncology.

Intervention

Patients in the intervention group were randomized to receive a "partnership consultation," which was a shared video consultation involving an oncologist, GP, and patients with cancer, alongside their "usual care." GPs were contacted only after obtaining patients' consent, and the GP had the option to refuse participation. Three to 6 weeks in advance, the sessions were scheduled during regular clinic hours. Patients were given the option to choose either the GPs' office or the oncologist's office for their consultations. In case the patient preferred to sit by the GP, the video consultation took place in that way, with the oncologist alone in his or her office at the hospital. GPs or oncologists may have had more than 1 patient in the intervention group. However, we do not have specific information about the individual oncologist for each patient in our database. The consultations were chaired by an oncologist within 12 weeks from the time of inclusion. Before the consultation, oncologists and GPs received information including a consultation guide with themes that may be relevant (Multimedia Appendix 2). Typically, the oncologist was assisted by an oncology nurse. A summary of the consultation was recorded in the hospital electronic patient record, shared with the GP, and accessible for the patient at an online portal (sundhed) for medical reports in Denmark.

Three to 6 weeks in advance, the sessions were scheduled during regular clinic hours. Patients were given the option to choose either the GPs' office or the oncologist's office for their consultations. In case the patient preferred to sit by the GP, the video consultation took place in that way, with the oncologist alone in his or her office at the hospital.

GPs or oncologists may have had more than 1 patient in the intervention group. However, we do not have specific information about the individual oncologist for each patient in our database.

The consultations were chaired by an oncologist within 12 weeks from the time of inclusion.

Prior to the consultation, oncologists and GPs received information including a consultation guide with themes that may be relevant (Multimedia Appendix 2). Typically, the oncologist was assisted by an oncology nurse.

A summary of the consultation was recorded in the hospital electronic patient record, shared with the GP, and accessible for the patient at an online portal (sundhed.dk) for medical reports in Denmark.

Randomization and Blinding

Following informed consent, patients were assigned in a 1:1 ratio through block randomization, with block sizes and sequences known only to the REDCap (Research Electronic Data Capture; Vanderbilt University) [15] data manager from our collaboration partners. The allocation was transparent for the patients, GPs, and oncologist. However, during baseline data collection, patients in the intervention group and enrolling nurse were kept blind of the randomization.

A project nurse at the research unit in the department of oncology conducted the randomization process and enrolled patients in the study following the patients' consent. Neither patients nor their GPs and oncologists in the intervention group were blinded to the patients' allocation status. Data analysts remained blinded to the allocation. GPs of patients in the control arm were not formally informed until they received the survey.

Primary Outcomes and Instruments

Patients were asked to complete questionnaires at baseline, and after 4 and 7 months. Upon arrival at the department of oncology, patients received information, a consent form, and a paper-based baseline questionnaire, which outpatient nurse collected after enrollment. Follow-up questionnaires were sent electronically using REDCap [15], which securely managed distribution and response collection. However, patients could request paper-based follow-up with prepaid return envelope.

An overview of primary and secondary outcomes can be found in Multimedia Appendix 3. The primary outcome included the single item "global assessment of inter-sectorial cooperation," which was part of the Danish questionnaire "Patients' attitude to the health care service" [14]. The English questionnaire "The patient cancer diary" [16] served as the basis for the 26-item Danish questionnaire. The adaptation was done based on interviews with Danish cancer patients and caregivers [17] and the English questionnaire template [16]. The questionnaire was chosen because it measures the study's aim, patients' perceptions of cross-sector cooperation, and has previously been used in a Danish cancer study [14]. Single items were scored on a 5-point Likert scale from strongly agree (1) to strongly disagree (5). The "not relevant" category was coded as missing.

This questionnaire comprises also 2 other single items and 5 index scales (secondary outcome; Multimedia Appendix 3), examining patients' attitude toward the cooperation in the health care system. There is no manual available for the questionnaire; however, 2 papers have been published that describe the validation and usage of the questionnaire [14,17]. For the 5 subscales, at most 1 missing was replaced by the mean of the other items in the corresponding subscale. A subscale was coded as missing if more than 1 single item in the scale were missing. The direction of the answer scale varied depending on the item. For instance, in the case of the primary outcome, a low score indicated a positive attitude toward the question, while for secondary outcomes (eg, global feeling of left in limbo), a high score indicated a positive attitude. However, for analysis purpose, all items were aligned so that a higher value indicated a positive attitude toward the questions. Primary and secondary outcomes were measured at the following time points: baseline, 4, and 7 months after baseline. Coding was done separately for each time point.

Other Parameters

Demographic data for patients including age, gender, education, marital status, having child, work status, comorbidity, diagnosis or cancer type were assessed through questionnaire which was completed by patients at baseline.

Deviation From the Protocol in Statistical Analyses

As outlined in the published protocol [11], the original statistical analyses plan aimed to conduct a simple group comparison at 7 months using *t* tests or Wilcoxon rank-sum tests. However, a deviation from the initial analysis strategy was decided due to the large amount of missing data associated with the primary variable at 7 months.

Definition of Intervention and Control Groups for Analysis

The main analysis strategy followed the intention-to-treat (ITT) approach, defining groups by random allocation (control and intervention). As a second approach, we defined 2 as-treated grouping approaches. First, we split the intervention group by degree of intervention fidelity: 1 group had the intervention as defined by protocol, the second did not receive the intervention due to technical issues, while the third did not receive the intervention for other reasons. Then, as-treated $group_1$ (AT1) comprised patients completing the video consultations; this group was compared with patients who did not receive the intervention (randomized to control or $subgroup_1$ or $subgroup_2$). As-treated $group_2$ (AT2) comprised patients with planned video consultations, regardless of completion due to technical reasons (AT1 and $subgroup_1$); this group was compared with patients randomized to controls and $subgroup_2$. As-treated groups were defined post hoc. Unless stated explicitly otherwise, we based the group definition on the ITT approach.

Revised Statistical Analysis

As a first step, we compared the change from baseline to 7 months between the 2 groups, as defined by allocation (ITT), through a linear regression model. This model was applied to measurements at both baseline and 7 months, using generalized estimating equations (GEE) to account for within-patient clusters. Robust variance estimation was used, and the group difference was modeled as time-by-group interaction. Similar estimates were presented for both post hoc and defined as-treated approaches. No additional covariates were considered in this primary analysis. The GEE approach was chosen to ensure

robustness of the statistical methods in the presence of missing data. Analyses specified in the protocol were also reported, restricted to complete cases. A corresponding analysis strategy was followed for secondary outcomes. Data analyses was done using Stata version 17 [18], and the significance level was set at 5%.

Ethical Considerations

Statement Regarding Human Subject Research Ethics Review

The Regional Ethics Committee on Biomedical Research in Denmark (S-20142000 - 138) and the Danish Data Protection Agency (2014-41-3534) peer reviewed and approved the study.

Informed Consent Descriptions

At the Oncological Department, Vejle Hospital, Denmark, outpatient clinic nurses obtained informed consent from patients for the PSP. Patients provided consent to participate in the randomized controlled trial, the video recordings, and the user perspective assessments on the same consent form. The consent forms were securely stored at the Clinical Research Unit, Department of Oncology, Vejle Hospital. The unit of randomization was the patient. Therefore, according to Danish law and the instructions of the Regional Ethics Committee on Biomedical Research, consent from GPs was not required. However, out of courtesy and to show consideration for their workload, oral consent was obtained from GPs when their patients were allocated to the intervention group. Before the study's start, written information about the trial was sent to all GPs in the Region of Southern Denmark. If a GP declined to participate, their patients were not invited to join the study.

GPs for patients in the control group were not contacted and were therefore unaware of their patients' participation in the study until they were asked to complete a questionnaire 4 months after the patients' inclusion.

Privacy and Confidentiality Protection Description

Data security in video consultations is essential. Patients demonstrate a high level of trust regarding data security, as they trust the health care staff using the technology. To ensure this trust, all video consultations were conducted on the Region of Southern Denmark's secure videoconference servers using virtual meeting rooms. These servers provide a highly secure connection with no third-party data processing, and meeting rooms could only be accessed by the participating parties. Before a video consultation, patients may have discussed confidential matters, such as alcohol consumption or smoking, which they had not shared with all health care providers. This could place patients in a dilemma. To address this, the intervention guide for oncologists and GPs includes a note to handle such situations sensitively.

Compensation Details

No compensation was provided to patients or oncologists. GPs were reimbursed through the standard payment system of the Region of Southern Denmark for participating in video consultations with a specialist at the hospital. The agreement used existing provisions for cross-sector cooperation and discharge follow-up. GPs received a fee for video consultations based on the time spent: €48 (at the time of the study, the exchange rate was approximately €1=US $1.10; fee number 4670) for up to 30 minutes and €97 (fee number 4669) for consultations exceeding 30 minutes. Therefore, they did not receive any additional payment for participation, nor were they paid by the study for their involvement in the video consultations. Furthermore, GPs were compensated for completing the questionnaires. Payment was provided by the Region of Southern Denmark and corresponded to one module (€18 at the time for the trial), equivalent to the payment for a standard patient consultation in their clinic.

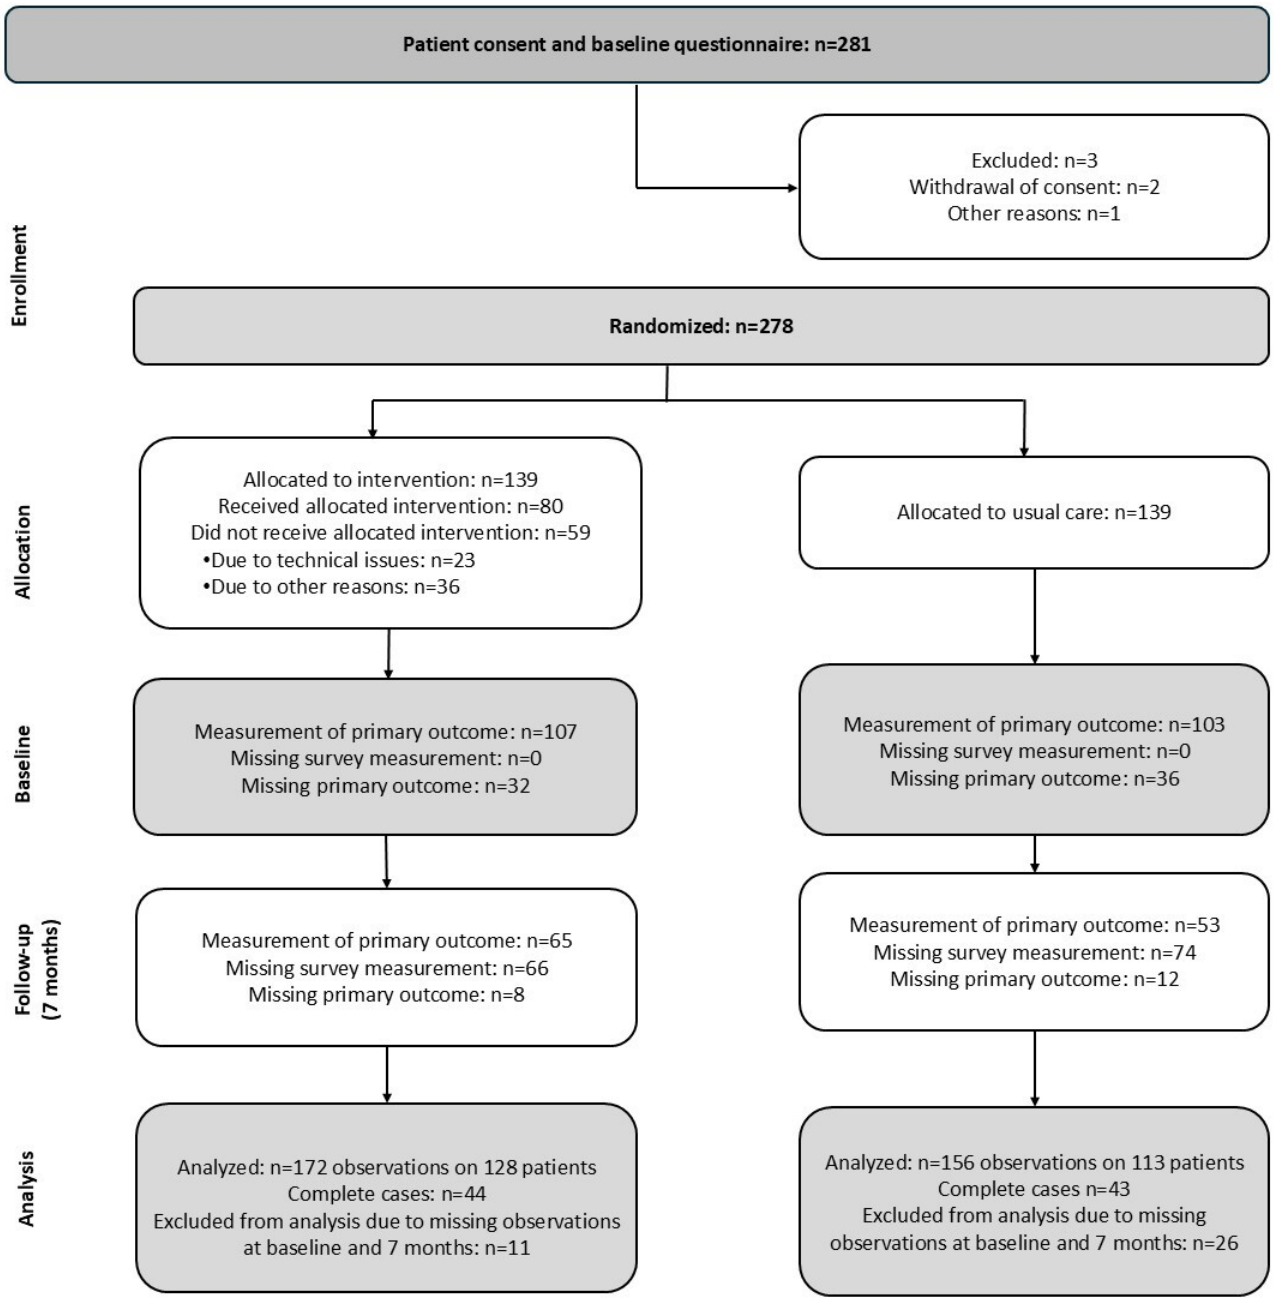
Results

Recruitment and Participant Flow

The patients were included between June 2016 and November 2019. In this study, 281 patients initially agreed to participate. Three patients were excluded due to withdrawal of the consent or other reasons. In total, 278 patients were randomized; 139 patients were allocated to the intervention group and another 139 to the control group. However, due to the following reasons, only 80 patients received the intervention as intended: GP refused participation for 22 patients; in 15 cases, IT failed; and for 8 patients, there were administrative (scheduling) issues. A total of 8 patients died before intervention, 3 patients were too ill, and 3 did not wish to participate in the intervention. See Figure 1 for the CONSORT (Consolidated Standards of Reporting Trials) flow diagram [19] (Checklist 1).

An overview of the GP-patient relationship can be found in Multimedia Appendix 4 to provide additional context.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram.



Baseline Data

As shown in Table 1, patients in the intervention and control groups had similar baseline characteristics. However, comorbidity was more frequent in the control group (58.3% vs 46.8%) than in the intervention group.

Table . Baseline characteristics of patients in the intervention and control groups.

Characteristics		Total (N=278), n (%)	Control group (n=139), n (%)	Intervention group (n=139), n (%)
Age (years), mean (SD)		65.2 (10.6)	63.8 (11)	66.6 (10)
Sex				
	Male	155 (55.6)	77 (55.4)	78 (56.1)
	Female	123 (44.4)	62 (44.6)	61 (43.9)
Education				
	Primary and upper secondary school	176 (63.3)	85 (61.1)	88 (63.3)
	Further education	76 (27.3)	41 (29.5)	35 (25.2)
	Higher education	16 (5.8)	7 (5)	9 (6.5)
Marital status				
	Single or missing[a]	81 (29.1)	48 (34.5)	33 (23.7)
	Married or residing with a companion	197 (70.9)	91 (65.5)	106 (76.3)
Children living at home				
	No children at home or missing[a]	244 (87.8)	120 (86.3)	124 (89.2)
	Children at home	34 (12.2)	19 (13.7)	15 (10.8)
Work status				
	Employed	89 (32)	46 (33.1)	43 (30.9)
	Public benefits	15 (5.4)	9 (6.5)	6 (4.3)
	Retired or missing[a]	174 (62.6)	84 (60.4)	90 (64.7)
Comorbidity				
	No	132 (47.5)	58 (41.7)	74 (53.2)
	Yes	146 (52.5)	81 (58.3)	65 (46.8)
Diagnosis or cancer type				
	Breast	33 (11.9)	17 (12.2)	16 (11.5)
	Gynecological	13 (4.7)	4 (2.9)	9 (6.5)
	Lung	106 (38.1)	53 (38.1)	53 (38.1)
	Gastrointestinal	110 (39.6)	56 (40.3)	54 (38.8)
	Other	16 (5.8)	9 (6.5)	7 (5)
	Incident cancer (yes or missing[a])	255 (91.7)	126 (90.6)	129 (92.8)

[a]There were less than 3 patients with missing information on marital status, number of children at home or work status, and 6 patients with missing information on incident cancer. These patients were grouped with the indicated categories.

Numbers Analyzed

In Table 2, an overview of the missing data for the primary outcome at different time points in both control and intervention groups is presented. Over time, there was a decline in participation in both the control group (38% at 7 months vs 74% at baseline) and the intervention group (47% at 7 months vs 77% at baseline), based on 278 randomized patients. In the ITT analyses, 172 observations on 128 patients from the intervention group and 156 observations on 113 patients from the control group were included. A total of 11 patients (intervention) and 26 patients (control) were excluded from the analysis due to missing observations at both baseline and 7 months.

A total of 59 participants failed to have the intervention as intended, due to technical problems or other reasons. Based on the subgroup analyses, the subgroup$_1$ had a higher percentage (78.3%) of nonmissing values, which gradually dropped to 39.1%% and 34.8% at the subsequent time points (Table 2). The subgroup$_2$ displayed a comparable pattern of missing data at various time points (83.8%, 35.1%, and 24.3%, respectively).

Table . Overview of the missing data for the primary outcome in both control and intervention groups at baseline and follow-up.

Group	Baseline					4 months				7 months			
	Total, n	Data available, n (%)	Data[a] missing, n (%)	Not relevant[b], n	Missing[c] survey, n (%)	Data available, n (%)	Data missing, n (%)	Not relevant, n	Missing survey, n (%)	Data available, n (%)	Data missing, n (%)	Not relevant, n	Missing survey, n (%)
Total	278	210 (75.5)	68 (24.5)	51	0	138 (49.6)	27 (97)	14	113 (40.6)	118 (42.4)	20 (7.2)	0	140 (50.4)
$Group_1$[d]	139	103 (74.1)	36 (25.9)	27	0	61 (43.9)	15 (10.8)	7	63 (45.3)	53 (38.1)	12 (8.6)	—[e]	74 (53.2)
$Group_2$[f]	139	107 (77)	32 (23)	24	0	77 (55.4)	12 (8.6)	7	50 (36)	65 (46.8)	8 (5.8)	—	66 (47.5)
$Subgroup_1$[g]	23	18 (78.3)	5 (21.7)	—	0	9 (39.1)	3 (13)	—	11 (47.8)	8 (34.8)	<3 (8.7)	—	13 (56.5)
$Subgroup_2$[h]	36	31 (83.8)	6 (16.2)	—	0	13 (35.1)	2 (5.4)	—	22 (59.5)	9 (24.3)	<3	—	27 (73)

[a]Data missing: the primary variable was absent, while other sections might have been answered.

[b]Not relevant: the primary variable was answered as “not relevant”; this is part of the data missing category.

[c]Missing survey: the entire questionnaire was missing for a specific time point.

[d]$Group_1$: randomized as control.

[e]Not applicable.

[f]$Group_2$: randomized as intervention.

[g]Intervention group was divided into the following subgroups based on reasons for not receiving the intervention. $Subgroup_1$: not received intervention due to technical problems.

[h]$Subgroup_2$: not received intervention due to other problems.

Outcomes and Estimations

Table 3 shows patients’ attitudes toward the cooperation between the primary sector and the department of oncology. The estimated within-group changes in the primary outcome between baseline and follow-up were −0.13 (95% CI –0.38 to 0.12) in the control group and 0.11 (95% CI −0.11 to 0.34) in the intervention group. The between-group difference was estimated as 0.24 (95% CI −0.09 to 0.58; *P*=.15). This suggest that, based on perceived global coordination, there was no noticeable differences between the ITT groups from the beginning to 7-month follow-up.

Table . Patients' attitudes toward the cooperation between the primary sector and the department of oncology.

Outcomes		Group	Baseline		7 months		Estimated change (95% CI)	Group-time interac-tion,(95% CI)	*P* value
			n	Mean (SD)	n	Mean (SD)

[a]ITT: intention-to-treat approach.

[b]C: control.

[c]Not applicable.

[d]I: intervention.

[e]AT: as-treated groups (AT1 and AT2).

[f]LIMBO: global feeling of left in limbo.

[g]FAM-Global: global support from general practitioner.

[h]FAM-Information: information from general practitioner subscale.

[i]FAM-Care: support from general practitioner subscale.

[j]FAM-knowledge: general practitioners' knowledge regarding treatment subscale.

In the context of the AT1 approach (Table 3), comparing patients who received the intervention with those who did not, the estimated within-group change in the primary outcome between baseline and follow-up was −0.10 (95% CI −0.33 to 0.12) in the control group and 0.17 (95% CI −0.08 to 0.42) in the AT1 group. The between-group difference was estimated as 0.27 (95% CI −0.07 to 0.61; *P*=.12).

For the AT2 approach (Table 3), the estimated within-group change in the primary outcome between baseline and follow-up was −0.09 (95% CI −0.33 to 0.14) in the control group and 0.10 (95% CI −0.15 to 0.34) in the AT2 group. The estimated between-group difference was 0.19 (95% CI −0.15 to 0.53) with the corresponding *P*=.27.

The estimated within-group and between-group changes in all secondary outcomes including 2 single items and 5 subscales showed no significant differences between the ITT groups from the beginning to 7-month follow-up (Table 3).

We also conducted the originally specified analyses on the primary outcomes at 7 months only, comparing intervention and control group in the ITT, AT1, and AT2 approach. The findings are presented in Table 4, showing similar *P* values.

Table . Additional analyses on primary outcomes at 7 months.

	Difference of means at 7 months (IV[a] minus control) (95% CI)	*P* value for *t* test	*P* value for Wilcoxon rank-sum test (exact)
ITT[b]	0.285 (−0.085 to 0.655)	.13	.11

AT2[d]	0.283 (−0.085 to 0.652)	.12	.12

[a]IV: intervention group.

[b]ITT: intention-to-treat approach.

[c]AT1: as-treated group$_1$.

[d]AT2: as-treated group$_2$.

Discussion

Principal Findings

This study found that the addition of a cross-sectoral video consultation to usual care did not significantly impact patients' perceived coordination of care. Both intervention and control groups showed high levels of perceived coordination at both time points, with no statistically significant differences over time or between the groups.

Comparison With Previous Work

Based on our knowledge, video consultation has been used for patients with cancer for many years [20]. A recently published systematic review showed virtual consultation over time has been developed and improved in many ways (eg, delivery platforms and stakeholder engagement) [21]. Despite this improvement, comparing our findings was challenging due to the lack of studies on patients' attitudes toward care coordination in multidisciplinary video consultations, which involve patients with cancer, oncologists, and GPs simultaneously.

A newly released scoping review revealed that specialist collaborations with GPs and patients can increase the effective quality of care in the follow-up phase for patients with cancer [22]. This comprehensive review did not report findings on patients' attitudes toward care coordination. Therefore, we believe that in this area, more studies should be initiated to capture a better picture of care coordination from patients' perspective and subsequently enhance the quality-of-care coordination for patients with cancer.

Limitations of the Study

Several limitations should be considered. First, a large percentage of participants in the intervention group did not proceed with the intervention, mostly due to GP refusal to participate, administrative or technical issues. This could affect the generalizability of our findings to the broader population or specific subgroups due to potential selection bias. However, it should be noted that the trial was carried out before the introduction of a standard, clinically available video setup during the COVID-19 pandemic. Since then, the technical aspects of video-based communication in everyday life and health care consultations have improved dramatically [23]. However, challenges related to establishing online meetings, achieving relevant views of all participants, and ensuring efficient sound quality persist. These issues can occasionally make scheduled consultations impracticable [24]. These facts highlight the relevance of the results of "the Partnership Study" and underscore the importance of our learnings for future health care, particularly in adapting the evolving landscape of telemedicine. Second, the low completion rate for video consultation (58%) and high rate of missing data in our study affected the quality of our data, consequently limited our ability to draw definitive conclusion on effectiveness of the intervention. As a result, we focused on addressing challenges encountered. Third, a considerable amount of missing data for the primary outcome at the 7-month time point might impact the statistical power and consequently lead to a lack of significance in our findings. Several factors can be contributed to this issue (eg, the lengthy follow-up period, focus of the process evaluation on the intervention rather than barriers to participants retention, inadequate assessment of the follow-up duration during the pilot test, reliance on survey distribution alone, particularly during COVID-19 pandemic). In addition, it is possible that a ceiling effect influenced the intervention's lack of superiority, as coordination scores were substantially higher, compared with findings from another department [14]. Fourth, the choice of single primary outcome variable that included "not relevant" response option may have constrained the depth of data obtained, because patients who had not experienced collaboration might have selected "not relevant." Fifth, in the as-treated analysis, some patients from the intervention group were combined with patients from the control group, which assumes that the nonreceipt of the intervention was unrelated to individual patients' characteristics. Therefore, our findings should be interpreted with caution. Sixth, the study does not provide insight into why some patients marked the primary outcome as "not relevant." It is possible that these patients had no experience with collaboration at the time of the survey, and this uncertainty limits our understanding of the factors contributing to missing data and how they may influence the study's conclusions. The handling of responses marked as "not relevant" as missing data may not actually capture patients' experiences, that raise concerns about the interpretation of the results (eg, generalizability of findings related to collaboration experiences).

Future Direction

Despite the lack of significant differences on primary and secondary outcomes of care coordination, limitations of our study may have implications for the research community in their future studies. For instance, our findings stress the need for further exploration into structural and engagement factors to strengthen future interventions.

The low completion rate for video consultation may indicate logistical and engagement challenges. Therefore, we encourage researchers in their future similar intervention to implement strategies that enhance patients' engagement and improve data completion rate.

We encountered challenges such as potential power problem in reaching statistical significance. Despite this, we believe it is crucial to delve deeper into these findings and explore underling factors. This could provide valuable insights for development of more effective interventions in future. Findings may also highlight more involvement of patients to address their concerns related to care coordination and consequently enhance their experiences with the health care system. Furthermore, the findings highlight the importance of continually evaluation of health interventions to understand the impacts over time and make timely and necessary improvement, particularly where we have clearly identified specific problems or challenges, like decreased patients' satisfaction.

Conclusion

Our study, conducted before the COVID-19 pandemic, found that the shared video consultation model, involving patients with cancer, oncologists, and GPs, did not result in a statistically

significant difference in patients' perceived coordination of care between the control and intervention groups. We suggest that technical issues impacting the intervention implementation and the potential ceiling effect may have contributed to these results. Therefore, we emphasize the necessity for additional evaluation of the conceptual notion of uniting patients with cancer, oncologists, and GPs, particularly considering the advancements in techniques, the adoption of virtual communication, and the expanding role of GPs in cancer care. Further exploration of specific aspects of care coordination may provide additional insights into areas for improvement in this innovative health care model. This study highlights the complexity of implementing collaborative health care interventions and emphasizes the importance of ongoing evaluation of the intervention to optimize patients' care coordination in cancer management. In addition, future research should focus on evolving trends in virtual communication among professionals and the public, as we think that leveraging post-COVID virtual communications could improve future health care interventions.

Acknowledgments

Financial support was provided by the Danish Cancer Society (R156-A10018-16-S49), the Region of Southern Denmark (14/39009), ML Jørgensen and GunnarHansen Foundation, and the University of Southern Denmark. The sponsors played no role in the planning, design, or implementation of the study. ChatGPT (version 3.5, OpenAI) was used to edit the first draft of the manuscript. However, the next versions were edited and revised by the authors.

Authors' Contributions

TBT and LHJ conceived the study, participated in study design and data collection, and revised the manuscript. JS, JJS, and DGH conceived the study, participated in study design, and revised the manuscript critically. MMS and SW analyzed the data, participated in the interpretation of the results, and revised the manuscript. FB made substantial contributions to the interpretation of the results and wrote the manuscript. All authors commented on and approved the final version of the paper.

Abstract

Background: The lack of information and awareness about clinical trials, as well as misconceptions about them, are major barriers to cancer clinical trial participation. Digital and social media are dominant sources of health information and offer optimal opportunities to improve public medical awareness and education by providing accurate and trustworthy health information from reliable sources. Infotainment, material intended to both entertain and inform, is an effective strategy for engaging and educating audiences that can be easily disseminated using social media and may be a novel way to improve awareness of and recruitment in clinical trials.

Objective: The purpose of this study was to evaluate whether an infotainment video promoting a clinical trial, disseminated using social media, could drive health information seeking behaviors.

Methods: As part of a video series, we created an infotainment video focused on the promotion of a specific cancer clinical trial. We instituted a dissemination and marketing process on Facebook to measure video engagement and health information seeking behaviors among targeted audiences who expressed interest in breast cancer research and organizations. To evaluate video engagement, we measured reach, retention, outbound clicks, and outbound click-through rate. Frequencies and descriptive statistics were used to summarize each measure.

Results: The video substantially increased health information seeking behavior by increasing viewership from 1 visitor one month prior to launch to 414 outbound clicks from the video to the clinical trial web page during the 21-day social media campaign period.

Conclusions: Our study shows that digital and social media tools can be tailored for specific target audiences, are scalable, and can be disseminated at low cost, making it an accessible educational, recruitment, and retention strategy focused on improving the awareness of clinical trials.

Trial Registration: ClinicalTrials.gov NCT03418961; https://clinicaltrials.gov/study/NCT03418961

KEYWORDS

cancer clinical trials; digital media; social media; infotainment; recruitment; education and awareness; edutainment; public engagement; cancer; lack of information; social media; health information; medical awareness; video series; public audience; low cost; research participants

Introduction

A total of 90% of Americans use social media [1] and over 40% of Americans watch web-based videos daily [2]. Digital media is a dominant source of health information, with 50% to 80% of internet users searching for health information on the web [3-5]. Unfortunately, misinformation and disinformation threaten the quality of health information available [6,7]. Given public interest in accessing web-based health information and the potential public reach, social media offers an optimal opportunity for public health practitioners and health care providers to improve public medical awareness and education

by providing accurate and trustworthy sources of health information. However, the attention span of social media audiences is typically short. Thus, digital content has to be engaging, meaningful, and attention grabbing [8,9].

One specific area of health care that can benefit from such strategies is cancer clinical trials. The lack of information and awareness about clinical trials, coupled with significant misconceptions about them, persist as major barriers to cancer clinical trial participation [10]. Only 3% to 5% of patients with cancer participate in clinical trials and over 50% of Americans report that the lack of awareness and information are major reasons for low participation rates [11-13]. This is the case despite one study reporting that 56% of respondents preferred the internet as a source of information about clinical trials [11].

Infotainment is defined as the delivery of broadcast material intended to entertain, engage, and inform [14]. Examples of this form of media in our culture vary but can include news talk shows, podcasts, and social media influencers. Its use may be a novel way to improve awareness and alleviate misconceptions that act as barriers to clinical trials. Moreover, since many trials close due to the lack of accrual [15], infotainment delivered on social media may be a viable clinical trial recruitment strategy.

The purpose of this study was to evaluate whether a clinical trial promotional video, disseminated on social media, could effectively drive health information seeking behaviors and, as a result, increase awareness about the clinical trial. To accomplish this goal, we instituted a dissemination and marketing process to measure health information seeking behaviors among public audiences on social media.

Methods

Video Development and Content

A clinical trial promotional video represents an underexplored method for engaging with targeted audiences. The trial we chose to feature was Southwest Oncology Group (SWOG) S1501, “Prospective Evaluation of Carvedilol in Prevention of Cardiac Toxicity in Patients with Metastatic HER-2+ Breast Cancer, Phase III.” [16] Collaborating with a clinical trial recruitment and retention specialist from the SWOG, we selected this trial based on its relative ease of understanding and to improve accrual performance. Our research team collaborated with the SWOG Cancer Research Network, a global cancer research community that designs and conducts federally funded clinical trials; The Hope Foundation for Cancer Research, a public charity with the mission of raising and contributing funds for the treatment and prevention of cancer; and Digital Health Networks (DHN), a media production studio and streaming service that specializes in producing, marketing, and distributing health care content and collecting viewership data.

The creation of the video was informed by the World Health Organization (WHO) Strategic Communications Framework [17] and the social cognitive theory [18]. The WHO Strategic Communications Framework asserts that effective health communications should be accessible, actionable, credible and trusted, relevant, timely, and understandable [17]. The social cognitive theory asserts that learning occurs in social contexts where individuals can influence and be influenced by others and their environment [18]. Using the social cognitive theory framework in the context of the health information seeking behavior of social media users, Zhang et al [19] found that (1) information quality, social media platform quality, and user experience have a significant positive effect on emotional arousal; (2) user experience, social support, and emotional arousal have a significant positive effect on self-efficacy; and (3) emotional arousal and self-efficacy have a significant positive effect on social media users’ health information seeking behavior. To this end, we sought to develop high-quality, emotionally engaging digital media that delivers accurate information about a clinical trial, with an embedded URL hyperlink to learn more information from a credible source, on a highly used social media platform to increase awareness about the trial and motivate users to seek additional information.

To ensure the information, language, and imagery provided in the video was medically accurate, a project steering committee, who chose the clinical trial of focus, was formed, consisting of SWOG Digital Engagement committee members, study investigators, and a representative from The Hope Foundation for Cancer Research. The video concept, script, and storyline were initially developed by a research team member who is also a filmmaker; cancer survivor; and long-standing member of the SWOG’s Digital Engagement, Adolescent and Young Adult, and Patient Advocates committees. The outline, script, and questions were submitted to the project steering committee for feedback, and regular communication was maintained throughout the process in multiple feedback loops. Updates were provided during committee meetings and were presented at biannual SWOG group meetings with storyboards, a rough and final cut of the video, and initial project results. This inclusive process encouraged committee members and meeting attendees to provide feedback, ask questions, and be part of the creative filmmaking process. The steering committee viewed the video and gave the final sign off prior to launch.

To engage audiences, the video attempted to parody cliché tropes often seen in pharmaceutical commercials. In our fictional video, Beth, a more relatable portrayal of a woman who is visually worn down from cancer treatment, is watching television and flipping through channels as a highly stylized, cheery commercial for the S1501 study comes on. It is akin to pharmaceutical advertisements commonly broadcast on television. Beth, feeling the side effects of treatment, dozes off but is awakened when she, in disbelief, is interacting with the commercial’s characters and asking the physicians questions about clinical trials and specifically the S1501 study. In this narrative structure, Beth’s role is to serve as a vehicle to convey the pertinent information the study team hoped the audience would learn. In the end, Beth is brought back to her reality. Appearing cautiously interested in the trial, she presumably seeks out further information about it. Video screenshots showing the main character (Beth), a paradoxical patient with cancer, and a scene with clinicians explaining the clinical trial to Beth is provided in Figure 1. The full video is available in Multimedia Appendix 1.

Figure 1. Video screenshots showing (left) the main character (Beth), (middle) a paradoxical patient with cancer, and (right) a scene with clinicians explaining the clinical trial to Beth.

Ethical Considerations

The National Cancer Institute Cancer Prevention and Control Central Institutional Review Board reviewed the recruitment/patient education video (protocol version dated June 6, 2019; study ID: S1501) and granted approval on July 24, 2019. The expedited review was conducted in accordance with the federally defined categories of expedited review stated in 45 CFR 46.110(b)(1)(ii) and 21 CFR 56.110(b)(2). The dissemination strategy was not determined to be human subjects research.

The study protocol and study materials for video 2 were reviewed and approved by the National Cancer Institute Institutional Review Board. We are publishing the results from a marketing strategy to see how it could inform research. The data presented herein represent information collected for the purposes of social media marketing, and we did not collect individual-level data. Rather, we collected population-level data to inform the effectiveness of marketing research. Institution review board approval and informed consent were not obtained as no human subject data were collected on an individual level, no data were obtained through interaction with any individuals, and we cannot ascertain the identities of individuals to whom data the belonged. The data collection was conducted by a medical entertainment company, and instead of keeping the data internal, we are sharing this information with the wider medical audience.

Identifiable individuals have granted consent for the use of their image in this publication.

Dissemination and Marketing Methods

For this work, we disseminated the video on Facebook (Meta) because of its number of users and daily interactions, campaign optimizations, low cost of advertising, analytic capabilities, and sophisticated audience targeting that identifies specific audiences based on users' interests and previous interactions [20]. DHN ran and coordinated the marketing campaign using their Facebook advertising account, and video performance data were captured using Facebook's advertising management platform.

The video ran daily from September 7, 2021, to September 27, 2021. The video length was 5 minutes and 10 seconds long, and the production cost was US $4000. Projects with a similar method would cost significantly more to produce; however, costs were kept at a minimum by filming at three free locations and DHN's in-kind production services, which included directing, editing, color correction, music and graphic licenses, and voice-over narration. The video consisted of two different campaigns. The purpose of the first campaign was to identify the optimal target audience who might be more engaged with the video content. For the first campaign, which was conducted from September 7, 2021, to September 10, 2021, we used Facebook targeting algorithms to disseminate the video to audiences who expressed interests in breast cancer research and to audiences who expressed interest in breast cancer organizations. We compared the engagement (number of views and outbound clicks to the S1501 clinical trial web page) between each group. The audience interested in breast cancer research had greater engagement and was chosen as our target audience for the second campaign, which ran from September 10, 2021, to September 27, 2021. Our second campaign disseminated the video to individuals who met the look-alike audience profile, which is an audience who shared similar indicated interests, characteristics, and behaviors to individuals who were interested in breast cancer research. This technique helped us identify potentially more engaged users who would more likely be interested in our video; this is where we spent the majority of our US $1000 advertising campaign budget.

Measures and Analysis

To evaluate video engagement, we measured four outcomes:

- *Reach* was defined as the number of people exposed to the video during the advertisement campaign.
- *Retention* was defined as the length of time that individuals watched the video. We measured the number of individuals who watched for at least 3 seconds and at intervals of 25%, 50%, 75%, and 100%.
- *Outbound clicks* were defined as the number of clicks on a "learn more button" under the video that was linked to the SWOG Cancer Research Network's S1501 patient information web page.
- *Outbound click-through rate* was defined as the percentage of times viewers saw a video and performed an outbound click.

We calculated frequencies and descriptive statistics to summarize each outcome.

Results

Reach, retention, outbound clicks, and outbound click-through rate are summarized in Table 1.

Table . Educational video engagement outcomes for the S1501 study.

Outcomes	Value
Length	5 min 10 s
Video reach, n	61,456
Length of video watched, n (% retained)	
At least 3 seconds	47,566 (77.4)[a]
25%	226 (0.5)[b]
50%	84 (37.2)[c]
75%	44 (52.4)[d]
100%	34 (77.3)[e]
Outbound clicks, n	414
Percentage increase in visitors	41,300
Outbound click-through rate, n/N (%)	414/61,456 (0.67)

[a]N=61,456.
[b]n=47,566.
[c]n=266.
[d]n=84.
[e]n=44.

In our first campaign, we found that the group interested in breast cancer research performed better with video views and outbound clicks than the group interested in breast cancer organizations (9764 views and 54 outbound clicks vs 2513 views and 25 outbound clicks). This informed our target look-alike audience for the second campaign. The video had a total reach of 61,456 individuals. A total of 77.4% (47,566/61,456) watched at least 3 seconds and among those, 0.5% (226/47,566) watched 25% of the video. The number of viewers dropped at each consecutive retention interval; however, the retention rate increased at each consecutive retention interval past 25%. A month prior to launch, the S1501 patient information clinical trial web page had only 1 visitor. During the 21-day dissemination campaign period, the video received 414 outbound clicks from Facebook to the patient-facing clinical trial page. The outbound click-through rate was 0.67% (414/61,456).

Discussion

Principal Findings

We found that with an active digital marketing dissemination strategy and a very modest marketing budget (US $1000), the video substantially increased health information seeking behavior by increasing visitors to the SWOG's S1501 patient information page from only 1 web page visit the month prior to campaign initiation to 414 web page visits during the campaign. Although research organizations have passively disseminated clinical trial–related content on social media platforms, this very active and intentional campaign to engage with the public is promising as it relates to clinical trial recruitment and illustrates the utility of using engaging digital content coupled with social media marketing as an effective strategy for clinical trial recruitment. Additionally, our study shows that digital and social media tools can be disseminated to specific target audiences at low cost, making it an accessible educational, recruitment, and retention strategy for clinical trials.

Our study shows that the health information seeking behavior of social media users may be impacted by immediate attrition. The average social media video watch time benchmark is 10 seconds, and Facebook's best practices suggest that video advertisements be 15 seconds or less [9]. Considering that the average Facebook video watch time is 4.6 seconds [21], our video (5 min 10 s), which only retained 0.5% of 3-second viewers, illustrates the challenge of delivering important information in a succinct way. In addition to video length and the lack of engagement, another factor that may have contributed to this decline is that although we used Facebook algorithms to target individuals who were interested in breast cancer research and breast cancer organizations, it is plausible that only a subset of these individuals were interested in learning about clinical trials. Interestingly, viewership retention across other intervals was drastically higher (37.2% retention at the 50% interval, 52.4% retention at the 75% interval, and 77.3% retention at the 100% interval). Viewers who watched 25% of the video (1 min 17 s) tended to stay for the duration of the video, suggesting an engaged audience. Although a drop-off in retention is expected, our data suggest that the first 45-60 seconds may be the most instrumental in capturing audiences and maximizing engagement among viewers who are interested in the video topic area. It is noteworthy that the number of outbound clicks (n=414) was substantially higher than the number of people who watched the full video (n=34). This indicates that certain individuals were compelled to seek further health information before they finished watching the video, although we do not know when during the duration of the video that they performed an outbound click. These data show that *completely watching* the video was not necessarily correlated with seeking additional information

(ie, outbound clicks) and further illustrates the importance of delivering compelling and engaging content within the first 60 seconds of video content. Finally, the outbound click-through rate (0.67%) was below the average outbound click-through rates of 0.89% across industries and 0.83% in health care, but above the 0.45% average in science [22,23], which may also provide insight into the level of engagement in the video.

In this burgeoning and ever-evolving social media landscape, digital marketing and its advanced analytical techniques allow researchers to engage with patients and potential trial participants where they are already consuming health information. It also allows for real-time data on what worked well and what did not work well, so that researchers can pivot their tact and capitalize on the most effective strategies to engage with an audience that is more likely to be interested in or eligible for their trials. Although this medium is novel in oncology, social media analytics have proven to be successful in informing engagement strategies for other industries, and future oncology research could benefit from these digital tools.

Comparison to Prior Work

Our research is aligned with limited previous studies that found web-based infotainment videos to be an effective approach in increasing public understanding about science and health care among web-based health information seekers [14,24,25]. One study found that narrative infotainment videos compared to expository videos resulted in more likes by viewers without a university education and better information recall among viewers [14]. Study findings that assess study recruitment with and cost effectiveness of social media advertisement for study enrollment are mixed [26-29]. A recent scoping review reported that 9 (27%) out of 33 studies that used both social media and traditional methods for recruitment to clinical trials achieved or exceeded their enrollment target, and one study reported that social media outperformed other recruitment methods. The review did not specify how many of these studies used video as a recruitment method, highlighting the need for more research to understand if infotainment videos disseminated on social media to target audiences may be a significant strategy for facilitating clinical trial recruitment [24,30].

Limitations

Our study is limited in that we were not the administrators of the S1501 study's public facing web page and did not retain detailed information about visitor activities or characteristics (eg, location, frequency, and time of visit). This limited our ability to ascertain if each outbound click was from a unique or repeat visitor and our ability to understand additional characteristics that may have impacted health information seeking behaviors. We recommend that research teams be the administrators of both outgoing (where the advertisement played) and incoming (where visitors were sent) visitor analytics to maximize data utility. Additionally, our study did not test whether outbound clicks resulted in actual recruitment; therefore, we cannot make assertions that the increase in web page visitors contributed to study recruitment [31]. In addition, our video did not include subtitles in English nor any other language. Since 85% of Facebook users interact with the platform with the sound off [32], future digital media engagement studies should consider the use of language subtitles as this feature might facilitate engagement and accessibility with a larger audience. Another limitation is that our target audience indicators may not have been the most appropriate indicators to capture audiences interested in a specific clinical trial. We cannot ascertain that outbound clicks reached potential participants, as opposed to other individuals who may have been interested in clinical trials (eg, researchers and providers). More specialized or specific targeting (eg, those meeting study criteria) should be used to capture audiences who would most benefit from and be engaged by video media for specific clinical trials. Finally, we tested engagement using only one social media platform. Social media platforms vary in the average length of videos and average video watch times. It is plausible that social media platforms that are more conducive to longer viewing times (eg, YouTube) may have yielded different viewership and engagement outcomes.

Future Directions

Emerging internet technologies and social media are widely used sources for health information. Our study found that infotainment disseminated using social media is a useful and effective approach in relaying complex health information, motivating interested viewers to seek additional health information, and driving public audiences to credible and reliable sources of information. It has promising utility in facilitating recruitment and retention strategies for cancer clinical trials and generating increased awareness about clinical trials among patients and the general public.

Acknowledgments

We would like to acknowledge the Southwest Oncology Group (SWOG) Cancer Research Network, The Hope Foundation for Cancer Research, Digital Health Networks, and Dr Justin Floyd and Dr Monika Leja for supporting this work. This research was supported by funding from The Hope Foundation for Cancer Research and SWOG Cancer Research Network National Institutes of Health/National Cancer Institute (NCI) award U10CA180888 and was also supported by Digital Health Networks. VH is supported by the NCI (K01CA248852, P30CA015704, UGCA286954, and U54CA132381), the American Cancer Society, and the Andy Hill Cancer Research Endowment Fund. Abstract

Background: Breast cancer is the most common malignant tumor and the fifth leading cause of cancer death worldwide, imposing a significant disease burden in China. Mammography is a key method for breast cancer screening, particularly for early diagnosis. Douyin, a popular social media platform, is increasingly used for sharing health information, but the quality and reliability of mammography-related videos remain unexamined.

Objective: This study aimed to evaluate the information quality and reliability of mammography videos on Douyin.

Methods: In October 2023, a search using the Chinese keywords for “mammography” and “mammography screening” was conducted on Douyin. From 200 retrieved videos, 136 mammography-related videos were selected for analysis. Basic video information, content, and sources were extracted. Video content was assessed for comprehensiveness across 7 categories: conception, examination process, applicable objects, precautions, combined examinations, advantages, and report. Completeness was evaluated using a researcher-developed checklist, while reliability and quality were measured using 2 modified DISCERN (mDISCERN) tool and the Global Quality Score (GQS). Correlations between video quality and characteristics were also examined.

Results: Among the video sources, 82.4% (112/136) were attributed to health professionals, and 17.6% (24/136) were attributed to nonprofessionals. Among health professionals, only 1 was a radiologist. Overall, 77.2% (105/136) of the videos had useful information about mammography. Among the useful videos, the advantages of mammography were the most frequently covered topic (53/105, 50.5%). Median values for the mDISCERN and GQS evaluations across all videos stood at 2.5 (IQR 1.63 - 3) and 2 (IQR 1 - 2), respectively. Within the subgroup assessment, the median mDISCERN score among the useful and professional groups stood at 2 (IQR 2 - 3) and 3 (IQR 2 - 3), respectively, surpassing the corresponding score for the unhelpful and nonprofessional groups at 0 (IQR 0 - 0) and 0 (IQR 0 - 0.75; $P<.001$). Likewise, the median GQS among the useful and professional groups was evaluated at 2 (IQR 1.5 - 2) and 2 (IQR 1 - 2), respectively, eclipsing that of the unhelpful and nonprofessional groups at 1 (IQR 1 - 1) and 1 (IQR 1 - 1.37; $P<.001$). The GQS was weak and negatively correlated with the number of likes ($r=-0.24$; $P=.004$), comments ($r=-0.29$; $P<.001$), and saves ($r=-0.20$; $P=.02$). The mDISCERN score was weak and negatively correlated with the number of likes ($r=-0.26$; $P=.002$), comments ($r=-0.36$; $P<.001$), saves ($r=-0.22$; $P=.009$), and shares ($r=-0.18$; $P=.03$).

Conclusions: The overall quality of mammography videos on Douyin is suboptimal, with most content uploaded by clinicians rather than radiologists. Radiologists should be encouraged to create accurate and informative videos to better educate patients. As Douyin grows as a health information platform, stricter publishing standards are needed to enhance the quality of medical content.

breast cancer; mammography; Douyin; information quality; social media; video; DISCERN; Global Quality Score; web-based education; cancer screening; health information; medical content

Introduction

Breast cancer is the second most common cancer and the fourth leading cause of cancer death worldwide. In 2022, an estimated 2.3 million new cases (11.6% of all cancer cases) were diagnosed, and 666,000 deaths (6.9% of all cancer deaths) occurred, and the number of new breast cancer cases is projected to reach 4.4 million by 2070 [1]. Among women, breast cancer is the most commonly diagnosed cancer, and it is the leading

cause of cancer deaths globally. In 2022, breast cancer accounted for approximately 15.4% of all deaths in global female patients and 6.9% of all cancer deaths [2]. As the second most common cancer in Chinese women, an estimated number of 357,200 new cases of breast cancer occurred in 2022, accounting for approximately 7.4% of total new cancer cases in China and 15.5% of global breast cancer cases [3]. The World Health Organization recently launched the Global Breast Cancer Initiative with the aim of reducing breast cancer mortality by fostering timely diagnosis and adequate treatment and patient management [4]. The 5-year survival rate in patients with early breast cancer is very high; thus, early screening, detection, and treatment are important [5]. Measures used for breast cancer screening in the "Guidelines for breast cancer diagnosis and treatment by China Anti-Cancer Association (2024 edition)" include mammography, ultrasonography, clinical breast examination, breast self-examination, and magnetic resonance imaging. Guidelines recommend that the starting age for breast cancer screening in the general risk population is 40 years. However, for people at high risk of breast cancer, the start of screening may be earlier than the age of 40 years. For those older than 70 years of age may consider opportunistic screening [6]. Mammography is one of the most effective methods for breast cancer screening, especially for early breast cancer diagnosis, and it has been a major contributor to the decline in breast cancer mortality rates [7-9]. At present, there is no nationwide screening program for breast cancer in China. A cross-sectional survey conducted with a convenience sample of 494 Chinese women indicated that participation in screening practices ranged from 27.5% for BSE, 36.4% for clinical breast examination, 23.5% for mammography, and 40% for ultrasonography [10].

With the widespread adoption of internet technology, web-based platforms have become a primary channel for accessing public information. As of June 2023, China's internet user base has expanded to 1.079 billion, with short video users reaching 1.026 billion, representing 95.2% of the total internet population [11]. The short video format has emerged as a dominant force in the new media landscape, due to its low barrier to entry, concise format, and rapid dissemination capabilities, making it one of the most preferred mediums for health information acquisition. While TikTok stands as a global social media giant, operating in over 160 countries with more than 1 billion monthly active users [12], its services are unavailable in China due to internet regulations. Instead, Douyin (the Chinese equivalent of TikTok, literally meaning "shaking sound") has established itself as a national phenomenon, boasting over 750 million daily active users and ranking among the country's most popular applications [13]. The platform's influence on health communication is particularly noteworthy. The Douyin Health Science Data Report indicates that daily health science content reaches more than 200 million users as of March 2023 [14]. This trend is further supported by data from the 2023 Douyin Health Lifestyle New Paradigm White Paper, which reveals that during the first half of 2023, the platform hosted more than 10 million creators specializing in health care knowledge content [15]. Notably, industry reports highlight that 42% of Douyin's user base comprises individuals aged 40 years and older [16], suggesting a significant engagement of mature audiences with health-related content on the platform.

Mammography screening often evokes feelings of anxiety and discomfort among patients, prompting many to seek preparatory information and clarification through social media platforms. High-quality educational videos can serve as valuable resources in this context, potentially contributing to improved health outcomes. Research evidence underscores the effectiveness of video interventions in promoting mammography screening. A study focusing on Chinese immigrant women demonstrated that culturally adapted videos, developed based on the health belief model, significantly enhanced screening intentions, breast cancer knowledge, risk perception, and understanding of mammography benefits [17]. Furthermore, empirical evidence indicates that brief preprocedure video interventions can substantially increase both physician referrals for screening mammography and patient compliance with screening completion [18]. These findings highlight the potential of video-based educational tools in addressing patient concerns and facilitating informed decision-making regarding breast cancer screening.

Despite the growing reliance on social media for health information, significant challenges persist regarding the reliability and accuracy of such content. The diverse backgrounds of content creators and viewers, coupled with the absence of robust verification mechanisms, make it difficult to assess the quality and credibility of health-related information on these platforms [19]. A comprehensive systematic review of reviews revealed that the prevalence of health misinformation on social media ranges from 0.2% to 28.8% [20], posing substantial risks to users. Exposure to inaccurate health information through videos may lead to severe consequences, including delays in seeking appropriate care or even life-threatening situations [21,22]. Previous research has extensively evaluated the quality of health-related content on traditional video-sharing platforms like YouTube and TikTok, covering various medical topics such as cervical spondylosis, gastroesophageal reflux disease, and broken heart syndrome [23-25]. However, the examination of mammography-related video content remains limited. To date, only 2 studies have assessed the quality of mammography videos on YouTube [26,27], both of which identified inconsistencies in the quality of information presented. Notably, no studies have yet evaluated mammography-related content on Douyin, the Chinese counterpart of TikTok. This research gap underscores the need for systematic evaluation of mammography-related short videos on Douyin, particularly considering its massive user base in China. Therefore, this study aims to comprehensively assess the quality and reliability of mammography-related short videos on Douyin by analyzing their characteristics, sources, and content.

Methods

Search Strategy

To minimize the bias introduced by personalized recommendation algorithms, we used 3 tactics: creating a new Douyin account specifically for evaluation, disabling Douyin's personalized recommendations to eliminate differential content

recommendations caused by user habits, and banning access to mobile location services. All videos were viewed without any actions such as downloading, liking, commenting, collecting, or sharing. Evaluation tasks were carried out by 2 qualified radiologists (Chuangying Zhu and HY) from the division of radiology in a tertiary teaching hospital.

The keywords "钼靶" ("mammography" in Chinese) and "钼靶检查" ("mammography screening" in Chinese) were searched in the Douyin app on October 22, 2023, with no limits placed on the release time. Douyin offers 3 ways to filter videos: overall ranking, most recent, and most likes. We used the overall ranking mode to retrieve the top 100 videos because most consumers use this default sorting option. We chose the threshold number of 100 for 2 reasons. First, Douyin's search function takes topic relevance into account; the most relevant mammography videos tend to appear at the top of the results list, and it is difficult to observe any pertinent videos when the results exceed 100. Second, most general health users apply the "least effort" principle when searching for information on the web; they tend to concentrate on the top search results. In this study, we included videos directly related to mammography. The exclusion criteria were videos not in Chinese, videos not related to mammography, duplicate videos, videos shorter than 10 seconds in length, and videos that were unavailable.

Data Collection

A Microsoft Excel spreadsheet was created by a researcher for data collection. Video information analyzed in this study was the identity of the uploader; the duration in seconds; the number of "likes" as indicated by the heart icon; the number of comments, saves, and shares the video received; and the number of days since the video was uploaded.

We divided the videos into 2 main groups according to whether the uploaders were professional or nonprofessional. Professional videos consisted of videos uploaded directly by board-certified physicians, health channels, and hospital channels. Most health channels and hospital videos were narrated by doctors. Nonprofessional videos included those uploaded by patients and other individuals.

Quality and Reliability Assessment

The quality and reliability of the video were evaluated based on the following criteria: the accuracy and comprehensiveness of the content, the clarity and fluency of information delivery, and the overall usefulness of the video to its intended audience.

No validated tools for assessing mammography video content are available in the literature. According to the American Cancer Society recommendations for the early detection of breast cancer [28] and the China Anti-Cancer Association Breast Cancer Diagnosis and Treatment Guide and Standard (2024 Edition) [6], 2 qualified radiologists (Chunmin Zhu and RH) from the division of radiology in a tertiary teaching hospital, with more than 10 years of experience in the radiological profession, developed a completeness checklist to assess the quality of mammography video content (Table 1). The 7 categories cover most aspects of mammography: conception, examination process, applicable objects, precautions, combined other examinations, advantages, and report. A video was awarded 1 point in each domain if it mentioned the content listed in Table 1, resulting in a final score ranging from 0 to 11. A score of 0 indicated that there was no accurate content in any of the 7 earlier-mentioned areas of mammography, whereas a score of 11 indicated that a video contained accurate information in all areas. Videos were then further categorized as useful or unhelpful according to the final score. Videos with a score of 0 were considered unhelpful if they only dealt with personal experiences or testimonies without providing any scientific content, whereas useful videos received a score of ≥1. We used the modified DISCERN (mDISCERN) tool and the Global Quality Score (GQS), previously used in many studies of Douyin, as instruments to assess the quality of information in each video.

Table . Completeness checklist.

Content	Description
Conception	1. Basic principles: mention that a mammogram is done with a machine designed to look only at breast tissue, with low-dose x-rays.
	2. Radiation: mention that mammogram exposes the breasts to small amounts of radiation.
Examination process	3. Remove upper body clothing: mention that the patient must remove clothing above the waist to have a mammogram.
	4. Pain: mention that it might feel some discomfort when the breasts are compressed, and for some women, it can be painful.
	5. Two positions for unilateral breast: mention that x-ray pictures of each breast are taken, typically from 2 different angles.
Applicable objects	6. Age: mention when to start a mammogram and how often.
	7. High risk: mention that women who are at high risk for breast cancer based on certain factors should get a mammogram every year, typically starting before 40 years of age.
Precautions	8. Special period: mention that women who are in a special period, such as preparing for pregnancy, pregnant, or breastfeeding, and those who have undergone breast augmentation surgery need to inform doctor in advance. Mammograms are generally not recommended for pregnant women. It is best to schedule the examination about a week after her period.
Combined other examinations	9. Mention that breast ultrasound and magnetic resonance imaging can help find some breast cancers that cannot be seen on mammograms.
Advantage	10. Mention that mammograms have a great advantage in detecting calcifications.
Report	11. Mention that what is the breast imaging reporting and data system.

The DISCERN criteria are a validated scoring system developed by an Oxford University research team to assess the information quality and reliability of content related to consumer health information on treatment options [29]. The mDISCERN tool was modified by Singh et al [30] and is based on a 5-point Likert scale that examines goals, reliability of information sources, bias, areas of uncertainty, and additional sources. According to the mDISCERN score, the reliability of video content is considered good for a DISCERN score of >3 points, moderate for a DISCERN score of 3 points, and poor for a DISCERN score of <3 points.

The GQS, which was developed by Bernard et al [31], is a 5-point Likert scale used to assess the quality of a video based on the flow of information, completeness of the information presented on a particular topic, and usefulness of information to patients. A GQS of 1 is considered very poor, 2 is considered poor, 3 is considered fair, 4 is considered good, and 5 is considered excellent. The detailed information for mDISCERN and GQS is available on the web as in Multimedia Appendices 1 and 2.

Before starting to score the videos, radiologists first reviewed the official DISCERN and GQS instructions and referred to a simplified Chinese version [32], the latter is more adapted to the Chinese language and culture. To ensure consistency, prescoring discussions were mandatory. After reaching a consensus on the first 20 videos, the evaluators independently reviewed the subsequent entries. The original scores of the 2 radiologists (C Zhou and HY) were independently recorded. The scores of mDISCERN and GQS given by the 2 researchers (C Zhou and HY) were averaged to obtain an overall score, which was then used in the analysis. Any disagreements about the completeness checklist were resolved by consensus.

Statistical Analysis

SPSS (version 27.0; IBM Corp) was used for data entry and analysis. Data are summarized as frequency (n) and percentage (%) for categorical variables and median (IQR) for ordinal variables. The normality of the data was analyzed using the Shapiro-Wilk test. Because the data were not normally distributed, the Mann-Whitney *U* test was used to compare the continuous variables between the 2 groups. Cronbach α coefficients were used to calculate the agreement between the 2 researchers. Spearman correlation tests were used to assess relationships between parameters. The correlations were interpreted based on the magnitude of the Spearman correlation coefficient (r), with the following thresholds used as a guide to describe the strength of the relationships: $r<0.1$ is considered a negligible correlation, $0.1\leq r<0.4$ is a weak correlation, $0.4\leq r<0.7$ is a moderate correlation, $0.7\leq r< 0.9$ is a strong correlation, and $r\geq 0.9$ is a very strong correlation. These thresholds were adapted from conventional guidelines for interpreting correlation coefficients, as discussed in the literature [33]. Differences were considered statistically significant at a P value of <.05.

Ethical Considerations

No clinical data, human specimens, or laboratory animals were involved in this study. All information used in this study was obtained from publicly released Douyin videos, and none of the data involved personal privacy. In addition, the study did not involve any interaction with users; therefore, no ethics review

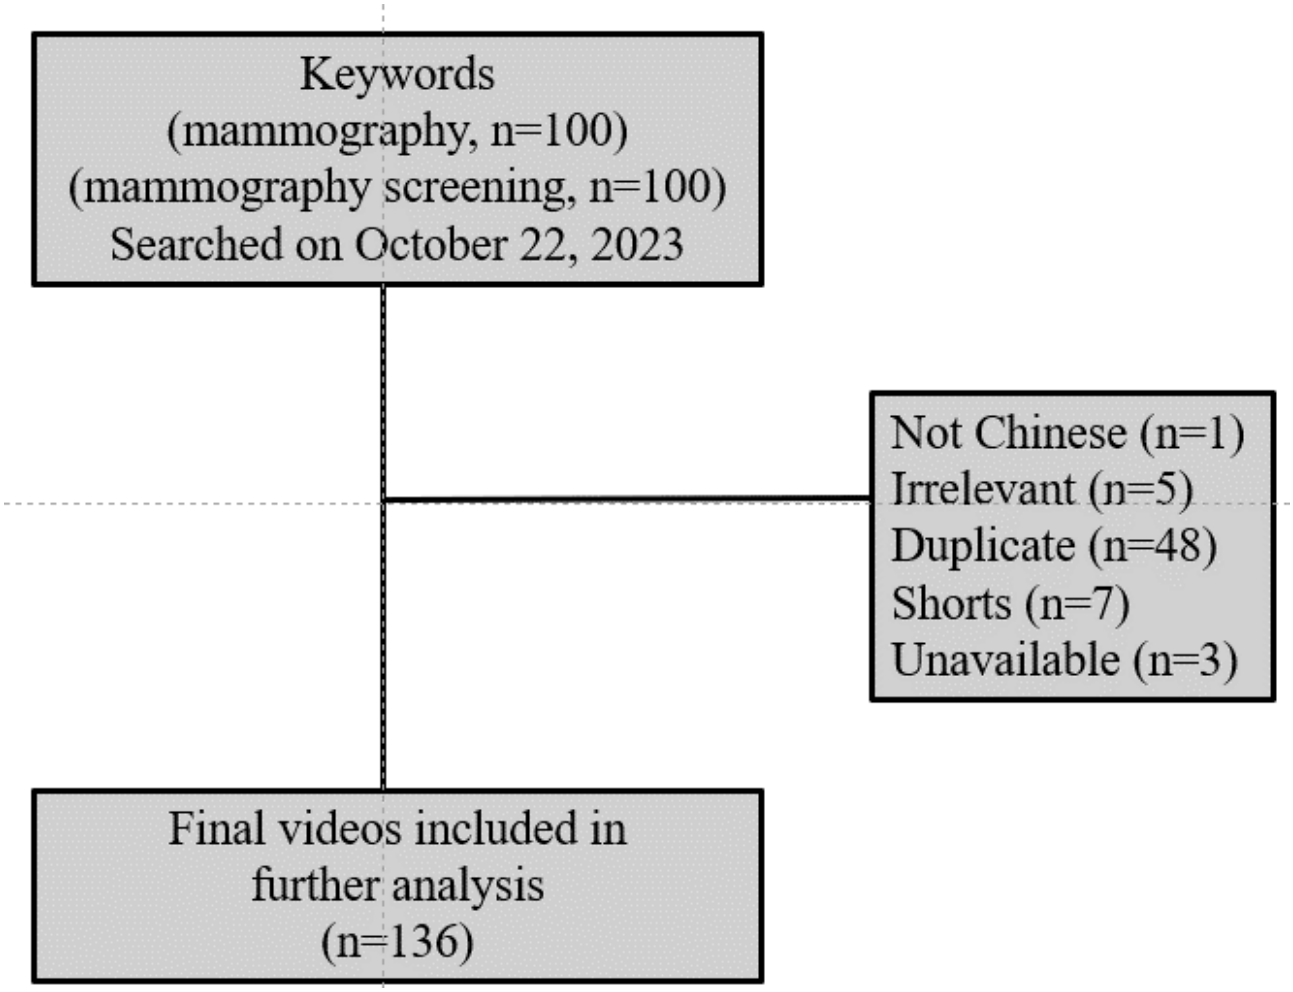
was required. All data were deidentified, and no individual users, videos, or screenshots are identifiable in this manuscript or its supplementary materials.

Results

Video Selection Process

In total, 200 videos were screened, and 136 were included in the study. The 64 excluded videos were 1 video in a non-Chinese language, 5 irrelevant videos, 48 duplicate videos, 7 short videos, and 3 unavailable videos (Figure 1).

Figure 1. Flowchart of videos included in the study.



Video Characteristics

The statistical analysis showed that the mammography videos ranged from 11 to 876 seconds. At the time of this study, the 136 short mammography videos had received 1,788,786 likes, 288,802 comments, 110,224 saves, and 598,393 shares. Each short video received 2 to 256,000 likes, 0 to 81,000 comments, 0 to 21,000 saves, and 0 to 145,000 shares. The most recent video was posted 21 days before the data collection, while the oldest had been on Douyin for more than 3 years. The median duration of the videos was 49.5 (IQR 32.5 - 76.75) seconds; the median indicators of engagement comprised 414 (IQR 155.75 - 1887.25) likes, 50.5 (IQR 20 - 286.25) comments, 56 (IQR 19-201.75) saves, and 61.5 (IQR 12 - 275.75) shares; and the median time since upload was 382.5 (IQR 116.25 - 635.75) days. The characteristics of the included videos are shown in Table 2.

Table . Characteristics of videos about mammography on Douyin.

Characteristics	Median (IQR)	Range
Duration (seconds)	49.50 (32.50 - 76.75)	11 - 876
Number of likes	414 (155.75 - 1887.25)	2 - 256,000
Number of comments	50.50 (20 - 286.25)	0 - 81,000
Number of saves	56 (19 - 201.75)	0 - 21,000
Number of shares	61.50 (12 - 275.75)	0 - 145,000
Days since upload	382.50 (116.25 - 635.75)	21 - 1208
Global Quality Score	2 (1 - 2)	0 - 4
DISCERN score	2.5 (1.63 - 3)	0 - 3.5

Uploader Douyin Account Characteristics

Most of the videos in our sample were contributed by professional users (112/136, 82.4%), while a relatively small proportion were contributed by nonprofessional users (24/136, 17.6%). Among professional users, most videos were created by board-certified physicians, followed by hospital channels and health channels (Table 3). Only 1 imaging physician was involved in the posting of 3 videos. The median video duration was significantly longer (P<.001) in the nonprofessional group and received significantly more comments (P=.004; Table 4).

Table . Proportion of videos by different types of uploaders.

Source	Description	Videos (n=136), n (%)
Professionals	Individuals or mechanisms who describe themselves as health professionals with certification	112 (82.4)
Board-certified physicians	Medical specialist who diagnoses, treats, and manages diseases and conditions related to breast cancer	106 (77.9)
Health channels	Organizations providing health knowledge	2 (1.6)
Hospital channels	Hospital platforms share health care information	4 (2.9)
Nonprofessionals	Individuals who share mammography experiences or medical personnel without certification	24 (17.6)

Table . Analysis of video characteristics by source.

Characteristics	Professional (n=112), median (IQR)	Nonprofessional (n=24), median (IQR)	*P* value
Duration (seconds)	46 (31.25 - 69.50)	96.50 (53 - 132.25)	<.001
Number of likes	382.50 (154 - 1658.50)	641.50 (155.75 - 15,223)	.33
Number of comments	44 (20 - 192.75)	165.50 (42.25 - 2900)	.004[a]
Number of saves	55.50 (19.5 - 182.5)	75.50 (10.25 - 2122.50)	.58
Number of shares	66 (12 - 198.75)	59 (11.5 - 4561.25)	.57
Days since upload	397 (137 - 648.25)	310.5 (78.25 - 611.50)	.66
Global Quality Score	2 (1 - 2)	1 (1 - 1.37)	<.001
DISCERN score	3 (2-3)	0 (0 - 0.75)	<.001

[a]P<.01.

As mentioned earlier, the selected videos were divided into useful and unhelpful groups based on scores of the completeness checklist. Of the 136 selected videos, the number of videos containing useful and unhelpful information was 105 (77.2%) and 31 (22.8%), respectively. Notably, despite uniformity in video days since upload between groups, uploads by unhelpful groups garnered more engagement metrics such as likes (median 6892, IQR 585 - 104,000), comments (median 1305, IQR 130 - 4103), saves (median 748, IQR 53-4381), and shares (median 1056, IQR 50 - 6071) relative to useful group, and this differential attains statistical significance (P<.01 for all; Table 5). Because the number of nonprofessional uploaders in the useful group was small (7/105), we could not compare this group.

Table . Analysis of video characteristics by usefulness.

Characteristics	Useful group (n=105), median (IQR)	Unhelpful group (n=31), median (IQR)	*P* value
Duration (seconds)	46 (31-69)	76 (46-114)	<.001
Number of likes	276 (131.50 - 815.50)	6892 (585 - 104,000)	<.001
Number of comments	35 (17 - 113.50)	1305 (130 - 4103)	<.001
Number of saves	47 (17-107)	748 (53 - 4381)	<.001
Number of shares	48 (10.50 - 158)	1056 (50 - 6071)	<.001
Days since upload	365 (104.50 - 675)	410 (151-538)	.77
Global Quality Score	2 (1.50 - 2)	1 (1 - 1)	<.001
DISCERN score	2 (2-3)	0 (0 - 0)	<.001

Information Content Comprehensiveness

Useful videos were analyzed based on the information they contained. Among all the categories, the advantages of mammography were the most frequently covered topic (53/105, 50.5%), followed in descending order by applicable objects (50/105, 47.6%), conception (47/105, 44.8%), examination process (44/105, 41.9%), combined other examinations (42/105, 40%), report (26/105, 24.8%), and precautions (11/105, 10.5%; Multimedia Appendix 3). Most of these videos (97/105, 92.4%) scored <5 points, and only 1 video received a maximum score of 7.

Video Reliability and Quality

The median (IQR) mDISCERN score and GQS of all videos were 2 (1 - 2) and 2.5 (1.63 - 3), respectively. The Cronbach α coefficients for reliability between the raters were 0.94 and 0.97 for the GQS and mDISCERN, respectively. The mDISCERN score and GQS of the videos in the useful and professional groups were significantly higher than those in the unhelpful and nonprofessional groups (all $P<.001$).

Correlation Analysis

Spearman correlation analysis revealed certain correlations among the characteristics of the videos. The video duration was positively correlated with the number of comments ($r=0.23$; $P=.008$), saves ($r=0.20$; $P=.02$), and shares ($r=0.19$; $P=.02$). Across all videos, Spearman correlation analysis revealed positive and significant correlations among the number of likes, comments, saves, shares, and days since upload ($P<.05$ for each pair).

The GQS was negatively or positively correlated with the number of likes ($r=-0.24$; $P=.004$), comments ($r=-0.29$; $P<.001$), and saves ($r=-0.20$; $P=.02$) as well as with the mDISCERN score ($r=0.65$; $P<.001$). The mDISCERN score was found to be negatively correlated with the number of likes ($r=-0.26$; $P=.002$), comments ($r=-0.36$; $P<.001$), saves ($r=-0.22$; $P=.009$), and shares ($r=-0.18$; $P=.03$). The correlation coefficients (r) reported in this study are generally below 0.39, indicating weak associations. In cases where the correlation coefficients are below 0.1, we consider these to be negligible. We acknowledge that the statistical significance of these correlations may be influenced by the sample size; therefore, we place greater emphasis on the magnitude of the correlation coefficients to better reflect the strength of the relationships. More detailed analytical results are shown in Table 6.

Table . Correlation analysis (Pearson *r* and 2-tailed *P* value) among the research variables.

Variable	Duration	Likes	Comments	Saves	Shares	Days since upload	GQS[a]	mDISCERN[b]

Discussion

Principal Findings

This is the first study in the literature to evaluate Douyin content on mammography videos. According to the findings of 2 independent reviewers (C Zhou and HY), more than three-quarters of the videos were uploaded by professional individuals or institutions, and videos containing content primarily concerned with disease knowledge were of higher quality and more reliable. Nevertheless, the overall quality of the mammography videos was poor according to the completeness checklist, GQS, and mDISCERN score. Additionally, the fact that seekers gave higher ratings to the lower-quality videos than the higher-quality videos suggests that most health viewers are not able to identify poor-quality medical information in videos.

The rapid development of digital technology and the widespread application of mobile intelligent terminals have caused various new media to become important platforms for sharing and exchanging scientific knowledge. This has further expanded the channels through which the public can understand and obtain information, broadening the breadth and depth of knowledge. There was an unprecedented reliance on social media platforms to seek information during the COVID-19 pandemic [34]. Douyin is a representative national short video platform, and

watching videos every day has become a part of many people's lives.

Currently, uploaders who share health information on the Douyin app are required to obtain certification materials that verify their affiliation with tertiary A hospitals as doctors. In our study, approximately 80% of mammography-related Douyin contents were uploaded by professional users. Most of them were clinicians; only 1 was an imaging specialist. These findings show that clinicians in tertiary A hospitals with a high level of expertise are enthusiastic about participating in the popularization of mammography-related information. A previous study also showed that radiology-related content on the increasingly popular social media platform TikTok is mainly posted by nonphysician radiology personnel [35]. In addition, our results suggest that the videos cannot cover all aspects of mammography, which may be due to the limited short length of Douyin videos. Furthermore, the most prevalent content of the videos was the advantages of mammography in detecting calcifications; few videos fully addressed other types of content during the examination. This finding may indicate that most publishers believe that the unique advantage of mammography is to help detect breast cancer at an earlier stage. As radiologists, they may be more likely to focus on pain and positioning or precautions during the examination and have a more accurate understanding of diagnostic reports [36]. Pain and discomfort during mammography may influence participation in screening programs and be detrimental to cancer prevention efforts [37]. More senior radiologists should be encouraged to become involved in mammography popularization. Specialized training and publicity should be provided to meet the public's need for knowledge about mammography.

The current results indicate that the reliability and educational quality of mammography-related videos on Douyin are unsatisfactory, with median mDISCERN and GQS evaluations across all videos stood at 2.5 (IQR 1.63-3), and 2 (IQR 1-2), respectively. This finding is in accord with previous studies that have examined low-quality videos on various health topics and found that this information may not be reliable on Douyin [38,39]. Studies on other video platforms, such as YouTube, also showed that the overall quality of videos providing disease information was poor [40,41]. Because the content of most videos lacks peer or institutional quality review, many may not be subject to quality control and may not be evidence-based; it is therefore not surprising that much of this content is inadequate [42]. Thus, patients should access certified organizations and sites such as those certified with the Health on the Net Foundation Code of Conduct certificate to obtain professional information and avoid being misled by social media. The Health on the Net Foundation Code of Conduct was created as a practical solution to help internet users recognize reliable health-related information on the internet while distinguishing it from potentially erroneous or hazardous content [43]. However, contrary to all these findings, in previous studies of the quality of Douyin videos on children with humeral supracondylar fractures, chronic obstructive pulmonary disease, and cosmetic surgery, the overall information quality and reliability of these short videos were satisfactory in China [44-46]. This might be explained by the assessment instrument's lack of comparability between different disease categories and the bias introduced by the use of different scoring criteria among different researchers.

The results also showed that videos posted by professionals had significantly higher reliability and GQS than those posted by individuals. This finding indicates that ownership is an important element that can be used to assess the reliability of videos. Video content may be considered trustworthy when produced by professionals such as doctors, medical organizations, and health information websites [47]. Unfortunately, our regression analysis revealed that the number of likes, comments, and saves had a weak negative correlation with both the mDISCERN score and GQS. The results showed that lay users had difficulty distinguishing useful information from a large number of videos. A common misconception is that digital information accuracy is directly related to the number of hits or views [48]. There are thousands of health-related videos promoting misleading information that get millions of views, such as videos that disparage vaccinations [49,50]. These results also indicate that effective regulatory measures are needed to control scientifically accredited information. In the future, it would be beneficial to develop an algorithm that ranks videos preferentially uploaded by a trusted medical center or professional. If the public had less access to unhelpful videos, the damage could be less.

Limitations

This study has some limitations. First, this was a cross-sectional study that examined a very small portion of a very large amount of data. The number of views, likes, and dislikes of health-related videos on the internet changes over time. The "snapshot" approach to data collection seems to be the main limitation of this study because the results may vary with the use of different search terms and according to the date and time of the search. Second, because of the limitations of the search criteria, it was not possible to include all video resources that fit the topic of this study. Although we included a relatively small percentage of videos, we considered it to be sufficiently representative, as videos beyond the top 100 have no significant impact on the analysis. Third, we only included videos uploaded on Douyin, which is a Chinese video-sharing platform; thus, the findings may not be generalizable to other social media platforms (eg, YouTube) or to other countries. Subsequent cross-linguistic research is required to fill this gap. Finally, the GQS and DISCERN are subjective assessment tools. Although 2 independent experts (C Zhou and HY) determined the ratings iteratively and used Cronbach α coefficients to quantify the agreement between the 2 raters, subjective differences still cannot be ignored. Looking ahead, future research should include broader cross-linguistic comparative studies, using more appropriate assessment instruments to validate our findings.

Conclusions

According to the findings of our study, a majority of the Douyin videos concerning mammography were uploaded by clinicians and exhibited poor quality and reliability. Patients should not use these videos as the only source of information about mammography because they may lead to misdirected or inappropriate interventions. Douyin is often used to obtain health-related information, and radiologists should be

encouraged to provide useful and accurate videos and to instruct patients appropriately. From the standpoint of preventing and curing breast cancer, there is a need for stricter standards and procedures for video publishing to improve the quality of medical content.

Acknowledgments

The authors thank Angela Morben, DVM, ELS, from Liwen Bianji (Edanz) for editing the English text of a draft of this manuscript.

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

The study was designed and planned by RH and Chunmin Zhu. Data collection, results interpretation, and manuscript writing were all carried out by HY and C Zhou. Chuangying Zhu reviewed the work. LH, HW, PC, and SZ contributed to the reagents, materials, and analysis tools. HY and C Zhou drafted the manuscript. Chunmin Zhu and RH reviewed and edited the manuscript. All authors have reviewed and revised the manuscript.

Abstract

Background: Relapse is a major event in patients with lymphoma. Therefore, early detection may have an impact on quality of life and overall survival. Patient-reported outcome measures have demonstrated clinical benefits for patients with lung cancer; however, evidence is lacking in patients with lymphoma. We evaluated the effect of a web-mediated follow-up application for patients with lymphoma at high risk of relapse.

Objective: This study aims to demonstrate that monitoring patients via a web application enables the detection of at least 30% more significant events occurring between 2 systematic follow-up consultations with the specialist using an electronic questionnaire.

Methods: We conducted a prospective, randomized phase 3 trial comparing the impact of web-based follow-up (experimental arm) with a standard follow-up (control arm). The trial was based on a 2-step triangular test and was designed to have a power of 90% to detect a 30% improvement in the detection of significant events. A significant event was defined as a relapse, progression, or a serious adverse event. The study covered the follow-up period after completion of first-line treatment or relapse (24 months). Eligible patients were aged 18 years and older and had lymphoma at a high risk of relapse. In the experimental arm, patients received a 16-symptom questionnaire by email every 2 weeks. An email alert was sent to the medical team based on a predefined algorithm. The primary objective was assessed after the inclusion of the 40th patient. The study was continued for the duration of the analysis.

Results: A total of 52 patients were included between July 12, 2017, and April 7, 2020, at 11 centers in France, with 27 in the experimental arm and 25 in the control arm. The median follow-up was 21.3 (range 1.3 - 25.6) months, and 121 events were reported during the study period. Most events occurred in the experimental arm (83/119, 69.7%) compared with 30.2% (36/119) in the control arm. A median number of 3.5 (range 1-8) events per patient occurred in the experimental arm, and 1.8 (range 1-6) occurred in the control arm (P=.01). Progression and infection were the most frequently reported events. Further, 19 patients relapsed during follow-up: 6 in the experimental arm and 13 in the control arm (P<.001), with a median follow-up of 7.7 (range 2.8 - 20.6) months and 6.7 (range 1.9 - 16.4) months (P=.94), respectively. Statistical analysis was conducted after including the 40th patient, which showed no superiority of the experimental arm over the control arm. The study was therefore stopped after the 52nd patient was enrolled.

Conclusions: The primary objective was not reached; however, patient-reported outcome measures remain essential for detecting adverse events in patients with cancer, and the electronic monitoring method needs to demonstrate its effectiveness and comply with international safety guidelines.

Trial Registration: ClinicalTrials.gov NCT03154710; https://clinicaltrials.gov/ct2/show/NCT03154710

KEYWORDS

patient-reported outcome measures; lymphoma; risk of relapse; relapse; randomized trial; web-based; quality of life; survival; detection; progression; T-cell lymphoma; Hodgkin lymphoma

Introduction

Relapse or progression is a major event in the management of lymphoma. Predictive factors for relapse include histological subtype, extranodal involvement, high metabolic volume, and elevated serum lactate dehydrogenase (LDH) levels [1]. Early detection of relapse correlates with survival. In most cases, relapse is detected by the appearance of symptoms, clinical signs, or biological abnormalities [2-4]. Repeated surveillance computed tomography (CT) detects asymptomatic recurrence in only 1.7% of patients and increases the risk of secondary cancers because of radiation overexposure [5-8]. Circulating tumor DNA monitoring may be used to detect early recurrence before the onset of symptoms; however, this method has not been validated [9]. Electronic patient-reported outcome measures (ePROMs) based on the Common Terminology Criteria for Adverse Events have emerged as a method of early detection. This has increased survival rates in some cases (locally advanced lung cancer) [10]. ePROMs affect early event detection and overall survival in patients with cancer [11-15]; however, such evidence is lacking for patients with lymphoma. In this study, we compare the effect of web-based follow-up with that of standard follow-up.

Methods

Overview

We conducted an open-label, longitudinal, prospective study between July 12, 2017, and April 7, 2020, at 14 centers in France.

Ethical Considerations

This study was conducted according to the 1975 Declaration of Helsinki, revised in 2008, and the guidelines of the International Conference on Harmonization of Good Clinical Practice in Biomedical Research. The Ouest II national ethics committee in Angers approved the study on November 8, 2016, and the Agence Nationale de Sécurité du Médicament approved it on November 22, 2016 (approval: 2021–A01670–41). All of the patients provided written informed consent, which included the points of analysis, the method of data collection, and the primary and potential secondary statistical analyses. All patient data were anonymized and no financial compensation was provided.

Study Population, Inclusion Criteria, and Exclusion Criteria

Patients with lymphoma who were aged 18 years or older and had a high risk of relapse were considered eligible for this trial. They could have T-cell lymphoma in the first partial or complete response, Hodgkin lymphoma in the second partial or complete response, or diffuse large B-cell lymphoma in the first partial or complete response with a revised high International Prognostic Index score (≥3) or in the second partial or complete response. Patients who had undergone autologous stem cell transplantation were not excluded. Eastern Cooperative Oncology Group performance status between 0 and 2, an internet connection, and affiliation to the French social security system were required. Patients were recruited during follow-up consultations by the referring physician at each center.

The exclusion criteria were an initial symptom score <7, progression within 3 months of the last treatment, brain or meningeal involvement, history of another cancer treated within 3 years—with the exception of skin cancer (except melanoma) and in situ cervical cancer—pregnancy, breastfeeding, and any psychiatric pathology that may prevent compliance with the protocol.

An initial symptom score was established in the previous Sentinel study. The e-request algorithm was more sensitive for patients who were not very symptomatic at inclusion and had an initial score of less than 7 (by summing scores from 0 to 3 for symptoms concerning cough, dyspnea, pain, anorexia, and asthenia: 0=no problem, 1=mild problem, 2=moderate problem, and 3=severe problem) [12].

Randomization

Randomization was planned through minimization once patients were enrolled in the study and programmed using ENNOV Clinical data management software. Patients were randomly assigned 1:1 to a routine follow-up (control arm) or web-mediated follow-up (experimental arm). Stratification was conducted at inclusion according to the center, performance status, autologous stem cell transplantation history, relapse, and lymphoma subtype.

Follow-Up

Patients were included no later than 3 months at the end of their last treatment. Follow-up was 24 months after enrollment. A medical consultation and a biological assessment were performed every 3 months. In the control arm, CT scans were performed every 6 months. In the experimental arm, scans were performed when medically necessary. Quality of life (QoL) was assessed by 2 questionnaires every 3 months (European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire of Cancer Patients [QLQ-C30] and Patient Health Questionnaire-9 [PHQ-9]) [16,17]. Patient satisfaction with the application was evaluated by an internal questionnaire for patients in the experimental group during the 6-month visit from inclusion.

Web Application

The Moovcare patient-reported outcome (PRO) system is a class 1 medical device registered by Sivan Innovation, Ltd.,

with Conformité Européenne marking obtained in July 2017. Versions 1.7 (from July 2017 to October 2019) and 1.8 (from November 2019 to April 2020) were used in this study. “The reimbursed indication of the MOOVCARE Lung device is the early detection of recurrences or complications for patients over the age of 16 with nonprogressive lung cancer after the last medical treatment, regardless of the histological type of the tumor”—an excerpt from the user guide [18]. The indication was validated by the data of the Sentinel Lung study (published in 2019), which demonstrated a survival benefit of 9 months for patients monitored by the application compared to standard monitoring (P=.005) [13].

A scientific committee adapted the questionnaire for patients who were being monitored for lymphoma, whereas the technical monitoring and the decision algorithm remained the same.

PRO data were collected using questionnaires sent by the application directly to the patient through a clickable link to their email address. Patients were asked to complete a 16-question self-assessment every 14 days for 24 months after being randomized to the experimental arm (smartphone or email). They were also able to report an event in the web application between the 2 questionnaires. The study coordinators provided them with a short training session on the application. If the patient failed to complete the questionnaire, a reminder was sent after 24 hours, and the health care team contacted the patient as necessary.

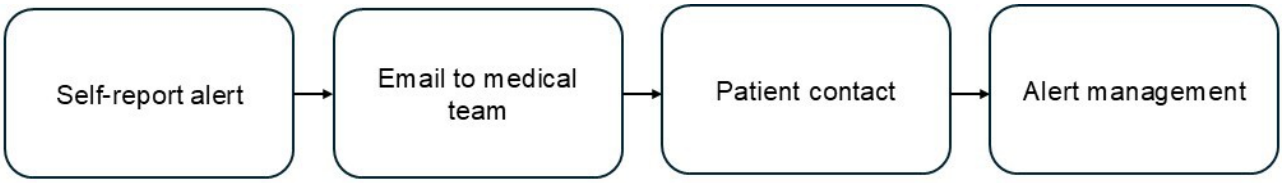
The questionnaire included 4 items, namely weight, LDH level (optional), hemoglobin level (optional), and a free comment (for other symptoms or remarks), and 12 following questions:

- Are you tired?
- Have you lost your appetite?
- Are you in pain?
- Are you short of breath?
- Do you feel depressed?
- Do you have a fever (temperature >38.1 °C, checked once at 1-hour intervals)?
- Do you have chills?
- Do you have pimples?
- Are you sweating profusely?
- Are you itching all over your body?
- Have you detected a lump under the skin or a lymph node?
- Have you noticed any abnormal swelling of the face or legs?

Patients were assigned a score based on their symptoms as follows: 0=no problem, 1=mild problem, 2=moderate problem, and 3=severe problem. An alert was triggered in the event of weight loss greater than 2 kg over 1 month, in the event of symptoms rated 3, the presence of fever or night sweats on 2 consecutive occasions, or elevation of serum LDH above 2-fold the normal level, or anemia indicated by hemoglobin levels of <10 g/dL.

In the event of an alert triggered by the application, an email was sent to the care team, with a reminder every 24 hours if there was no response (Figure 1). Patients could also report an event by writing a free text.

Figure 1. The decision algorithm used in this study.



Outcome Measures

The primary outcome was to demonstrate that follow-up via a web application could detect more significant events (including relapses) occurring between 2 routine follow-up consultations with the specialist in patients with lymphoma who were at high risk of relapse compared with standard follow-up. Secondary outcomes were overall and progression-free survival at 2 years, relapse rate at 2 years, QoL or patients in both arms, and compliance and satisfaction for the experimental arm.

Adverse and Significant Events

An adverse event was defined as any symptom reported by the patient either during the protocol consultation in the control arm or, through the application in the experimental arm. An event was considered significant if, the grade was greater (≥2) based on the Common Terminology Criteria for Adverse Events v4.02 or, if it prompted an imaging examination, treatment (of any kind), supportive care, unscheduled consultation, or emergency hospitalization.

QoL, Adherence, and Satisfaction

QoL was evaluated using the QLQ-C30 and PHQ-9 questionnaires at inclusion and, follow-up visits at 3, 6, 9, and 12 months. Patient adherence to the use of the web application was assessed according to the number of electronic questionnaires completed. A questionnaire had to be completed every 14 days. Patients completing less than 1 electronic questionnaire every 42 days (6 weeks) were considered noncompliant. Patient satisfaction with web monitoring and the use of the web application was assessed using a self-questionnaire at their 6-month follow-up visit.

Data Management and Statistical Analysis

Data Management

One electronic case report form (e-CRF; ENNOV Clinical) was created for each patient. The information required by the protocol was collated into the e-CRF, which included the data necessary to confirm compliance with the protocol and detect any major deviations, as well as the data necessary for statistical analysis. The information was collected without mentioning the

surname and first name in the e-CRF, with an identification number for the center and a patient number. Only the first letters of the patient's surname and first were visible. This code was the only patient identifier that appeared in the e-CRF, which made it possible to link e-CRFs to the corrresponding patients.

Statistical Analysis

Determination of the Size of the Study Population

The trial was based on a 2-step triangular test and was designed to have a power of 90% to detect a 30% improvement in the detection of significant events outside of routine consultations during the 6 months of follow-up with the web application. This is compared with a 60% rate of detection for significant events outside routine consultations among patients randomly assigned to conventional follow-up, with a significance of 5%. This sequential method made it possible to evaluate the application's effectiveness while controlling the power and type I error (the risk of falsely rejecting our null hypothesis) [19,20]. 40 evaluable patients were to be included per arm, and an interim analysis was to be performed when 20 evaluable patients per arm had 6 months of follow-up. Inclusion was not suspended before the 6-month follow-up.

Analysis of Variables, Progression-Free Survival, Overall Survival, and QoL Questionnaires

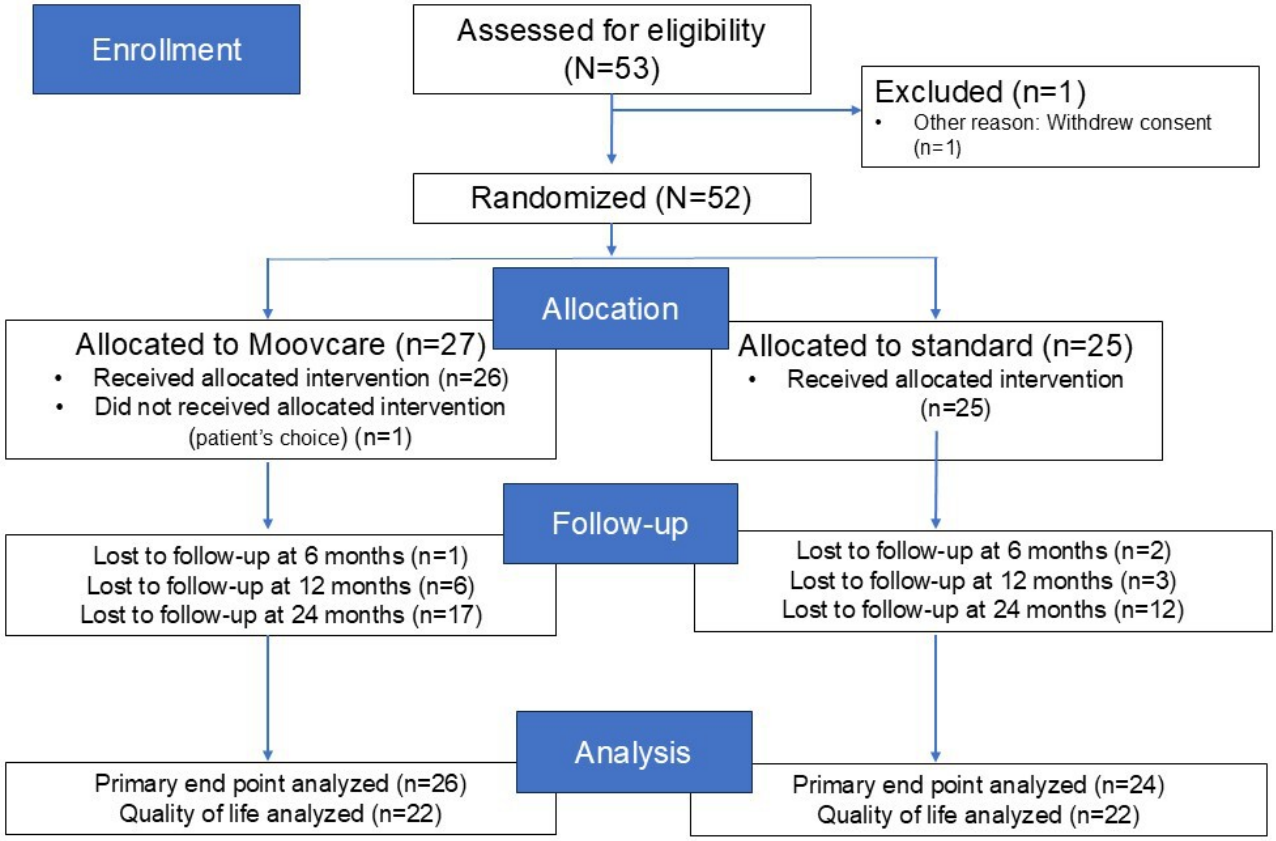
The analysis of the qualitative variables is presented in terms of numbers and percentages. The analysis of quantitative variables is presented as median or mean (SD) depending on the normality of the variable, whereas the minimum and maximum values are also indicated. The events are described in terms of frequency by etiological type (according to the Medical Dictionary for Egilatory Activities classification) and severity according to the NCI Common Terminology Criteria for Adverse Events version 4.02. For the analysis of censored data (overall survival and other event times), survival curves are plotted based on Kaplan-Meier estimates, and the median survival times and their 95% CIs are presented. For multivariate survival analyses, the Cox semiparametric model was used to calculate the odds ratios, which are presented with 95% CIs. The sensitivity of the application to detect a relapse and significant complications was calculated. The QoL scores were calculated according to the European Organisation for Research and Treatment of Cancer recommendations for the QLQ-C30 [16]. QoL is described for each measurement time, compared at inclusion, and then studied longitudinally using mixed analysis of variance models for repeated measures. PHQ-9 scores were calculated based on the recommendations described at each measurement time and compared at inclusion. Classes proposed in the literature (≤4; 5 - 14;>14) were used to describe the patients' state of depression [17]. Analyses were performed using SAS 9.3 software (SAS Institute, Inc).

Results

Study Design

A total of 53 patients were included between July 12, 2017, and April 7, 2020, from 14 centers in France: Le Mans (16/52, 31%), Besançon (9/52, 17%), Nantes (6/52, 11%), Bordeaux Bergonié (6/52,11%), Bordeaux Nord (6/52, 11%), Mont de Marson (4/52, 8%), Dijon (1/52, 2%), Grenoble (1/52, 2%), Paris (1/52, 2%), Strasbourg (1/52, 2%), and Vannes (1/52, 2%). One patient withdrew consent before randomization, and 27 patients were randomized to the experimental arm and 25 to the control arm. The median follow-up time was 21.3 (range 1.3 - 25.6) months. In total, 26 patients were evaluated at the primary end point in the experimental arm and 24 in the control arm (Figure 2). The Consolidated Standards of Reporting Trials (CONSORT) guideline (Checklist 1) was used to present the results.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flowchart diagram.



Patient Characteristics

The median age of the entire population was 65.6 (range 20.3 - 87.8) years; the median age was 64.3 (range 20.3 - 87.8) years in the experimental arm and 69.2 (range 23.9 - 84.4) years in the control arm (*P*=.99). Further, 80% of patients (40/50) had large diffuse B-cell lymphoma, 10% (5/50) had T-cell lymphoma, and 10% (5/50) had Hodgkin lymphoma. The 2 arms were well balanced with respect to age and histological subtype (Table 1).

The median time from initial diagnosis to randomization in the study was 7.7 (range 5.0 - 170.2) months. The median was 7.5 (range 5.3 - 58.2) months for the experimental arm and 7.8 (range 5.0 - 170.2) months for the control arm (*P*=.43).

Rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone were the primary first-line chemotherapeutic regimens. In the experimental arm, 17/26 (65%) patients received a single line of chemotherapy, and 9/26 (35%) received 2 lines. In the control arm, 16/24 (67%) patients received a line of chemotherapy, and 8/24 (33%) received a second line.

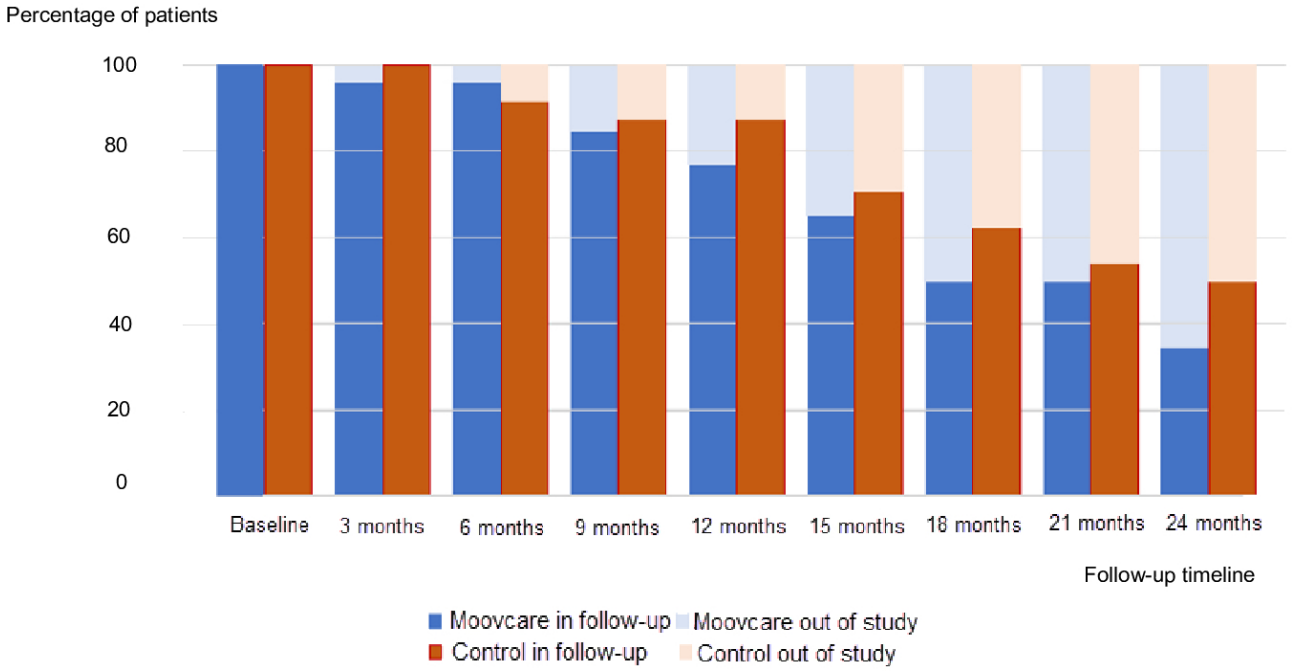
Follow-Up

In the experimental arm, 25/26 patients (96.1%) were still included in the study at the 6-month follow-up, 20/26 (76.9%) at 12 months, and 9/26 (34.6%) at 24 months. In the control arm, 22/24 (91.6%) were still being followed at 6 months, 21/24 (87.5%) at 12 months, and 12/24 (50%) at 24 months (Figure 3).

Figure 3. Patient follow-up.



The primary reasons for the loss of follow-up were the planned end of the protocol for 20 patients and the premature termination of the study by the sponsor (19 patients; Table 2).

Table . Reasons for discontinuing the study.

	Total, n	Web application, n (%)	Control, n (%)
Death	4	3 (75)	1 (25)
Investigator decision	2	0 (0)	2 (100)
Patient decision	1	1 (100)	0 (0)

Missing patient	2	1 (50)	1 (50)
Premature termination	19	11 (58)	8 (42)
Missing data	2	2 (100)	0 (0)

Events

During the study period, 119 events were reported (Table 3). Most occurred in the experimental arm (83/119, 69.7%) versus 36/119 (30.2%) in the control arm, with a median number of events per patient of 3.5 (range 1-8) in the experimental arm and 1.8 (range 1-6) in the control arm (P=.004). In the experimental arm, 47/83 (56.6%) events were reported directly by the medical team after a scheduled consultation, whereas 36/83 (43.3%) were reported through the web application.

In the control arm, 19/36 (52.7%) events were detected during a scheduled consultation, 2/36 (5.6%) during an unscheduled consultation, 9/36 (25%) during a consultation with another specialist, 3/36 (8.3%) during hospitalization, and 3/36 (8.3%) during a patient call.

Progression and infection were the most frequently reported events. 19 patients relapsed during follow-up, with a median follow-up time of 7 (range 1.9 - 20.6) months; 6 in the web experimental arm and 13 in the control arm (P<.001), with a median follow-up of 7.7 (range 2.8 - 20.6) months and 6.7 (range 1.9 - 16.4) months (P=.94), respectively. 13 patients were treated for relapse; 11 by chemotherapy and 2 by radiotherapy.

30 patients were infected (23 in the experimental arm and 7 in the control arm; P=.59): 5 patients had an influenza infection, and the infectious agent was not reported for the others. 14 patients received treatment; 13 with antibiotics, 1 with antivirals, and 1 with antibiotics and antivirals. The grade of adverse events was not available in 60 out of 119 (50.4%) cases, which limited data interpretation.

Event Management

Overview

Events led to 19 additional medical consultations with the referring hematologist in the experimental arm (alert management resulted in 8 additional medical consultations and 11 without an alert) versus 15 in the control arm (*P*=.99; Table 4). 30 consultations were conducted with other specialists (15 in the experimental arm and 15 in the control arm). For some events, several specialists or referring hematologists were required to manage the patient.

Table . Management of events.

	Total, n	Web application, n	Control, n	*P*-value[a]
Consultation with the oncologist	31	16	15	N/A[b]

Respiratory distress	1	1	0	
Medical treatment	39	28	11	.94

[a]The *P* value was calculated using the chi-square test for qualitative variables, the Wilcoxon test for quantitative variables, and the Fisher test for the lower variables.

[b]N/A: not assessed.

Emergency hospitalization was required for 8 patients (4 for progression, 1 for myocardial infarction, 1 for respiratory distress, 1 for thoracic pain, and 1 for balance disorder), with no difference between the 2 arms (*P*=.78). 22 scans were performed in the web experimental arm versus 72 in the control arm (61 scanners scheduled for follow-up and 11 not scheduled for events*; P*<.001).

39 events required treatment, with a total of 24 patients receiving medical treatment (16 in the experimental arm and 8 in the control arm; *P*=.11; Table 5). 56 prescriptions were filled (37 in the web experimental arm and 19 in the control arm*; P*=.64).

[b]N/A: not assessed.

QoL and Depression

The patients were asked to complete the QLCQ-30 questionnaire every 3 months for 1 year. 44 patients completed at least 2 QoL questionnaires during the study; 22 patients per arm (ie, 22/26, 84.6% in the experimental arm and 22/24, 91.6% in the control arm). The higher the score, the poorer the QoL (maximum score: 114). The median scores did not differ between the 2 groups at 12 months with it being; 45 in the experimental arm (range 39-61) and 44 in the control arm (range 30-69*; P*=.94).

Regarding depression, 42 patients completed the questionnaire (21 per arm; ie, 21/26, 80.7% in the experimental arm and 21/24, 87.5% in the control arm]. The score was 1.0 (range 0 - 15) in the experimental arm versus 1.5 (range 0 - 13) in the control arm (*P*=.73).

Satisfaction (Experimental Arm)

In total, 20 patients in the experimental arm completed the satisfaction questionnaire (20/25, 80%). Further, 95% (19/20) of patients who responded to the satisfaction questionnaire were

satisfied and reassured by the application, whereas 90% (18/20) felt better informed.

Survival

Four patients died during the trial; 3 in the experimental arm and 1 in the control arm (*P*=.34). Overall survival at 12 months was 87.1% in the experimental arm (95% CI 65%-95.7%) and 95.2% in the control arm (95% CI 70.7-99.3%; *P*=.32; Figure 4). Progression-free survival at 12 months was 83.2% in the experimental arm (95% CI 61%-93.3%) and 68.5% in the control arm (95% CI 44.9%-83.6%; *P*=.27; Figure 5).

Figure 4. Overall survival. Exp.: experimental.

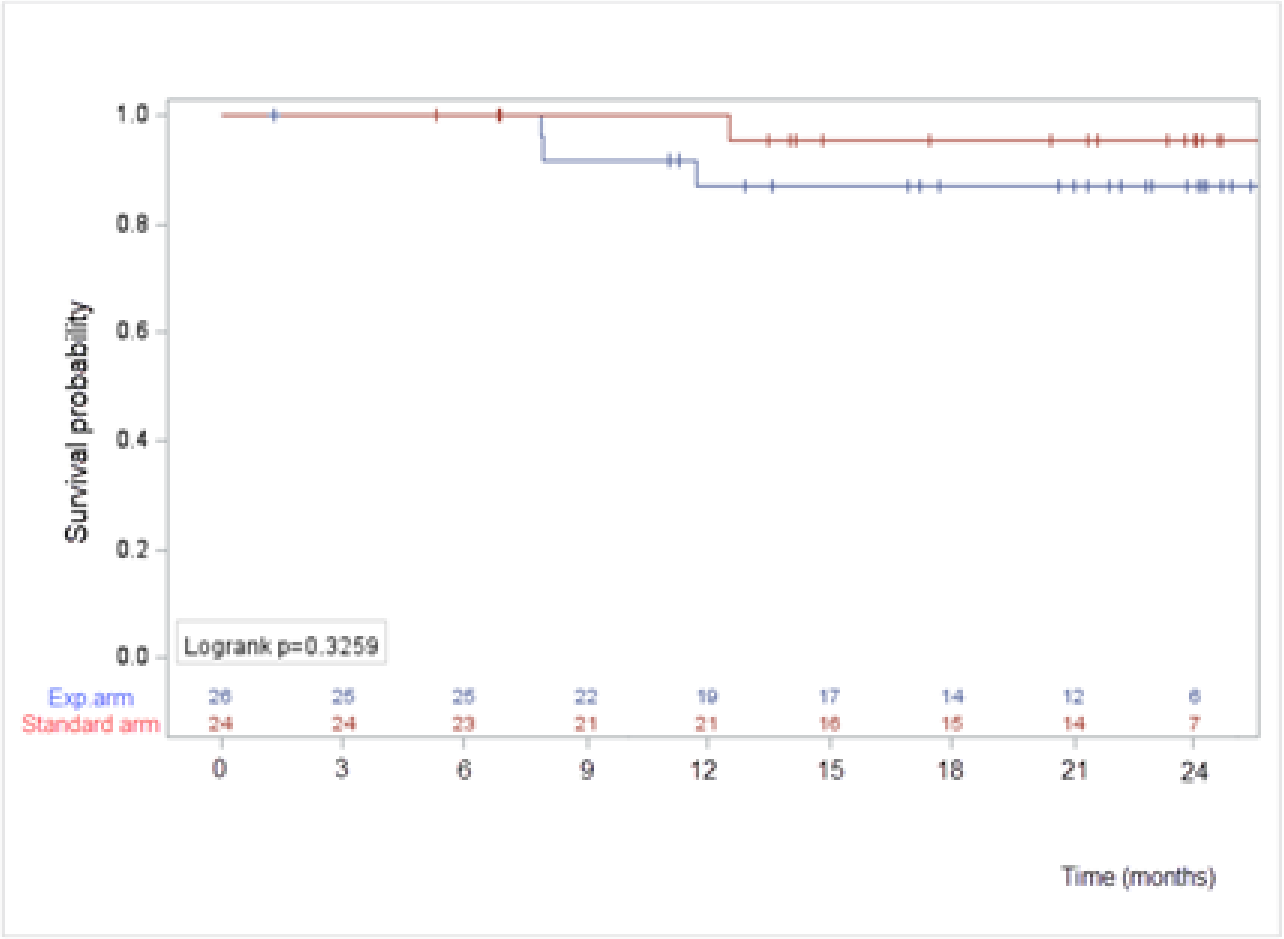

Figure 5. Progression-free survival. Exp.: experimental.

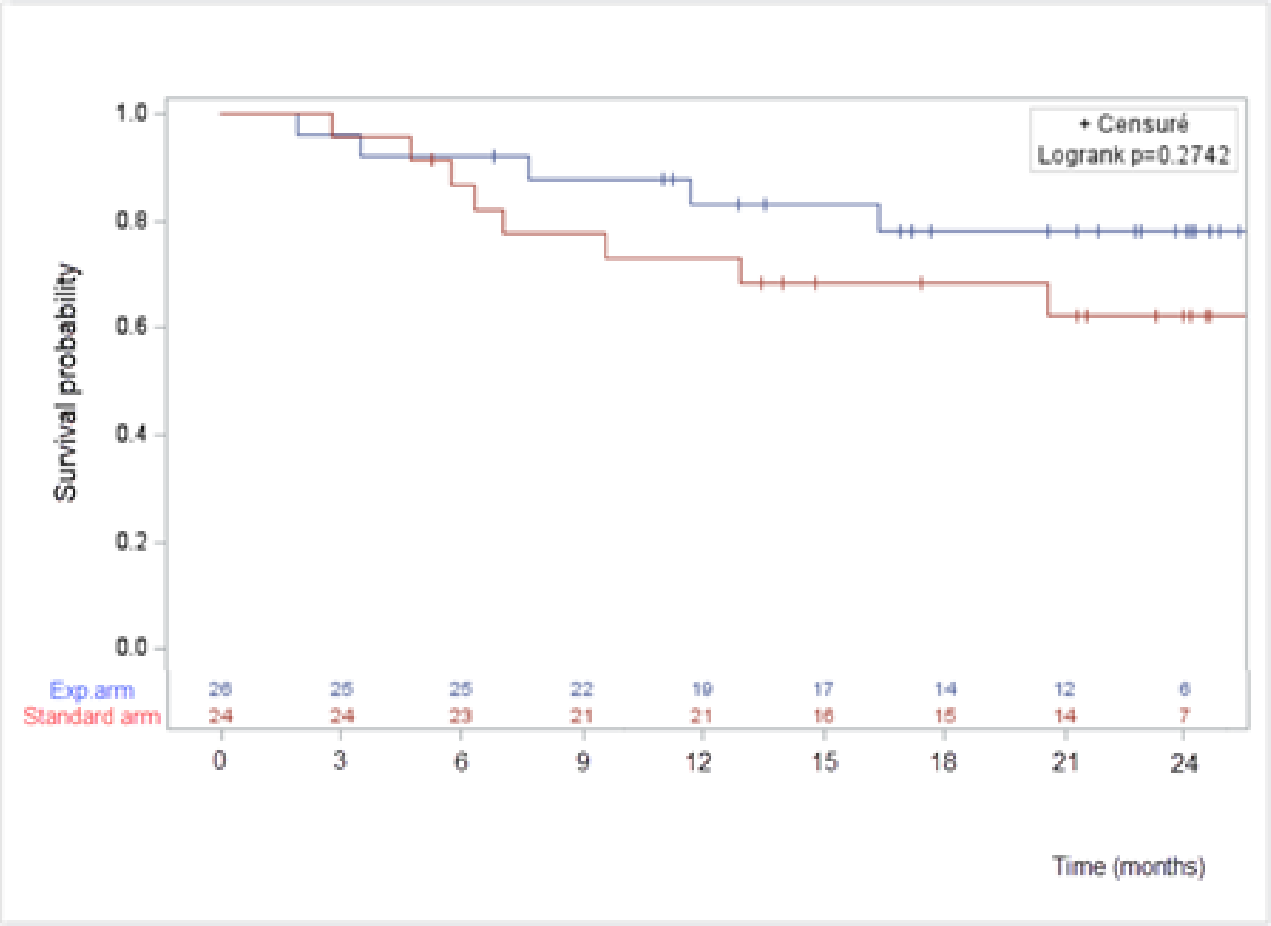

Protocol Deviations and Technical Failures in the Experimental Arm

Three alerts were not handled by the care team within the required time frame and were subsequently classified as minor (grade 1).

The automatic sending of questionnaires was stopped for 9/26 (35%) patients. For 3 patients, the questionnaires were sent in paper form. For the other 6, no solution could be found despite repeated interventions by the electronic application's technical department. One of these patients suffered 2 major events: myocardial infarction and relapse. These 2 events were not reported in the electronic application. Because of these technical problems, compliance could not be assessed.

Outcomes

An interim analysis was performed based on the protocol when the first 40 patients reached 6 months of follow-up. The results of this analysis did not reject the null hypothesis, which stated that there was no difference in the diagnosis of events between the 2 arms. The Sentinel Lymphoma Study Committee met on March 11, 2021, to oversee the analysis of the primary outcome, which indicated no difference in the diagnosis of significant events. A decision was made at the end of the meeting to discontinue the trial early. Based on the protocol, the study was terminated on March 15, 2021, following the sponsor's decision.

Discussion

Principal Findings

In this study, there is no difference in the occurrence of significant events between the 2 arms (median number per patient of 3.5 in the experimental arm and 1.8 in the control arm; P=.004). Progression, infection, and pain were the most frequently reported events. Patient satisfaction was very high and the patients felt reassured to have electronic monitoring. The patients included in the experimental arm underwent fewer scans compared with those in the control arm, without impacting overall survival, despite a short follow-up (P<.001).

Strengths and Limitations

First, the primary outcome of a 30% superiority of reporting significant events in the experimental arm has been overly optimistic. Thus, reducing the end point would have led to a substantial increase in the number of included patients. The number of events was probably not the best criterion for evaluating the effectiveness of remote monitoring. An improvement in QoL or a reduction in the risk of relapse would likely have been more relevant [13,15].

Second, technical problems with the web application occurred (electronic questionnaires not received, with major biases in event reporting). The incidents were not expected because of the experience of the software developer (Moovcare, Sivan Innovation, Ltd); however, there was a change in the technical

team between this publication on lung cancer and the start of our study [11-13]. The blocking of automatic questionnaires required 42 direct interventions by clinical study investigators with calls to the patient (firewalls and spam). IT support did not correct these recurring anomalies, despite the changes to the application in November 2019 (5 patients were included in the experimental arm after this date). These operational problems resulted in 15 meetings without resolution of the problems, with an average response time of 4.6 months from technical support (frequent changes to contact persons). As a result, the events in the experimental arm were not reported correctly, leading to study bias. The final report has been sent to the Agence Nationale de Sécurité du Médicament on June 29, 2021.

Finally, only 43% of the events were declared by the application in the experimental arm, which would indicate a problem with patient training.

Comparison With Prior Work

PROs are underestimated in clinical practice and trials for patients with lymphoma and have most often consisted of paper-based QoL questionnaires [21]. The measurement of PROs via electronic questionnaires has subsequently been evaluated in randomized trials with a low representation of patients with lymphoid malignancies [22]. However, Maguire et al [23] demonstrated that real-time electronic monitoring of symptoms was feasible during an initial chemotherapy cycle in patients with solid tumors and lymphoma, with a reduction in the intensity of side effects and anxiety, compared with a control group.

Future Directions

Proposals for the future include improving the study design by limiting the patient population to a single type of lymphoma, defining the objective to demonstrate an improvement in morbidity and possibly reduce cost, and guaranteeing the reliability of the electronic application. PROMs require standardization of analysis for comparative purposes. Therefore, it is necessary to regulate the use of health care applications to avoid malfunction and abuse [24]. Denis and Krakowski [25] defined 20 criteria of effectiveness, safety, and functionality that should govern the development of ePROMs. Telemonitoring applications should strive to improve patient compliance and prevent patients from dropping out due to a lack of understanding or receiving excessive notifications [26]. Telemonitoring applications must evolve with therapeutic innovations and be regularly reevaluated to demonstrate their long-term benefits on a larger scale [27]. Finally, guidelines are recommended for the design of clinical trials to evaluate the effectiveness of electronic solutions [28-30].

Conclusions

Sentinel Lymphoma is the first randomized phase 3 trial to evaluate the effect of remote monitoring on the detection of significant events in patients with hematological malignancies. Progression, infection, and pain were the most frequently reported events. Despite a high number of events (83 in the experimental arm against 36 in the control arm), the difference was not significant. A more targeted population, a more precise objective, and better security for remote surveillance solutions are recommended for subsequent projects.

Acknowledgments

The authors would like to thank the patients and their families, as well as Antoine Giraud for his advice. The authors would like to thank Enago for the English language review. This study was funded by Takeda.

Data Availability

All data from the study are freely available upon request to the corresponding author.

Authors' Contributions

KLD, MB, and ALS designed the study. ALS collected, analyzed, and interpreted the data. KLD drafted the first version of the manuscript. All authors participated in the preparation and revisions of the manuscript and approved the final version of the manuscript for submission.

Conflicts of Interest

KLD has received consulting fees from AstraZeneca, Abbvie, Incyte Janssen-Cilag, and Gilead.

Abstract

Background: Exercise can attenuate the deleterious combined effects of cancer treatment and aging among older adults with cancer, yet exercise participation is low. Telehealth exercise may improve exercise engagement by decreasing time and transportation barriers; however, the utility of telehealth exercise among older adults with cancer is not well established.

Objective: We aimed to evaluate the preliminary effectiveness of a one-on-one, supervised telehealth exercise program on physical function, muscular endurance, balance, and flexibility among older adults with cancer.

Methods: In this retrospective study, we analyzed electronic health record data collected from the Personal Optimism With Exercise Recovery clinical exercise program delivered via telehealth among older adults with cancer (≥65 y) who completed a virtual initial program telehealth assessment between March 2020 and December 2021. The virtual initial assessment included the following measures: 30-second chair stand test, 30-second maximum push-up test, 2-minute standing march, single leg stance, plank, chair sit and reach, shoulder range of motion, and the clock test. All baseline measures were repeated after 12-weeks of telehealth exercise. Change scores were calculated for all assessments and compared to minimal clinically important difference (MCID) values for assessments with published MCIDs. Paired samples *t* tests (2-tailed) were conducted to determine change in assessment outcomes.

Results: Older adults with cancer who chose to participate in the telehealth exercise program (N=68) were 71.8 (SD 5.3) years of age on average (range 65 - 92 y). The 3 most common cancer types in this sample were breast (n=13), prostate (n=13), and multiple myeloma (n=8). All cancer stages were represented in this sample with stage II (n=16, 23.5%) and III (n=18, 26.5%) being the most common. A follow-up telehealth assessment was completed by 29.4% (n=20) of older adults with cancer. Among those who completed a follow-up telehealth assessment, there were significant increases in the 30-second chair stand (n=19; mean change +2.00 repetitions, 95% CI 0.12 to 3.88) and 30-second maximum push-up scores (n=20; mean change +2.85 repetitions, 95% CI 1.60 to 4.11). There were no significant differences for the 2-minute standing march, plank, single leg stance, sit and reach, shoulder mobility, or clock test (P>.05). Nine (47.3%) older adults with cancer had a change in 30-second chair stand scores greater than the MCID of 2 repetitions.

Conclusions: Our findings suggest a one-on-one, supervised telehealth exercise program may positively influence measures of physical function, muscular endurance, balance, and flexibility among older adults with cancer, but more adequately powered trials are needed to confirm these findings.

Introduction

Adults aged 65 years and older currently account for 67% of cancer survivors (eg, individuals living with and beyond a cancer diagnosis) in the United States [1]. By 2040 it is projected that 73% of cancer survivors in the United States will be aged 65 years and older [2]. Cancer treatment compounds the normal effects of aging resulting in an accelerated aging effect [3]. A hallmark characteristic of accelerated aging is poor physical functioning [3]. Older adults with cancer experience worse physical function than their younger counterparts [4] and older adults without cancer [5,6]. Physical function plays a critical role in the health of older adults with cancer and poor function is associated with decreased cancer survival [7], increased all-cause mortality [8], and increased symptom severity [9].

Regular participation in exercise is one strategy to help mitigate declines in physical function among cancer survivors of all ages. Among older adults with cancer, individualized, in-person supervised exercise programming, including combined aerobic and resistance training, for at least 12-weeks significantly improves physical function [10,11], quality of life [12], muscular strength [10,11], aerobic endurance [10,11], and symptoms of anxiety and depression [11]. Despite the numerous benefits of exercise for older adults with cancer, participation in exercise in this population is low with only 12% of older cancer survivors meeting both the aerobic and strength training guidelines [13]. Reasons for low engagement among this population include: lack of available exercise programming in convenient locations [14], transportation concerns [14,15], lack of time [14,16], physical symptoms (eg, fatigue) [14,16,17], and comorbidities [14,17]. Strategies to reduce barriers to participating in exercise among older adults with cancer are needed to improve exercise engagement and physical function in this population.

Delivering exercise programs using telehealth is a useful strategy in attenuating these barriers. Telehealth delivery of exercise detaches the exercise program from a physical location, resulting in exercise engagement in a more convenient location, such as the home, eliminating the need for travel, and reducing overall time commitment [18]. Telehealth delivered exercise can also lower the cost of participation as participants do not need to pay for transportation or parking [18]. After transitioning two trials from in-person to telehealth exercise, due to the impact of the COVID-19 pandemic on in-person research, Winters-Stone et al [19] observed better adherence and retention for telehealth exercise compared to in-person exercise among adult cancer survivors of all ages. In addition to addressing these barriers, supervised, telehealth-delivered exercise programs among adult cancer survivors of all ages have demonstrated improvements in physical symptoms and comorbidities such as: physical function [20,21], aerobic endurance [20,22], muscular endurance [20,22], and fatigue [22]. Specific to older adults living with cancer, telehealth delivery of exercise programming is considered acceptable [23], feasible [24], and safe [25]. Moreover, older cancer survivors view telehealth delivery of exercise positively and report limited technology related barriers to telehealth exercise participation [26]. Barriers and facilitators to participating in telehealth exercise reported by older cancer survivors are similar to those reported by their younger counterparts [26]. To our knowledge, only two studies to date have evaluated effectiveness of supervised telehealth exercise programming (ie, delivered via telehealth in real time) exclusively in older adults with cancer [24,27]. Both trials delivered group resistance training programs and observed significant improvements in markers of physical function after participating in the program [24,27]. However, little is known regarding the effectiveness of one-on-one telehealth supervised exercise in older adults with cancer. Given the dearth of research, we sought to address the issue in this investigation.

The purpose of this investigation was to explore the preliminary effectiveness of a one-on-one, supervised telehealth clinical exercise oncology program among older adults with cancer on physical function, muscular endurance, balance, and flexibility. We hypothesized that participation in telehealth exercise would result in a statistically significant improvement in physical function, muscular endurance, aerobic endurance, balance, and flexibility among older adults with cancer.

Methods

Study Design and Sample

This was a retrospective analysis of electronic health record data collected between March 2020 and December 2021 from the Huntsman Cancer Institute (HCI) at the University of Utah's clinical exercise oncology program, the Personal Optimism With Exercise Recovery (POWER) program. This study was approved by the University of Utah Institutional Review Board (IRB_00072431). To be included in this analysis participants must have met the following inclusion criteria: (1) ≥65 years of age, (2) diagnosis of invasive cancer, and (3) completion of an initial POWER program assessment via telehealth. Demographic and clinical data including age, sex, race, ethnicity, cancer site, cancer stage, and cancer treatment history, were pulled from the medical record. Initial and follow-up assessment data were abstracted from the POWER program clinical database by a trained researcher (ERD) with support from certified exercise physiologists within our hospital-based exercise oncology program using a study specific spreadsheet developed in partnership with this study's team. Data were cleaned to ensure all measures were within a physiologically reasonable range and units were consistent within measures (eg, all plank assessments were reported in seconds). Cancer treatment history from manual data abstraction was verified with the electronic health record.

Exercise Program

The POWER program is a hospital-based exercise oncology program embedded into clinical practice at the HCI. Details of this clinical program have been previously published [28]; therefore, only pertinent details will be discussed here. While the program has traditionally been offered both in-person and via telehealth, the POWER program shifted to exclusive telehealth delivery due to the COVID-19 pandemic in March 2020 and continued to operate primarily via telehealth through December 2021. Anyone seeking care at the HCI is eligible to participate in the POWER program and patients can enroll in the program through self-referral or physician referral.

POWER provides personalized exercise prescriptions, including both aerobic and resistance training, to program participants based on an initial assessment conducted by a physiatrist and certified exercise physiologist with expertise in cancer via telehealth. The typical length of the program was 12-weeks, but varied based on participant preference. After about 12-weeks, participants were encouraged to complete a telehealth follow-up assessment to evaluate their progress (ie, reassess all baseline measures) and revise the exercise prescription to promote continued progress. Ultimately, the POWER program aims to help survivors become comfortable and capable of safely engaging in exercise independently.

The exercise prescription was individualized to each participant's needs and was informed by the initial telehealth assessment which included a review of medical and cancer treatment history, physical examination, review of current exercise behavior, and assessment of physical function, muscular endurance, and flexibility. Following the initial assessment each participant met with a certified exercise physiologist twice weekly, via telehealth, for the duration of their program, for a supervised, 60-minute resistance training session. Body weight training and resistance bands were the primary mode of resistance training delivery; however, the resistance training program may have also included resistance machines or free weights per participant access and preference. No equipment was provided to participants by the exercise program. Prescribed aerobic exercise was completed unsupervised by each participant. The goal of each participant's program was to work toward meeting the physical activity guidelines for cancer survivors [29].

Participants accessed the telehealth exercise visits directly through their online patient portal using any electronic device that was capable of video calls (eg, smartphone, tablet, laptop, etc). Telehealth visits were conducted directly through electronic health records (Epic Systems Corporation) which allow certified exercise physiologists easy access to the participants address, contact information, and emergency contacts. Participants' location for each telehealth exercise session and contact information, in case the telehealth session was disconnected, was verified by the certified exercise physiologist at the start of each session. While survivors had an out-of-pocket cost of approximately US $8 per telehealth exercise training visit, the baseline and follow-up assessments were covered by medical insurance reimbursement.

Measures

Overview

The following measures were included in the telehealth initial and follow-up assessments in the POWER program. When developing the telehealth assessment procedures, decisions about which measures to include were based on the feasibility of carrying out measures in a telehealth format and alignment with the in-person POWER program assessment [28]. When administering the telehealth assessments, the video camera angle was adjusted for each assessment so that the certified exercise physiologist could observe the full range of motion and ensure proper form was being used.

30-Second Chair Stand Test

Lower extremity function was evaluated with the 30-second chair stand test. Participants stood from a seated position, with arms crossed across their chest, and were instructed to stand up and sit down as many times as they could in 30-seconds [30]. The number of repetitions (ie, return to seated) completed in 30-seconds were recorded. Repetitions were counted using consistent methods across assessments and assessors to optimize the reliability of this assessment. The 30-second chair stand test has been shown to be a good predictor of lower extremity function in older adults [31] and safe to conduct using telehealth in adults with cancer [32]. Moreover, the 30-second chair stand test has good test-retest reliability in older adults with cancer (intraclass correlation [ICC]=0.89) [33,34]. A minimal clinically important difference (MCID) of 2.0 has been established for the 30-second chair stand test [35].

30-Second Maximum Push-Up Test

Muscular endurance was assessed using the 30-second push-up test. The starting position for push-ups was with the hands on the floor approximately shoulder width apart and arms straight. Participants were instructed to lower themselves down toward the floor until their chest was one fist width above the floor and then return to the starting position; this is one repetition. Participants were asked to complete as many push-ups as possible in 30-seconds. If the participant was unable to perform a standard push-up (on toes), they were able to modify by starting on their knees or performing wall push-ups depending on ability [36]. Any modifications made at baseline were replicated at follow-up.

2-Minute Standing March

Aerobic endurance was assessed using the 2-minute standing march test. Participants stepped in place with a step height no lower than the midpoint between the patella and iliac crest. The number of steps (right and left equals one) completed in 2-minutes were recorded. If necessary, participants could use one hand on a counter-top or a chair to assist with balance. The 2-minute standing march has been shown to be a good alternative to the 6-minute walk test [37,38] with strong test-retest reliability (ICC=0.99) when assessed among older adults via telehealth [39].

Single Leg Stance

Balance was assessed using a single leg stance. Participants were instructed to lift one foot off of the ground and balance on one leg without holding onto anything for support for as long as possible with their eyes open. The single leg stance was performed once on each leg. Time balancing without assistance (from hands or the other foot) was recorded for each leg. No maximum time cap was imposed for the single leg stance. The single leg stance test has demonstrated good reliability (ICC=0.86) among older adults [40].

Plank

Participants were asked to hold a forearm plank on either their toes or knees, self-selected based on their ability, for as long as they were able to assess torso muscular endurance. Each participant was instructed to keep their elbows directly under

their shoulders with forearms extended forward and a neutral spine and neck. The variation (ie, knees or toes) participants selected and total time participants were able to hold the plank were recorded. The plank assessment was not performed in cases where contraindications, such as cardiovascular concerns or upper extremity injuries, were present. Telehealth plank assessment has demonstrated good reliability (ICC=0.97) among adults [41].

Chair Sit and Reach

Hamstring flexibility was assessed using the chair sit and reach test. Participants sat on a chair near the front edge of the seat with one leg extended (ie, heel on the floor and foot dorsiflexed at approximately 90 degrees) and the other leg bent with the sole of the foot flat on the floor. Then they were asked to place one hand on top of the other with palms facing down. Participants were then instructed to slowly bend forward at the hips, keeping their back flat, as they reached down the extended leg as far as they could. A score was assigned based on how far participants were able to reach: a 2 for the toes, 1.5 for the ankle, 1.0 for the shin, 0 for anything above the shin. The chair sit and reach test has demonstrated good reliability (ICC=0.95) and validity among older adults [35,42].

Shoulder Range of Motion

Range of motion in the shoulder joint was assessed by measuring shoulder flexion, shoulder extension, and shoulder abduction. Range of motion for each movement was observed and visually estimated to the nearest 10 degrees during the telehealth initial assessment. Visual estimation of shoulder range of motion has demonstrated acceptable reliability (ICC=0.57 - 0.70) among adults [43].

Clock Test

The clock test is a modified back scratch test used to assess shoulder internal rotation. Participants were instructed to reach behind their back with their palm facing out with the goal of reaching their hand as far up their back as possible. The test was conducted on both the right and left sides. The test is scored by visually estimating the position of the arm in correspondence to a position on the face of a clock during the telehealth initial assessment. Scores range from six to eleven on the right and six to one on the left with eleven and one indicating the highest levels of shoulder flexibility, respectively.

Statistical Analysis

Descriptive statistics were reported as means and SDs or medians and IQRs for continuous variables and frequencies and percentages for categorical variables. Differences in age, BMI, and continuous initial assessment variables between older adults with cancer who did and did not complete a follow-up assessment were determined using independent samples *t* tests. Differences in categorical demographic, clinical, and initial assessment variables were assessed using chi-square tests. Among the older adults with cancer that completed a follow-up assessment, mean change variables were computed as the difference between the follow-up and baseline values. Missing assessment data were excluded case-wise to maximize the sample size for each variable. Change scores were compared to values considered to be the MCID. The 30-second chair stand test was the only assessment with a published MCID value [35]. Paired samples *t* tests were conducted to determine if there were significant differences in assessment outcomes following the exercise intervention. Cohen *d* effect sizes are reported as an indicator of effect size. A Cohen *d* of 0.2 was considered a small effect, 0.5 was considered medium, and 0.8 was considered large. For categorical outcomes mean change scores and 95% CIs were calculated to determine change across the intervention. All data were analyzed in SPSS (version 29.0; IBM Corp).

Ethical Considerations

The protocol and waiver of informed consent was approved by the University of Utah Institutional Review Board (IRB_00072431) in accordance with the Declaration of Helsinki. All data presented were deidentified using study identification numbers prior to analysis. Compensation was not included for this study.

Results

Participants

A total of 68 older adults with cancer completed an initial assessment via telehealth and participated in the POWER program between March 2020 and December 2021. Older adults with cancer who participated in POWER via telehealth were 71.8 (SD 5.3) years of age on average (range 65 - 92 y) and had a median BMI of 26.7 kg/m^2 (IQR 7.3; Table 1). Most older adults with cancer were female (n=45, 66.2%) and were not actively receiving treatment during their participation in POWER (n=40, 58.8%). The most common cancer types among older adults were breast (n=18, 26.5%), prostate (n=13, 19.1%), and multiple myeloma (n=8, 11.8%).

Table . Participant demographic and clinical characteristics.

Variable			Total sample (N=68)	Follow-up assessment completed (n=20)	Follow-up assessment not completed (n=48)	Baseline differences between groups, *P* value

[a]Not able to detect differences between groups.

[b]Active treatment: receiving any curative treatment during participation in the Personal Optimism With Exercise Recovery program.

[c]Statistical significance (*P*<.05).

[d]Treatment history: receiving the treatment type at any point in their care.

[e]Unimodal: 1 treatment type.

[f]Bimodal: 2 treatment types.

[g]Multimodal: 3 or more treatment types.

Of the 68 older adults who completed an initial assessment and participated in POWER, 29.4% (n=20) completed a telehealth follow-up assessment. The median time elapsed between initial and follow-up assessments was 16.5 weeks (IQR 5.75). The majority of older adults with cancer who completed a follow-up were on active treatment (n=12, 60%). Statistically significant differences were not observed among the following clinical and demographic variables among older adults with cancer who did and did not complete a follow-up assessment: age, BMI, sex, race, ethnicity, cancer stage, history of hormone therapy, immunotherapy, surgery, and radiation, number of treatment types, or cancer type. A statistically significant difference was observed for the proportion of older adults with cancer who reported being on active treatment (*P*=.04) and having received chemotherapy (*P*=.04) between those who did and did not complete a follow-up assessment.

Change in Measured Outcomes

Values for each measured outcome from the initial telehealth assessment are reported in Table 2. There were no significant differences in initial assessment outcomes between the follow-up and no follow-up groups (*P*>.05).

Table . Initial assessment data.

Variable	Follow-up assessment completed		Follow-up assessment not completed		Between group difference	Total sample	
	n	Mean (SD)	n	Mean (SD)	*P* value	n	Mean (SD)
Standing march	19	77 (35.4)	42	77.2 (33.3)	.98	61	77.1 (4.3)
30-s maximum push-up	20	12.9 (4.3)	38	13.2 (3.5)	.77	58	13.1 (3.8)
30-s chair stand	19	12.3 (6.7)	42	12.7 (5.8)	.84	61	12.6 (6)

Left	20	1.4 (0.6)	42	1.6 (0.4)	.16	62	1.6 (0.5)
Right	20	1.4 (0.6)	42	1.6 (0.5)	.40	62	1.5 (0.5)

Change in measured outcomes are reported in Table 3. Statistically significant changes were observed for the 30-second chair stand test (mean change +2.00 repetitions, 95% CI 0.12 to 3.88, Cohen *d*=0.51) and 30-second maximum push-up test (mean change +2.85 repetitions, 95% CI 1.60 to 4.11, Cohen *d*=1.06). Nine (47.3%) older adults with cancer had a change in 30-second chair stand scores that exceeded the MCID of 2.0 repetitions [35], and 14 (73.7%) older adults maintained their 30-second chair stand scores across the intervention. Although not statistically significant, positive changes were observed for the 2-minute standing march (mean change +12.79 repetitions, 95% CI −0.64 to 26.22, Cohen *d*=0.46), single leg stance on the left (mean change +4.80 s, 95% CI −0.67 to 10.27, Cohen *d*=0.44) and right (mean change +1.0 s, 95% CI −8.04 to 10.05, Cohen *d*=0.06), and shoulder abduction on the left (mean change +2.25 degrees, 95% CI −3.75 to 8.25, Cohen *d*=0.18) and right (mean change +0.25 degrees, 95% CI −4.34 to 4.84, Cohen *d*=0.03). The results from univariate analysis of covariance paralleled results from paired samples *t* tests.

Table . Change in assessment variables across the exercise intervention.

Variable	Quantity, n	Mean change	95% CI	*P* value	Cohen *d*[a]
Standing march	19	12.79	−0.64 to 26.22	.06	0.46
30-s maximum push-up	20	2.85	1.60 to 4.11	<.001[b]	1.06
30-s chair stand	19	2	0.12 to 3.88	.04[b]	0.51
Plank (s)	13	−5	−22.51 to 12.51	.55	0.17
Single leg stance (s)					
Left	18	4.8	−0.67 to 10.27	.08	0.44

Discussion

Principal Findings

This study aimed to evaluate the preliminary effectiveness of a hospital-based telehealth exercise oncology program on physical function, muscular endurance, balance, and flexibility among older adults with cancer. Our findings demonstrate that supervised, one-on-one telehealth exercise may positively influence physical function among older adults with cancer. Additionally, nearly half (n=9) of individuals who completed a follow-up assessment exceeded an MCID change in the 30-second chair-stand test, a marker of lower extremity function.

Comparison to Prior Work

The majority of research surrounding telehealth supervised exercise programs for older adults without [44,45] and with cancer [24,27] has focused on group exercise. Less is known about one-on-one telehealth exercise. Among older adults without cancer, participating in at least 12-weeks of supervised group telehealth exercise training prevents declines in physical function [44,45]. Among older adults with cancer, a feasibility study by Sattar et al [24] evaluated an 8-week group telehealth strength and balance training program and observed significant improvements in five time chair stand test scores. Additionally, Gell et al [27] carried out a pilot trial examining a 16-week group telehealth aerobic and resistance training program and observed significant improvements in 30-second chair stand test scores. Collectively, group telehealth exercise programming among older adults with and without cancer is effective at improving physical function.

Findings from this study contribute to the literature by addressing an important gap in our understanding regarding the effectiveness of one-on-one telehealth exercise among older cancer survivors. Among cancer survivors of all ages (range 14 - 83 y), effectiveness of one-on-one supervised telehealth exercise has been evaluated [22]. Following 12-weeks of one-on-one training with a cancer exercise trainer once per week, cancer survivors significantly improved cardiovascular endurance, muscular endurance, and flexibility [22]. Findings from our study support previous research suggesting one-on-one telehealth exercise programs may positively influence physical function among older adults with cancer. Without exercise

intervention, we would expect to see little to no change in physical function parameters over short durations in older adults living with cancer. Over 13-weeks Mikklesen et al [11] found a mean change of +0.4 repetitions in the 30-second chair stand test and −1.0 points in self-reported physical function among older cancer survivors receiving standard of care and no exercise intervention. Over longer durations (eg, ≥1 y) functional declines are greater and can persist for years following diagnosis [6]. Preventing declines in physical function is important in this population because physical function has been shown to have a protective effect against all-cause mortality in older adults with cancer [8].

In addition to examining the effect of one-on-one, supervised telehealth exercise on physical function in older adults with cancer, we also characterized older adults with cancer who chose to participate in a telehealth exercise program. This information adds to our body of knowledge by demonstrating that older adults with cancer can engage in one-on-one telehealth delivered exercise programs. Additionally, we observed that a significantly greater proportion of older adults with cancer who were on active treatment or had received chemotherapy completed a follow-up assessment. This finding suggests that older cancer survivors on active cancer treatment are willing to engage in telehealth exercise which is important as recent recommendations from the American Society of Clinical Oncology encourage cancer survivors on active treatment to participate in aerobic and resistance exercise [46]. Understanding who we are reaching with telehealth exercise programs, who may be missing, and who completes a telehealth follow-up assessment can inform the development of interventions to improve the engagement and reach of telehealth delivered exercise programming among cancer survivors of all ages.

Strengths and Limitations

To our knowledge, this is one of the first studies that has evaluated effectiveness of one-on-one telehealth exercise programming exclusively among older adults with cancer and characterized the older adults who used this programming. We consider this a strength of our work. Additionally, the use of an established hospital-based exercise oncology program with over 15 years of experience offering telehealth exercise ensured high-quality exercise programming in this study. However, our study is not without limitations. First, the low follow-up assessment completion rate resulted in a small sample size and an underpowered analysis to demonstrate statistically significant changes in all outcomes measured. Therefore, the findings from this study are preliminary and additional research with a larger sample is needed. Second, the retrospective design of this study may have resulted in selection bias of participants who were more motivated to exercise and follow-up. Highly motivated individuals may be more likely to complete a follow-up assessment in the program potentially confounding the effects of the telehealth exercise program. Third, baseline and follow-up assessments were scheduled based on the participants' availability which resulted in different staff conducting baseline and follow-up assessments for some participants. However, a small team of certified exercise physiologists administered all virtual assessments, adhering to standardized program procedures to minimize interrater variability. Fourth, the lack of a nonexercise control group limits the conclusions that can be made regarding the ability of telehealth exercise to prevent declines in physical function. Future work should consider a prospective study design and inclusion of potential confounding variables as covariates to determine the effectiveness of one-on-one telehealth exercise on markers of physical function.

Conclusions

In summary, older adults living with and beyond cancer are able to participate in an exercise oncology program delivered via telehealth. Our findings provide preliminary evidence that telehealth may be a beneficial tool to facilitate exercise program delivery among older adults following a cancer diagnosis. However, telehealth exercise should not be considered a one-size-fits-all all approach as in-person, telehealth, or a combination of the two may be a better fit for some older adults with cancer, based on their needs and preferences. Further research is needed to understand the magnitude of the effects of one-on-one, supervised telehealth exercise on physical function among older adults with cancer.

Abstract

Background: Exercise interventions are among the best-known interventions for cancer-related fatigue (CRF). Rural survivors of cancer, however, report specific barriers to engaging in exercise programs and lack overall access to effective programs.

Objective: The purpose of this investigation was to assess the feasibility of a novel telehealth exercise program designed specifically for rural survivors of cancer with CRF.

Methods: A single-arm clinical trial of the BfitBwell Telehealth Program was performed. Based on an established clinical program, this adapted 12-week program addressed barriers previously reported by rural survivors by providing synchronous videoconference exercise sessions (2 per program), asynchronous exercise sessions using a personal training smartphone or internet app (3-5 per week), and regular symptom (CRF) monitoring using automated emailed surveys (every 2 weeks). Personalized exercise prescriptions containing aerobic and resistance activities were implemented by cancer exercise specialists. Symptom-triggered synchronous sessions were initiated for participants failing to improve in CRF, as identified by a reference chart of CRF improvements observed during a supervised exercise program. Eligible participants were adult survivors of any cancer diagnosis who had completed treatment with curative intent in the past 12 months or had no planned changes in treatment for the duration of the study, lived in a rural area, and were currently experiencing CRF. Feasibility was assessed by objective measures of recruitment, data collection, intervention acceptability and suitability, and preliminary evaluations of participant responses. CRF was the primary clinical outcome (assessed using the Functional Assessment of Chronic Illness Therapy—Fatigue Scale [FACIT-Fatigue]) and was measured before, after, and 6 months after program completion.

Results: In total, 19 participants enrolled in the study, 16 initiated the exercise program, and 15 completed the program. A total of 14 participants were recruited through internet advertisements, and the total recruitment rate peaked at 5 participants per month. Participants completed 100% of initial and final assessments (30 assessments across all participants) and 93% (70/75 possible surveys across all participants) of emailed surveys and attended 97% (29/30 possible sessions across all participants) of synchronous exercise sessions. In total, 6 participants initiated symptom-triggered sessions, with 6 of 7 initiated sessions attended. The mean FACIT-Fatigue scores significantly improved (P=.001) by 11.2 (SD 6.8) points following the completion of the program. A total of 13 participants demonstrated at least a minimal clinically important difference in FACIT-Fatigue scores (≥ +3 points) at this time. FACIT-Fatigue scores did not significantly change from program completion to 6-month follow-up (n=13; mean change –1.1, SD 3.4 points; P=.29).

Conclusions: Results from this investigation support the feasibility of the BfitBwell Telehealth Program and a subsequent efficacy trial. Novel program components also provide potential models for improving exercise program efficacy and efficiency through asynchronous exercise prescription and symptom monitoring.

Introduction

Cancer-related fatigue (CRF) is one of the most common and functionally limiting symptoms reported by survivors of cancer, with an estimated prevalence of 49% to 62% [1-4]. It is present in over a quarter of survivors up to 10 years after the completion of treatment [5], and survivors regularly report CRF as the symptom preventing them from living a "normal" life as well as the cause of major life events such as employment changes [6]. Participation in exercise interventions is an established intervention for the improvement of CRF in survivors of cancer [7,8], and a multidisciplinary roundtable pronouncement by the American College of Sports Medicine (ACSM) indicated that there is strong evidence that exercise can significantly reduce CRF. The current ACSM recommendation for an effective exercise prescription to remediate CRF is moderate-intensity aerobic training at least 3 times per week for at least 30 minutes and moderate-intensity resistance training at least 2 times per week [9].

Survivors of cancer living in rural locations [10], however, commonly lack access to many supportive services compared to nonrural survivors, including clinical exercise programs [11]. Rural survivors commonly report many specific barriers to engaging in exercise programs including lack of knowledge of available programs, distance and transportation to programs, lack of access to a knowledgeable exercise provider, and lack of flexibility in programming (in terms of time and location) [12,13]. An overall lack of accessible exercise programs for rural survivors has been identified in a recent review [14]. A survey of rural survivors reported that only 38% and 10% were currently meeting aerobic and resistance training guidelines for survivors, respectively [12], demonstrating a clear need to increase accessible exercise programs for this population.

While current initiatives are designed to increase the accessibility of exercise programs for rural survivors of cancer [15,16], additional opportunities exist in the development of novel rural-focused program designs. The Exercise for Cancer to Enhance Living Well study in Canada [15] provides an exemplary model of using and improving clinical networks to increase awareness of and access to exercise oncology programs for rural survivors. The intervention itself, however, mirrors the available supervised programs by replacing in-person services with telehealth services, similar to other telehealth adaptations in the United States [17], which may not address all barriers experienced by survivors in rural areas. Beyond these examples, most other currently accessible exercise programs for rural survivors are phone-based walking programs [14]. Given that supervised exercise programs consistently demonstrate greater improvements in CRF compared to unsupervised programs [8], the efficacy of these current programs may be limited by the lack of consistent supervision and the recommended resistance exercise. Continued innovation in program designs specifically for the rural population is required to truly reduce geographic disparities targeting both improved accessibility and efficacy.

The purpose of this single-arm feasibility study was to assess a novel telehealth exercise program designed specifically for rural survivors of cancer with CRF, with an emphasis on replicating the CRF improvements seen in clinically supervised exercise programs. The program addresses known participation barriers for rural survivors and uses a validated reference chart of CRF improvement in a supervised program combined with regular symptom monitoring and symptom-triggered intervention. Data collection and outcome selection were designed to assess recommended objectives for feasibility studies [18] including recruitment, data collection, intervention acceptability and suitability, and a preliminary evaluation of participant responses. It was hypothesized that the program would demonstrate overall feasibility based on these objectives, providing support for a larger efficacy study.

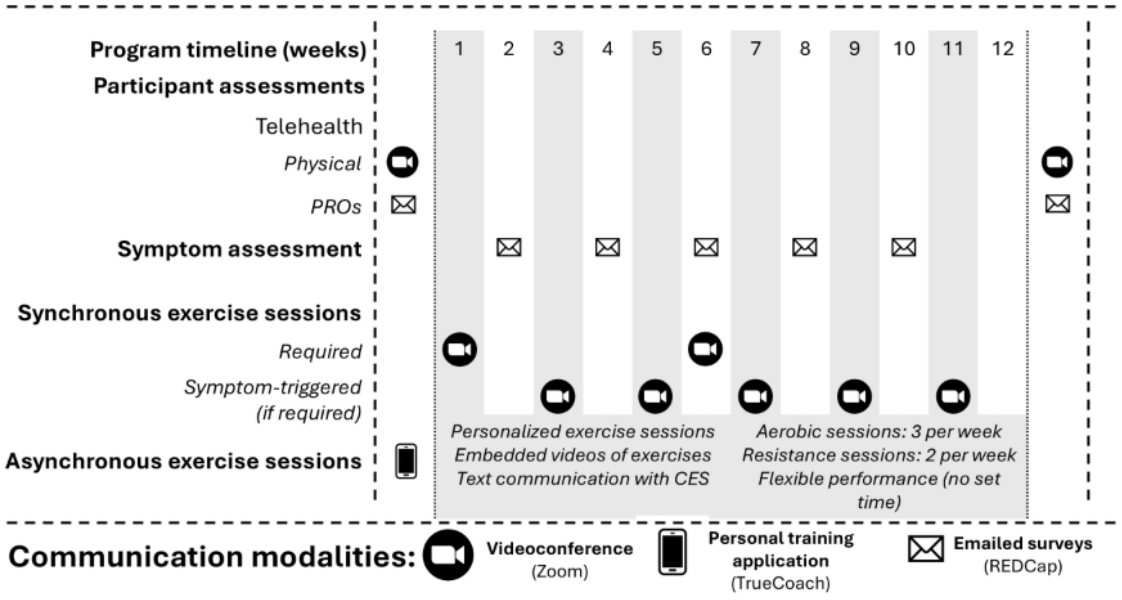
Methods

Study and Program Design

This was a single-arm clinical trial of the BfitBwell Telehealth Program (Figure 1), with assessments at baseline, program completion (12 weeks), and 6-month follow-up. Data collection occurred between November 2021 and September 2023. This 12-week telehealth exercise program was adapted from the clinically supervised BfitBwell Cancer Exercise Program [19,20]. Initial adaptations were made internally by program and research staff and designed to (1) address known barriers to exercise participation in rural survivors of cancer and (2) replicate the effects of a supervised clinical exercise program via telehealth. The specific barriers addressed were distance and transportation, lack of program flexibility (in regard to time and location), and lack of access to a knowledgeable exercise provider [12,13]. Participation in the BfitBwell Telehealth Program was decentralized, with centralized program oversight, to remove distance and transportation barriers. Three telehealth technologies were used: videoconferencing software (Zoom Video Communications, Inc), a personal training smartphone or internet app (TrueCoach Inc), and automated emails (REDCap [Research Electronic Data Capture]; Vanderbilt University

[21,22]). The majority of exercise sessions were delivered asynchronously (ie, without real-time interaction between the participant and cancer exercise specialist [CES]) via the personal training app to provide program flexibility. Participants received scheduled (eg, recommended day of performance) and personalized exercise sessions via the app, but the timing of performance was determined by participants (eg, participants could complete sessions at any time of day, and "missed" sessions could be performed on later days). The personal training app also allowed embedded text communication between the prescribing CES and the participant following each individual exercise or exercise session. This within-app communication facilitated direct access to a knowledgeable exercise provider, as did regular engagement via automated emails for symptom monitoring.

Figure 1. The design of the BfitBwell Telehealth Program with the timing of program components delivery. CES: cancer exercise specialist; PRO: patient-reported outcome; REDCap: Research Electronic Data Capture.



Symptom monitoring was accomplished by plotting individual participant CRF scores on a validated reference chart of CRF improvements during a supervised exercise program [23]. The reference chart displays the typical course of CRF improvement for individuals in the supervised BfitBwell Cancer Exercise Program, against which the progress of individual participants can be easily monitored. The supervised BfitBwell Cancer Exercise Program has demonstrated effectiveness for improving CRF [19,20]. This type of reference chart has previously been proposed to inform personalized rehabilitation in other clinical populations [24,25]. In the BfitBwell Telehealth Program, CRF was monitored every 2 weeks and used to initiate symptom-triggered exercise sessions for participants failing to improve as predicted by the reference chart (see Symptom Tracking and Symptom-Triggered Sessions section). This served as the primary means of replicating the effects of a supervised program in a rural setting, as the reference chart allows individual participant progress to be compared to that of similar participants from a supervised program.

Finally, to promote participant safety in this remote telehealth context, a detailed safety and emergency response plan was developed. This plan included regular verification of the physical location of all videoconference sessions and the identification of a nearby "local support individual" (though this individual did not need to be present for assessments or sessions). Detailed plans of action were developed for emergent and nonemergent adverse events.

Participants

Eligibility criteria for participation were adults ≥18 and ≤80 years of age, a diagnosis of any cancer type and any stage, completion of medical cancer treatment with curative intent within the past 12 months, or currently receiving treatment with no planned changes for the next 4 months. These criteria are similar to the patient population in the supervised BfitBwell Cancer Exercise Program and the associated CRF reference chart. Additional eligibility criteria included current moderate to severe CRF (>3 on a 10-point scale per National Comprehensive Cancer Network definition [26]), high-speed home internet and videoconference capable device (smartphone or laptop with camera), and residence in a rural area (defined here as >1-hour commute to a major city in Colorado or surrounding states with a known exercise oncology program, based upon review of a national program directory) [27]. Exclusion criteria included medical conditions that would impact the safety of, or participation in, a telehealth exercise program (eg, significant pulmonary or cardiovascular conditions and

mobility-limiting orthopedic conditions). These conditions were self-reported on screening forms and individually reviewed by a licensed physical therapist (RJM) to determine eligibility. Safety was again assessed by the same therapist during the initial assessment (see Assessments section)).

A power analysis was not performed a priori, but a goal of 20 enrolled participants (with 15 completing the program) was set at study initiation. This recruitment goal was based primarily on the capacity of the supporting clinical exercise program combined with historical attrition rates of 25%.

Recruitment and Enrollment

Initial recruitment efforts were made through clinical staff at a large urban cancer center that serves rural Colorado and surrounding states. Incoming and recent participants in the supervised BfitBwell Cancer Exercise Program were screened for eligibility. Recruitment efforts were later adapted to include targeted internet and social media advertisements (BuildClinical, LLC). Participants recruited through these efforts completed screening evaluations via emailed surveys or phone calls with study personnel. Eligible and interested participants were then invited to live videoconference sessions to further discuss the study and provide written informed consent. Enrolled participants were mailed all necessary equipment including a resistance exercise band set, a commercial fitness tracker (Withings Move, Withings Health), a smartphone tripod, an aerobic step (adjustable height 2-8 inches), and other necessary assessment equipment (eg, a measured length of rope, tape measure, and a pulse oximeter). Participants were incentivized to enroll by being allowed to keep all mailed study equipment, and gift cards were distributed to facilitate program and within-program survey completion.

Primary Clinical Outcome

CRF was the primary clinical outcome and was assessed using the Functional Assessment of Chronic Illness Therapy—Fatigue Scale (FACIT-Fatigue) [28]. The FACIT-Fatigue is one of the most common measures of CRF with demonstrated reliability and validity in survivors of cancer [8,29]. It is a 13-item scale with scores ranging from 0 to 52, with higher scores indicating less CRF, asking participants to consider how they have felt during the past week. The minimal clinically important difference (MCID) of the FACIT-Fatigue scale has been identified as 3 points [30].

Assessments

Initial and final assessments were performed via videoconference by a licensed physical therapist (RJM, separate from program CESs). In addition to collecting study outcomes, the initial assessment served as a final assessment of participant safety (based on the physical therapist's clinical observations and judgment) and provided information used by the CES to personalize the exercise prescription. Demographic and cancer-related information were collected, and basic measures of physical fitness and function were performed similar to prior studies of telehealth assessments in survivors of cancer (adapted to be performed safely if the participant was alone) [31]. Physical assessment outcomes included single limb stance [32], gait speed [33], timed up and go [33], 30-second sit-to-stand [34], and a 3-minute step test (following the Tecumseh protocol [35]). Participants were interviewed about previous exercise experience, exercise preferences and goals, and available exercise resources (eg, home equipment and local gymnasiums). Patient-reported outcomes were then collected via emailed surveys. These included the FACIT-Fatigue [28], Functional Assessment of Cancer Treatment—General [36], Hospital Anxiety and Depression Scale [37], and the Godin Leisure-Time Exercise Questionnaire (GLTEQ, modified to estimate weekly moderate to vigorous physical activity and resistance exercise) [38]. Assessments occurred within the 2 weeks prior to intervention initiation and after completion. Patient-reported outcomes were again emailed to participants 6 months following program completion (follow-up assessment).

Exercise Intervention

Exercise prescription followed current recommendations for survivors of cancer from the ACSM, specifically targeting 2 resistance exercise sessions and three 30-minute aerobic exercise sessions per week [9]. The prescribed exercise plan was delivered by 2 CESs employed by the supervised BfitBwell Cancer Exercise Program and resembled typical sessions for this program, previously described [19,20]. Both CESs (IAM and JJS) had an undergraduate degree in exercise science (or a related field), an exercise training certification (ACSM Certified Exercise Physiologist or equivalent), and at least 4 years of experience working exclusively with survivors in the supervised BfitBwell Cancer Exercise Program, and the primary CES (IAM) had an ACSM-CES certification. Resistance exercises targeted large upper and lower extremity muscle groups (using resistance bands, participant equipment, household objects, and body weight), and aerobic exercise was based on participant preference and available equipment (typically outdoor walking, treadmill walking, or stationary cycling). All exercise plans were personalized based on participant abilities, preferences, and available resources (established during the initial assessment).

Exercise Sessions

One-hour, synchronous videoconference telehealth exercise sessions were scheduled with all participants in weeks 1 and 6. These sessions were performed in real time with the CES and participants interacting via live videoconference, mirroring an in-person supervised exercise session. Session content focused on providing education on exercise, demonstration and practice of proper exercise form, and supervised performance of exercises prescribed in the subsequent 6 weeks. All other exercise sessions (except the symptom-triggered sessions described in the next section) were delivered asynchronously via the personal training smartphone or internet app and included detailed individualized exercise content with embedded videos of a program CES performing the prescribed exercises. Participants had to indicate each exercise as completed within each session, creating a self-report measurement of asynchronous session completion. The embedded text communication between the prescribing CES and participant was regularly reviewed by the CES, who would then respond and adapt subsequent asynchronous exercise sessions, as

necessary. The app was available via both smartphone app and internet browser.

Symptom Tracking and Symptom-Triggered Sessions

Participants were emailed the FACIT-Fatigue 2 days prior to initiating the exercise program and every 2 weeks during the program, with daily reminders sent for up to 3 days. FACIT-Fatigue scores were monitored using the CRF reference chart to detect whether an individual's progress matched the typical progress of similar individuals in a supervised exercise program, based on percentile rank established by initial scores. A symptom-triggered, synchronous videoconference exercise session was scheduled in the week following a FACIT-Fatigue score ≥3 points lower than the projected percentile at a given measurement time. The threshold was based on the MCID of the FACIT-Fatigue [30] in an attempt to ensure that symptom-triggered sessions were initiated due to a true lack of progress rather than normal variation or measurement error. Symptom-triggered session length ranged from 15 to 60 minutes, and a CES discussed program progress and challenges with the participant, with adaptations made to improve program response. These sessions were designed to mirror what would occur in a supervised program for participants who expressed a poor exercise response (eg, stated they continued to have fatigue) or in whom the CES identified a poor response (eg, performance plateau or decline). Common adaptations included changes in various exercise prescription components (Frequency, Intensity, Timing, and Type, via the ACSM guidelines [39]) and were made based on CES judgment in each occurrence. Emailed surveys also included a simple form for participants to ask exercise-related questions and request an additional videoconference exercise session the following week, even if not triggered by FACIT-Fatigue scores.

Outcomes

Rationale

All outcomes were designed based on the recommended objectives, with guiding questions, for feasibility studies, as described by Orsmond and Cohn [18]. The current investigation focused on the use of collected objective data. While the ability of the research team to conduct the study and provide the intervention was not directly assessed, evaluation of other objectives allowed an indirect assessment (eg, successful data collection and attendance rates support the ability of the research team to perform these tasks). "Success" thresholds for feasibility outcomes were not set a priori, but rather outcomes were assessed holistically following the study as a means of assessing overall feasibility, providing the context of experience acquired while delivering the pilot program.

Recruitment

The number of participants screened, determined eligible, and ultimately enrolled were tracked, as was the recruitment rate (participants enrolled per month). The medium by which enrolled participants were recruited was recorded (eg, clinical referral or targeted internet and social media advertisements). The demographics of enrolled participants were summarized and separated by those who did and did not complete the program.

Data Collection

Completion rates of all clinical program outcomes from the initial, final, and follow-up assessments were calculated. Completion rates of the within-program emailed surveys (of 5 total) were calculated.

Intervention Acceptability and Suitability

Attendance rates were calculated for videoconference assessments and synchronous exercise sessions (including both the standard [2 sessions] and symptom-triggered sessions [up to 5 sessions]). Completion rates were calculated for asynchronous exercise sessions (based on downloaded session logs including previously described self-reported completion). Program safety was assessed by recording the number and nature of adverse events.

Preliminary Evaluation of Participant Responses

Participant responses to the intervention were evaluated by calculating changes in patient-reported and physical outcomes from initial to final assessments. Maintenance of participant responses following the intervention was investigated by calculating changes in patient-reported outcomes from final to follow-up assessments. FACIT-Fatigue change was also assessed on an individual participant level, with the number of participants achieving an MCID following the program determined. Within-program individual changes were visually investigated by plotting FACIT-Fatigue scores on the CRF reference chart, along with the occurrence of symptom-triggered sessions.

Statistical Analysis

As a feasibility study with a small sample size, the majority of outcomes were summarized with descriptive statistics (counts, percentages, means, and SDs) and separately quantified for each assessment time point (initial, final, and follow-up) when appropriate. Following recommendations [18], the preliminary evaluation of participant responses was assessed using multiple approaches. In addition to the descriptive statistics provided for clinical outcomes and their change scores, the significance of change scores was assessed by statistically comparing these scores to 0 (ie, representing no change) using the nonparametric Wilcoxon signed rank test, as recommended for smaller studies as it does not assume a normal data distribution [40]. Significance was set at $\alpha<.05$, established a priori, without correction for multiple tests, but with the presentation of individual *P* values facilitating further scrutiny. The clinical meaningfulness of changes in FACIT-Fatigue scores, the primary clinical outcome, was assessed by summarizing the participant-level outcomes and visual investigations (see Preliminary Evaluation of Participant Responses section). Only participants with available data were included in each analysis, with sample sizes reported for each analysis. All statistical analyses were performed using R statistical software (R Foundation for Statistical Computing).

Ethical Considerations

This study was reviewed and approved by the Colorado Multiple Institutional Review Board (COMIRB # 20-2015) and registered on ClinicalTrials.gov (NCT04533165). All participants provided

written informed consent prior to enrollment. Participants were incentivized to enroll by being allowed to keep all distributed assessment and exercise equipment (approximate US $200 value). Within-program survey completion was incentivized by providing a US $50 gift card if at least 3 were completed. Participation in the final assessment was incentivized with a US $50 gift card upon completion. Study data were stored securely in REDCap, and analyses used deidentified data.

Results

Recruitment

Figure 2 displays the flow of participants from screening to program completion, with attrition at each stage. Ultimately, 51 survivors of cancer were screened, 19 enrolled in the program, and 15 completed the program. All enrolled participants reported a “White” racial background. No participants reported Hispanic or Latino ethnicity. Of the enrolled participants, 14 (74%) were recruited through internet and social media advertisements, 4 (21%) were recruited from a registry of past participants in the supervised BfitBwell Cancer Exercise Program, and 1 person was recruited through clinical connections at a large urban cancer center. When all recruitment efforts were active, the maximum recruitment rate was 5 enrolled participants per month. Demographics and cancer-related data for enrolled participants, separated by those who did and did not complete the program, are shown in Table 1, and reasons for study withdrawal are shown in Figure 2 (note that most withdrawal reasons are unrelated to demographic and cancer-related data). All subsequent results include only participants who completed the program (and follow-up assessment when relevant).

One participant was withdrawn from the study due to the clinical determination that participation in a telehealth exercise program would not be safe due to previously unreported balance impairments, making the participant ineligible for the investigation. This safety determination was based primarily upon movement observation and objectively supported by poor performance on physical measures (single limb stance=3.5 seconds, gait speed=0.92 m/s, and inability to perform step test despite adaptation). Upon informing the participant of this decision, the study team facilitated a connection to a nearby facility providing supervised and skilled rehabilitation.

Figure 2. Illustration of screening, enrollment, and attrition during the study. CRF: cancer-related fatigue.

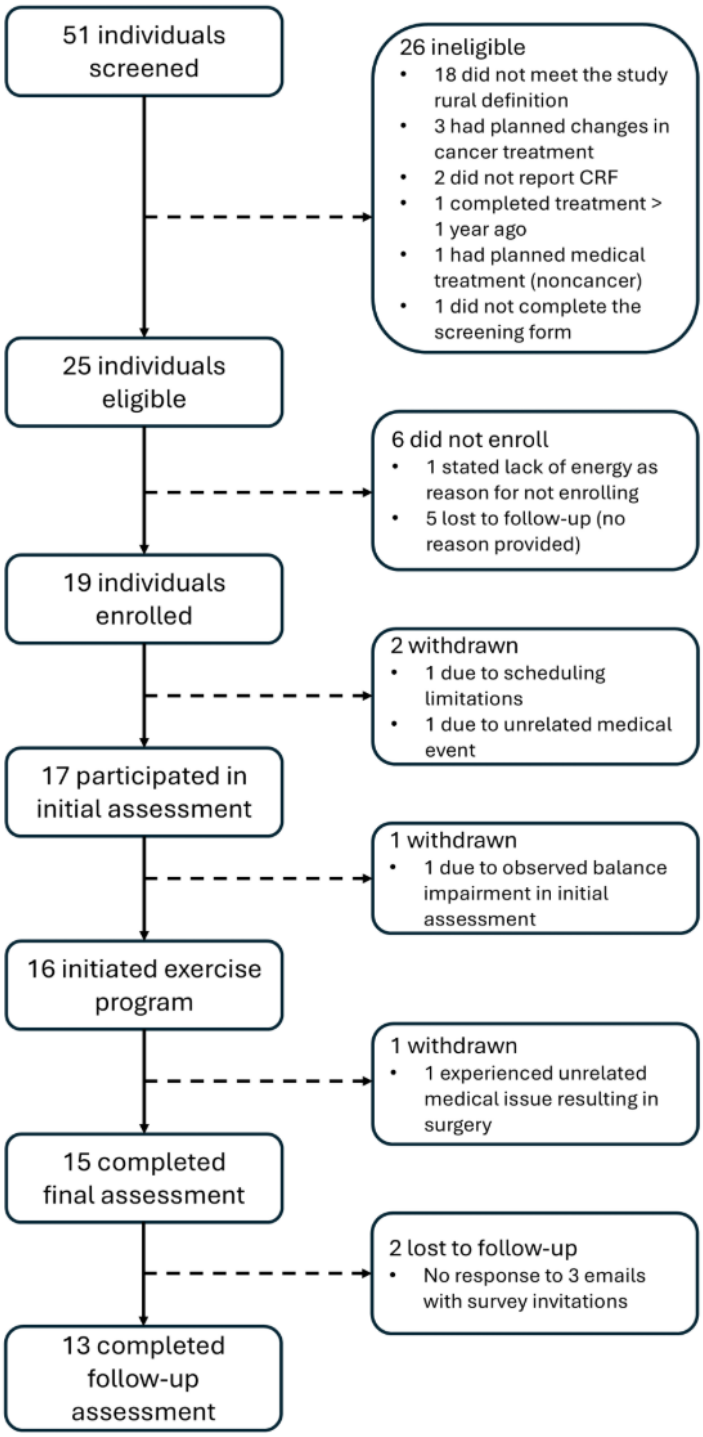


Table 1. Enrolled participant demographic and cancer-related information.

Data Collection

All physical assessment outcomes were successfully completed during the initial and final assessments except the 3-minute step test. In total, 3 participants were unable to maintain the required step rate for the duration of the test, 1 participant did not perform the test due to concerns of exceeding a safe heart rate (85% age-predicted maximum), and 2 participants experienced technical difficulties in measuring heart rate following completion of the test. All patient-reported outcomes were successfully completed at the initial assessment, and only 1 participant failed to complete both the Hospital Anxiety and Depression Scale and GLTEQ (presented last in emailed surveys) at the final assessment. In total, 13 (87% of those completing the program) participants completed all patient-reported outcomes at the follow-up assessment. The average completion rate of the within-program emailed surveys was 93% (70/75 surveys across all participants), with 12 (80% of those completing the program) completing 100%.

Intervention Acceptability and Suitability

Attendance at initial and final videoconference assessments was 100% (30/30 possible assessments attended across all participants). Attendance at videoconference exercise sessions (weeks 1 and 6) was 97% (29/30 possible sessions attended), with only 1 participant missing 1 session. In total, 7 symptom-triggered sessions were initiated in 6 participants, with 6 (86%) of these sessions attended. A total of 3 participants requested 1 additional session, and 1 participant requested 2 additional sessions (non–CRF related). A total of 5 participants did not trigger or request any additional sessions. Participants received an average of 58 (SD 7) asynchronous sessions each, with an average of 49 (SD 11) indicated as complete (49/58, 84%, individual range 38%-100% [23/60 and 60/60 possible sessions completed, respectively]).

In total, 7 adverse events were reported in 6 participants. Of them, 2 were minor musculoskeletal issues (muscle strains) likely related to the exercise intervention. The remaining events were unrelated to the exercise intervention (minor musculoskeletal issues and illness).

Preliminary Evaluation of Participant Responses

Table 2 displays the averages and changes in all outcomes at initial, final, and follow-up assessments. Group changes in all patient-reported outcomes from initial to final assessments were significantly different from 0 (in directions demonstrating improvement; all *P* values <.05, see Table 2 for individual values). Change in 30-second sit-to-stand was significantly greater than 0 (*P*=.005), and change in timed up and go trended toward being less than 0 (*P*=.09). At the follow-up assessment,

only self-reported resistance exercise (GLTEQ-Resistance) significantly decreased from the final assessment (*P*=.01).

Table 2. Patient-reported and physical outcomes at initial, final, and 6-month follow-up assessments (n=15).

Figure 3 displays the individual FACIT-Fatigue changes from the initial to final assessments. In total, 13 of 15 (87%) participants demonstrated an MCID in FACIT-Fatigue change. Figure 4 displays individual within-program FACIT-Fatigue scores, plotted on the CRF reference chart, for participants who did not require any symptom-triggered exercise sessions. Figure 5 displays individual within-program FACIT-Fatigue scores, plotted on the CRF reference chart, for participants requiring symptom-triggered exercise sessions, along with sessions attended. Of note, FACIT-Fatigue scores improved following symptom-triggered exercise sessions in 5 of 6 events, following previous declines.

Figure 3. Waterfall plot displaying individual participant (n=15) changes in FACIT-Fatigue from initial to final assessments. The sample mean and FACIT-Fatigue MCID are displayed as dotted lines. Note that an increase in the FACIT-Fatigue score indicates improved fatigue. FACIT-Fatigue: Functional Assessment of Chronic Illness Therapy—Fatigue Scale; MCID: minimal clinically important difference.

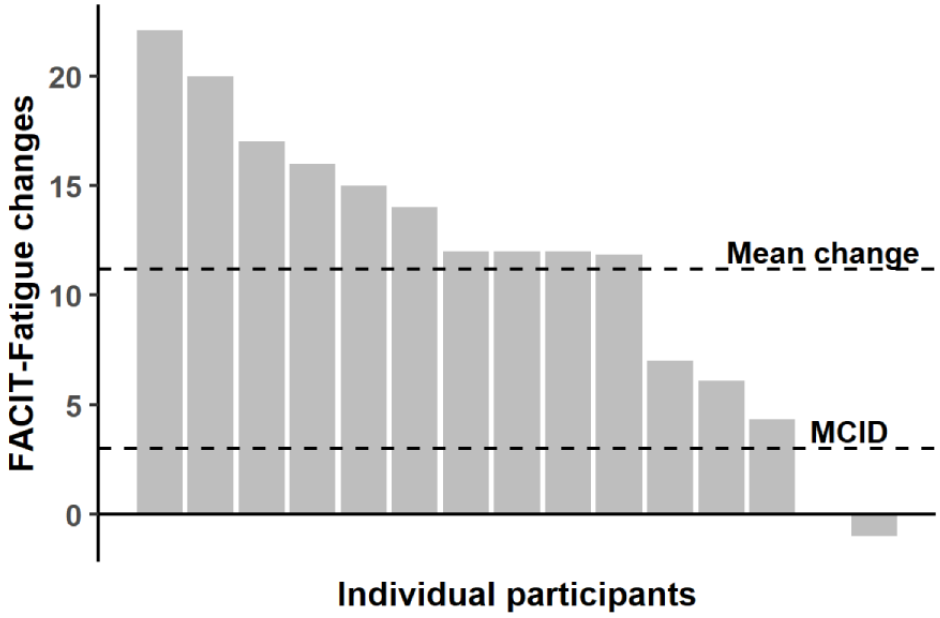

Figure 4. Within-program FACIT-Fatigue scores for participants with no required symptom-triggered exercise session (n=9) plotted on the cancer-related fatigue reference chart. FACIT-Fatigue: Functional Assessment of Chronic Illness Therapy—Fatigue Scale.

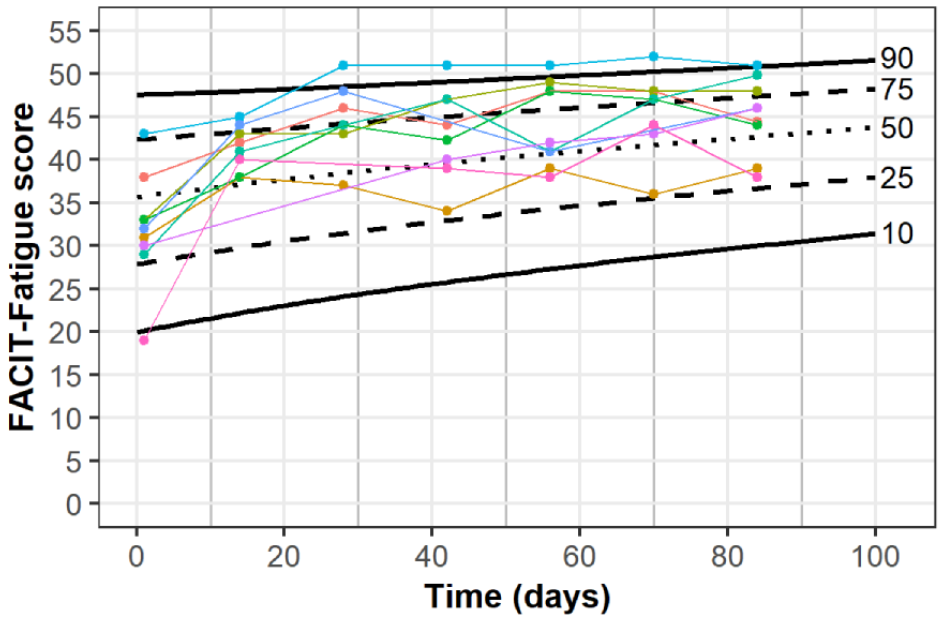

Figure 5. Within-program FACIT-Fatigue scores for participants requiring symptom-triggered exercise sessions (n=6) plotted on the cancer-related fatigue reference chart. Attended symptom-triggered sessions are indicated with circles. FACIT-Fatigue: Functional Assessment of Chronic Illness Therapy—Fatigue Scale.

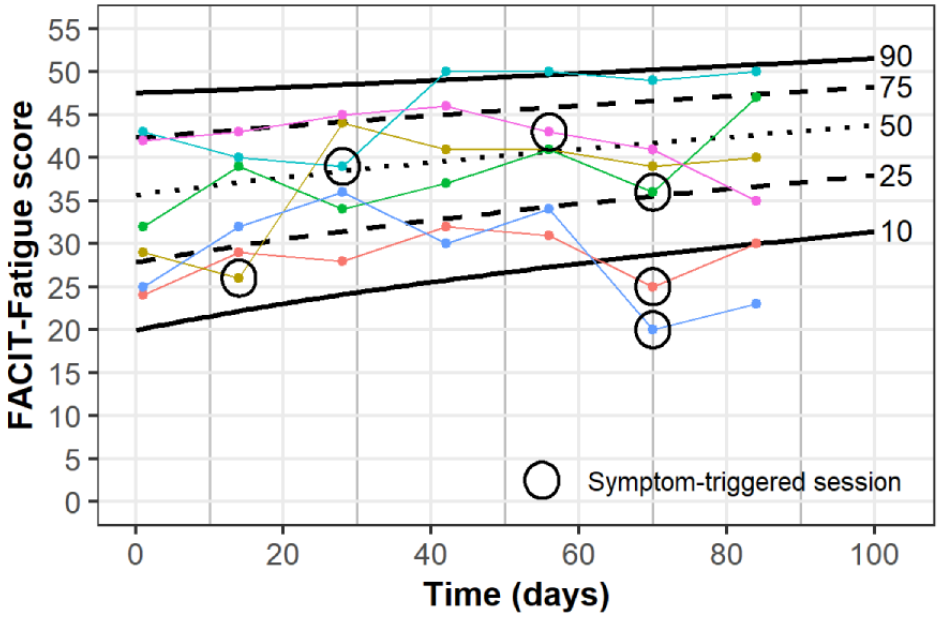

Discussion

Principal Findings

This investigation assessed the feasibility of the novel BfitBwell Telehealth Program for rural survivors of cancer with CRF. Initial recruitment barriers were overcome through the adoption of alternative strategies (targeted internet advertisements). Outcome completion rates and intervention adherence rates were high, demonstrating the feasibility of data collection and intervention acceptability and suitability. Significant and meaningful improvements in CRF were observed at both the group and individual levels in the preliminary evaluation of participant responses. Based on these assessments of the recommended objectives [18], the BfitBwell Telehealth Program appears to be highly feasible, supporting the progression to a large efficacy trial.

Comparisons to Prior Work

One of the main goals of this feasibility study was to adjudicate avenues for recruitment of eligible rural-living individuals. Given the barriers in accessing this population, it is not surprising that little work has been done specifically investigating the recruitment of rural-living people with cancer into exercise programs. A recent review of recruitment rates and strategies in exercise trials for survivors of cancer (not rural specific) revealed a low overall recruitment rate of 38%, with only 11% of included trials using web-based advertisements [41]. Additionally, “passive” strategies (including web-based advertisement) resulted in lower rates than “active” strategies (including clinic-based recruitment). Another larger exercise trial in rural survivors also demonstrated the success of active strategies such as community and clinical engagement [16]. Our findings contrast with these previous studies, in that only 5% of participants were enrolled as a result of active recruitment strategies (ie, clinical connections) at a large urban cancer center. A much more productive approach involved the use of targeted internet and social media advertisements. These approaches may indeed be considered more “active” than previous web-based approaches, as advertisements are routed to individuals based on their past internet activity. The reach of these advertisements to rural communities is undoubtedly broader than what can be achieved through clinic-based recruitment approaches. In our case, web-based recruitment might also provide a good match for individuals seeking a web- or telehealth-based program. More investigation is required into how to best engage and recruit rural survivors in exercise programming and associated clinical trials.

A unique aspect of our particular program was the reference chart–based monitoring of participant response to exercise along with the standardized addition of symptom-triggered sessions when participant progress deviated from the expected response. Lower than expected CRF improvements triggered additional sessions in 6 (40%) participants, and subsequent CRF scores appeared to improve following these symptom-triggered sessions (Figure 5). The purpose of these sessions was to mirror within-program exercise adaptations that are common in supervised clinical exercise programs in response to provider observations. While this facet of personalized exercise prescription is a relatively emergent feature in contemporary clinical research, the approach adheres to recommended best practices published by the National Comprehensive Cancer Network [42]. The current combination of symptom monitoring and symptom-triggered intervention is similar to a previous study of “chemotherapy-periodized” exercise, which demonstrated improved attendance when exercise prescription was adapted in anticipation of changing chemotherapy-associated symptoms during consecutive chemotherapy cycles [43]. Adaptations in the current program were made in accordance with the ACSM Frequency, Intensity, Time, and Type criteria of exercise prescription [39] and were

based on CES expertise and information gathered during participant discussions.

Exercise attendance and program completion rates in our study were high. In total, 15 of 16 (94%) participants completed the program, and attendance and completion of all exercise sessions ranged from 84% (49/58 asynchronous sessions completed, on average) to 97% (29/30 videoconference sessions attended, across all participants). Additionally, within-program CRF monitoring was objectively successful, with an overall survey completion rate of 93% (70/75 surveys completed, across all participants). In total, 9 participants did not require symptom-triggered exercise sessions, completing the program largely autonomously and asynchronously. The lack of symptom-triggered sessions indicates similar CRF improvement compared to participants in a supervised exercise program, despite a reduced number of real-time (or synchronous) exercise sessions compared to many of these programs [19]. The asynchronous method of providing exercise programming and supervision used in this investigation may hold promise for improving both exercise efficacy and program efficiency in telehealth exercise programs.

The mechanisms underlying the observed CRF improvements remain uncertain, given the current investigation is a feasibility trial. Nonetheless, several strategies are likely to have contributed to engagement with the exercise prescription, facilitating exercise-associated CRF improvements in this cohort. The programmatic design specifically addressed three known barriers to exercise engagement in rural survivors of cancer, which are not frequently or consistently addressed in other programs (beyond reducing travel burden) [12,13]: (1) the need to travel was completely removed, (2) asynchronous programming provided flexibility for where and when exercise was performed, and (3) several methods of communication provided direct access to a knowledgeable exercise provider. For the involved CES, an unanticipated benefit of asynchronous programming was that the time commitment required may be lower than for a supervised program. While perhaps obvious, pragmatic and cost-effective strategies for improved exercise engagement may prove critical to overall program effectiveness, where personnel costs and reimbursement funds limit more intensive strategies. To this end, additional investigation of objective measures of program efficiency using asynchronous exercise programming is required.

Strengths and Limitations

The primary limitation of this investigation is the lack of a control group and small sample size. Particularly in evaluating preliminary participant responses, the observed improvements during the program or in response to symptom-triggered sessions cannot be solely attributed to the intervention. However, several outcomes support the plausibility of the program influencing a meaningful improvement in CRF. First, the observed within-program improvements in CRF were similar to those documented in the supervised exercise program used to develop the CRF reference chart [23]. Second, significant improvements in CRF were observed immediately following the program, but no significant changes were observed in the 6 months following the program, indicating a lack of change due to time as well as the potential maintenance of program effects. Statistical analyses of pilot and feasibility trials, however, should be interpreted with caution [18]. Finally, on the participant level, the majority of participants (13/15, 87%) experienced a clinically meaningful improvement in CRF.

The sample in the current investigation is also likely biased in several ways. Given that participants responded to advertisements for an exercise intervention, the current sample is likely to reflect individuals who are able and willing to exercise. Additionally, the current sample is not large enough to adequately assess the contribution of various demographic and clinical variables on program adherence and response. The use of web-based recruitment methods and telehealth technology may discourage the participation of survivors without or not comfortable with technology. While the incorporation of this self-selecting sample population may contribute to a current "digital divide," parallel efforts are actively reducing technological barriers through efforts to increase the availability and acceptance of adequate technology and internet connections. For example, the Broadband Equity, Access, and Deployment Program [44] seeks to expand high-speed internet access throughout the United States, facilitating a societal migration to technology-based health care interventions (including exercise). Given that the current investigation was performed during the COVID-19 pandemic, participants' perspectives of and adherence to telehealth exercise may have been positively influenced in a manner unrepresentative of their more general context.

The used definition of rurality was developed independently by the research team, designed to target a population in need of services in the local region (Colorado and surrounding states). While this emphasis on local context is appropriate for this small feasibility study, future studies targeting larger populations in larger regions should use standardized rurality definitions to facilitate broader generalizations [10]. The telehealth tools used to facilitate access to this rural population may also contribute to a decrease in the fidelity of the prescribed exercise prescription. Specifically, only self-report completion data were available for asynchronous exercise sessions, limiting the knowledge of actual completion and performance. Future work could integrate additional technology (eg, improved activity trackers) to objectively assess the performance of these sessions.

Finally, while this investigation supports the feasibility of the BfitBwell Telehealth Program, it does not represent a comprehensive assessment of feasibility. While one set of recommended assessments was followed, multiple alternative definitions of feasibility and associated measures exist. Specifically, the assessment of intervention acceptability can be complex, including both quantitative and qualitative evaluations [45]. Nonetheless, the presented feasibility assessments provide strong support for further investigation of this program and its methods.

Conclusions

The BfitBwell Telehealth Program used several telehealth modalities combined with regular within-program symptom monitoring and symptom-triggered intervention to deliver an exercise program to rural survivors of cancer with CRF. This

investigation demonstrated high program feasibility, supported by positive assessments of recruitment, data collection, intervention acceptability and suitability, and preliminary evaluation of participant responses. Novel methods used by the program also provide a potential model for improving exercise program efficiency by using asynchronous exercise prescription. Future work should pursue large-scale efficacy testing, objective assessments of program efficiency, and systematic investigations of the effects of within-program exercise adaptations.

Abstract

Background: Although physical activity (PA) is recommended for patients with cancer, changes in PA across cancer diagnosis and treatment have not been objectively evaluated.

Objective: This study aimed to assess the impact of cancer diagnosis and treatment on PA levels.

Methods: This was a retrospective cohort study using a Japanese claims database provided by DeSC Healthcare Inc, in which daily step count data, derived from smartphone pedometers, are linked to the claims data. In this study, we included patients newly diagnosed with cancer, along with those newly diagnosed with diabetes mellitus for reference. We collected data between April 2014 and September 2021 and analyzed them. The observation period spanned from 6 months before diagnosis to 12 months after diagnosis. We applied a generalized additive mixed model with a cubic spline to describe changes in step counts before and after diagnosis.

Results: We analyzed the step count data of 326 patients with malignant solid tumors and 1388 patients with diabetes. Patients with cancer exhibited a 9.6% (95% CI 7.1%-12.1%; *P*<.001) reduction in step counts from baseline at the start of the diagnosis month, which further deepened to 12.4% (95% CI 9.5%-15.2%; *P*<.001) at 3 months and persisted at 7.1% (95% CI 4.2%-10.0%; *P*<.001) at 12 months, all relative to baseline. Conversely, in patients with diabetes, step counts remained relatively stable after diagnosis, with a slight upward trend, resulting in a change of +0.6% (95% CI –0.6% to 1.9%; *P*=.31) from baseline at 3 months after diagnosis. At 12 months after diagnosis, step counts remained decreased in the nonendoscopic subdiaphragmatic surgery group, with an 18.0% (95% CI 9.1%-26.2%; *P*<.001) reduction, whereas step counts returned to baseline in the laparoscopic surgery group (+0.3%, 95% CI –6.3% to 7.5%; *P*=.93).

Conclusions: The analysis of objective pre- and postdiagnostic step count data provided fundamental information crucial for understanding changes in PA among patients with cancer. While cancer diagnosis and treatment reduced PA, the decline may have already started before diagnosis. The study findings may help tailor exercise recommendations based on lifelog data for patients with cancer in the future.

Introduction

With the increasing number of cancer survivors, attention has been paid to not only cancer remission but also quality of life, which strongly correlates with physical activity (PA) in patients with cancer [1,2]. PA has been reported to be associated with a favorable prognosis in cancer survivors, with associations demonstrated in various cancer types, such as breast and colorectal cancers [1,3].

Although PA is a pivotal factor in patients with cancer, objective evidence on how it declines after cancer diagnosis and treatment is still lacking. Objective evaluation of prediagnostic PA is challenging. Previous studies that compared PA before and after cancer diagnosis relied on retrospective recall [4,5], which may introduce recall bias [6]. Therefore, research using objective precancer onset data is necessary to avoid this bias. However, this is challenging in studies that recruit participants after hospital visits.

Recently, many studies have leveraged real-world data collected during daily clinical practice and patients' daily lives [7]. With advancements in digital devices, access to patients' daily life data has improved [8]. Furthermore, the prevalent use of smartphone apps has facilitated the routine tracking of step counts, which strongly correlate with PA levels [9,10]. A daily step count of at least 10,000 steps is recommended for adults by the World Health Organization, while Japan's Ministry of Health, Labour and Welfare sets a more realistic target of 8000 steps per day for adults [11,12]. Integrating step count data obtained using smartphones with medical information allows for objective evaluation of changes in PA from the prediagnosis period. Thus, this study aimed to assess the effect of cancer diagnosis and treatment on PA levels by analyzing real-world step count data.

Methods

Data Source

This was a retrospective cohort study analyzing a database provided by DeSC Healthcare Inc, in which daily step count data are linked to a Japanese claims database [13,14]. Briefly, members of affiliated health insurance associations can access the Kencom smartphone app, developed by DeSC Healthcare Inc, free of charge. Daily step counts were measured using the Kencom app, synchronized with smartphone pedometers [13,14]. The Kencom database was integrated and anonymized with the Japanese claims database in affiliated health insurance associations under the opt-out agreement. Subsequently, DeSC Healthcare Inc merged data from various insurance associations, creating a large, longitudinal database for research use [13,14]. Diseases were classified according to *International Classification of Diseases, 10th edition* (*ICD-10*) codes. This database, which integrates step count information with medical information, mainly includes employees of large businesses and their dependents [13,14]. In this study, step count data were used to quantify PA levels.

Study Population

This study included patients newly diagnosed with malignant tumors (*ICD-10* code: C). In addition, patients newly diagnosed with diabetes mellitus (*ICD-10* code: E11-E14), a representative chronic disease in which the importance of PA is widely recognized [15], were included as a positive control, given the expectation that step counts would increase after diagnosis [16]. The inclusion of newly diagnosed patients also simplified the identification of index time [17]. Data between April 2014 and September 2021 were analyzed. The observation period spanned from 6 months before diagnosis to 12 months after diagnosis. The detailed eligibility criteria are described in Table S1 in Multimedia Appendix 1. Patients who did not receive treatment were excluded, and the Japanese Claims database has been validated as having over 98% specificity for identifying patients using this method [18].

Statistical Analysis

We applied a generalized additive mixed model with a cubic spline to describe changes in step counts. Individual-specific random effects, age at diagnosis, seasonal effects, day of the week (weekday, weekend, or holiday), and sex were included as covariates. Days with missing step count records were excluded from the analysis. A negative binomial distribution was assumed for step counts because of the considerable variability.

Subgroup analysis was performed on changes in step counts stratified by treatment method and cancer type. The definitions of treatment methods and cancer types are described in Tables S2 and S3 in Multimedia Appendix 1, respectively. Statistical analyses including data cleaning were conducted using R version 4.3.1 (R Foundation) with packages *mgcv* (version 1.8-42) and *ggplot2* (version 3.4.2).

Ethical Considerations

The Kyoto University Graduate School and Faculty of Medicine Ethics Committee approved this study (reference R3514). The need to obtain written informed consent from patients was waived because the data were anonymized.

Results

Study Population

A final cohort of 326 patients with malignant solid tumors and 1388 patients with diabetes met the eligibility criteria and were included in the analysis (Figure S1 in Multimedia Appendix 1). Table 1 shows patient characteristics and their respective cancer treatments. The median age of patients with cancer was 51 (IQR 45-56) years, and that of patients with diabetes was 50 (IQR

44-55) years. The median proportion of missing step count days during the observation period was 0.5% (IQR 0.0%-2.1%) among patients with cancer and 0.2% (IQR 0.0%-1.9%) in patients with diabetes. Further data on specific cancer diagnoses and the corresponding treatment for patients with cancer are described in Table S4 in Multimedia Appendix 1.

Table 1. Patient characteristics.

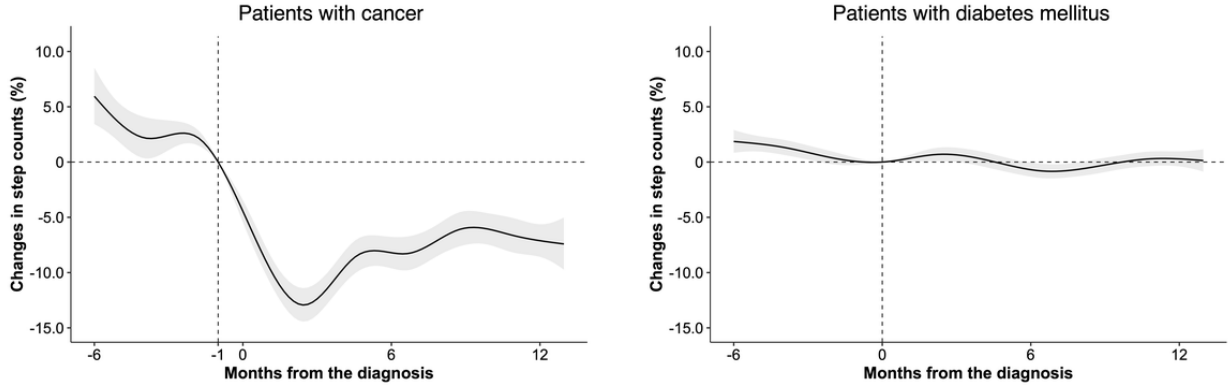
Characteristic	Patients with cancer (n=326)	Patients with diabetes mellitus (n=1388)	*P* values
Age (years), median (IQR)	51 (45-56)	50 (44-55)	.38
Male sex, n (%)	194 (59.5)	1144 (82.4)	<.001
Surgeries, n (%)	207 (63.5)	—[a]	—
Small interventions[b], n (%)	114 (35)	—	—
Radiation, n (%)	67 (20.6)	—	—
Conventional cytotoxic chemotherapies, n (%)	67 (20.6)	—	—
Molecular targeted therapy, n (%)	16 (4.9)	—	—
Immunotherapies, n (%)	3 (0.9)	—	—
Daily step counts for the reference month[c], median (IQR)	5754.9 (4219.2-7283.5)	6210.6 (4339.4-8015.8)	.01
Year of diagnosis, n (%)			
2015	6 (1.8)	49 (3.5)	—
2016	24 (7.4)	137 (9.9)	—
2017	52 (16)	204 (14.7)	.44
2018	81 (24.8)	324 (23.3)	—
2019	102 (31.3)	414 (29.8)	—
2020	61 (18.7)	260 (18.7)	—

[a]Not applicable

[b]The following procedures were classified as small interventions: cervical conization, diagnostic laparoscopy and thoracoscopy, endometrial curettage, excision of skin tumors, orchiectomy, transurethral resection of bladder tumors, and upper and lower gastrointestinal endoscopic surgeries (mucosal resection, polypectomy, and submucosal dissection).

[c]Reference month is month −1 for patients with cancer and month 0 for patients with diabetes mellitus (Figure 1).

Figure 1. Estimated daily step count changes before and after diagnosis. Daily step count changes in (left) patients diagnosed with cancer and (right) patients diagnosed with diabetes mellitus are described. Shading indicates the SE. Month 0 signifies the month of diagnosis. For patients with cancer, the baseline for step count change was defined as the first day of month −1, accounting for the time needed for pathology after biopsy or diagnostic surgery to confirm diagnosis.



Changes in Step Counts

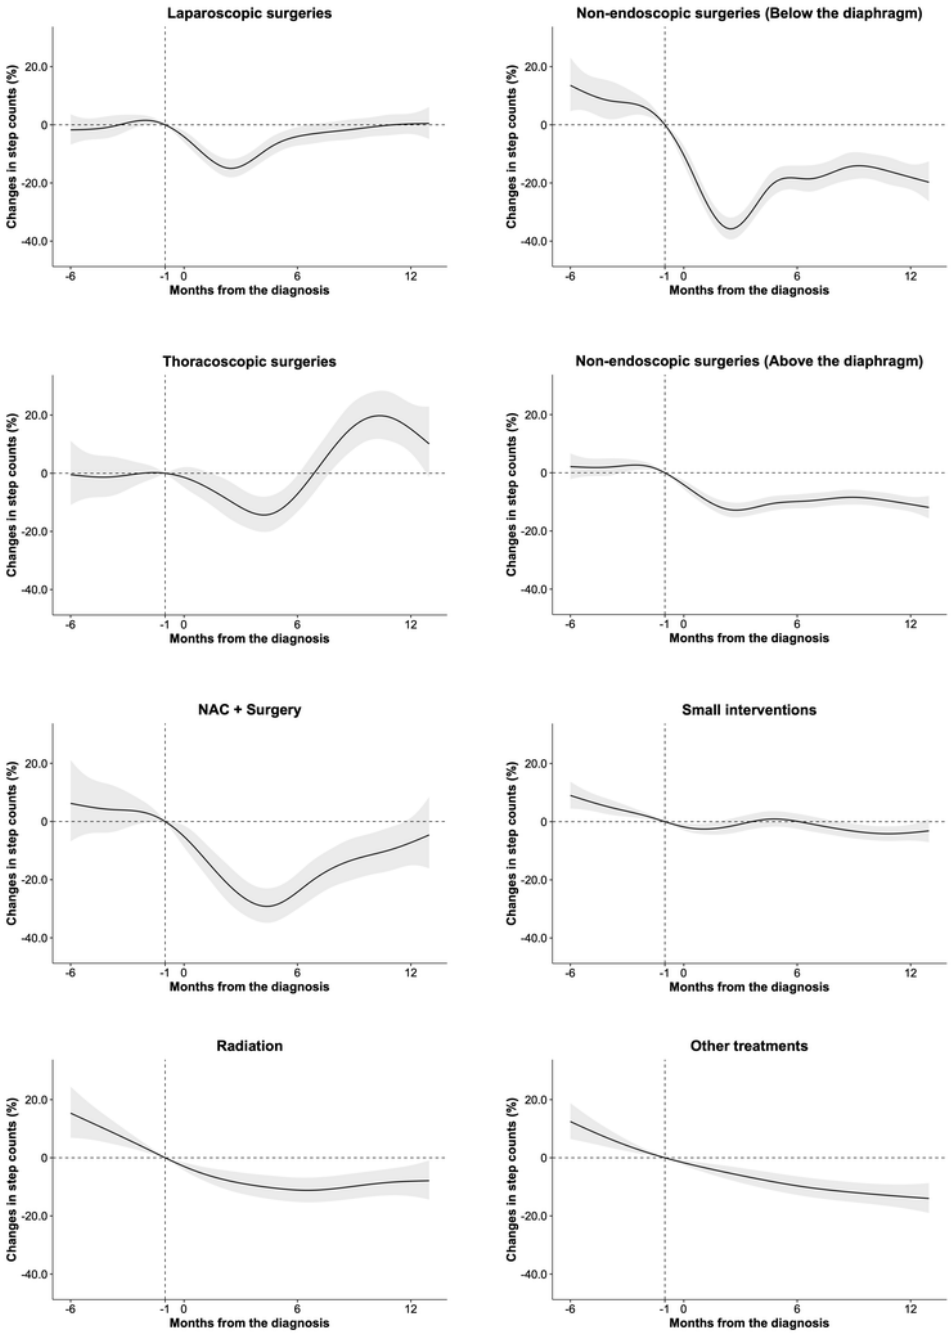
The results of the descriptive analysis of step count data are presented in Figure S2 in Multimedia Appendix 1. Step counts showed no significant difference between patients with cancer and those with diabetes 2 months before diagnosis (*P*=.17) but declined significantly in the former during the diagnosis month (*P*<.001). In subsequent analyses, the baseline for step counts in patients with cancer was therefore set at the beginning of the month before diagnosis. Figure 1 shows the percent change in step counts over time in relation to the time of diagnosis. Patients with cancer showed a 9.6% (95% CI 7.1%-12.1%; *P*<.001) reduction in step counts from baseline in the month of diagnosis, which deepened to 12.4% (95% CI 9.5%-15.2%;

P<.001) at 3 months and persisted at 7.1% (95% CI 4.2%-10.0%; *P*<.001) at 12 months, all relative to baseline. Conversely, in patients with diabetes, step counts remained relatively stable after diagnosis, with a slight upward trend, resulting in a change of +0.6% (95% CI –0.6% to 1.9%; *P*=.31) from baseline at 3 months after diagnosis. The change from baseline at 12 months after diagnosis was not significant (+0.3%, 95% CI –1% to 1.6%; *P*=.68).

Changes in Step Counts According to Treatment Modalities

Figure 2 shows the results of the subgroup analysis stratified by treatment modalities. Patients who received systemic chemotherapy without surgery were classified as the other treatment group because of the limited number of patients. There were no significant changes in the distribution of patient numbers by treatment group across the years (*P*=.69; Table S5 in Multimedia Appendix 1). At 3 months after diagnosis, the reduction in step counts from baseline was 14.3% (95% CI 8.0%-20.1%; *P*<.001) in the laparoscopic surgery group and 34.2% (95% CI 26.6%-41.1%; *P*<.001) in the nonendoscopic subdiaphragmatic surgery group. At 12 months after diagnosis, step counts remained decreased in the nonendoscopic subdiaphragmatic surgery group, with an 18.0% (95% CI 9.1%-26.2%; *P*<.001) reduction, whereas step counts returned to baseline in the laparoscopic surgery group (+0.3%, 95% CI –6.3% to 7.5%; *P*=.93). At 12 months after diagnosis, the nonendoscopic supradiaphragmatic surgery group showed a 10.9% (95% CI 5.7%-15.7%; *P*<.001) step count reduction, whereas this reduction was not seen in the thoracoscopic surgery group, and the step count change was not significant (+15.2%, 95% CI –0.4% to 33.1%; *P*=.06).

Figure 2. Estimated daily step count changes before and after diagnosis by treatment methods: Other treatments include conventional cytotoxic chemotherapy, immunotherapy, molecular targeted therapy, small interventions with chemotherapy or immunotherapy, and chemoradiotherapy. Shading indicates the SE. NAC: neoadjuvant chemotherapy.



Changes in Step Counts According to Cancer Type

Figure S3 and Table S6 in Multimedia Appendix 1 show the results of the subgroup analysis stratified by cancer type. A significant postoperative reduction in step counts was observed in patients with gynecologic cancers, and the majority of them underwent nonendoscopic surgeries (endometrial cancer: 4/5, 80%; cervical cancer: 3/6, 50%; and ovarian cancer: 3/4, 75%). Conversely, in gastrointestinal and urologic cancers, where abdominal surgeries were also performed, the proportion of patients who underwent small interventions or laparoscopic surgeries was high, and the postoperative reduction in step counts was not as pronounced.

Discussion

Principal Findings

The analysis of objective pre- and postdiagnostic lifelog data showed that step counts in patients with cancer decreased with cancer diagnosis and treatment, with step counts already below baseline at the beginning of the diagnosis month and failing to return to baseline 12 months later. Conversely, the change from baseline in those newly diagnosed with diabetes was not significant. The decline in step count varies with treatment and cancer type.

Comparison With Previous Work

To the best of our knowledge, this is the first study to objectively describe the decline in PA levels from precancer diagnosis using lifelog data on step counts. Previous studies that relied on retrospective recall have reported a decline in PA by 59% after treatment of breast cancer [4]. In colorectal cancer, the reduced PA during treatment improved after treatment completion [5]. Our analysis using objective real-world data provides a closer representation of real-life events. In patients with diabetes, while the increase in step counts was not significant, an upward trend was observed after diagnosis, consistent with previous reports [16].

This study showed possible variations in PA measured as step count based on the specific treatment modality used. Treatments for specific cancer types are typically standardized. However, by analyzing patients with varying cancer types, this study explored the impacts of different treatments on step counts. Interestingly, a prominent decrease in step counts was observed in patients who underwent nonendoscopic surgery, suggesting that opting for less invasive surgical approaches may help mitigate the decrease in step counts. However, this result should be carefully interpreted because patients requiring open surgery may have had more advanced stages with worse prognoses or require more intensive treatment. Further examination is needed to assess the long-term impact of surgical approaches on PA.

Measuring PA has become increasingly accessible through the use of smartphones and other wearable devices [8]. Previous studies have been conducted to categorize PA in patients with cancer using these devices. However, no established threshold has been identified [19]. This study adds new insights by focusing on changes in PA, which are recorded as step counts. Step counts serve as a valid and useful surrogate marker of PA, and a decrease in step counts is strongly associated with an increase in all-cause mortality [20,21]. Therefore, conducting close follow-ups on posttreatment PA levels using step counts has the potential to contribute to patient-centered care and personalized recommendations for PA, which remain insufficient [2]. Further studies are needed to address tailoring recommendations for PA during cancer treatment according to cancer type, treatment approach, and comorbidities.

Limitations

This study has some limitations. First, influences beyond cancer diagnosis and treatment, such as aging, societal changes, and changes in smartphone pedometer specifications due to device upgrades or replacements by users, may be involved. However, minimal changes in step counts in the diabetes group indicated a limited impact of these factors. Second, the proportion of patients managed with small interventions was high, indicating that a considerable number of patients were detected at an early stage. This might be because this study included relatively young patients with a median age of 51 (IQR 45-56) years, primarily employees of large businesses and their dependents, who were exclusively Kencom app users, indicative of a potential high health awareness demographic. Therefore, this population may not represent the general Japanese population. However, the decline in step count levels would be more pronounced in patients with a higher prevalence of advanced-stage cancer, who are likely to undergo more invasive treatments [22]. Third, the cancer stage was not determined in this study. However, because treatments are generally determined by cancer stage, results stratified by treatment may have higher generalizability to populations with different cancer stages. Fourth, the follow-up period in this study was 1 year, which did not allow for the analysis of step count data in relation to patient prognosis. PA may improve prognosis in cancer survivors [1,3]. Therefore, further studies are needed to assess its effect on patient prognosis. Finally, step count data may not fully reflect actual PA levels, as its accuracy can be affected by factors, including the possibility that individuals are not always carrying their smartphones.

Conclusions

This study used objective pre- and postdiagnostic step count data and showed that while PA decreased with cancer diagnosis and treatment, the decline may have already started before diagnosis. The decline varies with treatment and cancer type, with a notable decrease in patients who underwent nonlaparoscopic abdominal surgeries. Assessing PA using step count data has the potential to contribute to patient-centered care. This finding may help tailor exercise recommendations based on lifelog data for patients with cancer.

Abstract

Background: The APPROACH pilot study explored the feasibility and acceptability of an app (NHS Active 10) with brief, habit-based, behavioral support calls and print materials intended to increase brisk walking in people diagnosed with cancer.

Objective: Following UK Medical Research Council guidelines, this study assessed the implementation of the intervention, examined the mechanisms of impact, and identified contextual factors influencing engagement.

Methods: Adults (aged ≥18 y) with breast, prostate, or colorectal cancer who reported not meeting the UK guidelines for moderate-to-vigorous physical activity (≥150 min/wk) were recruited from a single hospital site in Yorkshire, United Kingdom. They were randomly assigned to the intervention or control (usual care) arm and assessed via quantitative surveys at baseline (time point 0 [T0]) and 3-month follow-up (time point 1 [T1]) and qualitative exit interviews (36/44, 82%) at T1. The process evaluation included intervention participants only (n=44). Implementation was assessed using data from the T1 questionnaire exploring the use of the intervention components. The perceived usefulness of the app, leaflet, and behavioral support call was rated from 0 to 5. Behavioral support calls were recorded, and the fidelity of delivery of 25 planned behavior change techniques was rated from 0 to 5 using an adapted Dreyfus scale. Mechanisms of impact were identified by examining T0 and T1 scores on the Self-Reported Behavioural Automaticity Index and feedback on the leaflet, app, call, and planner in the T1 questionnaire and qualitative interviews. Contextual factors influencing engagement were identified through qualitative interviews.

Results: The implementation of the intervention was successful: 98% (43/44) of the participants received a behavioral support call, 78% (32/41) reported reading the leaflet, 95% (39/41) reported downloading the app, and 83% (34/41) reported using the planners. The mean perceived usefulness of the app was 4.3 (SD 0.8) in participants still using the app at T1 (n=33). Participants rated the leaflet (mean 3.9, SD 0.6) and the behavioral support call (mean 4.1, SD 1) as useful. The intended behavior change techniques in the behavioral support calls were proficiently delivered (overall mean 4.2, SD 1.2). Mechanisms of impact included habit formation, behavioral monitoring, and support and reassurance from the intervention facilitator. Contextual factors impacting engagement included barriers, such as the impact of cancer and its treatment, and facilitators, such as social support.

Conclusions: The APPROACH intervention was successfully implemented and shows promise for increasing brisk walking, potentially through promoting habit formation and enabling self-monitoring. Contextual factors will be important to consider when interpreting outcomes in the larger APPROACH randomized controlled trial.

Introduction

Background

The number of people being diagnosed with cancer is continuing to increase in the United Kingdom, with an estimated 4 million adults living with and beyond cancer (LWBC) by 2030 [1]. Many people LWBC experience challenges related to cancer and its treatment, including increased fatigue, pain, psychological distress, and reduced physical capacity [2-5]. These challenges can significantly impact their quality of life and well-being [6]. Therefore, the importance of improving outcomes for those LWBC is vital [7]. A large body of trial data demonstrates that physical activity (PA) improves many outcomes after a cancer diagnosis, including reduced fatigue, pain, anxiety, depression, and sleep problems and an overall improvement in quality of life [8-11]. Observational data suggest that PA is also associated with improvements in survival [12-14]. In light of this ever-growing evidence base, the World Cancer Research Fund recommends that people LWBC follow the guidelines for healthy populations in achieving at least 150 minutes of moderate-to-vigorous PA (MVPA) per week and recommend limiting the amount of time spent sedentary [15]. Despite this, many people LWBC are physically inactive, with Macmillan Cancer Support (United Kingdom) estimating this to be as high as 80% of those LWBC not meeting recommended PA levels [16]. This is supported by the systematic review of 41 studies conducted by Wong et al [17] that indicated that only around a third of people LWBC were meeting PA guidelines, although this ranged from 16% to 88% across studies. Brisk walking is a form of MVPA that may be more appropriate for people LWBC due to its accessibility and achievability. In a systematic scoping review of 98 studies in people LWBC, walking was cited as the preferred type of PA across all cancer types and treatment stages [18].

The APPROACH Intervention

APPROACH is an app-based, multicomponent intervention informed by extensive development work with individuals with breast, prostate, or colorectal cancer and cancer nurse specialists [19,20]. It focuses on promoting and monitoring brisk walking using a publicly available mobile phone app, alongside brief behavioral support in the form of a specially designed leaflet, walking planner cards, and 2 phone or video calls with a trained researcher (CB) [21]. In line with the Medical Research Council framework for intervention development and evaluation, the pilot trial explored the feasibility and acceptability of conducting a complex PA intervention trial with people LWBC. A total of 90 people diagnosed with breast, prostate, or colorectal cancer were recruited for the pilot randomized controlled trial (RCT), with 49% (n=44) randomly assigned to the intervention group and 51% (n=46) to the control group. APPROACH pilot results demonstrated a high retention rate (97%) and high assessment completion rates (>86%), indicating that the trial procedures were feasible and acceptable to be carried out as intended in a confirmatory, phase-3, larger trial [22]. In addition, results showed that the intervention was delivered successfully with 98% receiving at least 1 behavioral support call and 95% of participants downloading the app [22].

Conducting a Process Evaluation

The importance of conducting process evaluations within RCTs has been emphasized to explore the way in which any complex intervention is implemented [23,24]. This can help uncover why interventions are successful or unsuccessful, determine why they may have unexpected consequences, as well as explore how an intervention that is effective can be optimized [23]. Moore et al [25] provided specific guidance for carrying out process evaluations, which highlighted the importance of exploring the implementation (eg, the fidelity of intervention calls), the mechanisms of impact (eg, views on the different components of the intervention), and the contextual factors influencing use and outcomes (eg, barriers or facilitators to engagement) [25].

Therefore, this paper extends the published APPROACH feasibility results [22] with the following aims: (1) to evaluate the implementation of the APPROACH intervention and the fidelity of the delivery of intended behavior change techniques (BCTs), (2) to identify the potential mechanisms of impact that underlie behavior changes attributed to the APPROACH intervention, and (3) to better understand how contextual factors influence engagement with the APPROACH intervention.

Methods

Design

This was an embedded design, mixed methods study where qualitative and quantitative data were collected simultaneously with equal priority [26]. Data were collected as part of the APPROACH pilot RCT [21,22]. The pilot RCT compared an app-based, brisk walking intervention delivered alongside usual care with a control arm (usual care alone) in people diagnosed with breast, prostate, or colorectal cancer at a single hospital site. The trial was registered on the International Standard Randomized Controlled Trial Number registry on April 16, 2021 (ISRCTN 18063498). The primary outcome for the pilot and future RCT is weekly minutes spent brisk walking (a cadence of 100 steps per min or more [27) measured by an activPAL accelerometer (PAL Technologies Ltd). Following baseline assessments, participants were individually randomly assigned (1:1 allocation) using minimization to either the control or intervention arm, stratified by cancer type (breast, prostate, or colorectal) and disease status (metastatic vs not).

Participants

The pilot RCT included 90 participants: 49% (n=44) in the intervention arm and 51% (n=46) in the control arm. All participants had a confirmed diagnosis of breast, prostate, or colorectal cancer (localized or metastatic). At the point of screening, localized participants had to be within 6 months of completion of radical treatment. This criterion was not applied to participants with metastatic disease. All participants required a clinician's sign-off that their life expectancy was >6 months. All participants self-reported achieving <150 minutes of MVPA weekly. Full inclusion and exclusion criteria have been published previously [21].

Procedure and Description of Intervention

The recruitment procedure and trial data collection have previously been described [21,22]. Participants completed assessments at baseline (time point 0 [T0]) and 3 months (time point 1 [T1]; operationalized as 12-16 wk after randomization). The intervention included an endorsement letter from a member of the participant's clinical team, alongside the provision of a leaflet with information about the importance of PA after cancer and a recommendation and instructions on how to download the freely available NHS Active 10 app. The NHS Active 10 app promotes brisk walking in bouts of 10 minutes, called "Active 10s." This was augmented with 2 behavioral support phone or video calls with the intervention facilitator (CB). The app was chosen after previous qualitative work with people LWBC, and clinicians identified key features that were important to be offered within the app and highlighted the importance of the app being supported by a professional organization, such as the NHS [19,20]. These behavioral support calls were underpinned by habit theory [28] and BCTs shown to be effective in promoting PA [29-31] and involved supporting participants in downloading and using the app and discussions around setting PA goals. The intervention facilitator was trained in the principles of behavior change theories and in the application of BCTs [32], with a thorough understanding of habit theory [33]. This training, alongside previous experience in delivering health behavior change interventions, allowed them to conduct conversations with patients closely mirroring those a health care professional might have with a patient in a routine care situation. The intervention calls took place via Zoom (Zoom Video Communications) [34] or telephone and were recorded by the intervention facilitator with the participants' permission. The first call took place approximately 1 week after randomization, and the second call took place approximately 4 weeks after the first call to check in with the participant about their goals and recap any information required. Participants were asked during the first intervention call if they had downloaded the NHS Active 10 app, and the intervention facilitator noted this in their records. Participants were also given 12 copies of a walking planner card that was designed to enable them to plan how many "Active 10s" they were aiming for and how they were going to achieve these, including where and when they would complete them.

Implementation of the APPROACH Intervention

Delivery of the Intervention

The implementation of the intervention was explored by looking at whether each component was delivered as intended and the participants' use of each intervention component. Between 12 and 16 weeks after randomization participants completed the T1 questionnaire. Participants were asked about the intervention, including the following: whether they downloaded the app (yes or no), their self-reported app use if still using the app (less than monthly, monthly, fortnightly, weekly, 3-4 times a week, almost every day, or every day), how long they used the app for if they had stopped using it (never, once, less than monthly, fortnightly, weekly, 3-4 times per week, almost every day, or every day), perceived accuracy of the app in recording their time spent walking (5-point scale from not accurate to very accurate), whether they read the leaflet (all, some, or did not read), used the walking planner cards (yes or no), and received either behavioral support call (yes or no).

The Usefulness of Intervention Components

Participants rated the usefulness of the call for going through the leaflet information, downloading the app, and thinking about ways to use the app to increase their brisk walking (5-point scale from not at all useful to extremely useful). Using the same scale, they rated the usefulness of the app and sections of the leaflet for supporting their walking.

Delivery Fidelity of Behavioral Support Calls

The recorded intervention calls were coded by 1 researcher (SW) to assess delivery fidelity. All calls were listened to and coded according to a 25-item checklist of BCTs [31] as presented in the study's protocol paper [21]. Each item represented a BCT paired with the intended delivery technique (Multimedia Appendix 1). If a participant received 2 calls, these were combined when coding delivery of the BCT. A 5-point rating scale was applied to the fidelity checklist using an adaptation of the Dreyfus scale [35,36] ranging from low fidelity (0), indicating that the facilitator did not mention the intended BCT at all, to expert (5), indicating that the facilitator delivered the BCT to an exceptional standard (Multimedia Appendix 2). A value of ≥3 represented competent delivery of an individual BCT, thus presenting successful delivery. A second researcher (SS) coded a subset of interviews (n=5). It was agreed that if there was a discrepancy of over 20% in the coding, then the transcript would be discussed among the researchers. This occurred for 1 transcript that was double coded. This iterative process enabled SW to incorporate any learnings from the discussion into the coding of all transcripts and allowed a more consistent coding of the data.

Mechanisms of Impact and Contextual Factors Influencing Engagement

T0 and T1 Questionnaires

Habit strength for walking ("going for a walk" and "walking briskly") was assessed using the Self-Report Behavioural Automaticity Index (SRBAI) [37] in the T0 and T1 questionnaires. Participants responded on a 7-point scale ranging from disagree to agree for 4 statements on their perceived

automaticity of performing the behavior. An average score across items was calculated, representing the level of automaticity for the behavior being measured. Higher average scores indicate stronger habit or greater automaticity [37]. The SRBAI is presented in Multimedia Appendix 3. Mechanisms of impact and contextual factors impacting engagement were also identified by examining responses to the T1 questionnaire about the delivery of intervention components and their perceived usefulness.

Qualitative Interviews

Participants were asked in the initial study consent form if they agreed to be invited to participate in a semistructured interview at the end of the study. After the completion of all other data collection at T1, all participants who agreed were invited to be interviewed. Two members of the research team (SS and FK) carried out the interviews. SS and FK were involved in organizing assessments with participants throughout the pilot RCT. The interviews followed a topic guide exploring trial procedures, and participants were asked to give feedback on the intervention components (Multimedia Appendix 4). Interviews took place over the phone and, with the participants' permission, were audio recorded and transcribed verbatim. Contextual factors were explored in the interviews and were described in terms of barriers and facilitators of engaging with the intervention.

Data Analysis

Implementation of the APPROACH Intervention

The T1 questionnaire responses on intervention components were explored descriptively by calculating percentage frequencies and, where relevant, measures of central tendency. Mean scores were calculated for the delivery of each BCT in the intervention calls as well as an overall mean fidelity score for each call.

Mechanisms of Impact and Contextual Factors Influencing Engagement

The data from the questionnaires and interviews were pooled during interpretation to investigate the mechanisms of impact and contextual factors of intervention engagement. Qualitative and quantitative data were analyzed separately. The SRBAI results from the T0 and T1 questionnaires were explored descriptively using medians and IQRs due to the skewness of the data. The T1 questionnaire responses on intervention components were also used to identify mechanisms of impact.

Three authors (SW, FK, and SS) analyzed the data from the qualitative interviews using reflexive thematic analysis [38,39]. Inductive coding was undertaken, with these codes then used to develop themes, and early and final themes were discussed throughout the coding process among multiple authors (FK, SS, and PL). While initial coding was inductive and focused on identifying commonalities across the transcripts, final theme development was also organized by focusing on the outlined process evaluation aims on exploring the delivery of the intervention, the mediating processes (mechanisms of impact), and the barriers and facilitators to engagement (contextual factors). All interview transcripts were managed in NVivo (version 12; Lumivero) to facilitate analysis and data management.

Data were integrated using a complementarity approach where the interpretation of quantitative and qualitative results together allowed a more holistic interpretation of the findings [40].

Ethical Considerations

This pilot study was approved by the Yorkshire & The Humber-South Yorkshire Research Ethics Committee (21/YH/0029, Health Research Authority and the local hospital. All participants gave informed consent and the data reported are anonymized.

Results

Overview

Table 1 presents the sample characteristics of the 44 participants in the intervention arm. Most (42/44, 95%) of the participants were of White ethnicity, comprising an equal number of male participants (22/44, 50%) and female participants (22/44, 50%), with a mean age of 63 (SD 11; range 40-85) years. Participants had received a diagnosis of breast cancer (18/44, 41%), prostate cancer (18/44, 41%), or colorectal (8/44, 18%) cancer. The CONSORT (Consolidated Standards of Reporting Trials) diagram and the flow of participants through the study have previously been reported [22]. After eligibility screening and assessment of interest in taking part, the study information sheet was sent to 148 patients, and 63% (n=93) consented to participate, with 61% (n=90) being randomized.

Table 1. Characteristics of the APPROACH intervention group (N=44).

Characteristics	Participants, n (%)
Sex	
Male	22 (50)

Implementation of the APPROACH Intervention

Overview

In total, 2 (5%) of the 44 participants withdrew from the intervention group for reasons unrelated to the intervention (frustration with the accelerometer and increased caring responsibilities). Most (41/42, 98%) participants who remained in the study answered the section of the T1 questionnaire on intervention feedback. Moreover, 1 (2%) of the 42 participants did not complete this section on intervention feedback.

Delivery of the Intervention

Leaflet

In the T1 questionnaire, 78% (32/41) of the intervention participants reported reading the entire intervention leaflet, while 10% (4/41) reported reading some of it, and 12% (5/41) reported not reading it at all. Of those who did not read it at all, 80% (4/5) stated that they did not remember receiving the leaflet, and 20% (1/5) stated that it was not relevant to them.

NHS Active 10 App

At the time of the first behavioral support phone call, the intervention facilitator recorded that 95% (42/44) participants had downloaded the NHS Active 10 app, with 93% (39/42) independently downloading it before the first intervention call and 7% (3/42) downloading it during the call. However, 2% (1/43) of the participants left call 1 not having downloaded it. In the T1 questionnaire, 95% (39/41) of the intervention participants self-reported successfully downloading the app. In total, 5% (2/41) of the participants were not asked about their use of the app as they reported not downloading the app earlier in the questionnaire. Most (33/39, 85%) participants reported still using the app. Of these, 82% (27/33) reported using it "almost every day or every day," and 18% (6/33) reported that they used it "3-4 times per week." A few (5/41, 12%) participants reported using the app during the study but were no longer using it. When asked how long they had used the app, the participants reported using it for "1 week," "2 weeks," "1 month," "2 months," and "3 months." In addition, 2% (1/41) of the participants reported not using the app at all despite downloading it.

Planner Cards

In the T1 questionnaire, 83% (34/41) of the participants reported using the walking planner cards, whereas 17% (7/41) did not, including 1 participant who said they did not receive any cards. Other nonuse was mainly explained in terms of not finding it helpful/not needing to plan (5/41, 12%) or having a more physical job (1/41, 2%). Of those who used the planners, 65% (22/34) reported using the planners for the full 3 months, whereas others reported using them for 2 weeks (4/34, 12%), 1 month (4/34, 12%), or 2 months (4/34, 12%).

The Usefulness of Intervention Components

Overview

The perceived usefulness of the intervention components is presented in Table 2.

Table 2. Perceived usefulness of the APPROACH intervention components (n=41).

Intervention components[a]	Values, mean (SD)	Respondents, n (%)
Behavioral support call	4.1 (1.0)[b]	40[c] (98)
Leaflet sections		
Physical activity and cancer	3.8 (0.9)[b]	36[d] (88)
Walking	4.0 (0.8)[b]	36[d] (88)
Information about Active 10	3.9 (0.8)[b]	36[d] (88)
Instructions on how to download Active 10	4.0 (0.8)[b]	36[d] (88)
Walking habits	4.1 (0.7)[b]	36[d] (88)
Walking websites	3.8 (1.5)[b]	36[d] (88)
Mean usefulness of leaflet sections	3.9 (0.6)[b]	36[d] (88)
App usefulness in participants still using the app	4.3 (0.8)[b]	33[e] (80)
App usefulness in participants who had stopped using the app	2.6 (0.9)[b]	5[e] (12)
App accuracy in participants still using the app	3.9 (1.2)[f]	33[e] (80)
App accuracy in participants who had stopped using the app	2.2 (0.8)[f]	5[e] (12)

[a]The perceived usefulness of the walking planner card was not explored in the time point 1 questionnaire (n=41).

[b]A 5-point scale from not at all useful to extremely useful.

[c]One person reported not receiving a behavioral support call and was not shown this question.

[d]Five people reported that they had not read the leaflet and were not shown these questions.

[e]One participant reported downloading but never using the app to track their walking. Two participants self-reported not downloading the app earlier in the questionnaire. These participants were not shown this question.

[f]A 5-point scale from not accurate to very accurate.

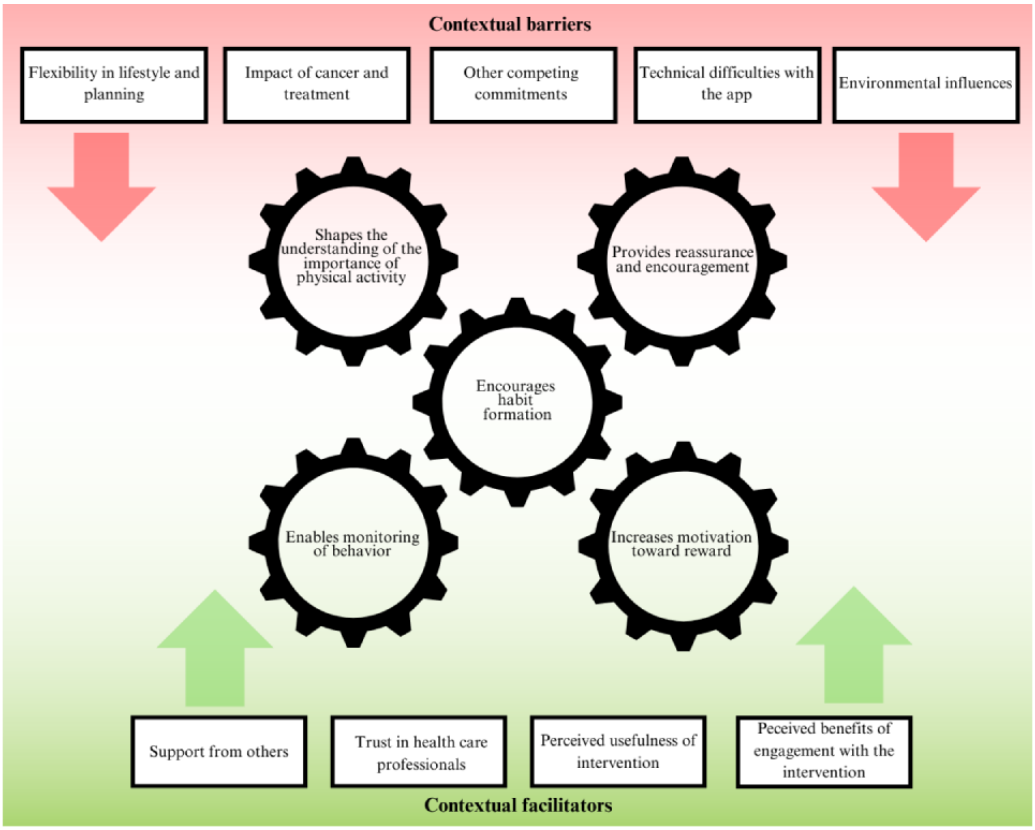
Delivery Fidelity of Behavioral Support Calls

Most (43/44, 98%) of the participants received the first behavioral support call. The mean time from randomization to the first intervention call was 11.6 (SD 9.8; range 5-57) days, and the mean time from randomization to the second intervention call was 39.2 (SD 9.0; range 33-78) days. In total, 31 (72%) of the 43 calls were conducted on Zoom and 12 (28%) via telephone. Most (40/41, 91%) of the participants received the second call. Some (22/40, 55%) of these calls were conducted on Zoom and 45% (18/40) via telephone. In total, 81 intervention calls from 42 participants were included in the analysis (n=42, 52% first calls and n=39, 48% second calls). One intervention participant did not receive any calls, and another participant was removed from the analysis due to a recording issue with the first call, so neither of their calls was included in the fidelity results. The overall mean delivery fidelity score across all BCTs and all participants was 4.2 (SD 1.2), which demonstrates overall proficient delivery. Some (18/25, 72%) of the BCTs had a rating of >4, 16% (4/25) had a rating of 3 to 4, and 12% (3/25) had a rating <3. The BCT called provide information on health consequences had the highest fidelity (4.98). This was followed by action planning (4.90) and habit formation (4.88). The BCT called framing/reframing had the lowest fidelity (1.31). Nonspecific reward (2.71) and nonspecific incentive also displayed low fidelity. The delivery fidelity of each BCT that was intended to be delivered during the calls is presented in Multimedia Appendix 1.

Mechanisms of Impact and Contextual Factors Influencing Engagement

Figure 1 presents the theme diagram showing the identified mechanisms of impact and the contextual barriers and facilitators that affect these mechanisms and intervention engagement.

Figure 1. Theme diagram presenting the identified mechanisms of impact and the contextual barriers and facilitators that affect these mechanisms.



T0 and T1 Questionnaires

All (44/44, 100%) intervention participants completed the SRBAI at baseline. All (42/42, 100%) participants who remained in the study completed the SRBAI at T1. As mentioned earlier, most (41/42, 98%) of the participants who remained in the study answered the section of the T1 questionnaire on intervention feedback.

Qualitative Interviews

Of the 42 participants who remained in the study, 86% (n=36) took part in the qualitative interviews. A few (n=3, 7%) participants did not give a reason for declining to participate, and 2 (5%) participants consented to the interview but then did not respond to the interview invitation. Moreover, 1 (2%) participant did not feel up to taking part in the interview due to illness-related side effects.

Mechanisms of Impact

Identified mechanisms of impact are outlined in the subsequent sections with exemplar quotes indicating the participants' self-identified sex (male or female) and age.

Shapes Understanding of PA and Its Importance

Many participants reported gaining information about brisk walking and its benefits as well as information on how to use the app through the intervention call and the leaflet:

> *...the lady basically went through everything. That was probably the most helpful thing. How to use things and everything.* [Female participant; aged 42 y]

The delivery of comprehensive and meaningful information enhanced participants' understanding of the target behavior and provided them with a clear purpose for implementing it:

> *She went thoroughly through the app with me...Then when she started to explain it, I thought yes, that makes sense.* [Male participant; aged 60 y]

Enables Monitoring of Behavior

Participants reported that having 2 intervention calls was motivating as it helped them to reflect on their progress between the calls:

> *...the follow up call halfway through was touching base and seeing how I was getting on which obviously encouraged me to do it.* [Male participant; aged 73 y]

The feedback on behavior received via the app showing daily, weekly, and monthly minutes of brisk walking was considered effective. Participants reported that they found the tracking feature motivated them to continue their walking efforts:

> *And actually, when I realised I wasn't doing enough, when I felt able to, I extend my walk to get the thirty minutes.* [Female participant; aged 60 y]

Several participants reported using the planner cards to record their walks afterward rather than planning with them upfront. However, this sense of accountability through recording their activity engaged them to keep walking:

> *I wrote down what was on my app, every day, how many minutes walking I did everyday.* [Female participant; aged 62 y]

Increases Motivation Toward Rewards

Many participants reported that the app was the primary intervention component that kept them most motivated and engaged, particularly through the trophies or cups awarded (for every 10 min of brisk walking):

> *I did enjoy getting them cups every day, I thought that were great.* [Female participant; aged 61 y]

Participants often reported walking a few more minutes to achieve the next reward or cup on the app, some even referring to being obsessed or addicted to achieving their goals:

> *...if I get to say 28 minutes, I'll just do the extra two to make it thirty.* [Female participant; aged 49 y]
>
> *30 has been the minimum goal I've gone for. So even if it's not been a nice day or if I'm tired...I still go out...it's addictive.* [Male participant; aged 75 y]

The achievability of these rewards influenced engagement, with several participants reporting exceeding their targets and wishing that more rewards were available:

> *That's another downside, you can't set your goal to any more than three.* [Female participant; aged 61 y]

Participants also reported a sense of satisfaction when being able to tick off completing their walks in their planners:

> *...you can see something, you're achieving something.* [Female participant; aged 47 y]

Encourages Habit Formation

Many participants reported feeling that they had formed habits throughout the intervention period, and this enabled them to establish and maintain their walking and brisk walking habits:

> *It's part of it now, it's part of your day, it's part of your walk so its not I'm going I've got to do this, I've got to do that...It's just a normal day for us going for a walk. And you get back and you think, mmm, I didn't realise I was doing that quick.* [Female participant; aged 65 y]

This is also supported by the SRBAI results for "walking," where total SRBAI scores in the intervention group increased from baseline (mean 4.1, SD 1.6) to T1 (mean 4.7, SD 1.9). Similarly, total SRBAI scores for "brisk walking" in the intervention group increased from baseline (mean 4.0, SD 1.7) to T1 (mean 5.1, SD 1.8).

Providing Reassurance and Encouragement

Many participants recalled how helpful and friendly the facilitator was in the intervention calls:

> *...they were lovely, caring and friendly.* [Female participant; aged 61 y]

This positive rapport helped participants adhere to their brisk walking, and they recalled feeling encouraged and supported throughout the intervention period:

> *...it's useful because it makes you feel as if you're not forgotten.* [Male participant; aged 73 y]

Contextual Factors

The contextual factors influencing engagement are summarized according to barriers and facilitators with exemplar quotes indicating the participants' self-identified sex (male or female) and age.

Barriers

Flexibility in Lifestyle and Planning

Data from the qualitative interviews and the T1 questionnaire indicated that participants felt the planners, in their intended use (to plan walks each week), were not flexible enough and did not fit their lifestyles:

> *...it didn't work for me at all because every day is different.* [Female participant; aged 42 y]

Related to this, some participants suggested making the planners daily, rather than weekly, which would allow more nuanced plans to be made:

> *...it wasn't going to be at the same time every day so it just needed breaking down into a daily thing.* [Female participant; aged 57 y]

The Impact of Cancer and Its Treatment

Several participants reported in the interviews and the T1 questionnaire that their cancer diagnosis and treatment sometimes made it difficult to engage with the intervention:

> *...this was just after my treatment and I was tired a bit.* [Female participant; aged 67 y]
>
> *I couldn't plan, because I was in and out of different appointment times.* [Female participant; aged 57 y]

This was also seen when participants were asked about the appropriateness of the app for people LWBC, with several participants reflecting on how differing experiences may help or hinder engagement:

> *I had some days where I felt like I didn't want to see daylight, not talk to anybody...I think on those bad days I wouldn't have wanted to be bothered with it.* [Female participant; aged 67 y]

Many participants discussed that the appropriateness of the timing of the intervention would be dependent on where the patient was in their cancer care. Although many participants noted that taking part in the intervention during treatment would have been too difficult for them due to the side effects, several also suggested that using the intervention during treatment was suitable as it gave them something else to focus on:

> *No I wouldn't have been able to do it when I was having chemo, I could barely even walk round the garden.* [Female participant; aged 58 y]
>
> *This gave me something else to think about you know something on a daily basis which took me mind off you know that three-week cycle as much as it could.* [Male participant; aged 65 y]

Other Competing Commitments

Several participants reported not having time to walk due to factors, such as having caring responsibilities, working hours, and appointments:

> *...well the kids can't walk with me they have only got little legs, who is going to watch them?* [Female participant; aged 41 y]

Technical Difficulties With the App

In the interviews, several participants reported experiencing difficulties with the recording of walks on the app if there was a lack of signal or due to the phone's positioning. For example, sometimes participants found the recording differed depending on what pocket their phone was in:

> *...if I had it in my trouser pocket by my leg it worked all fine, ok, no problem at all, if I had it in my shirt pocket it didn't register anything.* [Male participant; aged 73 y]

This is supported by the T1 questionnaire results indicating that perceived app accuracy was an issue that likely influenced use and engagement with the app over time:

> *Didn't find the app as accurate as it could be and doubted its recordings on occasions.* [Female participant; aged 41 y]

Environmental Influences

Participants described how the weather played an influential role in their ability and motivation to go on their walks:

> *What it's going to be like when it starts raining and it's really awful weather I don't know.* [Female participant; aged 40 y]

As well as hindering their ability to go out on a walk, some participants also described feeling guilty if they did not go out and walk due to the weather:

> *There were some days where it was absolutely throwing it down outside…and I thought oh no and I really felt guilty that I'd not actually done it.* [Female participant; aged 61 y]

Facilitators

Support From Others

Many participants talked about telling people of their involvement in the trial and their efforts to increase their walking, describing a sense of accountability from sharing the experience with others:

> *...so now it's a case of, "Have you got your minutes in yet dad?" and it, everyone's sort of like joining in with it.* [Male participant; aged 75 y]

In addition, having someone to go on a walk with and even having family members and friends also use the app was described as encouraging and gave participants a sense of comradery in changing their behavior:

> *It made us all as a family go for a walk. It not just helped me with that. It helped all of us.* [Female participant; aged 42 y]

Personal contact from the study team also facilitated engagement, with several participants reporting that they felt supported and that they had the opportunity to get in touch if needed:

> *...it were good to know that somebody you know, I'd phone and they'd take an interest.* [Female participant; aged 61 y]

Trust in Health Care Professionals

Several participants noted that endorsement from their health care professional facilitated their engagement with the intervention and willingness to change their behavior, as their medical team is seen as a credible source of information:

> *So the fact it had come from the doctor made me want to do it even more.* [Female participant; aged 42 y]

Perceived Usefulness of the Intervention

The perceived usefulness of the intervention components appeared to influence engagement in the target behavior, with participants reporting that some components (eg, app) were more helpful than others (eg, planners).

Overall, the behavioral support call was rated as useful (mean 4.1, SD 1; Table 2). In the qualitative interviews, the participants reported finding the calls useful as a source of information and motivation as well as helping them to regain their focus:

> *You know, if you've got an issue you can talk to somebody about it. But also it keeps you motivated.* [Female participant; aged 56 y]

The leaflet was generally rated as useful (mean 3.9, SD 0.6), particularly the sections on "walking," "downloading the app," and "walking habits" (Table 2). The qualitative data suggested that although this was useful for reading initial information about the benefits of brisk walking and particularly for downloading the app, some participants reported limited recollection of the leaflet at the follow-up point:

> *I did have a quick flick through it. And obviously the bit about finding the app.* [Female participant; aged 49 y]

T1 questionnaire results indicated a mean usefulness of 4.1 (SD 1) for the app, but with higher ratings among the 33 participants still using it compared to the 5 who had ceased. Most (28/38, 74%) of the users found it extremely useful or very useful. Participants who reported still using the app reported higher perceived accuracy of the app in recording their time spent walking compared to those not using the app anymore (Table 2). This is supported by the qualitative findings, with participants reporting still using the app and finding it enjoyable to monitor their progress on it:

> *I use it all the time now...I still want to make sure I have got at least two cups.* [Male participant; aged 74 y]

The usefulness of the planner explored in the qualitative interviews highlighted that although the planners were useful to get started and to form habits, their use ceased over time due to factors such as not finding planning as helpful long-term,

finding the app sufficient to motivate them, and just forgetting to use them:

> *I think you need the planner thing for the first week or so but after that I don't think you do.* [Female participant; aged 56 y]

Perceived Benefits of Engagement With the Intervention

Where participants felt they were benefiting from taking part, they reported feeling motivated to continue their brisk walking, reporting feelings of enjoyment, better mood and well-being, and improvements in physical health and fitness:

> *I definitely felt better in myself, there's no question about that. I felt fitter as well.* [Male participant; aged 60 y]

As well as the direct impact of the intervention, many participants also reported feeling more able to engage in activities of daily living, such as going shopping, socializing, and doing housework because of their improved fitness and well-being:

> *I have started going out with more friends...getting out a bit more and feel better and everything.* [Female participant; aged 67 y]

Discussion

Summary of Findings

This study combined data collected as part of the APPROACH pilot RCT to assess the implementation of a multicomponent, app-based behavioral intervention to promote brisk walking in people LWBC. The findings of this process evaluation demonstrated proficient implementation of the intervention and suggest that there are several mechanisms of impact underlying the efficacy of the intervention as well as contextual factors that can be barriers or facilitators to engagement.

Successful Implementation of the APPROACH Intervention

The successful delivery of intervention components and intended BCTs is essential for attributing any changes in behavior to the intervention in question [41]. This study demonstrated proficient implementation, with most participants reporting engagement with the intervention components, including downloading the app, reading the leaflet, receiving the behavioral support call, and using the planners. In addition, fidelity is rarely reported in evaluations of PA interventions [29]. In a systematic review of 21 studies assessing the quality of measuring delivery fidelity in PA interventions, Lambert et al [42] reported considerable heterogeneity in evaluating delivery fidelity. This study reports high delivery fidelity of the intended BCTs in the behavioral support calls [21]. While interventions with only a single intervention facilitator often exhibit higher fidelity, investigating how various intervention facilitators across different contextual settings deliver BCTs is essential for understanding the real-world application and scalability of interventions [43]. Particularly where multiple intervention facilitators are involved in the delivery, future research should consider factors such as personal characteristics and individual context when evaluating intervention delivery [44,45].

The BCTs called information on health consequences, action planning, and habit formation showed the highest fidelity, and these BCTs appear to influence key mechanisms of impact highlighted by participants in the qualitative interviews. Empowering participants with information on why they should go walking and providing them with information about its benefits appeared to enhance their engagement and adherence to their planned walks. The delivery of and engagement with the action planning BCT is promising, as this BCT was shown to be associated with larger effect sizes in a systematic review of 26 studies evaluating BCT effectiveness in PA interventions in adults who are healthy and inactive [29]. This study extends this finding and suggests that this BCT is suitable and appropriate for people LWBC and should be included in future intervention designs with this population. The BCTs that were not successfully delivered included those called nonspecific reward, nonspecific incentive, and framing or reframing. Despite the BCT called nonspecific reward receiving a low fidelity rating in the recorded behavioral support calls, the qualitative interviews suggested that this BCT was effectively covered in other aspects of the intervention, with participants reporting enjoying working toward the rewards and trophies in the NHS Active 10 app. The low delivery fidelity of the BCT called framing/reframing could be attributed to participants' voluntary enrollment in a PA trial. It is likely that they already recognized the importance of PA even without fully recognizing its role in life beyond a cancer diagnosis [46,47].

BCTs Underlying Change

The mechanisms of impact identified by participants in the qualitative interviews and follow-up questionnaire were in line with previous research. For instance, self-monitoring of behavior is one of the most frequently used components in complex PA interventions [48], and multiple systematic reviews have demonstrated its effectiveness in increasing PA that is maintained long-term [49-51]. In this intervention, the NHS Active 10 app allowed participants to track their brisk walking and total walking, and participants reported that being able to see their improvement over time motivated them to continue their behaviors. In a similar pilot RCT using a self-monitoring app alone, Ormel et al [52] reported that participants in the intervention group increased their activity more from baseline to 6 weeks, but this difference was not maintained at 12 weeks. The authors attributed this to a potential loss of novelty and interest in the app. Although not powered to detect differences in PA, the findings of this study suggest that the second behavioral support call was important in continuing encouragement of monitoring of behavior and reviewing of goals, with participants describing a sense of accountability with the later call. This feedback indicates that a light-touch intervention call to check in with participants can be beneficial in consolidating commitment to PA goals in people LWBC. While technology can help reduce resource demands, future research should consider the benefits of a low-burden behavioral support call to augment an app as an already powerful and scalable intervention component.

Participants extensively discussed the app as the driving component of the intervention, supporting our previous reports of high engagement with the NHS Active 10 app [22]. The

discussions revealed that another mechanism underlying behavior change in this context was the ability of the app to increase motivation toward reward using gamification techniques [53]. The performance of the desired behavior (brisk walking) was reinforced by the positive feelings of encouragement and dedication resulting from these cups and trophies in the app.

Encouraging Habit Formation

The APPROACH intervention was informed by habit theory [21], and the identification of habit formation as a mechanism of impact in both the qualitative interviews and questionnaire data demonstrates that this BCT was delivered effectively in the intervention. Participants reported that the leaflet, app, behavioral support call, and planners helped to establish sustainable walking habits. Gardner et al [54] define habit formation as "learning cue–behaviour associations, that when cued, automatically generate action impulses." This sense of automaticity was described by participants in the qualitative interviews, whereby consistent repetition of their walking daily led to the enactment of brisk walking. This meant that they engaged in brisk walking even during activities that previously would not have involved this exercise intensity. These findings are also supported by the increased SRBAI results from baseline to follow-up, which showed an increase in the initiation of walks as well as the way walking was executed (ie, briskly) [55]. The importance of encouraging long-term engagement in PA after the intervention period is highlighted in systematic reviews of PA maintenance in cancer populations that report only modest improvements at longer follow-up time points [30,56]. The results of this study endorse the integration of habit theory into future interventions aimed at increasing PA to overcome the challenge of sustaining behavioral changes over time [56].

To reinforce the idea of habit, the walking planner cards were designed to promote habit formation, facilitate planning, and prompt participants to engage in PA [21,54]. However, both questionnaire data and interview data showed that the structured design of the planner cards was not compatible with the day-to-day changing schedules and lifestyles of some participants, highlighting the importance of conducting this process evaluation to account for and reconsider this contextual aspect of the intervention and future similar interventions. The need for flexibility in lifestyle and planning was reported as a barrier by participants and further confirmed by the reflections of the intervention facilitator (CB) after discussing their use with participants.

Barriers to Engagement: Cancer Impact and Competing Commitments

Other contextual barriers included the impact of cancer and its treatment, having other competing commitments, technical difficulties with the app, and environmental influences. The side effects of cancer and its treatment have previously been identified as a key barrier to PA participation in systematic reviews [18] as well as in our own preparatory work for this pilot RCT [19]. Participants in this study reported that the impact of cancer and its treatment inhibited their ability to engage in some elements of the intervention due to different physiological, structural, and psychological factors. Cancer-related fatigue is the most reported symptom in people LWBC who have undergone treatment with prevalence estimates of up to 90% of those treated with radiotherapy and 80% of those treated with chemotherapy [57,58]. In this study, participants discussed fatigue symptoms and felt that engaging with the intervention during treatment would have been difficult. Beyond this physiological barrier, the structural barrier of having any appointments for their cancer care also reduced their ability to engage with some components, including the planner card, as there were many hospital appointments that they had to attend and plan around. We have previously reported on the perceived suitability of the timing of the APPROACH intervention, with most participants feeling that it was reasonable [22]. While some participants felt that engaging during treatment would be difficult, others felt that it was useful to have something else to focus on and have control over [22]. Previous reviews in this area have also reported discrepancies in the preferred timing of PA intervention delivery within the cancer care pathway [18,59]. Involvement in PA at an earlier stage has been associated with improved treatment response, tolerance, and quality of life [13,60,61]. Considering, the delivery of the APPROACH intervention during and after the treatment for cancer is still endorsed while recognizing the contextual barriers, such as this, when interpreting APPROACH intervention outcomes. These findings highlight the importance of involving patient perspectives in future intervention design with this population, with the acknowledgment that different stages of the treatment pathway can facilitate or inhibit PA participation and should be accounted for when assessing intervention delivery and engagement.

Driving Engagement: Support, Trust, and Perceived Benefits

Facilitators to engagement included having support from others, trust in health care professionals, the perceived usefulness of the intervention, and the perceived benefits of engagement with the intervention. The BCTs called social support (practical) and social support (emotional) were competently delivered in line with the protocol [21,31]. Accordingly, participants recognized how having support from others, such as family members and partners, enhanced their engagement with the intervention and how they felt supported by the intervention facilitator. Social support has previously been identified as highly important in PA engagement [62], with reasons, such as accountability, being cited as helping to facilitate and promote engagement [63]. In our preparatory work for this RCT, trust in health care professionals emerged as a crucial factor influencing engagement [19], and this was highlighted again in this study, where incorporating an endorsement letter from the clinical care team enhanced app credibility.

Limitations

Limitations of this study include that only 1 intervention facilitator delivered all behavioral support calls, which may explain the high-fidelity ratings. It is crucial to consider the transferability of the intervention across individuals, particularly when envisioning integration into routine NHS care [20,22]. In addition, there may be some recall bias influencing results, as most of the questionnaire data were collected at the 3-month

follow-up [64]. Participants may have had difficulty in answering questions on earlier components (eg, leaflet information) compared to components they were still using (eg, app). Due to the pilot nature of this study, where feasibility and acceptability were the main outcomes of interest, we were unable to examine how engagement with each intervention component influenced the primary outcome of brisk walking. For future research, the application of the Multiphase Optimization Strategy with a factorial design could offer more insights into how differing engagement with each component can impact the main outcomes and help inform intervention optimization for larger efficacy RCTs [65,66]. Finally, despite its recognition as a potential mechanism, it is difficult to assess how the intervention helps to establish longer-term habits, which are key for PA maintenance [67], as this pilot RCT only examined outcomes at 3 months.

Conclusions

This study extends our previously published findings on the APPROACH pilot RCT [22] by demonstrating that the intervention was delivered as intended with high levels of engagement from participants. In addition, this paper highlighted the potential mechanisms through which change occurs, such as habit formation and behavioral monitoring, which are in line with the intended BCTs used in this intervention. The process evaluation also highlighted important contextual factors to consider when progressing to the APPROACH main trial, including facilitators, such as social support, which played a significant role in promoting adherence to the intervention. The protocol for the definitive RCT will report on adaptations made to APPROACH based on the feedback gathered in this study. This process evaluation provides strong support for the progression to the stage-3, definitive RCT to evaluate the effectiveness of the APPROACH intervention (began in November 2023) and enables a more nuanced understanding of how the APPROACH intervention works and the contextual factors to consider with implementation.

Acknowledgments

The authors would like to thank Yorkshire Cancer Research for funding this pilot study and the participants for dedicating the time to participate and complete the assessments. They also thank the extended APPROACH team members Rithu Anand and Gaby Heuchan for their help with carrying out trial tasks.

Abstract

Background: Survivors with head and neck cancer (HNC) face challenging treatment consequences that can lead to severe disruptions in swallowing and result in weight loss, malnutrition, and feeding tube dependence. Caregivers (family or friends who provide support), therefore, often encounter distressing nutritional caregiving burdens and feel unprepared to provide adequate support at home.

Objective: The purpose of this mixed methods study was to develop a mobile support app to support HNC caregiving with an emphasis on nutritional support following treatment.

Methods: We assessed perspectives on nutritional recovery challenges and mobile support app preferences in (1) a national panel of oncology dietitians using a web-based cross-sectional survey and (2) survivors with HNC completing treatment within the past 24 months and their nominated caregivers using dyadic semistructured interviews. Descriptive statistics for survey data were synthesized with thematic analysis of interview data to characterize nutrition-related perceptions and intervention preferences; results were integrated, and themes were translated to high-priority main menu domains and subdomains for a mobile app for caregivers.

Results: Surveys were completed by dietitians (n=116, 100%; female n=87, 50%, with >10 years practice experience). Interviews included survivors with HNC (n=15; 12/15, 80% male, and 6/15, 40% with oropharynx cancer) and their caregivers (n=13; 11/13, 85% female, and 10/13, 77% spouses). Dietitians, survivors, and caregivers perceived that the majority of nutritional concerns assessed (eg, swallowing, feeding tube management, weight maintenance, and caregiver distress about nutrition) were very or extremely important to caregiving in the 6 months following treatment conclusion. The caregiving tasks rated highest in importance by dietitians included tracking nutritional concerns (n=113, 97%), working together as a team on nutritional concerns (n=104, 90%), and making care decisions (n=102, 88%). Five themes emerged from dyadic interviews, including types of nutritional challenges faced, that competing symptoms were difficult to separate from nutritional challenges, the emotional challenges related to nutrition and recovery, the diverse set of medical and support tasks taken on by caregivers, and information and resource needs in caregivers. Qualitative interview and survey themes guided the content of the Healthy Eating and Recovery Together (HEART) app with an intake tracker and sections for nutrition recovery support, other competing caregiving tips, peer support, and caregiver self-care.

Conclusions: Results pinpointed optimal content for a mobile app for caregivers of individuals with HNC and support the acceptability of implementing the HEART app following HNC treatment.

head and neck cancer; cancer survivorship; caregiving; nutrition; mobile health; app development; mixed methods

Introduction

Approximately 522,846 people were living with oral cavity, pharynx, and larynx cancers in the United States in 2021 [1,2]. With increasing numbers of survivors with head and neck cancer (HNC), it is imperative that survivorship concerns are addressed [3,4]. Survivors with HNC face extremely difficult treatment consequences that impair their nutritional well-being [5]. Specifically, HNC and its multimodal treatments [6] can result in oral health problems related to swallowing, speech, mucositis, and dry mouth [7] that disrupt nutritional intake during and after treatment. Most survivors with HNC experience weight loss during treatment [8-11]. Population-level analyses using Surveillance, Epidemiology, and End Results data have estimated that approximately half of patients with HNC need a feeding tube and 40% - 45% of survivors with HNC experience dysphagia-related morbidities up to 2 years following treatment [12]. These nutritional recovery challenges impair the quality of life substantially [13-17].

Nutritional challenges in survivors with HNC also impact their caregivers [18,19], family members, and friends who provide cancer-related support. Relative to caregivers for people with other cancer types, caregivers of people with HNC confront unique support tasks such as feeding tube management, meal preparation, and speech support [6,19-22]. Caregivers report feeling unprepared for their roles in nutritional caregiving, sometimes experiencing a disconnect between survivors' goals and their own, and experiencing significant unmet needs as caregivers [23-29]. While interventions for caregivers caring for a loved one with cancer have been designed and tested [30-33], few evidence-based interventions are available to support caregivers of people with HNC with a focus on nutritional caregiving tasks in the early posttreatment period. Challenges in providing high-quality comprehensive support to caregivers of people with cancer include cost (financial and time) and competing demands while caring for a loved one [34-36], complexity of survivors' needs [20], and high prevalence and extent of emotional concerns among both survivors and caregivers [37,38].

Digital health strategies may overcome some of these barriers and offer a promising way to reach and support caregivers of survivors with HNC, particularly during the transition from cancer care to home, a critical point at which in-person interventions may not be feasible [39]. Research is growing on the feasibility, acceptability, and efficacy of digital health interventions for caregivers of people with cancer, with encouraging results for interventions designed to decrease burden and improve mood [39-45]. To guide the development of a mobile app to support nutrition-related caregiving among caregivers of people with HNC, this mixed methods study characterized nutritional challenges and caregiving tasks and intervention preferences in HNC oncology dietitians and survivor-caregiver dyads.

Methods

Study Design

Using a concurrent parallel mixed methods design [46], this study included a cross-sectional, web-based survey of a national panel of oncology dietitians and semistructured interviews with survivors with HNC and caregivers. We selected a mixed methods approach to facilitate gathering the perspectives of three groups, including dietitians, survivors with HNC, and caregivers [46]. A mixed methods approach also allowed for a more comprehensive understanding of the unmet needs of caregivers of people with HNC to drive the selection of content in a supportive care app to address those needs. Our team included researchers with expertise and training in HNC, cancer survivorship, oncology caregiving, and mobile health. We used a team approach to reflexivity with discussion and attention to the potential of the research team's background to influence research findings.

The purpose of this mixed methods study was to characterize nutritional challenges and caregiving tasks and intervention preferences in HNC oncology dietitians (quantitative) and survivor-caregiver dyads (qualitative and quantitative). We concurrently collected survey data from dietitians. Both quantitative and qualitative data were considered of equal priority and were analyzed separately and then integrated using the merging technique [47] as described below. Data were collected between April and September 2018. The GRAMMS (Good Reporting of A Mixed Methods Study) checklist was used to guide the mixed methods approach and reporting [48] (Checklist 1). Multimedia Appendix 1 provides the interview guide and surveys.

Dietitian Surveys

A convenience sample of dietitians was recruited by posting a study notice on the listserv for the Oncology Nutrition Dietetic Practice Group of the Academy of Nutrition and Dietetics. Dietitians were eligible for the 15-minute web-based survey if they reported providing care for patients with HNC in the past 6 months; the survey was hosted on REDCap (Research Electronic Data Capture; Vanderbilt University). The 67-item survey was developed by the study team. All items were optional, and participants could return to the survey over time if requested. The survey assessed demographic (race, ethnicity, sex, and age) and practice (credentials, years practicing as a dietitian, practice setting, and number of patients with HNC seen per week) characteristics. In addition, perceptions of the importance of posttreatment concerns in caregiving (0=not at all important to 4=extremely important) and perceived importance and difficulty (0=not important or difficult at all to 4=extremely important or difficult) of a variety of support tasks for caregivers of people with HNC, guided by the transactional model of caregiving were assessed (eg, tracking nutritional intake, changes and patterns in symptoms, and making care decisions [49]). Other measures included ratings of nutritional support resource needs (0=not at all to 4=extremely) in caregivers of people with HNC (eg, screening process to identify caregiver nutritional concerns, assessment tool to identify caregiver distress, and educational materials) and barriers to

addressing support needs (1=not a barrier at all to 4=major barrier) in caregivers of people with HNC (eg, time, caregiver interest, lack of evidence about the value of caregiver programs, and leadership). Participants then reviewed example app screens and then answered questions about the preferred focus of app content (eg, increasing caregivers' awareness of the importance of addressing nutritional challenges, changing caregivers' attitudes about improving nutritional status, and encouraging help-seeking for nutritional support) using an adapted version of the app-specific subscale in the Mobile App Rating Scale [50] (1=strongly disagree to 6=strongly agree) and an open-ended question. Finally, participants completed an open-ended question asking them to describe any specific suggestions they had for the development of a mobile support app for HNC caregivers.

Dyad Interviews

Survivors with HNC who completed treatment with curative intent 6 - 24 months prior to enrollment and were free of disease, and their caregivers, were recruited at the Medical University of South Carolina Hollings Cancer Center, with initial screening for eligibility by chart review. Inclusion criteria included being 18 years or older, completing treatment for stage I-IVA HNC (mucosal squamous cell carcinoma of the oral cavity, oropharynx, hypopharynx, and larynx), and experiencing nutritional challenges at the end of treatment as assessed by a 6-item screen. Survivors were excluded if they were unable to identify a primary caregiver, and survivors and caregivers were excluded if they either did not speak English or were cognitively impaired. After mailing a study letter and determining eligibility via phone screen, dyadic interviews were scheduled. Informed consent documents were signed, and dyadic interviews were conducted in person by 2 female investigators with training in qualitative methods (KS and MS). Interviewers did not know the participants and were not involved in their clinical care. Interviews were continued until we reached saturation in themes [51]. They were conducted in a private room, audio-recorded, and lasted approximately 45 minutes. Field notes were taken to provide interview observations.

We developed a semistructured interview guide using a cancer survivorship quality of life framework [52] to examine participants' reflections on the physical, emotional, and social challenges they experienced at the end of treatment and in the 6 months following treatment conclusion, with an emphasis on nutritional challenges and caregiving. Survivors and caregivers were asked to describe their emotional and physical well-being at the end of treatment. They were asked specifically about nutritional challenges, expectations they had about intake abilities, and the caregiver's role in nutritional recovery. Finally, they were asked about caregiver needs and suggestions for resources to better meet their needs at the end of treatment. Participants then viewed a set of example app screens (eg, nutrition tips, recipes, and stress management advice) on a tablet, after which they provided feedback on the content and format of a future app. After the interview, survivors and caregivers completed separate brief paper-based surveys assessing demographic (age, race, sex, and education), clinical (stage, treatment type, and nutritional status at the end of treatment), and technology access (home computer and smartphone) characteristics. They also completed ratings of the importance of caregiving tasks (0=not important to 4=extremely important) and ratings of agreement (1=strongly disagree to 6=strongly agree) about the benefits of checking in with caregivers after treatment, providing support messages to caregivers, and the importance of providing practical information to help with patients' nutritional recovery.

Ethical Considerations

Study procedures were approved by the Medical University of South Carolina Institutional Review Board (Pro00066211). A waiver of written informed consent was granted for dietitian surveys; after reading a study statement, participants advancing to the survey implied consent. Dyads completed written informed consent before completing interviews and received a copy of the signed consent for their records. All screening and survey data were stored in password-protected databases. The underlying databases were hosted in a secure data center. All data were identified only by code number (participant IDs). Dietitians completing surveys were entered into a lottery to receive a US $25 gift card to thank them for their time. Survivors with HNC and caregiver participants each received a US $50 gift card.

Statistical Analysis and App Development

Descriptive statistics were used to characterize survey data on dietitian and survivor-caregiver dyad demographic characteristics, perspectives about posttreatment, and caregiving challenges, and app preferences using R (R Core Team) [53]. Interviews were transcribed and analyzed using rigorous content analysis methods for systematic theme identification [54] in NVivo software (QSR International) [55]. Transcripts were coded by pairs of independent coders (KS, JO, and HK) and regrouped and reorganized until the investigators agreed on categories. This initial inductive theme identification process was followed by team meetings to finalize themes and guide implications for the intervention design. We sought trustworthiness in the qualitative data analysis approach by including prolonged engagement with the data, triangulating data, and using an audit trail to finalize themes [56]. Quantitative and qualitative data were analyzed separately, and then a data synthesis integration step was used to guide app development [57]. We selected the mixed methods integration approach of merging [47] and brought our quantitative and qualitative results together for elaboration. For example, the quantitative results (eg, perceptions and preferences of dietitians, survivors, and caregivers) were merged with key themes identified in interviews used to offer a more in-depth understanding of appropriate content for the app. Our interdisciplinary team of HNC clinicians, researchers, and developers completed a set of planning meetings to translate study results into app content by discussing the meaning of themes, identifying potential similarities and differences across themes, and mapping the themes to content using a consensus-based approach. The app development method was an agile approach, specifically rapid application development or rapid application building, which focuses on timely delivery in a fast-paced environment with the use of prototyping and iterative development [58]. The research team worked closely with the development team to review and

test evolving prototypes; a final prototype was pretested with 2 caregiver volunteers who were not involved in interviews or development activities.

Results

Participant Characteristics

Dietitians

All dietitians (n=116, 100%) were female, and the majority were registered dietitians (n=115, 99%) and White (n=110, 95%). Most practiced more frequently in the outpatient (n=107, 92%) versus inpatient (n=23, 20%) setting; options not mutually exclusive. Half had more than 10 years of experience working with patients with HNC, and most (n=87, 75%) cared for 1 - 10 patients with HNC per week.

HNC Dyads

A total of 50 survivors mailed a study letter. Several (n=15, 30%) were ineligible due to exclusion criteria, while others declined (n=20, 40%) due to scheduling conflicts prohibiting attendance at the in-person interview, lacking interest or reporting being too ill, or overwhelmed to participate. In total, 15 survivors enrolled in the study and nominated a caregiver. All survivors completed the in-person interview and 11 survivors were accompanied by their caregivers (8 spouses and 3 children). Scheduling conflicts precluded interview completion for 4 caregivers in person, 2 of whom were interviewed independently by phone (n=13 caregivers overall).

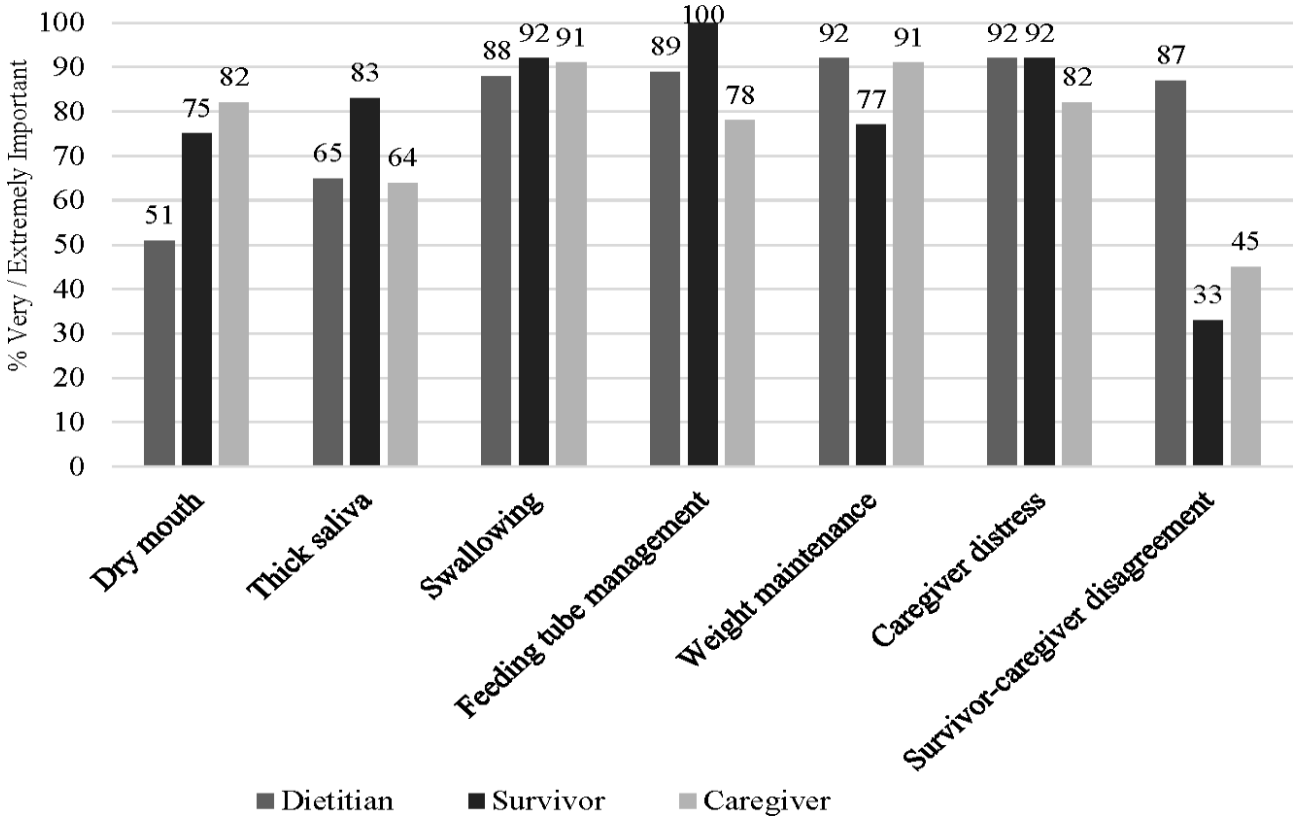
Most survivors (n=12, 80%) were male, while most caregivers (n=10, 77% spouse) were female (n=11, 85%). A total of 83% (n=19) of survivors and 87% (n=20) of caregivers were White, and age varied from 28 to 79 years (mean age 66, SD 15.1 for survivors and 61, SD 16.6 for caregivers). A total of 20% (n=3) of survivors and 27% (n=3) of caregivers had a high school or lower education. The most common cancer types included oropharynx (n=6, 40%) and oral cavity (n=3, 20%). Most survivors had surgery (n=14, 93%) and radiation (n=12, 80%); not mutually exclusive. One-third (n=5, 33%) had a liquid diet and approximately half (n=7, 47%) had a feeding tube at the end of treatment. Finally, most participants had a home computer (n=13, 87% survivors; n=13, 100% caregivers) but fewer survivors than caregivers had a smartphone (n=11, 73% vs n=10, 90%).

Posttreatment Challenges

Perceptions of HNC Nutritional Concerns in Caregiving

In the 6 months following treatment completion, dietitians, survivors, and caregivers perceived that the majority of nutritional concerns assessed were important to caregiving (Figure 1). The caregiving concerns rated most important (ie, very or extremely) by dietitians included weight maintenance (n=107, 92%), feeding tube management (n=103, 89%), caregiver distress about nutrition (n=103, 89%), and swallowing (n=102, 88%). The caregiving concerns rated as most important by survivors included feeding tube management (n=8, 100%), swallowing (n=14, 92%), and caregiver distress about nutrition (n=14, 92%). The caregiving concerns rated most important by caregivers themselves included weight maintenance (n=10, 91%), swallowing (n=10, 91%), caregiver distress about nutrition (n=9, 82%), and dry mouth (n=9, 82%).

Figure 1. Dietitian, survivor, and caregiver perceptions of the nutritional concerns in caregiving after treatment. This figure reports data from dietitian (n=116), survivor (n=15), and caregiver (n=11) surveys. Each caregiving concern endorsed at the very or extremely important level is graphed for dietitians, survivors, and caregivers.



Perceptions of HNC Caregiving Tasks

Most dietitians perceived all evaluated caregiving tasks to be very or extremely important to survivors' recovery. The highest-rated caregiving tasks included tracking nutritional concerns (n=113, 97%), working together as a team on nutritional concerns (n=104, 90%), and making care decisions (n=102, 88%). Relative to importance, most dietitians did not perceive that the measured caregiving tasks were overly difficult for caregivers to perform. The caregiving tasks most frequently endorsed as very or extremely difficult included navigating the health system (n=45, 39%), making care decisions (n=44, 38%), and interpreting changes in nutritional status (n=40, 34%).

HNC Recovery Challenges

Dyadic interviews identified 5 unique themes, which are described below with example quotes from survivors and caregivers shown in Textbox 1.

Textbox 1. Themes identified in interviews with survivors with head and neck cancer and their caregivers.

Nutritional challenges were expected but extremely frustrating with weight loss and disrupted intake caused by texture/taste, swallowing, dry mouth and sticky saliva concerns

Exemplary survivor quotes:

- Well, the issue for me is that, I mean I couldn't taste food and water tasted really weird. So I basically ate because I knew I was supposed to. Not because I enjoyed it.
- [My wife] said, “Baby, please eat, eat something.” Cause I mean, I'm doing my best...I'm trying, I'm trying, I'm trying, and I'm trying but I wish I could just eat something.
- Peg tube blockages [happened because] protein powder didn’t dissolve well, gurgling, irritation. Part of lining of my wound started sticking out and ached. After hospital discharge, I was given a nutrient solution from a medical supply company and then had diarrhea, night sweats, and projectile vomiting. Lost 26 pounds.

Exemplary caregiver quotes:

- I kept weighing him and you know in the back of your mind you know that losing weight is a sign of cancer and you really, in your mind you know it's gone, you think it's gone. But there's that worry that maybe it's not really gone and that's why his weight is still going down. So that really confused me about his weight.
- But what bothered me was that he won't eat or couldn't eat and he lost a lot of weight. He looked terrible, and he didn't have energy. I didn't know what to fix when we get home. I tried to do mostly liquid stuff but there's only so much liquid stuff you can do. The thing is, they had pulled all of his molars before the surgery, because they figure if he had a radiation, it would have to have his teeth fit. Well, with no teeth, you can't chew.
- It did affect him quickly and he dropped the weight like a ton of bricks. It was a challenge to get anything down him and it was like I wanted to do things on his schedule but it was just really, really difficult. We tried this and we tried that and we tried you know, tried several different things.

Other competing symptoms were common and difficult to separate from nutritional challenges

Exemplary survivor quotes:

- Well, the pain had a lot to do with that. Your neck, shoulders, arms and hands are in lots of pain and discomfort.
- When I finished everything, I think the last two weeks for me were the worst, where the radiation had really taken on where it had in my jaw because I could probably open my mouth the width of my finger.
- I had two really bad sores in my mouth that didn't make it fun to eat anything. When I started again occasionally, I would get some irritation from eating crunchy foods.
- I couldn't raise my arms up above my shoulders… I think my taste was coming back and the physical therapy really, I mean, that really turned me around. I started feeling a lot better. They really rehabbed my shoulders.

Exemplary caregiver quotes:

- And the sores that was on his neck kind of bothered me. Some nights he couldn't sleep normally. You know, you just go to sleep but he couldn't.
- It was more helplessness than anything. There's not anything you can do for him. You can't force him to eat because the pain was there.
- His stomach was upset a lot. After the radiation was over for a period of time after the radiation was over. It was just miserable. And also he is having [GI] issues.
- But as far as some of the other issues as far as being nauseous, we had to deal with that. The doctor gave her medicines for that, another big one is constipation. Oh, that one is a tough one.

Emotional challenges related to nutrition and recovery were common

Exemplary survivor quotes:

- Oh, yeah, confused, I mean the cancer just takes the world, just takes a lot out of yourself and I wondered if I'm going back to work and how I'm going to feel at the end of the day, for how long I would be able to see my brand new granddaughter.
- I'm still at the point where anything - I'm still afraid…because you know I still do have a lump down there, I know every time I swallow my saliva I know it’s there and I can feel it and it's - that's one thing that's always going back of my mind.
- Emotionally, I was depressed especially after the radiation specifically. Physically, I couldn't swallow. I couldn't eat. It was the most egregious treatment I ever had my life and if I knew what the outcome was going to be I would have never done it.

Exemplary caregiver quotes:

- I was with her through her depression. I think, I was depressed along with her. Seeing my mother not being able to eat or any of that and on Sundays we have Sunday dinners at her house so, we went ooh, about a good two, three months without having Sunday dinner at mom's unless one of us had to go over and cook.
-

Depression lingered, it's always in the back of your mind - is it coming back? Or did they get it all? Or those kinds of things and then what's going to be next?

- At the end of treatment I was a basket case. I checked on him constantly when he slept.

Caregivers take on a diverse set of medical and support tasks

Exemplary survivor quotes:

- Well my wife made up a chart and we had everything, I want to say laminated, definitely a plastic cover over it which was a good thing. We had it all laid out there [to monitor intake].
- But I mean-- patience. Because we're going to fight back, not meaning to be mean. But we're hurting. We're just trying to get back—we're trying to get better. I would just say, frustration. That'd be a better word. Because it is frustrating. And you seem to take it out on the ones you love the most.
- I know I relied on them a lot to get me and to help me get to the tub, to get me out of the tub. At that time, it wasn't easy. If I was this big, they wouldn't have been-- it would take a couple of them.

Exemplary caregiver quotes:

- I went to the grocery store and I just went up and down the aisle trying to find something that he could eat.
- You wouldn't believe what I've learned to do from the last year. Changing IV's. Trained to do those things. There's nothing I wouldn't do for him anyway, but I was nervous I would maybe do something wrong and harm him accidentally.
- Knowing that he's like a glass half empty kind of guy, I tried to keep everything - I didn't... not that I didn't think about it, but I just kept thinking positive. That they got it all.
- You need someone who have their best interest at heart. There's times that she's not in her right state of mind with everything that is going on so, we go to these doctor's appointments or we go to certain things, you have to have someone that is there that's going to ask the doctors the question.

Caregivers need information about what to expect with nutritional challenges and recovery

Exemplary survivor quotes:

- [My caregiver] was given a calorie intake document for a day and that was what we're trying to keep at, but there's no real specifics given us - as to how we should accomplish that.
- Yeah, I think seeing a nutritionist would have been a plus. That was never approached to us. Maybe while I was in the hospital. Given some kind of program to try to keep certain calories or what kind of foods and how to build up to.
- I think that we should have been counseled about … a feeding tube. There was no plan. There was no nutritional plan. So, full disclosure and a plan to support that disclosure would have been great. And early on in the planning – you need it in the treatment planning phase.

Exemplary caregiver quotes:

- It would be nice to have a list of do's and don'ts, a list of things that have worked for patients in the past like, you know. Puddings, Jell-O's, more common-sense and anything but having a list would be really nice when you're in a grocery store and going, okay, he's gonna need blank, blank, blank and blank.
- Well, I think they should give you a folder with all the instructions for about everything. Nutrition, food to eat, everything that needs to be done on our way. Or even we didn't know you had to have this port flushed.
- Okay, I think what could be helpful...it seems to me, if somebody can be pre-briefed as to what difficulties they may have with the-- like the chewing aspects and the saliva aspects, and what things that people have found in general that might be worth avoiding, that would be a helpful thing.

Theme 1: Nutritional Challenges Were Expected but Extremely Frustrating With Weight Loss and Disrupted Intake Caused by Texture or Taste, Swallowing, Dry Mouth, and Sticky Saliva Concerns

Both survivors and caregivers reported an array of nutritional challenges at the end of treatment that required special diets and feeding tubes. With challenges in swallowing, texture, and taste during recovery, dyads reported difficulty finding diets that were satisfying and tolerable, and often caregivers experienced distress in encouraging their loved ones to eat. Shopping, cooking, and communicating and negotiating with one's loved one around intake were also commonly reported challenges. Weight loss was reported by all survivors and caused significant distress, particularly in caregivers. The routine around feeding was reported to be very tedious.

Theme 2: Other Competing Symptoms Were Difficult to Separate From Nutritional Challenges

Survivors experienced many symptoms in addition to and related to nutritional concerns. For example, participants reported fatigue, mobility challenges, nausea, sores, and pain, and recovery challenges that often exacerbated nutritional and caregiving concerns. The array of symptoms caused frustration in survivors and worry in caregivers.

Theme 3: Emotional Challenges Related to Nutrition and Recovery Were Common

The emotional challenges faced by survivors and caregivers included frustration, fear, uncertainty, confusion, and depression. They reported frustration associated with eating challenges and the persistent focus on feeding and symptom management. Some participants reported worry and fear about survivors not regaining functional abilities. Relatedly, confusion and uncertainty about the future were commonly described by both survivors and caregivers. Caregivers expressed fear about weight loss and choking, as well as their ability to care for their loved ones. Both survivors and caregivers reported depression and other psychosocial concerns, and both also emphasized the importance of caregiver well-being.

Theme 4: Caregivers Take on a Diverse Set of Medical and Support Tasks After Treatment Completion

Caregivers focused on practical, nutritional, and emotional support tasks. Common practical tasks included providing transportation to and attending health care appointments, helping a loved one get around, and managing medications and stoma and IV care. Common nutritional support tasks included monitoring weight loss and intake, grocery shopping, researching recipes, preparing meals, and caring for feeding tubes. Emotional support tasks included supporting survivors' frustration with recovery and nutritional challenges and trying to keep a positive attitude. It was common for caregivers to report distress about support challenges, and they sometimes faced resistance from their loved ones around eating. Caregivers described a dynamic process of being persistent, creative, and patient.

Theme 5: Caregivers Need Information and Resources About What to Expect and How to Cope With Nutritional Challenges

Caregivers described feeling unprepared to support nutritional recovery and said they would have benefited from additional resources and support at the end of treatment. They emphasized the importance of early education during the treatment planning process to provide a better understanding of what to expect, resources and tools to support food preparation, and tips to help monitor intake. Survivors and caregivers both highlighted interest in meeting with a dietitian, yet also raised concerns about information overload.

Caregiver Needs and App Recommendations to Support Caregivers

Dietitians endorsed caregivers' time constraints (100/116, 86%) and caregivers being overwhelmed (102/116, 88%) as major barriers to meeting caregivers' needs. They also endorsed oncology clinics lacking designated staff to coordinate caregiver resources (70/116, 60%), higher priority care issues (n=72/116, 62%), and clinical team time constraints (n=70/116, 60%) as barriers. In light of unmet needs and to better support caregivers' provision of quality nutritional support to survivors with HNC, dietitians rated the importance of a variety of services and resources. While all 8 proposed services were rated by the majority (≥60%) of dietitians as very or extremely important, the highest ranked services or resources included a clinic referral process to link caregivers to appropriate nutritional resources (104/116, 90%), educational materials about diet (92/116, 79%), one-on-one counseling about nutrition (103/116, 89%), and training in nutritional support and symptom management (90/116, 78%).

Dietitians' responses to an open-ended question after reviewing example app screens yielded suggestions for new app content, including recipe recommendations, intake tracker, encouragement about caregiving tasks, and support for the caregiver's own well-being. Exemplary quotes include:

> *Caregivers want recipes! Tips for sore mouths, mucositis and dry mouth ... trouble-shooting enteral tube issues, constipation tips.*
>
> *Specific tips on adding high-calorie foods for weight maintenance (low in acid, soft/liquid). Same for high protein foods for tissue healing and muscle mass maintenance/recovery. Tips for frequent eating until appetite improves or side effects diminish (nausea, early satiety).*
>
> *Having exercises listed that can maintain muscle strength would be great. Also, a tracking device for the number of tube feedings completed and fluid intake would be helpful.*
>
> *It is important for the caregiver to have one set number to call for info. So many times, they try to get info from the internet which isn't always helpful.*
>
> *Support for caregivers themselves knowing they are not alone and such a big part of success moving forward.*

Survivors and caregivers' survey responses indicated that dyads were in strong agreement that checking in with caregivers after survivors complete treatment (12/15, 80% and 9/11, 82%, respectively) and providing support messages to caregivers (11/15, 73%, and 10/11, 91%, respectively) would be helpful. In addition, dyads were in strong agreement that it is important to provide practical information to caregivers to help survivors' nutritional recovery (15/15, 100%, and 10/11, 91%, respectively).

Feedback from dyads' responses to open-ended questions after reviewing example app screens included keeping the content simple, providing tips about what foods to avoid, providing recipes and dynamic nutrition information as needs change, including tips from other survivors with HNC and caregivers, and emphasizing support for caregiver well-being and self-care. Examples of exemplary quotes include:

> *This is like your personal resource right here at your fingertips - you're not alone. Let them know you're here if they need you. Simplicity is important.* [Caregiver]
>
> *Provide more advice about foods you can eat and problems with specific types of food groups…practical information with step-by-step directions. Food suggestions based on symptoms.* [Survivor]

Prepare caregivers for the possibility that the patient may not like the same dishes caregivers prepared before and not to take this personally. [Caregiver]

Encourage caregivers to ask for support from others: Doesn't mean you're less of a person [if you ask for help]. You need all the help you can get and a lot of the time you don't want to ask for it. [Caregiver]

It is important to ask about how the caregiver is doing; I feel guilty for not asking how she was doing. In general, we are in the dark; anything that brings some light into the room is helpful. [Survivor]

Data Synthesis: App Development

Building on results from all surveys and interviews underscoring the high need and interest in a comprehensive caregiver app, we designed the Healthy Eating and Recovery Together (HEART) app. The overall goal of the app was to support caregivers of survivors with HNC as they transition to the home setting after completing treatment and decrease their unmet needs and caregiver burden. The study investigators evaluated qualitative themes from dyad interviews side by side with quantitative themes observed in dietitian and dyad surveys. Team meetings were used to identify similarities in themes that were translated to high-priority main menu domains and subdomains for the app. The integration of survey and qualitative data resulted in an expansion of the findings, as the qualitative themes provided a detailed understanding of quantitative findings about caregivers' unmet needs and responsibilities as caregivers. The research team worked closely with the development team to review and test evolving prototypes, and a final prototype was pretested with 2 caregivers. The app was updated with feedback over the course of these steps (eg, we updated icons, modified menu choices, added instructions to components, reordered messages, and modified color choices). HEART includes educational information, caregiving tips and encouragement, and resources, with 4 elements, including survivor nutritional support, intake tracker, caregiver toolkit, and support videos (Table 1 provides more detailed descriptions and sample screenshots). The app also provides caregivers with notifications twice a week to check in with them about their concerns and deliver real-time resources mapped to current concerns. Two main areas in the app's content included a focus on survivor-caregiver teamwork and support of caregivers' own well-being.

Table . Content of the HEART[a] app.

App section	Content	Results guiding content	Screenshot
Nutritional support	Tips and encouragement for supporting a loved one with nutritional intake	A need for coverage of a broad array of topics to support the dynamic nutritional recovery process with content on common issues, recipes, and oral care support.	
Intake trackers	Supports tracking of feeding tube, liquid diet, and solid food in real time to monitor quantity, tolerability, and preferences, with the ability to share the intake journal with others.	Caregivers experience distress in monitoring intake and need a simple, convenient way to support monitoring.	
Caregiver toolkit	Emphasis on caregiving tasks and how caregivers can take care of their own physical and emotional well-being with tips and relaxation techniques	Caregivers feel unprepared for their roles as caregivers and face significant burdens, often overlooking their own well-being.	
Support videos	Survivor, caregiver, and clinician videos to support nutritional recovery and well-being	Interest in social support and increased interaction with dietitians and other survivors and caregivers.	
My resources	Stores biweekly prompts and tailored resources	Participants desire real-time connections and resources that are dynamically matched to their changing needs during recovery and caregiving.	

[a]HEART: Healthy Eating and Recovery Together.

Discussion

Principal Results

Survivors with HNC and their caregivers face exceptionally difficult posttreatment concerns that negatively impact their quality of life [28,59-61]. Caregivers are often tasked with addressing survivors' nutritional challenges in the home setting, yet many are unprepared for these caregiving tasks [20,24]. Getting adequate nutritional intake, maintaining a healthy weight, and managing physical symptoms and emotional distress are imperative for survivors of HNC during the posttreatment period; yet, there is a paucity of tools available to support survivors and their caregivers in meeting these goals [31,32]. This study addressed this important survivorship care gap, specifically the availability and accessibility of high-quality interventions to support nutritional caregiving. Recognizing the

value of stakeholder input in intervention development [62-64], we used mixed methods to assess the perspectives of survivors, and then also used responses from caregivers and oncology dietitians to guide the development of an app to support caregivers at the end of treatment. Previous studies have emphasized the acceptability of apps for cancer caregivers while also calling for more formative research to ensure their suitability [43,44,65,66]. While we intended to focus this tool on nutritional caregiving support, study results led to a more comprehensive product focused on nutrition and other survivor recovery concerns, plus caregiver self-care. The final HEART app includes nutrition support with an intake tracker, along with tips and encouragement for other caregiving areas (daily support, emotional support, and medical support), support videos from peers and clinicians, and a caregiver toolkit (taking care of yourself and relaxation exercises).

To guide app development, dietitians provided their perspectives on caring for and supporting HNC dyads. They endorsed a broad array of important nutritional concerns for HNC caregiving, including swallowing, feeding tube management, weight maintenance, and caregiver distress about nutrition. They also perceived that there were multiple nutritional care tasks that were important to survivors' recovery, including monitoring nutrition, making care decisions, and working together with their survivors as a team to manage nutritional concerns. While most dietitians did not rate these care tasks as extremely difficult for caregivers to manage, the number of tasks endorsed was substantial, and the importance to survivors' recovery was rated highly, indicating that an app intervention would likely need to be complex and cover a comprehensive set of nutritional concerns. These results suggest that an app should help caregivers be flexible and skilled in multiple nutritional care tasks. Additionally, dietitians' perceptions regarding potential survivor-caregiver mismatch on nutritional goals were consistent with previous studies [18,26], which may suggest that a focus on teamwork in dyads would be beneficial in an app [67,68].

HNC survivor-caregiver dyads in this study confirmed the challenges reported by dietitians in both surveys and interviews. First, survey results highlighted similar nutritional caregiving concerns after treatment in survivors, caregivers, and dietitians. Second, interviews confirmed the types of nutritional challenges experienced and the emotional toll they take on dyads, consistent with previous studies [5,6,69,70]. Results also highlighted that nutritional caregiving tasks were compounded by other competing HNC recovery concerns (eg, support for pain, mobility, pain, fatigue, and emotional challenges); it was difficult for caregivers to focus on nutrition without considering these additional concerns. As highlighted in previous research, caregivers take on a multitude of caregiving tasks and need resources matched to these responsibilities [14,19,20], again supporting the coverage of a broad array of HNC caregiving [20] content in an app.

Dietitians also endorsed high barriers to meeting caregiver needs, including clinician time constraints and a lack of designated staff to coordinate resources. While increasing research has prioritized interventions to meet caregiver needs [31,71], cancer care settings are not adequately resourced to address their needs [72,73]. Technology tools such as the HEART app may be a promising approach to address these barriers and complement other interventions to support caregivers [39,74]. Dietitians in this study endorsed a broad variety of strategies and content to include in an app to support caregivers. Dietitians tended to prefer high-resource strategies for inclusion in an app, such as intake tracking, training, screening processes, educational resources, and counseling. Survivors and caregivers confirmed interest in an app for caregivers with check-ins, support, and practical tips. Both dietitians and dyads recommended the provision of recipes and support for caregivers' own well-being. Dietitians uniquely recommended an intake tracker, while dyads uniquely recommended tips from peers.

While mobile health intervention development and testing to support caregivers of people with cancer is growing and shows evidence of promising acceptability, adherence, and some improvements in short-term outcomes such as caregiver burden [41-43,45,65,75,76], more research is needed in this area to better understand caregiver adoption and engagement in these interventions, impacts on caregiver psychosocial and health outcomes, and best practices for disseminating such intervention in practice using rigorous methods. Of key importance, few studies have focused on HNC caregiving and nutritional support. Apps to support caregivers of people with HNC also have the potential for supporting and addressing HNC dietitian time constraints by supporting their recommendations outside of the clinic; more research is needed in this area.

Strengths and Limitations

The strengths of this study include its mixed methods approach with data collection from multiple perspectives, including those who had experienced HNC recovery, served as an HNC caregiver after treatment, and provided clinical care for HNC survivor-caregiver dyads. The integration of survey data and qualitative data allowed for the examination of similarities and unique findings across qualitative and quantitative themes, ultimately allowing a deeper understanding of perspectives to guide the HEART app. Dietitians were recruited from across the United States, and qualitative interviews with dyads were used to supplement surveys and provide a more in-depth understanding of survey results. The app's focus on nutritional support, particularly after the end of treatment, is innovative and would help address an area of major concern for HNC providers, survivors, and caregivers. In the context of changing digital health use patterns over time, it is important to note that an important limitation of this study is that the data were collected in 2018. However, it is notable that digital health use and engagement rates have increased over time, and this expanded reach and growing societal acceptance of these tools are therefore encouraging [77]. Other limitations of this study include recruitment of dyads from only one medical center, recruitment of a convenience sample of dieticians, and a modest sample size for interviews, all of which limit the transferability of findings. In addition, we experienced a lack of diversity in clinical and sociodemographic factors for surveys and interviews. We selected a parallel convergent approach for data collection and analysis and followed with an integration approach (merging) to synthesize our mixed methods data; while a sequential approach may have allowed more iterative app

development and testing, this approach was selected to facilitate rapid technology development.

Conclusions

In summary, this study identified the optimal content for a mobile support app for caregivers of people with HNC and supported the acceptability of implementing this intervention at the end of treatment. Future steps include evaluating the implementation of the HEART app and its impact on survivor and caregiver outcomes. It will be important for a future study to rigorously test the HEART app in a prospective clinical trial.

Abstract

Background: Due to multifaceted outpatient regimens, children receiving hematopoietic stem cell transplants (HCTs) are at high risk of medication nonadherence, leading to life-threatening complications. Mobile health (mHealth) interventions have proven effective in improving adherence in various pediatric conditions; however, adherence intervention literature on HCT is limited.

Objective: This study aimed to assess the usability of a mHealth intervention (BMT4me) designed to serve as a real-time, personalized tool for medication management or adherence, symptom tracking, and journal keeping.

Methods: Following a mixed methods approach, 14 caregivers (n=11, 79% female; n=10, 71% White) of children aged 2 - 18 (mean age 8.51, SD 5.18) years in the acute phase (first 100 d) post-HCT were recruited. Caregivers were asked to use the BMT4me app for 100 days or until weaning of the immunosuppressant medications to measure usability. The System Usability Scale (assessing functionality and acceptability), reaction cards (assessing desirability), caregiver satisfaction (assessing satisfaction) with the app, and semistructured interviews (assessing participant experience using the app and feedback regarding features) were conducted at two time points, at enrollment and study completion.

Results: The mean System Usability Scale score was 86.15 (SD 12.81) at enrollment and 73.13 (SD 16.13) at study completion, with most participants reporting the app easy to use and accepable during both time points. At enrollment, 80% (n=12) of caregivers reported that the app was effective in motivating them to stay on schedule, and 87% (n=13) indicated they would recommend it to others. At study completion, 75% (n=6) of caregivers found the app helpful for tracking their child's medication schedule, and 64% (n=5) would recommend it to others. Caregivers described the app as "accessible," "useful," and "valuable." Qualitative interviews during both time points revealed caregivers' positive reactions to the app, particularly regarding medication reminders, tracking symptoms, and notes features, while also providing suggestions for improvements, such as integrating the BMT4me app with electronic medical records, incorporating educational content, adding fields for recording vital signs, and important phone numbers.

Conclusions: The BMT4me app demonstrated promising usability as a mHealth intervention among pediatric patients undergoing HCT. Caregivers considered the app user-friendly and valuable, with positive feedback on its features, such as medication reminders and symptom tracking. Despite minor reported issues with app functionality, the overall acceptance of the app suggests its potential to support families in managing complex treatment. The findings from this study will inform the feasibility of testing in larger randomized controlled trials.

Introduction

Pediatric hematopoietic stem cell transplants (HCTs) are an intensive life-saving treatment for several malignant and nonmalignant disorders [1]. However, HCT often requires a long hospital stay that is stressful for the children and their caregivers [2]. Symptom and medication management are important components of the HCT experience, and it is critical for caregivers to adhere to recommendations and communicate with the care team [3]. After discharge, caregivers must follow complex medication regimens with various dosages and frequent dose adjustments, increasing the risk for nonadherence [4,5]. In the pediatric HCT population, 52% to 73% [2,6,7] of patients do not take medications as they are prescribed during the treatment course. Therefore, medication adherence is a primary concern for health care providers and caregivers after pediatric HCT [8,9]. Many factors impact medication adherence rates, including patient-related factors, forgetfulness, therapy side-effects, complexity and length of treatment, and route of administration [10-13]. Although medication adherence in pediatric HCT is understudied and interventions are limited, research in other pediatric chronic conditions has demonstrated the potential of mobile health (mHealth) interventions in improving medication adherence [14-16].

As smartphones become nearly ubiquitous in daily life, mHealth interventions can improve families' ability to manage their child's medical care [17,18]. Recent estimates show that over 5 billion people have access to mobile phone services around the world [18]. Additionally, a study of adults with chronic diseases suggests that mobile apps as mHealth intervention tools are more effective for improving medication adherence than non-mHealth interventions [19]. mHealth interventions have resulted in better clinical outcomes (eg, increase in health-related quality of life, symptom management, and decrease in readmissions and treatment anxiety) [20-22] through behavior change and enhancement of adherence to treatment [23-25]. mHealth interventions allow individuals and caregivers to track medication doses and symptoms, make notes of discussion points with their health care team, and find educational resources and support networks [26-29]. However, such interventions have yet to be tested to promote medication adherence among children in the acute phase post-HCT (ie, hospital discharge to day 100) [30].

This paper reports a longitudinal mixed methods pilot study examining the usability of a mHealth intervention (BMT4me) with caregivers of children in the acute phase following HCT. This intervention helps caregivers to record and track their child's medications, set reminders, report symptoms, and take notes on their child's progress. The goal is to inform future refinement of the intervention, a feasibility trial, and a pilot randomized controlled trial examining efficacy.

Methods

Study Design

Data are from a longitudinal mixed methods study to assess the usability of a newly developed mHealth intervention for pediatric post-HCT medication management. The study was conducted at a large Midwestern children's hospital from September 2021 to January 2023. Eligible caregivers were identified from the HCT clinic schedule and inpatient HCT unit based on the following eligibility criteria: (1) English-speaking, (2) 18 years of age or older, (3) having a child between 2 and 18 years of age undergoing allogeneic HCT, and (4) having a smartphone (either Android or iPhone) at recruitment and during the study period. All 20 caregivers of children who received HCT during the study period and met the eligibility criteria were approached for participation. A total of 15 caregivers consented to participate in the study, while 5 caregivers declined due to reasons including being busy with caring for the child and not being comfortable using the apps in general. One caregiver withdrew after initial consenting, resulting in a final cohort of 14 caregivers.

Ethical Considerations

The study was approved by the Nationwide Children's Hospital Institutional Review Board (approval STUDY00000910) and was designed in accordance with the ethical standards laid out by the Declaration of Helsinki. Eligible interested participants provided informed consent prior to enrollment and were assigned ID numbers for confidentiality. Recordings of qualitative interviews were destroyed after completion of the transcription, and identifying information in the transcripts was removed. All participant information has been anonymized in this paper, including the text, tables, and figures. Upon completion of the study, all participants received a US $20 gift card as compensation.

Measures

Demographic Data Form

Caregivers self-reported the child's and their own background characteristics, including age, sex, race, ethnicity, education level, and family income at the time of study enrollment.

System Usability Scale

Caregivers rated 10 items on a 5-point Likert scale to evaluate the functionality and acceptability of the BMT4me app. Total scores range from 0 to 100, with scores >68% considered above average [31]. Internal consistency (Cronbach α=0.91) and convergent validity (r=0.81 with a 7-point scale of "user-friendliness") have been well established [32,33].

Caregiver Satisfaction

Investigators developed a 9-item survey to obtain feedback regarding caregiver app use, benefits, burdens, barriers, suggested modifications, and overall satisfaction. Questions were rated on a 1 to 4 scale, with higher total scores indicating greater caregiver satisfaction.

Reaction Card

Reaction cards were developed by Microsoft as part of a "desirability toolkit" to elicit immediate reactions, thoughts, or opinions from individuals regarding a particular tool or technology [34]. Using a reaction card of 55 listed words, caregivers provided feedback on the desirability of the BMT4me app. The words and the number of times they were chosen were summarized to indicate the overall attitude toward the app. Higher frequencies of positive words indicated greater usability, while higher frequencies of negative words indicated lower usability [35].

Qualitative Interview

Qualitative nterview guides were developed using a combination of literature review, expert consultation, and pilot testing to ensure relevance and clarity. Questions were designed to elicit in-depth perspectives on key study themes while allowing for flexibility in participant responses. A semistructured format was used to balance consistency across interviews, with the opportunity for participants to elaborate. The semistructured interviews were transcribed verbatim and analyzed using NVivo software (QSR International).

BMT4me App

The development of the BMT4me app (Figures 1 and 2) followed a user-centered, multiphase iterative approach. This method actively involved patients, caregivers, and health care providers at every stage of the app's creation. Initially, a wireframe (Figure 1) was designed, serving as a simple visual representation of the app's structure and content [36].

Feedback was then collected from caregiver and child dyads, which informed the creation of the BMT4me app prototype (Figure 2). Afterward, health care providers assessed the prototype, and feedback led to further refinement of the app.

Figure 1. Version 1 of mobile health app wireframes.

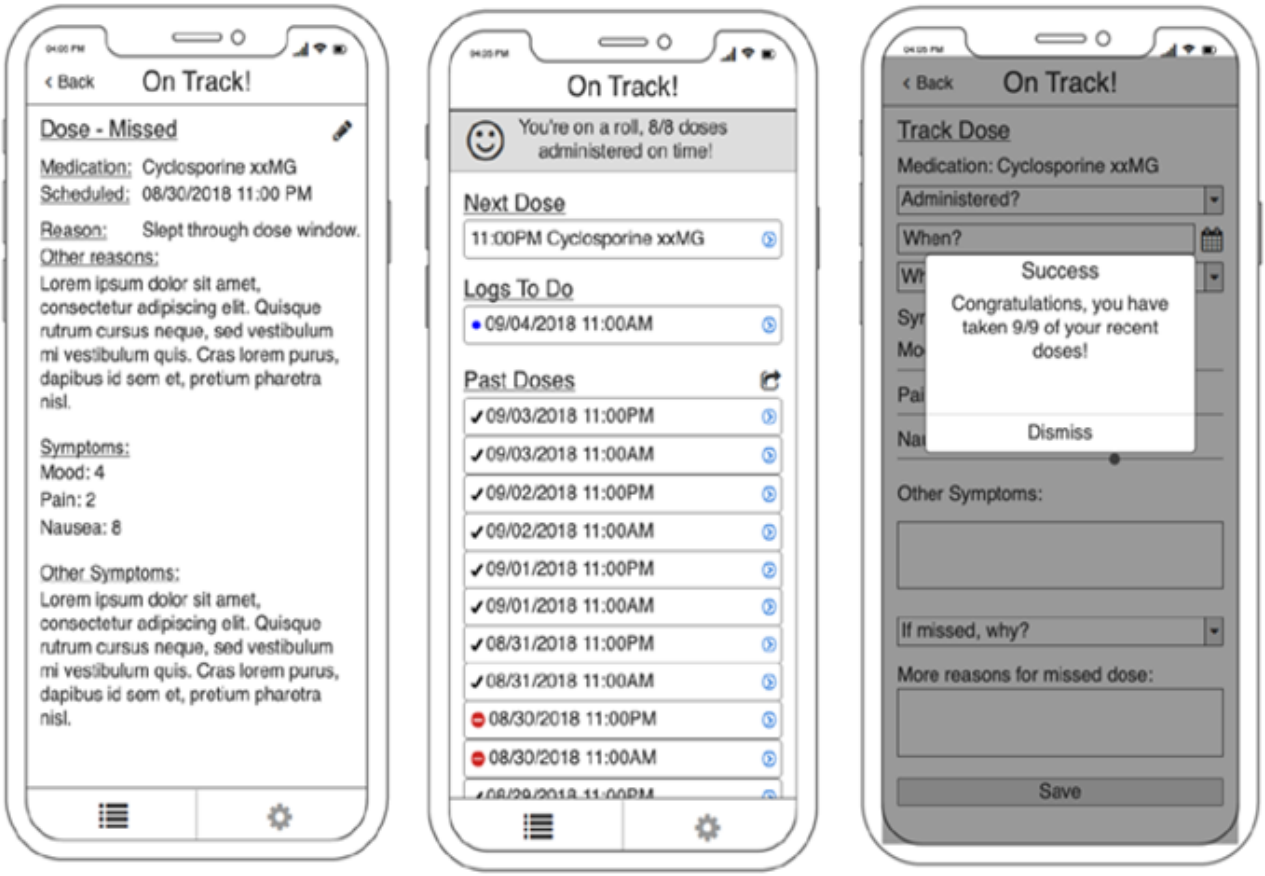

Figure 2. Revised BMT4me app prototype.

The BMT4me app was developed for both iOS and Android devices as a real-time, personalized medication management or adherence tool, and to track medication, symptoms, and side effects. Medications, doses, and schedules can be manually typed into the app by the user or entered using the image-to-text feature, which converts the medication label into text. Through pop-up notifications, the BMT4me app reminds caregivers of the medication doses and schedule, while also recording the time medication was taken and reasons for missed doses. Symptom ratings are represented by emojis on a slider scale of 1 to 10. Additional features include a note section to upload pictures and for recording any details of care to communicate with the provider. In the case of shared caregiver responsibility, the app can be installed on separate devices using the same sign-in code to sync information in real-time between caregivers. Amazon Web Services were used for data storage and app database management.

Procedures

If eligible, recruitment occurred either before or on the day of the child's discharge following HCT or at the first HCT clinic visit postdischarge. Trained research staff introduced the study, and interested caregivers provided written informed consent prior to participation.

To facilitate app login and use, participants received a unique QR code for activating the BMT4me app on their smartphones, and the research team helped with installation. Understanding and engagement with the app were evaluated in the following steps (further explained in [37]).

Step 1: Unobtrusive Observation to Measure the Intuitiveness of the Interface (10 - 15 Min)

Ease of Navigation

This was how quickly and accurately participants were able to find features and complete tasks, as well as any moments of hesitation or confusion when navigating the menu and buttons.

Task completion

This was how quickly and accurately participants found features or completed tasks such as inputting medications, symptoms, or notes.

Error frequency

This included mistakes made while interacting with the app, such as tapping the wrong button or misunderstanding the instructions.

Flow and Progression

This was how naturally participants moved through the app interface without guidance.

Caregivers were encouraged to interact with the app independently, without guidance from the study staff, to evaluate the intuitiveness of the app's interface. During this phase, research staff observed and recorded participant progress related to the other steps described below.

Step 2: Interactive Observation (10 - 15 Min)

After observing independent app use, the research team started to interrupt the participants and ask questions regarding observed cues. Caregivers were encouraged to share their thoughts and criticisms of the app. The discussion was based on individual participant cues, and preprescribed questions were not possible.

Step 3: Debriefing (15 - 20 Min)

Caregivers were asked to share their experience with the app, including the app's interface and content, as well as thoughts on incorporating the app into their daily routine. Feedback regarding the strengths and weaknesses of the app was also collected.

Step 4: Passive Use Observation

To ensure caregivers understood the app, research staff provided a detailed introduction, answered participant questions, and had the caregivers practice adding medications and tracking symptoms. Participants were invited to continue using the BMT4me app at home for 100 days or until the child had been weaned off the immunosuppressant medications. Participants' passive use data on app use and phone activity was digitally logged

Caregivers then evaluated the usability of the BMT4me app at the beginning and end of the study, using the System Usability Scale (SUS), Caregiver Satisfaction, and Reaction Card assessments. SUS, Caregiver Satisfaction, and Reaction cards were completed after participants independently interacted with the app for 5 - 10 minutes during enrollment. Participants completed enrollment measures in the hospital prior to discharge, and they had an option to complete them either electronically via REDCap (Research Electronic Data Capture; Vanderbilt University) on a study iPad or using paper and pencil. Exit measures were completed electronically, where participants were emailed the survey link. Participants were invited to continue using the BMT4me app at home in the acute phase post-HCT (100 d or until the child had been weaned off the immunosuppressant medications) because the risk of nonadherence and complications such as GVHD is highest during that time. The BMT4me app collected daily data on medication-taking, the time medication was taken, reasons for missed doses and barriers, symptoms, and notes. Passive use data on phone activity and app use were digitally recorded and sent to the research team by software developers each week. During the study, research staff followed up with participants weekly to provide technical app support if needed.

Upon completion of surveys, semistructured interviews were also conducted in-person, both at the beginning and end of the study, to explore app use experiences, helpful features, suggestions for future improvements, and barriers encountered while using the app at home. To schedule the interviews, participants were contacted by research staff via phone call or email. During their child's clinic visit, semistructured interviews, lasting approximately 15 - 20 minutes, were conducted by research staff trained in qualitative interview methods. The study investigator conducted fidelity checks to ensure consistency across the research staff's qualitative interview techniques. All interviews were audio-recorded for analysis.

Data Management and Analysis

Data cleaning and verification were completed using Excel (Microsoft Corp), and the data were then analyzed using SPSS software (version 26; IBM Corp). Descriptive statistics (frequencies, means, and SDs) summarized quantitative data, including demographic characteristics, BMT4me app activity, and survey responses. During the passive observation period, passive data modules recorded phone activity and caregivers' app use (such as time, date, and duration of use). Descriptive statistics were applied to analyze the phone activity, and correlation analysis was conducted to examine use patterns over time. Usability and acceptability of the BMT4me app were assessed by averaging total scores from the SUS. The proportion of participants who enrolled and completed the study was examined to assess the feasibility of the intervention.

Semistructured interviews were transcribed verbatim for content analysis and were organized and coded using NVivo software. Initially, the study team read the transcripts to familiarize themselves with the data. Afterward, the team generated an initial list of codes to align with study questions, and later, the codes were sorted to create a thematic framework. For consistency and accuracy, themes and code groups were then revised systematically by the team's identified coders (MS, MK, and Kathryn A Vannatta), and the thematic framework was adjusted to reflect any changes. Once the review was complete, final codes and themes were reviewed by the study's principal investigator (MS), and any disagreements were resolved through consensus with the coding team. Finally, findings were interpreted and reported in relation to existing literature.

Results

Participants

Initially, 15 caregivers were enrolled in the study (Table 1). Among them, 10 (67%) were approached at discharge and 5 (33%) at the first BMT follow-up visit postdischarge. One caregiver opted out after consenting for the study, and 2 were lost to follow-up, one at week 2 and the other at week 3, both due to transfer of care to another institution. Most caregivers were female (n=11, 79%), White (n=10, 71%), non-Hispanic (n=13, 93%), married (n=9, 64%), and had a college-level education (n=8, 57%). More than half of caregivers reported an annual family income of ≤US $75,000 (n=8, 57%). All caregivers were biological parents of the children. The sample of children was mostly male (n=10, 71%), White (n=10, 71%), and non-Hispanic (n=13, 93%).

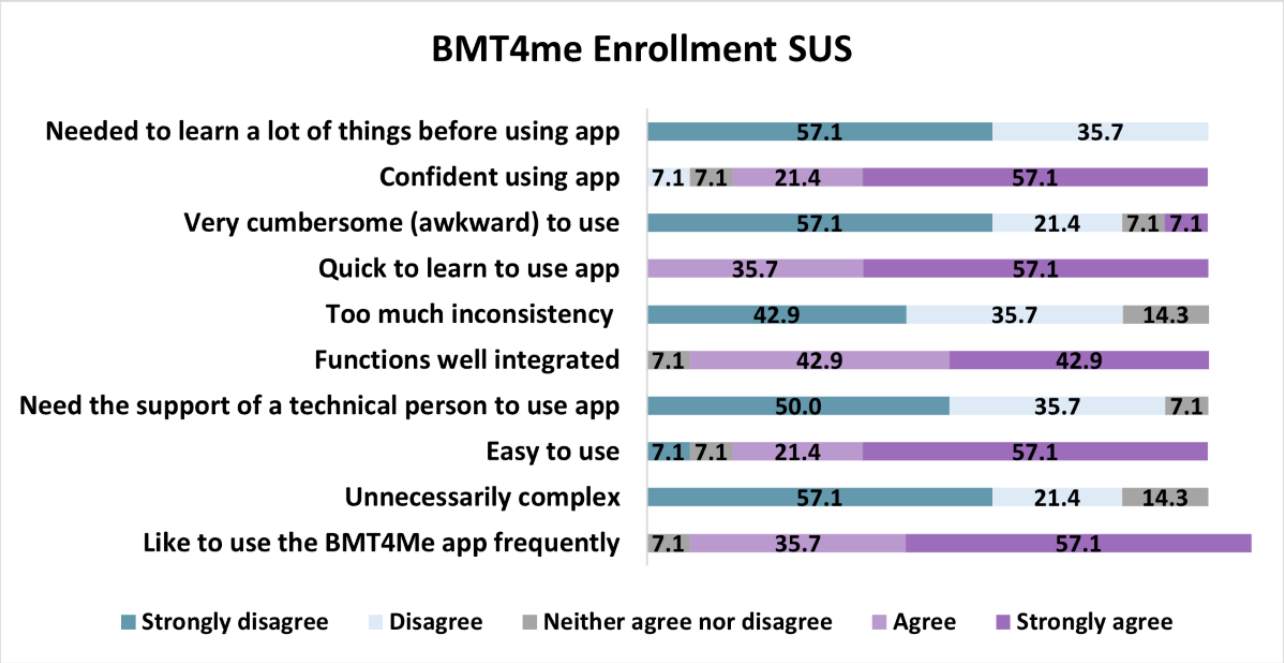
Usability

SUS

At enrollment, the average SUS score was 86.15 (SD 12.81), and the median was 87.5 (IQR 62.5 - 97.5). On individual items, caregivers reported that the app was quick to learn (n=13, 93%), they were confident using the app (n=11, 79%), the app was easy to use (n=11, 79%) and that they would like to use the BMT4me app (n=13, 93%; Figure 3).

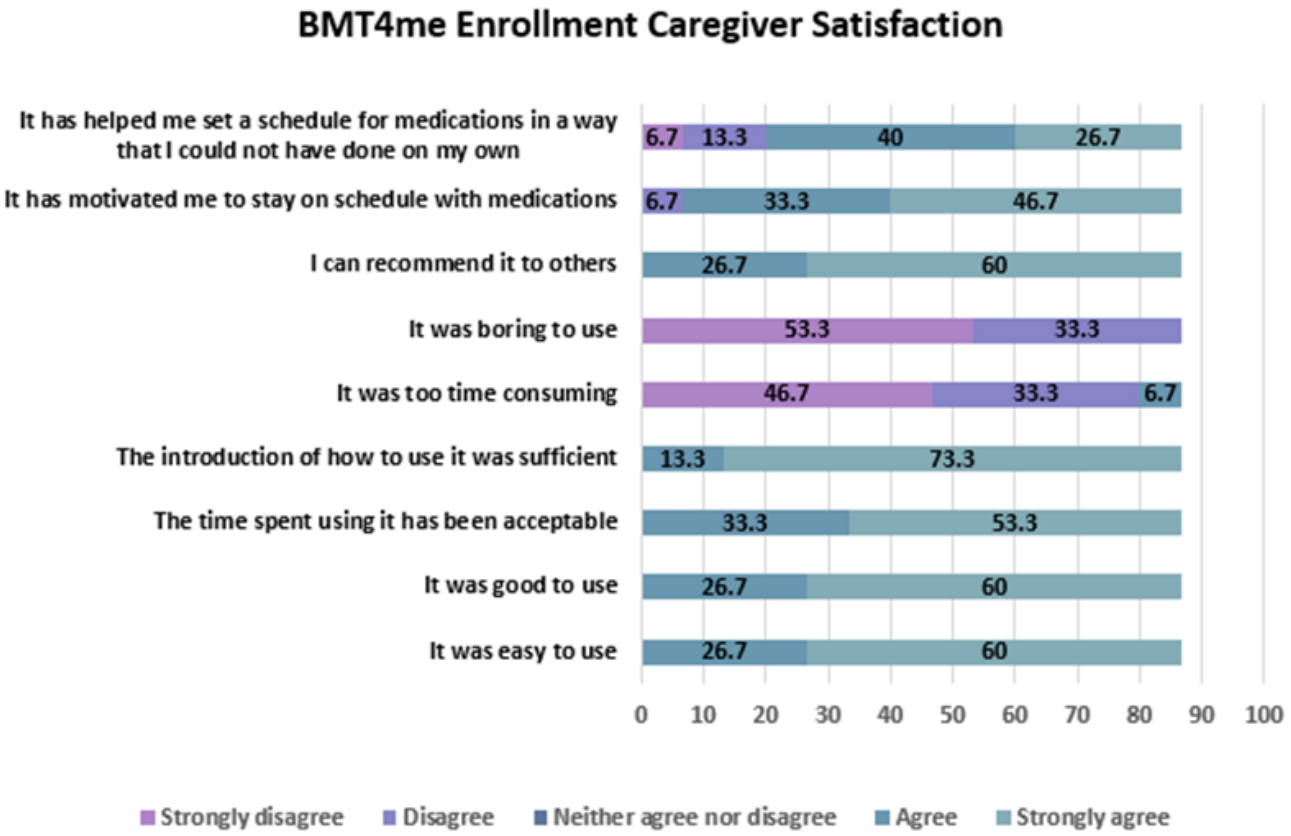
Figure 3. Enrollment SUS survey responses from caregivers. SUS: System Usability Scale.



Caregiver Satisfaction

Participants reported that the BMT4me app was easy to use (n=13, 87%) and effective in motivating them to stay on schedule with medications (n=12, 80%). Most did not find it time-consuming (n=12, 80%) or boring (n=13, 87%). Caregivers indicated they would recommend the app to others (n=13, 87%) and felt it helped them maintain their child's medication schedule in ways they could not have managed on their own (n=10, 67%; Figure 4).

Figure 4. Enrollment caregiver satisfaction survey responses.



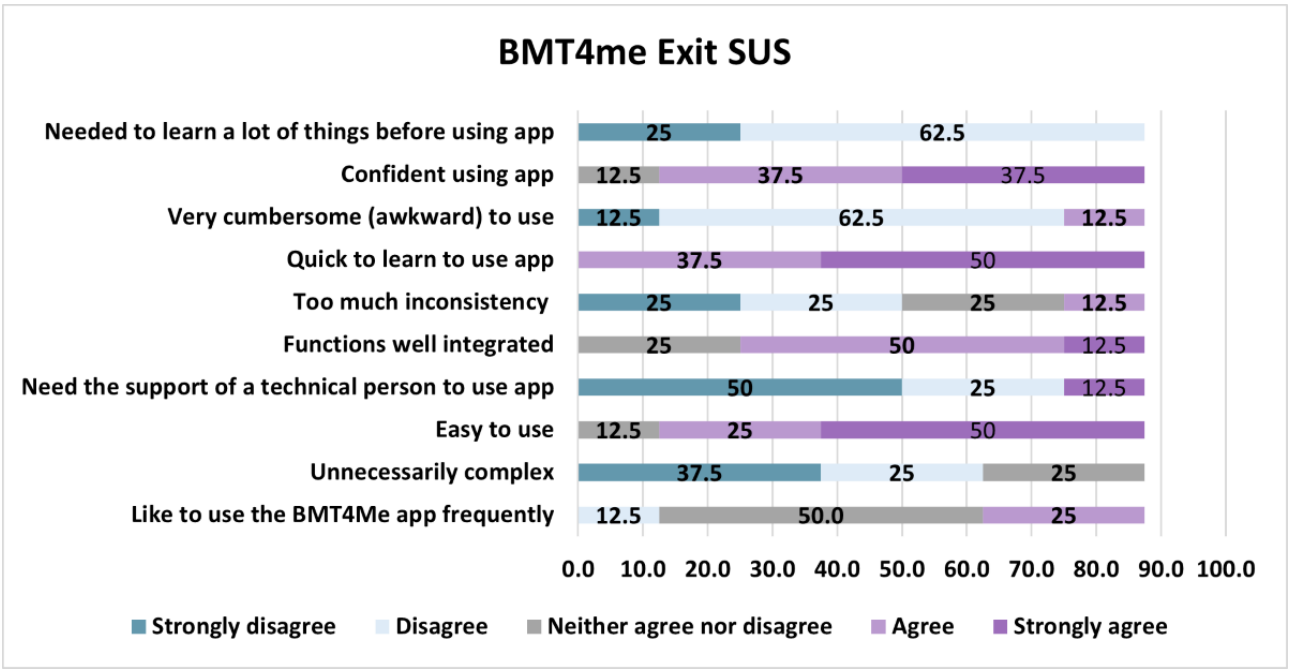
Reaction Cards

Most caregivers expressed a positive reaction after their initial use of the app with the top three endorsed reactions being the app was accessible (n=11, 73%), useful (n=11, 73%), and easy to use (n=10, 67%), which received the highest percentage of responses (Multimedia Appendix 1).

SUS

At study completion, the mean SUS score was 73.13 (SD 16.13), and the median was 75.0(IQR 50 - 86.3). On individual items, caregivers reported the app was quick to learn (n=7, 88%), they were confident in using the app (n=6, 75%), app was easy to use (n=6, 75%), and that features were well-integrated (n=5, 65%; Figure 5).

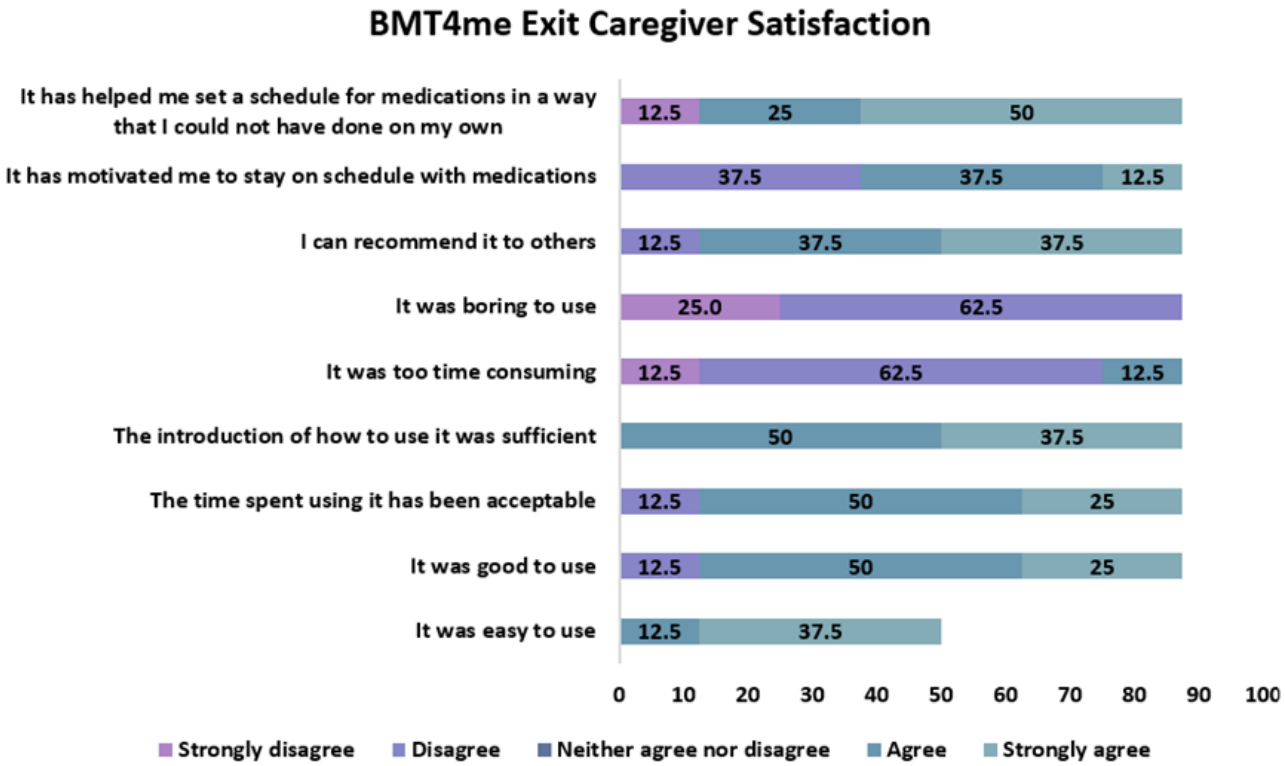
Figure 5. Exit SUS responses from caregivers. SUS: System Usability Scale.



Caregiver Satisfaction

Caregivers reported that the app was helpful in keeping track of their child's medication schedule (n=6, 75%), while also being good to use (n=6, 75%) and not boring (n=7, 88%). A total of 6 caregivers indicated that they would recommend the app to others (n=6, 75%; Figure 6).

Figure 6. Exit caregiver satisfaction survey responses.



Reaction Cards

After a few weeks of interaction with the app at home, most caregivers expressed positive reactions to the app. The top three endorsed reactions were accessible (n=7, 88%), useful (n=7, 88%), and valuable (n=7, 88%), which received the highest percentage of responses (Multimedia Appendix 2).

Feasibility

Of the 14 caregivers who successfully installed the app, 7 (50%) caregivers did not use the app after the initial sign-in, 2 (14%) caregivers added their child's regimen, and 5 (36%) caregivers used the app for at least 1 week. In total, 2 (14%) caregivers used the app for 1 week, while the other 3 (21%) caregivers used the app until study weeks 2, 6, and 7, respectively (Figures 7 and 8).

Descriptive analyses were conducted for the app data (Multimedia Appendix 3) . A total of 1579 app engagement activities were recorded, of which 286 (18%) were for "loading the app," suggesting the number of times enrolled caregivers either attempted logging in or opening the app. The "creating a medication" feature, indicating medication entry into the app, was used 172 (11%) times. The feature "create a dose" was used 552 (35%) times, reflecting the number of times a medication was either entered or edited. A total of 100 (6%) responses were registered for the "take-all-doses." The "take-all-doses" feature pertained to the number of times enrolled caregivers registered on the app that their child took all their prescribed medications. The note feature was used 24 (2%) times. Caregivers used the app to enter their child's symptoms 22 (1%) times. Four of the enrolled caregivers used the note feature at least once.

Figure 7. Weekly app engagement.

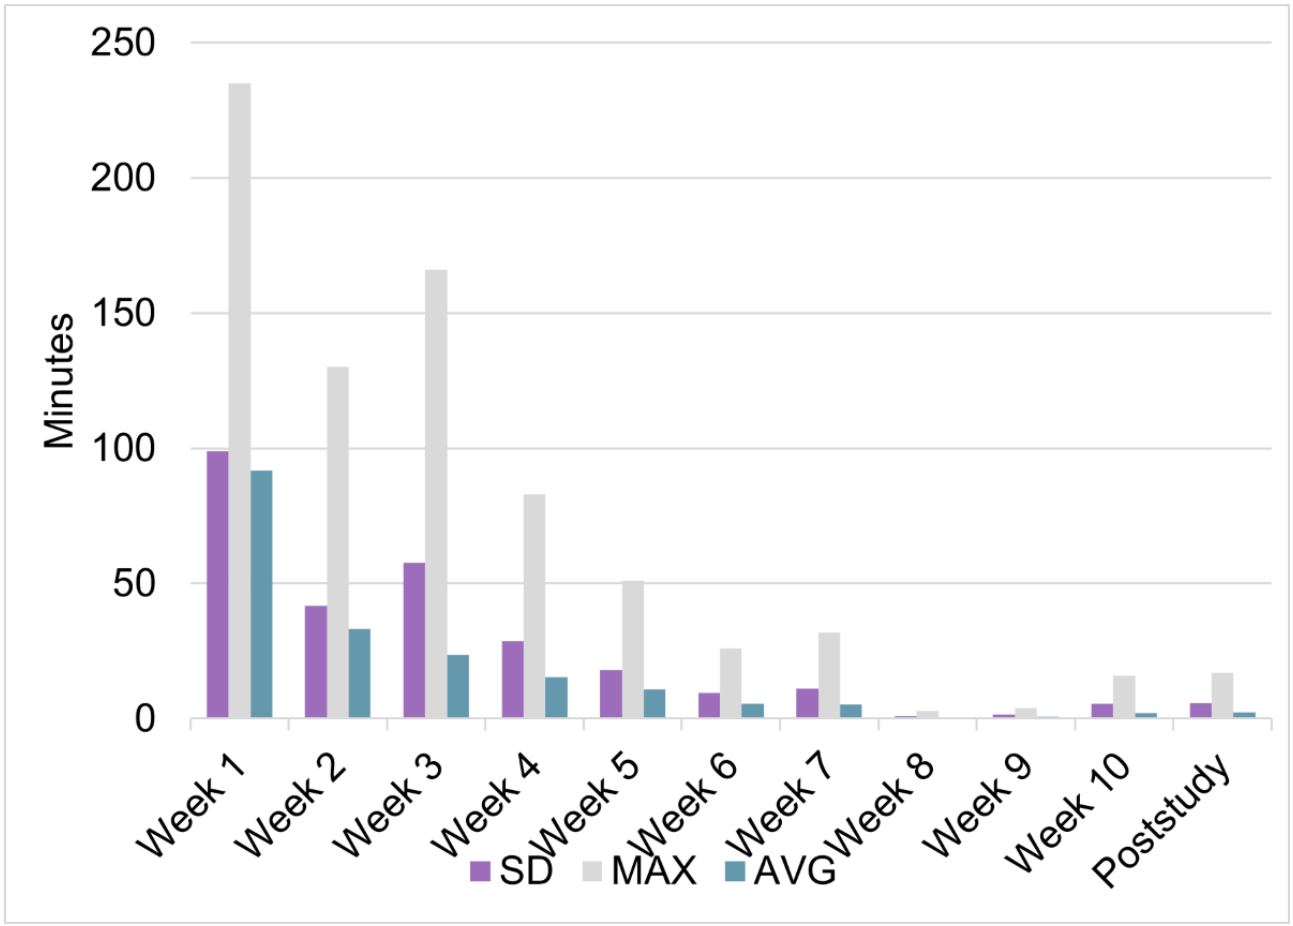


Figure 8. Weekly app engagement by individual user.

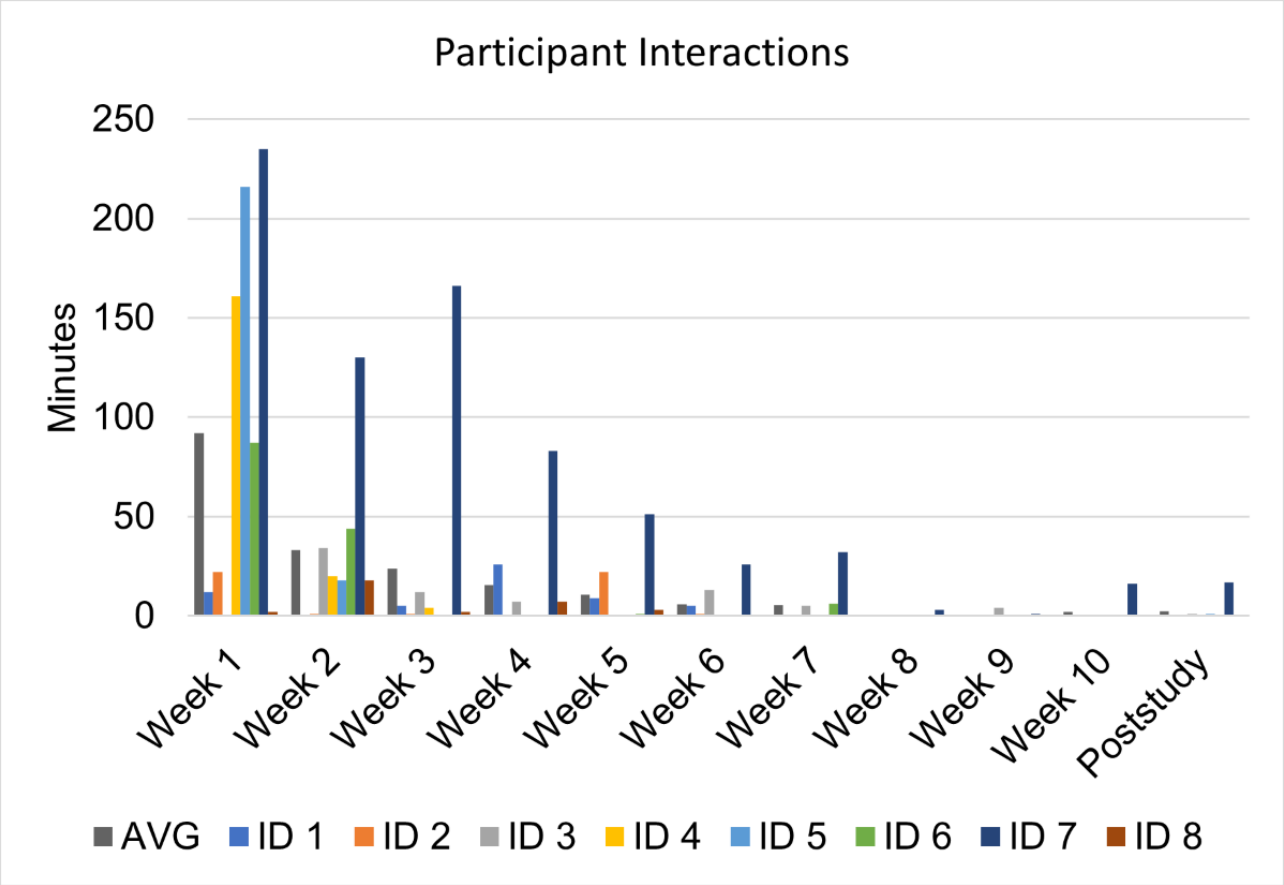

Semistructured Interviews

Our qualitative analysis of both enrollment and exit semistructured interviews found that medication reminders were highly favored by 43% (n=6) of families, while recording side effects and symptoms were reported by 21% (n=3) of participants, and writing notes was favored by 14% (n=2). Participants also suggested several new features for the app (Table 2). Half of the families (n=7, 50%) recommended integrating the app with electronic medical record (EMR) to automatically add prescribed medications and appointments and to allow providers to review app activity for pattern identification. EMR is a secure member website that allows patients to access their health information, view appointments, medical test results, and medication therapies, and communicate with their providers [38]. Additionally, 14% (n=2) of families suggested including educational content about common symptoms posttransplant and a search field for medications and their uses. Another 14% (n=2) recommended a field for recording vital signs, such as temperature and blood pressure. Finally, 14% (n=2) proposed adding important contact numbers such as pharmacies, providers, and support groups to the app.

Table . Features suggested by participants.

Features families suggested	Value, n (%)
Integrate with EMR[a] to automatically add prescribed medications and appointments to the app, as well as allowing the provider to review app activity to identify patterns.	7 (50)
Including educational content such as frequently experienced symptoms after transplant, and a field to look up medications and for what they are used.	2 (14)
A field for recording vitals such as fever and blood pressure on the app.	2 (14)
Include important numbers in the app, such as pharmacy, provider, and support groups.	2 (14)

[a]EMR: electronic medical record.

During the enrollment interviews, 3 key themes regarding usability and features of the app were identified (Table 3). Ease of use was the most frequently recurring theme. Participants repeatedly highlighted the intuitive design, which made navigation and operation simple, especially for those who were less technologically skilled. Several participants remarked that grandparents, who lack digital proficiency, could use the app without any issues. Another significant theme was the app's

ability to keep families "on track" with medication schedules and doses. Caregivers expressed enthusiasm for using the app at home to manage a variety of medications and doses and record symptoms. Participants appreciated the ability to mark off administered medications and track notes, finding the digital logging of all information in one place helpful.

Table . Participants' reflections on the use of the BMT4me app.

Themes identified from qualitative interviews	Quotes from enrollment interviews	Quotes from exit interviews
Easy to use	• "It's very simple. Even if my mom had to do that, I think it would be simple for her to use it." [ID 5] • "It looks straightforward and easy to use." [ID 3]	• "It was pretty easy to use. It's pretty intuitive, I think. I think it's easy to pick it up and just start entering things, which is very helpful. Like, it's pretty straightforward." [ID 3] • "It's really pretty self-explanatory. So easy usage which is always nice because if it's complicated, you kind of don't want to deal with it, you know, human nature kind of thing." [ID 11]
Keep us on track	• "I think it'd be useful to help keep us on track. Hopefully not forget any doses." [ID 6] • It seems like it could help to keep on schedule and just like simple reminders of what to do, certain things especially get put and medications." [ID 13]	• "I think having something to be able to keep track of things for you is the number one way to get to have success with them after care because when I left the hospital, like the first time after he had his treatment, I was completely overwhelmed. It was like, how am I going to keep track of all of this stuff?" [ID 3] • "It was nice because if you just didn't realize what time was, it would ring and kind of let you know like, hey, it's time to take medications that so just getting into the swing and kind of getting used to taking all that medication too so." [ID 2]
Helpful	• "I think it would be helpful. You know, just having it. To mark off you've taken it or having the option to have notes to look back on. Have it all on one place and you always have your phone with you, so." [ID 2] • "Yeah, I mean, especially if she's taking a lot of meds I don't remember, like knowing like getting a reminder would probably help you." [ID 8]	_[a]
Technical difficulties	–	• "The other thing I noticed that sometimes it reminded me, sometimes it didn't." [ID 3] • "It says symptoms recorded and it says what time when the dose was taken at nine p.m. But then you can go back and look, it says it was given at eight p.m." [ID 1]
Nontech preferences	–	• "You got a pencil and the journal, you know I can easily, you know, erase. And I just like to have everything in front of me on one page. I'm a visual person and then like going next to next page, you know?" [ID 5] • "I have it in my head, I know what it is to do, so I don't really need it." [ID 13]

[a]Not applicable.

Upon study completion, families reiterated the app's ease of use and its effectiveness in maintaining medication routines (Table 3). Participants described the app as easy and self-explanatory, allowing them to quickly enter information and interact with it. They emphasized that simplicity was highly desirable, as a complicated interface would deter use. Additionally, participants noted that the app's ability to help them stay on track with medication regimens was helpful, particularly when life's demands could interfere with their child's medication schedule. However, new themes also emerged during the exit interviews. One notable theme was technical difficulties. Some families reported experiencing glitches or

issues with the app's functionality, which occasionally hindered their ability to fully use the app. Another emerging theme was a preference for nondigital methods. A subset of families expressed a preference for traditional, paper-based methods of managing health care routines. These participants indicated that while the app offered useful features, they were more comfortable with paper-based tracking and reminders.

Discussion

Principal Findings

The BMT4me app was developed in collaboration with health care providers, caregivers, and patients to aid in medication management, improve adherence monitoring, and track symptoms or medication side effects in real-time [37]. This pilot study aimed to evaluate the usability of the BMT4me app among caregivers of children during the acute phase post-HCT. The caregiver-reported mean SUS score of 73.13 (SD 16.13) at study completion indicated a favorable perception among caregivers, surpassing the threshold of 68 and demonstrating above-average usability. Most caregivers found the app easy to learn and use, with well-integrated features, fostering confidence for independent use at home. These findings are consistent with prior research emphasizing the significance of intuitive design and user-friendly interfaces in mHealth apps [39,40].

The positive usability feedback suggests that the app's design and features were well-received, enhancing caregivers' confidence in managing their child's complex medication regimen [41]. Engagement with the app generally depends on user motivation, perceived value, and satisfaction. As highlighted by Kim et al [42], technology must be both useful and enjoyable, with perceived value and satisfaction stemming from the overall user experience [42]. Caregiver satisfaction emerges as a critical factor for sustainability. Similar to existing literature, out of the participants who use the app regularly, the satisfaction with the BMT4me app was high [43,44]. Most caregivers in this study reported the app as helpful for tracking their child's medication schedule, finding it easy to use, and expressing willingness to recommend it to others. These sentiments were further echoed in qualitative interviews, with caregivers affirming the app's ease of use and effectiveness in navigating their child's post-HCT journey.

Current literature highlights a preference among users for mHealth apps that allow communication with health care providers [45]. This aligns with this study, where 50% (n=7) of caregivers recommended integrating EMR with the BMT4me app and including important contact numbers to facilitate easy communication with health care providers through the app. Including educational content in the mHealth apps has been shown to be preferred among individuals with chronic illnesses [46-48]. This trend was similarly observed in this study, with 14% (n=2) of our participants suggesting the inclusion of information on frequently experienced symptoms after HCT, along with details about medications and their uses.

While initial reactions to the app were positive, the sustainability of long-term use among our sample was constrained. Several caregivers stopped using the app beyond the initial sign-in phase, highlighting potential barriers such as technical challenges, time constraints, feeling overwhelmed, inconvenience, or perceived lack of necessity. Identifying and addressing these barriers is crucial for optimizing app design and implementation strategies to foster sustained engagement among caregivers. Notably, a significant proportion of participants used the app for the first few weeks postdischarge, establishing medication-giving routines before stopping the use. This suggests that the BMT4me app may serve as a valuable resource in assisting families with establishing medication administration habits, particularly during the initial phase of treatment. Some caregivers also expressed the potential value of the BMT4me app in the broader oncology population and wished to have access to it earlier in their child's treatment journey. The app's ability to accommodate the transition from a simple to a complex medication regimen, characterized by frequent changes in medications and dosages, underscores its potential utility beyond the HCT context.

Caregiver feedback on the BMT4me app indicated a generally positive experience from enrollment to study completion, however, some areas showed declines. The mean SUS score decreased from 86.15 to 73.13, reflecting a decrease in overall usability satisfaction; nevertheless, it surpassed the 68% cut-off for usability. Initially, 73% (n=11) of caregivers found the app accessible and useful, and 67% (n=10) found it easy to use [31]. These ratings improved with continued interaction, with 88% (n=7) later describing the app as accessible, useful, and valuable. Caregiver satisfaction measure showed minimal change from enrollment to completion, demonstrating high caregiver satisfaction throughout the study.

Analyzing app engagement activities provided insights into caregivers' usability patterns and preferences. For instance, some features demonstrated more active engagement than others, such that creating and administering doses suggested active engagement in medication management, while note-taking and symptom tracking exhibited low utilization. Therefore, there are potential areas for improvement to better address caregivers' diverse needs and preferences. This observation aligns with existing literature, which often highlights the importance of user-centered design in health apps to enhance engagement and adherence [49]. Studies have shown that while medication management tools are frequently used due to their direct impact on patient care, features like symptom tracking and note-taking require more intuitive interfaces and clear benefits to encourage consistent use. By addressing these gaps, developers can create more effective and comprehensive health management tools that cater to the varied needs of caregivers, ultimately improving patient outcomes [23,50,51].

Overall, this study underscores the importance of user-centered design with a mixed methods approach. By using multiple methods of data collection and data sources, we gained an in-depth understanding of patients with HCT and their families' complex needs. The results suggest that while the BMT4me app has significant potential, there are critical areas that require attention for sustained engagement and effectiveness. Future development should focus on overcoming technical challenges, enhancing the perceived value of lesser-used features, and ensuring the app remains a supportive tool throughout the entire treatment journey. By addressing these gaps, the BMT4me app

can be optimized to better meet the evolving needs of caregivers and patients and improve their health outcomes and quality of life.

Limitations

In addition, this study is not without limitations. First, the use of a single pilot recruitment site may restrict the generalizability of our findings. Although we included a diverse group of children who received HCT at this institution, the small number of caregivers may not represent the broader population. The demographic characteristics of our caregiver (female, White, and non-Hispanic) and child (male, White, and non-Hispanic) cohorts are consistent with other studies in this population [52-54]. However, while our cohort reflects the typical demographics of the pediatric HCT population and their caregivers, it is important to acknowledge that our results may be limited in their broader generalizability. Future research should aim to include a more diverse sample to ensure that findings are relevant across different demographic groups. Furthermore, our recruitment was limited to English-speaking caregivers, due to the app only being available in English. Future versions of the app should be developed in multiple languages to allow for more inclusive recruitment and to examine the app's usability across diverse linguistic and cultural groups. Including caregivers who speak other languages could have enriched the diversity and applicability of our findings. Another limitation is the variability in the timing of app distribution. Participants received the app at different stages of their HCT journey, some on the day of discharge and others after discharge. This inconsistency could have influenced their established medication routines, potentially affecting the outcomes such that participants who were recruited after discharge were less likely to use the app due to already having a system in place for medication management. Additionally, technical issues with the app were noted, which could have impacted the user experience and the app's usability and sustained engagement. Addressing these barriers is crucial for optimizing the app's design and ensuring sustained use. Future improvements should focus on enhancing technical stability, expanding user-centered features, and increasing accessibility to diverse populations.

Conclusions

Despite these limitations, we demonstrated the usability of the BMT4me app among caregivers of children undergoing HCT. This study extends the literature by providing insights into caregiver technology expectations and needs and highlights the potential of mHealth tools to manage medication adherence at home. Notably, 50% (n=7) of caregivers expressed that integrating the app with EMR would be helpful, benefiting both caregivers and health care providers by streamlining access to medication-taking patterns and updating medication regimens. Furthermore, there is potential to adapt this work for children with other chronic conditions, extending the benefits of the BMT4me app beyond the HCT context. The study findings offer valuable insights into the feasibility of conducting a larger randomized controlled trial, potentially leading to significant improvements in adherence and clinical outcomes in children post-HCT.

Acknowledgments

We would like to thank the families who generously participated in this work. We are also grateful for the support of the Information Technology Research and Innovation group at the Nationwide Children's Hospital, specifically Brannon Oiler, Brandon Abbott, and John Luna, for app design and development. We would also like to thank Dr Kathryn A Vannatta for her assistance in qualitative coding. This research was supported by a grant from the National Institute of Nursing Research of the National Institutes of Health (K99 NR019115). The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health. No generative artificial intelligence was used to write the manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

MS contributed toward conceptualization, methodology, funding acquisition, supervision, writing—original draft, writing-review, and editing. MK contributed toward formal analysis, visualization, writing—original draft, writing—review, and editing. PG contributed toward formal analysis, visualization, writing—original draft. ES contributed toward formal analysis, and writing—original draft. AP, RB, WL, and CG contributed to writing—original draft. All authors read and approved the final version of the manuscript.

Abstract

Background: Cytoreductive surgery combined with hyperthermic intraperitoneal chemotherapy (CRS-HIPEC) can improve survival outcomes for individuals with gastrointestinal (GI) cancer and peritoneal disease (PD). Individuals with GI cancer and PD receiving CRS-HIPEC are at increased risk for malnutrition. Despite the increased risk for malnutrition, there has been limited study of nutritional interventions for individuals receiving CRS-HIPEC.

Objective: We aimed to test the feasibility, acceptability, and usability of Support Through Remote Observation and Nutrition Guidance (STRONG), a multilevel digital health intervention to improve nutritional management among individuals with GI cancer and PD receiving CRS-HIPEC. We also assessed patient-reported outcomes, including malnutrition risk, health-related quality of life, and weight-related measures.

Methods: STRONG is a 12-week digital intervention in which participants received biweekly nutritional counseling with a dietitian, logged food intake using a Fitbit tracker, and reported nutrition-related outcomes. Dietitians received access to a web-based dashboard and remotely monitored patients' reported food intake and nutrition-impact symptoms. Implementation outcomes were assessed against prespecified benchmarks consistent with benchmarks used in prior studies. Changes in patient-reported outcomes at baseline and follow-up were assessed using linear and ordered logistic regressions.

Results: Participants (N=10) had a median age of 57.5 (IQR 54-69) years. Feasibility benchmarks were achieved for recruitment (10/17, 59% vs benchmark: 50%), study assessment completion (9/10, 90% vs benchmark: 60%), dietitian appointment attendance (7/10, 70% vs benchmark: 60%), daily food intake logging adherence (6/10, 60% vs benchmark: 60%), and participant retention (10/10, 100% vs benchmark: 60%). Most participants rated the intervention as acceptable (8/10, 80% vs benchmark: 70%) and reported a high level of usability for dietitian services (10/10, 100%). The benchmark usability for the Fitbit tracker to log food intake was not met. Compared to baseline, participants saw on average a 6.0 point reduction in malnutrition risk score (P=.01), a 20.5 point improvement in general health-related quality of life score (P=.002), and a 5.6 percentage point increase in 1-month weight change (P=.04) at the end of the study.

Conclusions: The STRONG intervention demonstrated to be feasible, acceptable, and usable among individuals with GI cancer and PD receiving CRS-HIPEC. A fully powered randomized controlled trial is needed to test the effectiveness of STRONG for reducing malnutrition and improving patient outcomes.

Trial Registration: ClinicalTrials.gov NCT05649969; https://clinicaltrials.gov/study/NCT05649969

KEYWORDS

gastrointestinal cancer; peritoneal disease; cytoreductive surgery combined with hyperthermic intraperitoneal chemotherapy; digital health intervention; nutrition; feasibility

Introduction

Malnutrition is commonly observed among individuals with gastrointestinal (GI) cancer and can severely affect disease prognosis, quality of life, and survival [1,2]. Individuals with GI cancer are at high risk of developing peritoneal disease (PD), the metastasis of cancer to the abdominal cavity, which occurs in about 40% of patients with GI cancer [3]. Cytoreductive surgery combined with hyperthermic intraperitoneal chemotherapy (CRS-HIPEC) can offer survival benefits for individuals with GI cancer and PD [4,5]. CRS-HIPEC is a 2-step approach that removes all visible cancerous tumors in the abdomen through a surgical procedure, followed by heated chemotherapy during surgery [5]. Due to the invasive nature of this extensive operation, postoperative morbidities are common, including weight loss, which occurs in more than 90% of individuals receiving CRS-HIPEC [6]. Malnutrition, arising from loss of appetite and malabsorption, occurs in about 50% to 60% of individuals receiving CRS-HIPEC, which can negatively affect postoperative outcomes (eg, length of hospital stay, hospital readmission, and mortality) [7-10]. After CRS-HIPEC, patients often experience a decline in nutritional status, heightening the importance of adequate nutritional support in the postoperative period [6,11].

Medical nutrition therapy (MNT), which includes dietitian-led nutritional counseling and additional dietary interventions, has been shown to improve nutritional outcomes for individuals with GI cancer [12,13]. However, multilevel barriers hinder access to MNT and its effectiveness. At the system level, there may be limited outpatient services for nutritional counseling, fragmented oncology and nutritional care, and inconsistent nutrition-screening procedures across clinics [14,15]. For example, a survey among surgical oncologists who specialize in CRS-HIPEC showed that only one-third of providers reported the availability of malnutrition screening at their practice [16]. At the provider level, available dietitians may be lacking, and MNT is not routinely provided to individuals with cancer [14,17,18]. There are also many barriers at the patient level, including the lack of adherence to nutritional programs due to clinical factors (eg, difficulties swallowing, fatigue, nausea, and pain) and nonclinical factors (eg, lack of motivation and time constraint) [19]. Digital nutritional interventions, such as remote monitoring, can help patients overcome barriers to accessing and adhering to traditional nutritional interventions and can improve patient outcomes [20,21]. However, research on digital nutritional interventions for individuals with cancer is limited [22]. There is a need to develop and test digital nutritional interventions, particularly for individuals receiving CRS-HIPEC who are at high risk for malnutrition.

To address this gap, the goal of this study is to pilot test the Support Through Remote Observation and Nutrition Guidance (STRONG) intervention, a multilevel digital health intervention to improve nutritional outcomes. The study aims (1) to assess the feasibility, acceptability, and usability of the STRONG intervention for individuals with GI cancer and PD undergoing CRS-HIPEC and (2) to evaluate patient-reported outcomes, including malnutrition risk, health-related quality of life, and weight-related measures. To the best of our knowledge, this is the first digital nutritional intervention conducted among individuals receiving CRS-HIPEC, who are at high risk of postoperative malnutrition and face unique barriers to accessing and using MNT [7,20,21]. Findings from this study will inform broader interventions to manage cancer-related malnutrition and guide a future randomized controlled trial to evaluate the impact of the STRONG intervention.

Methods

Study Design

We conducted a single-arm feasibility trial of STRONG, a 12-week digital intervention to improve postoperative nutrition. Guided by the Obesity-Related Behavioral Intervention Trials model, the goal of the single-arm study was to identify potential technical issues with digital health delivery, assess the optimal length of intervention delivery, and gather participant feedback on acceptability to inform intervention refinement prior to larger testing in a randomized trial [23]. The intervention was developed based on the Theoretical Domains Framework, a theory used to understand and address multilevel behavior change (ie, patient and clinician behavior) in health care settings [24]. Participants received biweekly MNT (6 sessions) that included nutritional counseling with a registered dietitian and continuous remote monitoring of participants' dietary needs by the dietitian. In addition, participants logged daily food intake using a Fitbit device (Inspire 2) and completed 5 study assessments related to patient malnutrition, nutrition-related symptoms, and quality-of-life outcomes (at baseline and 4, 8, 12, and 16 weeks after study enrollment). Participants provided feedback on the intervention's acceptability and usability (at week 12).

Participants

Individuals who met the following criteria were eligible to participate in the study: (1) older than 18 years, (2) diagnosed with primary GI cancer, (3) diagnosed with PD, (4) underwent curative-intent CRS-HIPEC at Moffitt Cancer Center (Moffitt; with cytoreduction completeness score of 0 - 1), (5) transitioned to a postoperative oral diet, (6) were able to speak and read English, and (7) provided informed consent. Individuals were excluded from the study if they met any of the following criteria: (1) had documented or observable psychiatric or neurological condition that would inhibit with study participation, (2) were undergoing treatment for another primary cancer, and (3) received postoperative parenteral or enteral nutrition.

Recruitment

Potential participants were identified through a collaboration between Moffitt's GI clinic staff and the study coordinators. In addition, we screened the patients' electronic health records (EHRs) to determine their eligibility. Eligible participants were contacted by phone, unencrypted email, videoconference, or in-person meetings to introduce them to the study and determine their interest in participating. The participants who provided informed consent were given study materials and equipment during patient visits or by mail, including (1) a welcome packet and checklist describing the study components, instructions on using and caring for the Fitbit tracker and tablet, and brief instructions on estimating food portion size; (2) a Fitbit tracker; and (3) a study loaned tablet to log daily food intake with the Fitbit application already downloaded and synced. Participants also had the choice of downloading the Fitbit application on a personal device if preferred. Within 3 to 5 days of the participant receiving the Fitbit tracker, one of the study coordinators (RH, OS, and SD-C) contacted the participant to confirm that they were able to use the device. Participants received an introduction to the Fitbit tracker before undergoing CRS-HIPEC. Recruitment occurred from December 2022 to July 2023.

Intervention

Dietitians reviewed the participants' food intake and nutritional assessments and conducted 6 biweekly telehealth or in-person counseling sessions with them. During these visits, the dietitian established individualized dietary plans that included a calorie goal, discussed challenges to dietary intake, and made recommendations for improving nutrition. If a participant did not record food intake for 5 days or more, a study coordinator contacted the participant to discuss barriers to using the Fitbit tracker and to encourage continued tracking. Study assessments were completed on REDCap (Research Electronic Data Capture; Vanderbilt University), a web-based software platform [25,26], on a paper survey, or in person using a tablet during clinic visits.

Measures

Sociodemographic Characteristics

Participants' sociodemographic characteristics were obtained from the EHR and the baseline survey. Information collected included age, sex at birth, race or ethnicity, marital status, primary language preference, whether the participant resided in an urban area (defined by matching the participant's zip code using the 2010 US Department of Agriculture rural-urban commuting area codes) [27], 2022 Area Deprivation Index (ADI; an area-level measure of socioeconomically disadvantaged neighborhoods ranging from 0 to the 100th percentile nationally, with higher percentiles indicating more disadvantaged neighborhoods) [28], insurance type, highest educational attainment, and annual household income.

Clinical Characteristics

Clinical characteristics were obtained from the EHR and included tobacco use, BMI, Charlson Comorbidity Index, and cancer type or histology. The peritoneal cancer index was also measured, which grades the extent of PD on a scale from 0 to 39, with higher scores indicating a more extensive disease [29]. Eastern Cooperative Oncology Group performance status was measured, which captures the extent to which the disease affects a patient's activities of daily living; the grades included in this study ranged from 0=fully active to 4=completed disabled [30]. Cytoreduction completeness score was measured, which captures the extent of the residual tumor, and was used to determine whether the patient underwent CRS-HIPEC for curative intent [31]. The patient's nutritional status was measured by the Patient-Generated Subjective Global Assessment (PG-SGA) Short Form, with scores ranging from 0=no risk to 36=highest risk [32].

Implementation Outcomes

The data on feasibility, acceptability, and usability of the intervention were collected through objective intervention data or measured by a participant survey at the end of the intervention (week 12). Implementation outcomes were assessed against prespecified benchmarks consistent with benchmarks (60% - 70%) used in previously reported single-arm digital health interventions for patients with cancer (Multimedia Appendix 1) [33,34]. The feasibility benchmarks of successful implementation of the intervention within the GI clinic included recruitment rate (≥50%), percentage of participants who completed baseline study assessment (≥70%), percentage of participants who completed 4 of 5 study assessments (≥60%), participant retention at the end of the intervention (≥70%), participant retention at the end of the study period (≥60%), percentage of participants who attended at least 4 of 6 dietitian appointments (≥60%), and percentage of participants who logged food intake for 63 of 90 days (≥60%).

Acceptability, defined as the participant's level of satisfaction with the intervention, was measured by the Acceptability of the Intervention Measure, a 4-item scale (score ranges 0 - 20) [35,36]. A ≥70% response rate with a score >12 on the Acceptability of the Intervention Measure was used as the cutoff for establishing acceptability, indicating that participants on average had a positive experience with the intervention [35].

Usability was assessed in 2 ways. Usability, defined as the extent to which individuals were able to use the Fitbit tracker and application to log food intake, was measured by the 10-item System Usability Scale (SUS; score ranges 0 - 100) [37]. A ≥65% response rate with a score >68 on the SUS was used as the cutoff, indicating that participants on average perceived the Fitbit tracker and application to be easy to use [37]. Usability of the clinical dietitian services, including the dietitian's interpersonal skills and patient-perceived health benefits of the dietitian service, was measured by a validated 8-item scale (score ranges 0 - 24) that has been used in outpatient MNT interventions for patients with cancer [38,39]. A ≥70% response rate with a score >12 was used as the cutoff for establishing acceptability, indicating that participants on average had a positive experience with the dietitian services [39].

Patient Outcomes

To evaluate the secondary aim of this study, patient outcomes were obtained from their EHR or study assessments and included malnutrition risk measured by the PG-SGA, health-related quality of life measured by the Functional Assessment of Cancer Therapy—General [40] and the Functional Assessment of

Anorexia/Cachexia Treatment—Anorexia/Cachexia Scale [41], BMI, weight, and 1-month weight change.

Analyses

Descriptive statistics were computed to describe the study sample and assess whether prespecified benchmarks for feasibility, acceptability, and usability were met at the end of the intervention. Given the small sample size, continuous variables were summarized using median and IQR, and categorical variables were summarized using frequency and percentage. Changes in patient outcomes at baseline and the end of the study period (week 16) were assessed using linear regressions for continuous outcomes and ordered logistic regressions for ordinal outcomes. Models included participant fixed effects to obtain within-participant estimates, and SEs were robust and clustered by the participant. We adhered to the CONSORT (Consolidated Standards of Reporting Trials) guidelines for pilot and feasibility studies and study reporting (Checklist 1) [42]. All analyses were performed in Stata (version 18; StataCorp).

Ethical Considerations

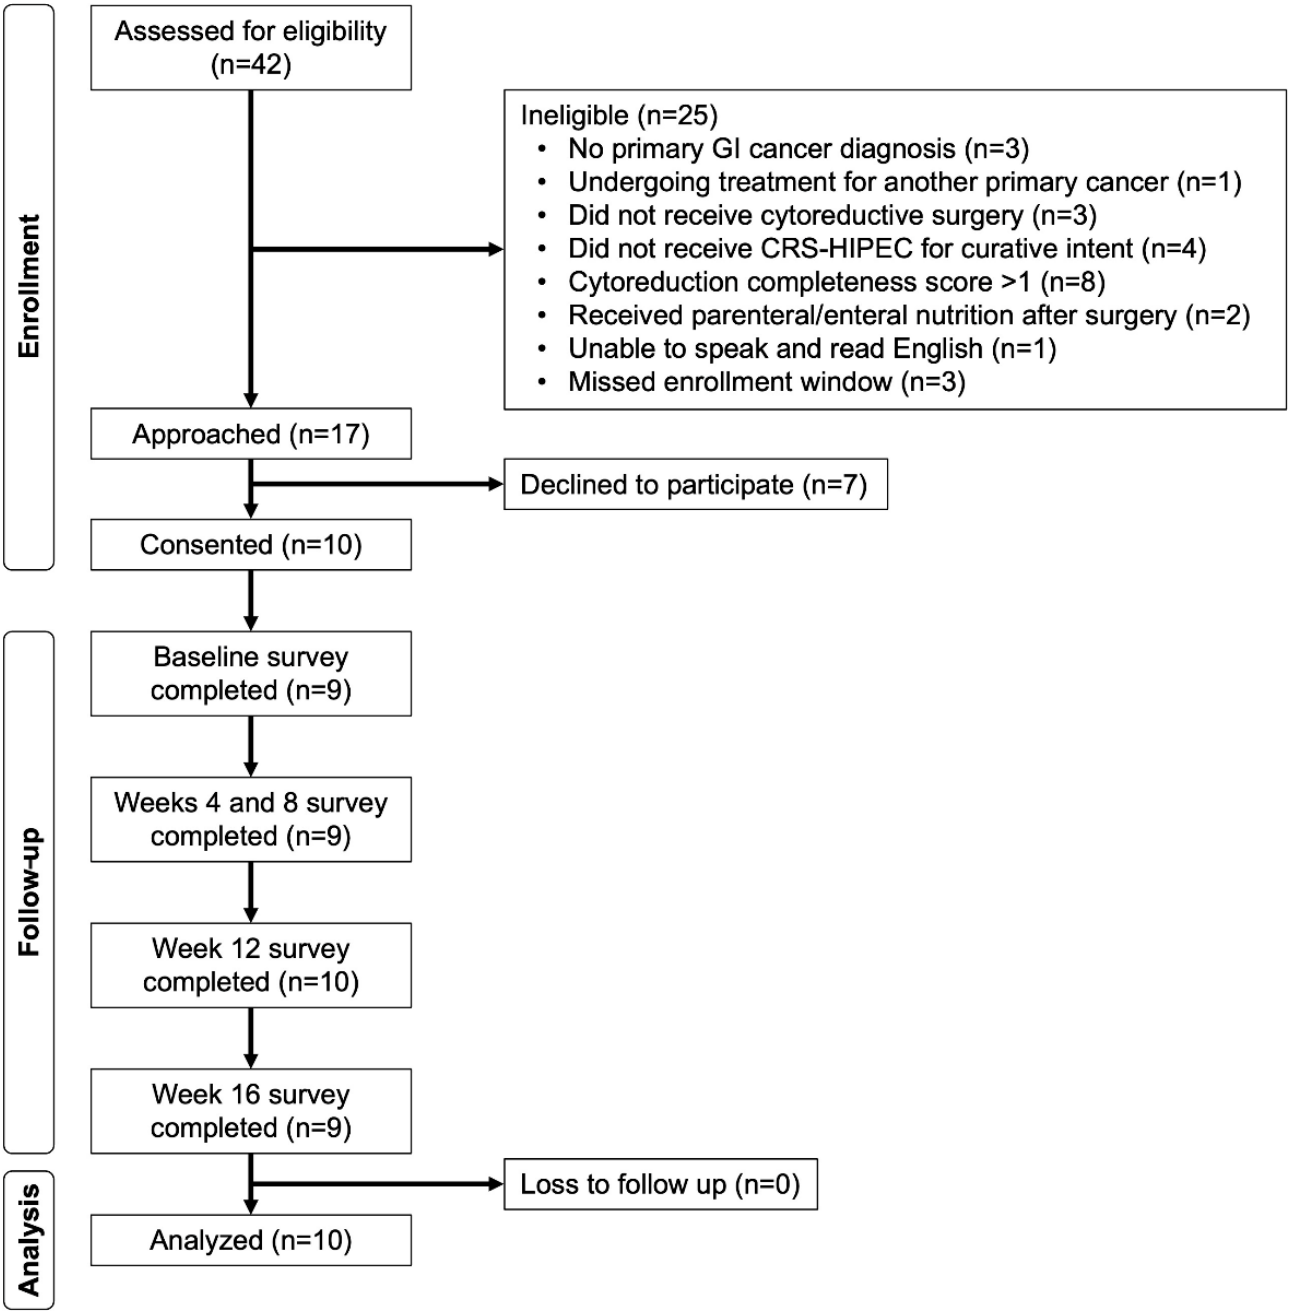
The trial (ClinicalTrials.gov NCT05649969) was conducted at a single site, Moffitt, a National Cancer Institute (NCI)–designated comprehensive cancer center. The study was approved by Moffitt's Institutional Review Board of Record, Advarra (protocol Pro00066098). Informed consent was obtained from all participants. To protect participants' confidentiality, deidentified information and pseudonym IDs (eg, Participant 1) were entered into participants' Fitbit profiles. The study staff maintained a separate password-protected file behind Moffitt's firewall linking participant IDs to patient identifiers (eg, name and medical record number). Paper questionnaires were stored in a locked file cabinet in an office with a locked door. Only the study team had access to participant research data, and only trained staff with appropriate approvals had access to patient medical records. Participants were compensated with a US $25 gift card for completing each of the 5 study assessments; participants who completed all 5 assessments received an additional US $25 gift card.

Results

Sample Characteristics

Among the patients (n=42) screened for eligibility, 25 patients were deemed ineligible (Figure 1). Of the 17 patients approached, 10 patients consented to participate in the study. All 10 participants completed at least 1 assessment, and no participants were lost to follow-up.

Figure 1. CONSORT diagram of the single-arm feasibility trial of the STRONG intervention. CONSORT: Consolidated Standards of Reporting Trials; CRS-HIPEC: cytoreductive surgery combined with hyperthermic intraperitoneal chemotherapy; GI: gastrointestinal; STRONG: Support Through Remote Observation and Nutrition Guidance.



Study participants had a median age of 57.5 (IQR 54.0 - 69.0) years; 8 (80%) participants were female, and 10 (100%) were non-Hispanic White (Table 1). In total, 6 (60%) participants were married, 1 (10%) had never been married, and 3 (30%) were divorced. All participants spoke English as their primary language and resided in an urban area. The median ADI of participants was in the 30th percentile nationally (IQR 24-32), with a higher ADI indicating a more disadvantaged neighborhood. In total, 4 (40%) participants received health insurance through employment, 4 (40%) received public insurance, 1 (10%) had direct-purchase insurance, and 1 (10%) did not provide insurance-type information. The highest education attained by participants was some college for 3 (30%) participants, a bachelor's degree for 3 (30%) participants, or a graduate or professional degree for 4 (40%) participants. Participants' annual household income ranged from US $35,000 to ≥US $100,000.

In total, 8 (80%) participants never smoked tobacco, and 2 (20%) were former smokers (Table 1). The median BMI of participants was 28 (IQR 27.3-29.5), and participants had a median Charlson Comorbidity Index of 7 (IQR 7-9). A total of 6 (60%) participants were diagnosed with appendiceal cancer, 2 (20%) with colorectal cancer, and 2 (20%) with peritoneal mesothelioma. The median peritoneal cancer index was 21.5 (IQR 13.0-25.5). Participants were all fully active or able to carry out light or sedentary work, with a median Eastern Cooperative Oncology Group performance status of 0 (IQR 0-0). No participants at baseline were assessed to be at low

malnutrition risk, 2 (20%) were at medium risk, and 7 (70%) were at high risk.

Table . Participant characteristics at baseline of the STRONG[a] intervention.

Characteristic	Participant (N=10)
Sociodemographic characteristics	
Age (years), median (IQR)	57.5 (54.0-69.0)
Sex at birth, n (%)	
Male	2 (20)
Female	8 (80)
Race or ethnicity, n (%)	
Non-Hispanic White	10 (100)
Marital status, n (%)

[b]ECOG: Eastern Cooperative Oncology Group.

Feasibility

Among the eligible patients (n=17) who were approached to participate in the study, 10 (59%) consented to participate (Table 2). In total, 9 (90%) participants completed the baseline assessment and completed 4 of 5 assessments. All participants completed the assessment at the end of the intervention (week 12), and 9 (90%) participants completed the follow-up assessment at week 16. A total of 7 (70%) participants attended at least 4 of 6 dietitian appointments, and 6 (60%) participants logged food intake for at least 63 of the 90 days (median logged 76, IQR 15 - 87 days). Adherence to logging food intake decreased slightly over the span of the intervention, from 7 (70%) participants meeting the benchmark number of days logging food intake in the first 30 days (median logged 29, IQR 15 - 30 days) to 5 (50%) participants meeting the benchmark in the last 30 days (median logged 15, IQR 0 - 27 days; not shown in table).

Table . Feasibility outcomes of the STRONG[a] intervention.

Outcome	Benchmark (%)	STRONG intervention, n/N (%)
Recruitment		
Eligible patients who consented	≥50	10/17 (59)
Study assessment completion		
Participants who completed baseline assessment	≥70	9/10 (90)
Participants who completed 4 of 5 study assessments	≥60	9/10 (90)
Retention		
Participants retained at the end of the intervention (week 12)	≥70	10/10 (100)
Participants retained at the end of the study period (week 16)	≥60	10/10 (100)
Intervention adherence		
Participants who attended at least 4 of 6 dietitian appointments	≥60	7/10 (70)
Participants who logged food intake for 63 of 90 days	≥60	6/10 (60)

[a]STRONG: Support Through Remote Observation and Nutrition Guidance.

Acceptability and Usability

Among the 10 participants who completed the week 12 assessment, 8 (80%) rated the intervention as acceptable (benchmark score >12), with a median score of 18 (IQR 16 - 20; Table 3). In total, 5 (50%) participants rated the Fitbit tracker and application as usable for logging food intake (benchmark score >68), with a median score of 68.8 (IQR 54.4 - 90). All participants (100%) were satisfied with the dietitian services (benchmark score >12), with a median score of 23.5 (IQR 17.8 - 24.0). One participant reflected on the high acceptability of the dietitian services and said, “The program added a lot of value. It helped with my recovery, especially with getting the right nutrition. It has been really great!” Another participant conveyed the value of the digital nature of the STRONG intervention, expressing “The ZOOM meetings were wonderful because I am over an hour from the hospital. The [nutritionist]

was also a great encourager and contributed to my healing process."

Table . Acceptability and usability outcomes of the STRONG[a] intervention (N=10).

Outcome	Benchmark	STRONG intervention
Acceptability		
Acceptability of the Intervention Measure	≥70% response rate with score >12	8 (80)
Usability		
Fitbit	≥65% response rate with score >68	5 (50)
Dietitian services	≥70% response rate with score >12	10 (100)

[a]STRONG: Support Through Remote Observation and Nutrition Guidance.

Patient Outcomes

Compared to baseline, average PG-SGA malnutrition scores saw a decrease of 6 points (*P*=.01), with a corresponding reduction in patients with high malnutrition risk (*P*=.03; Table 4). Functional Assessment of Cancer Therapy—General scores increased by an average of 20.5 points (*P*=.002), and Functional Assessment of Anorexia/Cachexia Treatment—Anorexia/Cachexia Scale scores increased by an average of 7.4 points (*P*=.03), indicating an improvement in participants' health-related quality of life. There was no change in participants' average BMI or weight, suggesting a stabilization of weight loss. This is supported by a 5.6 percentage point increase in the average 1-month weight change (*P*=.04), in which participants saw a slight weight gain compared to the previous month at week 16.

Table . Changes in patient outcomes between baseline and the end of the intervention.

Patient outcomes (n=9)	Baseline	Week 16	*P* value[a]
Patient-Generated Subjective Global Assessment Short Form score, mean (SE)	11.7 (3.8)	5.7 (4.3)	.01
Low risk, n (%)	0 (0)	3 (33)	.03
Medium risk, n (%)	2 (22)	5 (56)	.03
High risk, n (%)	7 (78)	1 (11)	.03
Functional Assessment of Cancer Therapy—General score, mean (SE)	70.4 (15.4)	90.9 (10.5)	.002
Functional Assessment of Anorexia/Cachexia Treatment—Anorexia/Cachexia Scale score, mean (SE)	28.9 (4.3)	36.3 (7.8)	.03
BMI (kg/m^2), mean (SE)	27.5 (5.5)	26.3 (4.2)	.09
Weight (lb), mean (SE)	172.3 (29.1)	165.3 (22.0)	.09
Weight change since 1 month ago (%), mean (SE)	−5.2 (4.8)	0.4 (3.1)	.04

[a]*P* values of continuous outcomes were computed from linear regression models. *P* values of ordinal outcomes were computed from ordered logistic regression models. All models included participant fixed effects. SEs were robust and clustered by the participant.

Discussion

Principal Findings

The goal of this trial was to evaluate the feasibility and acceptability of the STRONG intervention for individuals with GI cancer and PD undergoing CRS-HIPEC. Our findings demonstrated that the STRONG intervention was feasible to be implemented with high participant recruitment, adherence, and retention to the intervention. Participants rated the intervention favorably and found the dietitian services to be both acceptable and usable. This rating is consistent with previous pilot studies assessing the implementation of mobile phone–based nutritional intervention for individuals with cancer [43,44]. Patient outcomes, including malnutrition risk, health-related quality of life, and 1-month weight change, saw marked improvement. Given that this study was a single-arm intervention without a comparison group, we were unable to attribute the changes in patient outcomes to the intervention alone without considering the effects of cancer treatment and disease progression. The successful implementation of STRONG in this study, positive feedback from participants, and promising improvements in patient outcomes suggest that a future, fully powered trial with a comparison group is warranted. Our team is currently evaluating potential improvements to STRONG and assessing alternative food logging approaches in preparation for a randomized controlled trial of STRONG.

Comparison With Prior Work

Malnutrition screening, counseling, and related interventions remain underused in cancer care [45,46]. Nutritional counseling has been shown to improve the nutritional status, quality of life, and survival for individuals with GI cancer [47,48]. Digital nutritional interventions show clear benefits over traditional MNT, including efficiency, accessibility (eg, reduced transportation barriers), and the ability to remotely monitor patients outside of a traditional clinic visit [22]. Digital tools can also help individuals maintain adherence to nutritional interventions [14]. In our study, despite undergoing a complex surgical procedure, participants were able to adhere to the dietitian visits and food logging in the postoperative period. We hypothesize that this may be facilitated by strong support from the clinic team. Members of the surgical and dietitian teams encouraged patients to participate in the intervention and periodically checked on participants to monitor their progress through the intervention. This study is innovative in that individualized and remote monitoring of dietary needs bridges the gap between the clinical need for close, in-person patient follow-up and the substantial barriers for this patient population to access nutritional support.

Prior studies have shown that digital nutritional interventions are feasible and effective for achieving weight loss among survivors of cancer [49,50]. However, there has been limited research on the use of digital health interventions for individuals with malnutrition to maintain weight or to prevent weight loss. To the best of our knowledge, this is the first digital nutritional intervention conducted among individuals receiving CRS-HIPEC, who have increased risk for malnutrition and face unique barriers to accessing and using traditional MNT [7,20,21].

One study that assessed food-intake tracking with a Fitbit device among individuals with colorectal cancer undergoing surgery found decreased acceptability of the intervention in the postoperative period due to the complexity of the Fitbit application [51]. In our study, we also found declining adherence to tracking food intake over time. The benchmark for tracking food intake was not achieved and was driven primarily by 3 participants who logged 0, 3, and 12 days over the course of the intervention. The decline in adherence to tracking food intake was driven primarily by 2 participants who logged 12 and 24 days over the first 30 days of the intervention, followed by no additional days logged over the rest of the intervention period. It was unclear why these participants were disengaged with tracking food intake, as they did not provide any qualitative feedback.

Further research is needed to investigate why the usability of Fitbit may be low (eg, differences in digital literacy) and what strategies could be used to improve usability. One potential explanation is the choice of the usability measure. Our study team used a generic SUS that was not targeted to mobile health specifically [52]. In future studies, we plan to include mobile health–specific measures of usability to see how that may affect usability ratings. Another potential explanation is that study participants did not have sufficient education on how to use the Fitbit. Since this pilot study, our team has added teach-back sessions to the Fitbit training. Additionally, our team has created a paper version of the food log as an alternative for patients who cannot manage electronic food logging even after training. A third hypothesis is that participants may only need to food log for a certain amount of time before learning enough about their dietary patterns to manage their nutrition. Further study is needed on the optimal time needed for food logging for malnutrition self-management.

Future digital health interventions should assess the eHealth literacy of participants and make efforts to address participant concerns about the potential complexity of digital interventions [53,54]. One approach may be to target participants with low eHealth literacy with additional technical support and resources to ensure equal and inclusive participation in the intervention [53]. Another approach to improve adherence to food tracking may be to adopt a tracking system designed for patients with cancer (eg, the Automated Self-Administered 24-Hour Dietary Recall developed in collaboration with the NCI) [55]. Recent developments in image processing technology can also be leveraged to reduce the burden on participants in tracking food intake [56]. For example, artificial intelligence–enabled applications such as MyFitnessPal, Fastic, and Noom enable food tracking through capturing photos of the foods via a smartphone [56]. However, the feasibility of these technologies for individuals with cancer has yet to be fully explored.

Limitations

Our study should be considered in light of the following limitations. First, this is a single-arm feasibility study conducted at an NCI-designated comprehensive cancer center. Therefore, the study findings may not be generalizable to other settings. Second, the study sample is small and consisted only of non-Hispanic White participants, limiting generalizability to other patient populations. There is a critical need to test the intervention in a more diverse population, across a wider range of settings, and on a larger sample. Additionally, our study focused on extending nutritional support in the postoperative setting, which has been previously recommended for individuals receiving CRS-HIPEC [57,58]. Further research is needed to test nutritional interventions for this population prior to surgery, which may improve CRS-HIPEC tolerance and reduce the likelihood of nutrition-related, postoperative complications [57,58]. Finally, this study was a single-arm trial without a comparison group. Findings on changes in patient outcomes over time cannot be solely attributed to the effect of the intervention without considering the effects of cancer treatment and disease progression. A larger, fully powered randomized controlled trial is needed to rigorously evaluate the impact of STRONG on patient outcomes.

Conclusions

Our study demonstrated that STRONG, a digital health intervention aimed at improving nutritional management for individuals with GI cancer and PD receiving CRS-HIPEC, is feasible, acceptable, and usable. Future studies are needed to establish the effectiveness of the STRONG intervention and to evaluate its implementation in more diverse patient populations and settings.

Acknowledgments

This study was funded by a Moffitt Cancer Center Innovation Award that was awarded to BDP and KT. Generative artificial intelligence tools were not used in any portion of the manuscript writing.

Data Availability

The datasets generated during and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

YCL drafted the manuscript and conducted the data analyses. RH served as a study coordinator for the trial. BDP and SPD helped conceptualize the study and assisted with patient recruitment for the trial. JM served as the study dietitian for the trial. EH served as the research project manager for the trial. OS and SDC served as a study coordinator for the trial. JBP, JD, and AAT helped conceptualize the study. KT helped conceptualize the study, obtained funding for the study, and provided overall scientific direction for the study. All authors reviewed the final draft of the manuscript and provided feedback.

Abstract

Background: Digital interventions for supportive care during cancer treatment incorporating electronic patient-reported outcomes (ePROs) can enhance early detection of symptoms and facilitate timely symptom management. However, economic evaluations are needed.

Objective: This study aims to conduct a cost-utility analysis of an app for ePRO and interactive support from the perspective of the payer (Region Stockholm Health Care Organization) and to explore its impact on patient health care utilization and costs.

Methods: Two open-label randomized controlled trials (RCTs) were conducted, including patients undergoing neoadjuvant chemotherapy for breast cancer (B-RCT; N=149) and radiotherapy for prostate cancer (P-RCT; N=150), recruited from oncology clinics at 2 university hospitals in Stockholm, Sweden. EORTC QLQ-C30 scores were mapped to EQ-5D-3L to calculate quality-adjusted life years (QALYs). Intervention and implementation costs and health care costs, obtained from an administrative database, were used to calculate incremental cost-effectiveness ratios (ICERs) in 3 ways: including all health care costs (ICERa), excluding nonacute health care costs (ICERb), and excluding health care costs altogether (ICERc). Nonparametric bootstrapping was used to explore ICER uncertainty. Health care costs were analyzed by classifying them as disease-related or acute.

Results: In both RCT intervention groups, fewer QALYs were lost compared with the control group (P<.001). In the B-RCT, the mean intervention cost was €92 (SD €2; €1=US $1.03). The mean cost for the intervention and all health care was €36,882 (SD €1032) in the intervention group and €35,427 (SD €959) in the control group (P<.001), with an ICERa of €202,368 (95% CI €152,008-€252,728). The mean cost for the intervention and acute health care was €3585 (SD €480) in the intervention group and €3235 (SD €494) in the control group (P<.001). ICERb was €49,903 (95% CI €37,049-€62,758) and ICERc was €13,213 (95% CI €11,145-€15,281); 22 out of 74 (30%) intervention group patients and 24 out of 75 (32%) of the control group patients required acute inpatient care for fever. In the P-RCT, the mean intervention cost was €43 (SD €0.2). The mean cost for the intervention and all health care was €3419 (SD €739) in the intervention group and €3537 (SD €689) in the control group (P<.001), with an ICERa of –€1,092,136 (95% CI –€3,274,774 to €1,090,502). The mean cost for the intervention and acute health care was €1219 (SD €593) in the intervention group and €802 (SD €281) in the control group (P<.001). ICERb was €745,987 (95% CI –€247,317 to €1,739,292) and ICERc was €13,118 (95% CI –68,468 to €94,704). As many as 10 out of the 75 (13%) intervention group patients had acute inpatient care, with the most common symptom being dyspnea, while 9 out of the 75 (12%) control group patients had acute inpatient care, with the most common symptom being urinary tract infection.

Conclusions: ePRO and interactive support via an app generated a small improvement in QALYs at a low intervention cost and may be cost-effective, depending on the costs considered. Considerable variability in patient health care costs introduced uncertainty around the estimates, preventing a robust determination of cost-effectiveness. Larger studies examining cost-effectiveness from a societal perspective are needed. The study provides valuable insights into acute health care utilization during cancer treatment.

Introduction

Managing symptoms during cancer treatment is essential for patients' quality of life, workability, and performance [1]. Symptoms such as pain, fatigue, and gastrointestinal problems commonly lead to emergency department visits [2]. Emergency department visit rates appear to be higher among patients with cancer than in the general population, although the magnitude or underlying reasons for this remain understudied [3].

Electronic patient-reported outcome (ePRO) interventions have gained recognition as convenient and safe tools for promoting the early detection of symptoms and adverse events [4,5]. Collecting ePROs has demonstrated high acceptance [6-8], long-term feasibility [9], and positive outcomes related to physical and psychological symptoms [10-15], as well as increased survival [16]. ePROs are also suggested to help mitigate unplanned acute care and unnecessary hospitalizations during cancer treatment; however, this assertion requires more robust empirical confirmation [17,18]. In our studies, the use of the interactive app Interaktor was associated with a decreased symptom burden during radiotherapy (RT) for prostate cancer [19], neoadjuvant chemotherapy (NACT) for breast cancer [11], and up to 6 months after surgery for pancreatic cancer [20].

Health economic evaluations are essential for supporting the implementation of cost-effective interventions [21,22] and guiding decision-makers [23]. A cost-utility analysis (CUA) is one type of health economic evaluation that compares the costs and health outcomes of medical treatments or care by estimating the cost required to improve a unit of health outcome [24]. Quality-adjusted life years (QALYs) is a generic measure of disease burden that accounts for both life quality and quantity. One QALY corresponds to 1 year of perfect health, while 0 represents death [25]. In Sweden, the National Board of Health and Welfare (NBHW) has defined a cost per QALY of €9685 (€1=US $1.03) as low, more than €48,423 as high, and more than €96,846 as very high [26].

Most health economic evaluations of ePRO interventions have focused on patients with advanced or metastatic cancer [27]. Lizée et al [28] demonstrated the cost-effectiveness of ePRO from a national health insurance perspective, despite increased costs, due to associated survival benefits. Velikova et al [29] evaluated the cost-effectiveness of ePRO for patients undergoing systemic treatment for colorectal, breast, or gynecological cancer, comparing the cost per additional QALY gained at 18 weeks after randomization from both health care and societal perspectives. The analysis considered costs for the intervention manual, software maintenance, and patient time off work but excluded intervention development costs. No significant cost differences were observed between the intervention and usual care groups. The study indicated a 55% likelihood of cost-effectiveness at the National Institute for Health and Care Excellence cost-per-QALY threshold.

This study was conducted alongside 2 randomized controlled trials (RCTs) of the ePRO intervention Interaktor during NACT for breast cancer (B-RCT) and RT for prostate cancer (P-RCT). The primary aim is to evaluate the cost utility of the app for ePRO and interactive support from the health care provider's perspective (Region Stockholm Health Care Organization). Additionally, the study examines the impact on patients' health care utilization and associated costs.

Methods

Ethical Considerations

The research was approved by the Swedish Ethical Review Authority (permit numbers 2013/1652-31/2 and 2017/2519-32). Written informed consent was obtained from all patients at the time of study inclusion. Data were deidentified to protect participants' privacy. Patients received written and verbal information about their right to opt out without affecting their subsequent care. No compensation or payment was provided for participation.

Study Design

Between 2016 and 2019, Interaktor was evaluated through 2 parallel prospective open-label RCTs, with symptom burden as the primary endpoint, measured using the EORTC QLQ-C30 version 3.0 [30]. Patients were consecutively recruited from oncology clinics at 2 university hospitals in Stockholm, Sweden. Eligible and interested patients met with a researcher who provided detailed information about the trial. Refer to the previously published study protocol and clinical effectiveness article [11,31] for details on the eligibility criteria, intervention design, and randomization process. No changes were made to

the methods after the protocol was registered (NCT02479607 and NCT02477137) and the trials commenced.

Samples

One RCT included a sample of patients with breast cancer treated with NACT (B-RCT), and the other included a sample of patients with prostate cancer treated with RT (P-RCT). In both RCTs, patients were randomly allocated to the intervention or control group. In the B-RCT, there were 74 patients in the intervention group and 75 patients in the control group. Of these, 69 (93.2%) in the intervention group and 71 (94.7%) in the control group completed the follow-up and were considered complete cases (Multimedia Appendices 1 and 2). In the P-RCT, a total of 150 patients were randomly allocated to the intervention (n=75) or control (n=75) group. Of these, 58 (77%) in the intervention group and 56 (75%) in the control group completed the follow-up questionnaires and were considered complete cases [32] (Multimedia Appendices 2-4). The sample size for both RCTs was estimated based on an effect study conducted with patients receiving RT for prostate cancer [19], with symptom distress as the primary outcome. The effect size difference (Cohen d=0.54) indicated that, for 90% power at P<.05, 71 patients were required in each group.

Intervention and Standard Care

The Interaktor smartphone and tablet app is an ePRO intervention designed for daily symptom reporting and interactive support during cancer treatment. It includes a symptom questionnaire, graphs of symptom reporting history, self-care advice related to disease and treatment-associated symptoms, and links to websites with additional information. Oncology ward nurses are alerted via SMS text messages when severe symptom levels are reported. Nurses can access patients' reports through a web interface, which facilitates patient-clinician communication. Depending on the alert, nurses contact the patient within 1 hour or 1 day. The Interaktor versions used in this study did not include any institutional affiliation display or logo.

Patients in the intervention group reported daily via the Interaktor app on weekdays, starting from their first day of treatment and continuing until 2 weeks after treatment in the B-RCT (mean treatment duration: 15 weeks in both groups) and, until 3 weeks after treatment in the P-RCT (mean treatment duration: 5 weeks in both groups). In the intervention groups, registered nurses at the patients' oncology units responded to the symptom report alerts. Additionally, a researcher was available to assist with any technical questions or issues. Outside office hours, patients were advised to contact health care personnel according to the standard procedure of their oncology clinic. The intervention and app content remained unchanged during the evaluation process. Patients received daily reminders if a report had not been submitted. A comprehensive description, including screenshots, has been published previously [7].

All patients, in both the intervention and control groups, received standard care, which included an assigned contact nurse and a visit with the physician before treatment.

Data Collection

Before randomization, patients self-reported sociodemographic characteristics, including education level, marital and occupational status, and baseline outcomes via questionnaires. In the B-RCT, follow-up (via postal questionnaires) occurred 2 weeks after the end of NACT or the day before surgery, whichever came first. In the P-RCT, follow-up was 3 weeks after the conclusion of RT. Medical history and clinical treatment data were obtained from the patients' medical records, including comorbid conditions, tumor histopathology, cancer stage, and prostate-specific antigen score before treatment initiation, as well as the type and number of cancer treatments planned and completed, and reasons for discontinuing or altering treatment. Data on mortality and cause of death were obtained from the Stockholm and Gotland Regional Cancer Centre and the Swedish NBHW (Multimedia Appendix 5).

Health Care Utilisation and Costs

Administrative data on each patient's health care utilization and costs, from the first day of treatment and for 6 months thereafter, were obtained from the Stockholm Region Council administrative database (VAL). The database includes variables on primary care and emergency department visits (VAL-OVR) and hospitalizations (VAL-SLV) for Stockholm Region Council patients [33]. Health care costs were estimated using a variable (SIMKOST [simulerad kostnad/simulated cost]) that calculates the cost of visits based on the profit and loss account for the respective care branch. SIMKOST reflects approximately 90% of the costs for individuals' visits to outpatient care and 99% of the costs for inpatient care (Multimedia Appendix 6). Intervention costs were based on a fiscal estimate provided by the company that developed the app, expressed as a 1-time implementation/startup cost of €5212, with weekly licensing costs per capita of €39 for nurses and €2.25 for patients (Multimedia Appendix 6).

Data Analysis

Statistical Analysis

Data were handled using Microsoft Excel 2016 with the add-in XL-STAT, IBM SPSS Statistics version 27, and STATA 16 (StataCorp LP). Clinical trials with an RCT design should be analyzed using the intention-to-treat (ITT) principle [34], so missing values were imputed as the mean per group and time [32]. Health care utilization and cost values were imputed for 2 patients in each intervention group (B-RCT and P-RCT). In the P-RCT, EORTC dimension scores were imputed at baseline for 2 patients per group, and at follow-up for 15 patients in the intervention group and 20 patients in the control group. In the B-RCT, follow-up values were imputed for 5 patients in the intervention group and 4 patients in the control group. Distribution normality was assessed using skewness and kurtosis. All costs were adjusted for inflation from 2019 to 2022 [35] (×1.0764) and converted from Swedish kronor (SEK) to Euros (€) using the average exchange rate for April 2022 of 10.3257 SEK=€1 [36]. Nonparametric bootstrapping (1000 replications) was used to test nonnormally distributed variables, calculate the incremental cost-effectiveness ratios (ICERs), and explore sample uncertainty regarding the mean ICERs [37].

Health Outcome

EORTC QLQ-C30 [30] dimension scores were mapped onto EQ-5D-3L [38] health state utilities using a response mapping algorithm [38,39] (Multimedia Appendix 4). The original algorithm includes British utility weights [40], which were replaced with Swedish weights according to Burström et al [41] for this study. The mean predicted EQ-5D value (EQ-5DP) before treatment minus after treatment was used to measure effectiveness, with a smaller reduction in mean EQ-5DP indicating better outcomes.

Intervention Costs

The overall startup cost was divided by the total number of patients diagnosed and treated with the respective treatment regimens in the Stockholm Regional Council and Gotland Region for the years 2016-2018 (518 patients with breast cancer treated with NACT and 683 patients with prostate cancer treated with RT). Given that system updates may incur additional costs beyond the license fees, a time frame of 3 years was considered reasonable. The estimate assumed 5 nurses per 100 patients, with no additional costs for nurses to handle symptom alerts. Based on each patient's number of weeks in treatment (wt), the intervention costs were calculated per equations (1) and (2) for B-RCT and P-RCT, respectively:

$$(5212/518) + ([39 \times 5/100] \times [wt]) + (2.25 \times wt) \quad \textbf{(1)}$$

$$(5212/683) + ([39 \times 5/100] \times [wt]) + (2.25 \times wt) \quad \textbf{(2)}$$

Cost-Utility Analysis

Stochastic CUAs [42] were conducted for each RCT by calculating ICERs in 3 different ways. For ICERa, each patient's intervention cost, along with all health care costs from randomization through 6 months, was included. For ICERb, each patient's intervention costs, plus acute health care costs from randomization and the subsequent 6 months, were considered. Given the considerable variation in patient health care costs, which introduced substantial uncertainty in the cost-effectiveness estimates, a third ICER (ICERc) was calculated by dividing the intervention group's intervention costs minus the control group's intervention costs by the difference in QALYs lost between the 2 groups. The rationale behind this approach is that patients' health care utilization during cancer treatment is influenced by multiple factors, and a much larger study would be necessary to demonstrate a significant reduction in health care costs. Therefore, it was deemed appropriate to assess cost-effectiveness under the assumption that health care costs are not substantially affected. To capture the gradual change in the quality of life during treatment, QALYs lost were calculated linearly as follows: ([EQ-5DP after treatment minus EQ-5DP before treatment]/2) × (individual treatment duration in weeks/52). For visualization, bootstrap values of the incremental intervention costs and incremental health outcomes (QALYs) were plotted on cost-effectiveness planes.

In the P-RCT, the RT treatment was standardized with minimal variation between patients, so RT costs were excluded from both CUAs. By contrast, the B-RCT did not allow for standardized subtraction of treatment costs, so all health care costs were included. The analysis was conducted from the payer perspective (Stockholm Region Council) and focused on the patient's treatment duration (less than 1 year), meaning that no discounting of costs or results was applied. The cost per QALY, as defined by the Swedish NBHW, was used to evaluate cost-effectiveness.

ICERa=[(intervention costs + IG total health care costs) – (CG total health care costs)]/(IG change in QALY – CG change in QALY)

ICERb=[(intervention costs + IG acute health care costs) – (CG acute health care costs)]/(IG change in QALY – CG change in QALY)

ICER=[(IG intervention costs) – (IG intervention costs)]/(IG change in QALY – CG change in QALY)

Exploration of Health Care Utilization and Costs

Within each RCT, variables for total and acute health care visits and costs were generated by summing each participant's visits and costs, conditional on the VAL variable AKUT (acute) being marked as yes or no. Additionally, variables for health care utilization related to the respective cancer treatments were created through a qualitative analysis of the International Statistical Classification of Diseases and Related Health Problems (ICD) codes, using a conventional and summative approach [43]. All ICD codes for acute outpatient and inpatient visits within each RCT were compiled in Excel sheets, and the occurrence of all unique codes was counted. These ICD codes were either grouped or coded based on similarities into predefined and emerging categories. Examples of these categories include fever/neutropenia (D709C, R502, R508, and R509), gastroenteritis/colitis (K521 and A047), anemia (D649), urinary tract infection (N390), and urinary problems (R339, N390, R301, N390X, N304, N109, T830, R391, R319, and N300; Multimedia Appendix 7).

Each patient's visits and costs, according to the categories, were calculated to create variables used as dependent outcomes in multivariate regression analysis. Depending on the level of overdispersion, Poisson, negative binomial, or binary logistic models with a log-link function were fitted [44]. The variable "Group" was coded as control=0 and intervention=1. Prior studies have suggested an association between diminished performance status [45,46], the presence of multiple chronic diseases in older individuals [47], and increased costs. Therefore, the continuous variables—age at inclusion, Charlson Comorbidity Score, and Baseline EQ-5DP score—were included as covariates. The reference category was arranged in ascending order. For the B-RCT, each patient's number of NACT cycles was included as an independent variable. By contrast, for the prostate cancer trial, treatment was standardized, and all patients underwent a similar number of treatments.

Results

B-RCT

Health Outcome

The mean EQ-5DP before treatment was 0.86 in the intervention group and 0.87 in the control group. After treatment, the mean EQ-5DP was 0.84 in the intervention group and 0.80 in the

control group (*P*=.036, effect size=0.099). A statistically significant difference was observed in the mean changes in EQ-5DP from before to after treatment between the intervention and control groups (*P*=.012, effect size=0.042). The greatest difference in change was observed in the Anxiety/Depression dimensions (Multimedia Appendix 8). The CONSORT (Consolidated Standards of Reporting Trials) checklist is presented in Multimedia Appendix 9 (also see Multimedia Appendices 1 and 3).

Cost-Utility Analysis

The intervention group patients had a mean QALY loss of –0.004 (SD 0.002) from before treatment to after treatment, while the corresponding figure for patients in the control group was –0.012 (SD 0.002; *P*<.001). The mean cost for the Interaktor app per patient was €92 (SD €2). The mean total cost for the intervention and all health care was €36,882 (SD €1032) for patients in the intervention group and €35,427 (SD €959) for control group patients (*P*<.001). The ICERa was €202,368 (€SD 811,136; 95% CI €152,008-€252,728). The mean cost for the intervention and acute health care was €3585 (SD €480) in the intervention group and €3235 (SD €494) in the control group (*P*<.001). ICERb was €49,903 (SD €207,042; 95% CI €37,049-€62,758; Table 1). Lastly, when health care costs were excluded from the analysis, the ICERc was €13,213 (SD €33,327; 95% CI €11,145-€15,281; Table 1).

Exploration of Health Care Utilization and Health Care Costs

The mean outpatient cost for patients in the intervention group was €27,571 (SD €6392), while in the control group, it was €26,348 (SD €5800). In both groups, approximately 2% of the outpatient costs were attributable to acute care: €554 out of €29,321 (1.9%) in the intervention group and €562 out of €26,348 (2.13%) in the control group.

In the intervention group, 13 out of 74 (18%) patients had an acute outpatient visit for fever, with a total of 34 visits. In the control group, the corresponding proportion was 9 out of 75 (12%), with a total of 21 visits. Additionally, 7 out of 74 (9%) patients in the intervention group had an unplanned admission from outpatient to inpatient care, accounting for 37 unplanned admissions. In the control group, 6 out of 75 (8%) had an unplanned admission from outpatient to inpatient care, totaling 29 unplanned admissions.

The mean inpatient cost per patient was €9207 (SD €5254) in the intervention group and €9093 (SD €5460) in the control group. Approximately one-third of all inpatient care cost was acute in both groups (€2932/€9207, 31.85% in the intervention group and €2665/€9093, 29.31% in the control group). The most common diagnoses during acute inpatient care episodes in both groups were fever, gastroenteritis/colitis, anemia, and urinary tract infection. The variable group (intervention/control) was not associated with the number of visits for fever, gastroenteritis/colitis, anemia, or urinary tract infection, nor were age, health-related quality of life (HRQOL) before treatment, comorbidities, or the number of NACT (Table 2).

[g]Neoadjuvant chemotherapy treatments

Negative binomial multivariate regression analysis revealed that the independent variable group (intervention/control) did not significantly affect the predicted log odds of patients' health care costs (*P*=.949). For acute outpatient health care costs, the analysis showed that age, health-related quality of life at baseline, and comorbidities significantly predicted costs. Older age (*P*=.002) and better health-related quality of life (*P*<.001) were associated with lower acute outpatient health care costs. By contrast, a higher number of comorbidities was associated with increased acute health care costs (*P*=.02; Table 3).

P-RCT

Health Outcome

The mean EQ-5DP before treatment was 0.88 in the intervention group and 0.89 in the control group. After treatment, the mean EQ-5DP was 0.87 in the intervention group and 0.88 in the control group (*P*=.51). The mean difference in EQ-5DP from before to after treatment was not statistically significant between the intervention and control groups (*P*=.94). The most prominent differences in change were observed in the dimensions of Pain/Discomfort and Anxiety/Depression (Multimedia Appendix 5).

Cost-Utility Analysis

The intervention group patients scored a mean QALY loss of –0.0008 (SD 0.0006), while the corresponding figure for the control group was –0.0009 (SD 0.0006; *P*<.001). The mean total cost of the Interaktor intervention per patient was €43 (SD €0.2). The mean total cost, including the intervention and all health care, was €3419 (SD €739) for the intervention group and €3537 (SD €689) for the control group. The ICERa was –€1,092,136 (SD €35,155,229; 95% CI –€3,274,774 to –€1,090,502). The mean total costs for the intervention and acute health care were €1219 (SD €593) in the intervention group and €802 (SD €281) in the control group. The ICERb was €745,987 (SD €16,006,924; 95% CI –€247,317 to €1,739,292). Lastly, when health care costs were excluded from the analysis, the ICERc was €13,118 (SD €1,314,743; 95% CI –€68,468 to €94,704; Table 4).

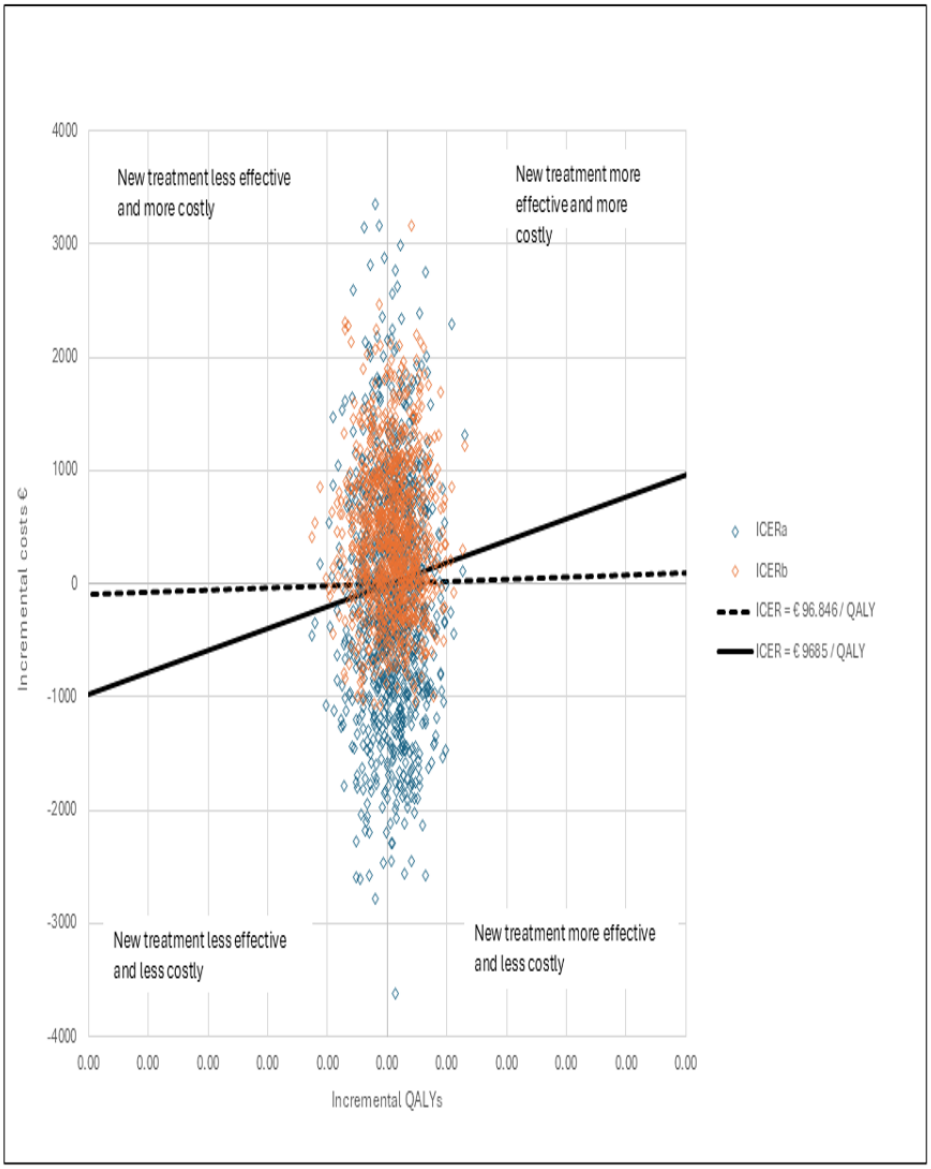

Figure 4. Prostate cancer cost-effectiveness plane ICERc. ICER: incremental cost-effectiveness ratio; QALY: quality-adjusted life year.

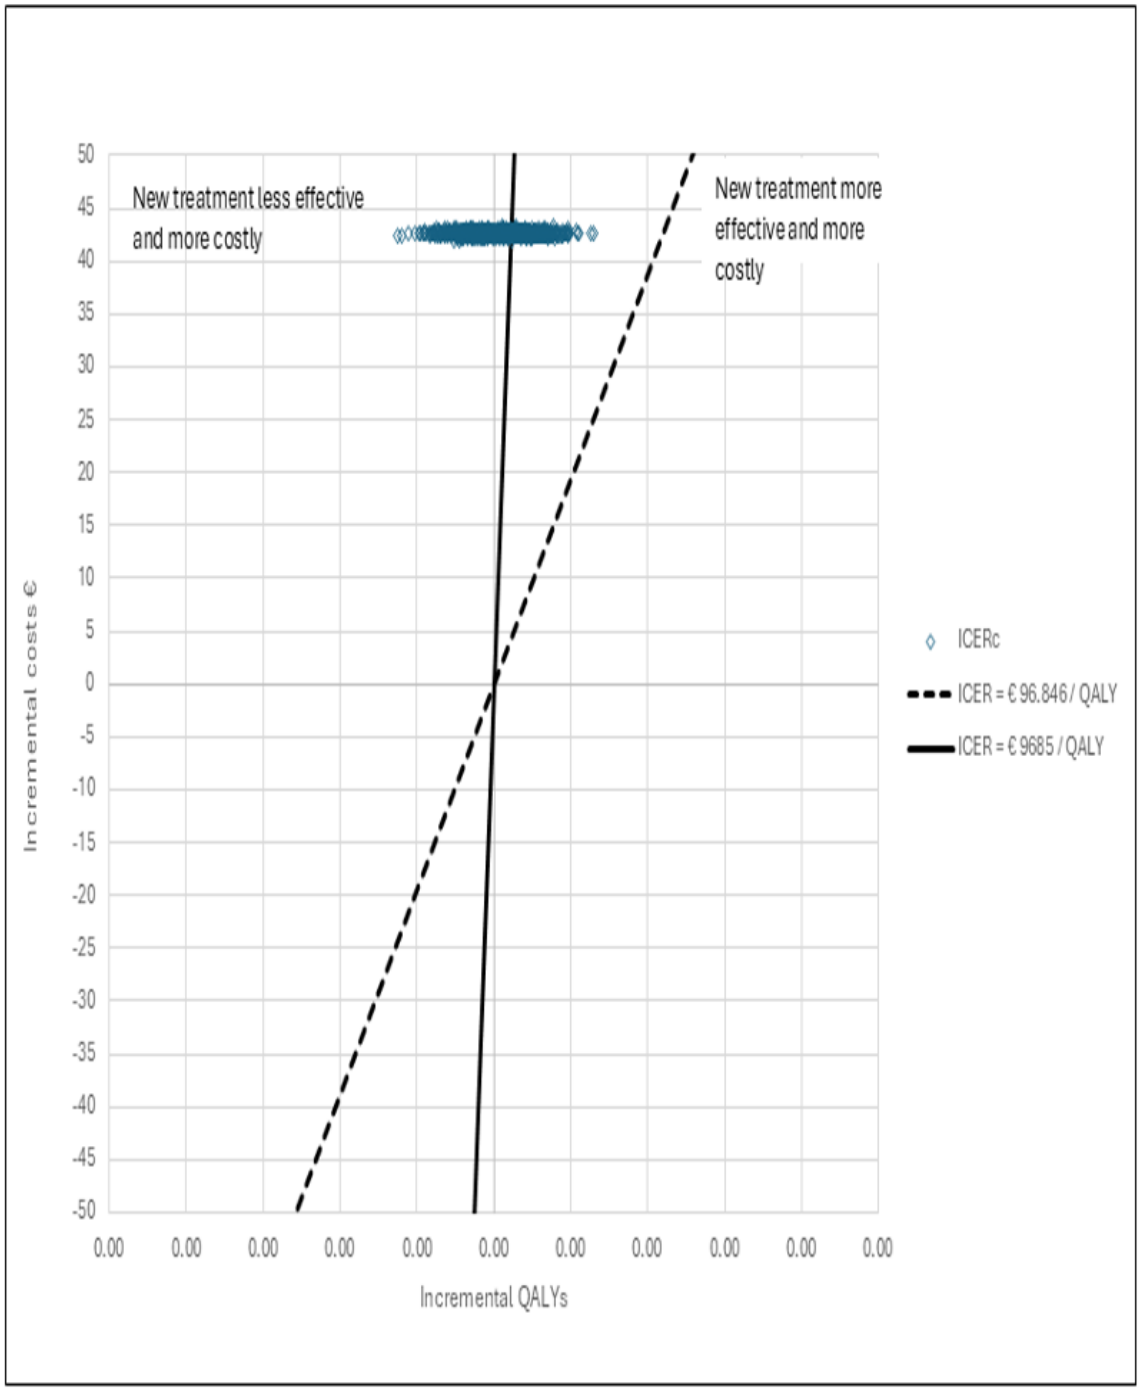

Exploration of Health Care Utilization and Health Care Costs

The mean outpatient cost for patients in the intervention group was €2077 (SD €1386), while in the control group, it was €2488 (SD €2403); €121 out of €2077 (5.83%) outpatient cost in the intervention group was for acute care, compared with €126 out of €2488 (5.06%) in the control group. In both groups, 25 patients (33%) had an acute outpatient care visit.

Acute outpatient care for urological problems was required by 5 of 75 (7%) patients (7 visits) in the intervention group and 6 of 75 (8%) patients (14 visits) in the control group (Table 5). Regarding acute outpatient visits for urological problems that resulted in unplanned admissions from outpatient to inpatient care, this occurred for 1 patient in the intervention group (1 admission) and 2 patients in the control group (3 admissions).

[g]Intervention/Control; reference category=Control

[h]*P* value for the independent variable in the Binary Logistic Regression Model.

The mean inpatient cost was €1321 (SD €5460) in the intervention group, compared with €1049 (SD €4240) in the control group. In the intervention group, €1054 out of €1321 (79.79%) inpatient care costs were attributed to acute care, while the corresponding figure in the control group was €684 out of €1049 (65.20%). The most common diagnoses during acute inpatient care episodes in the intervention group were R060 dyspnea (4 episodes) and I214 acute subendocardial infarction (3 episodes). In the control group, the most common diagnoses were N390 urinary tract infection (3 episodes) and anemia D630/D649 (2 episodes).

Negative binomial multivariate regression analysis revealed that higher HRQOL before treatment was associated with a decrease in the number of outpatient care visits (*P*=.002). Multivariate binary logistic regression indicated that higher HRQOL before treatment was negatively associated with both having an acute outpatient care visit for urological problems (*P*=.02) and having an inpatient care episode (*P*=.04). Therefore, patients with better HRQOL before treatment were less likely to have an acute outpatient visit for urological problems and less likely to experience an inpatient care episode (Table 5).

Discussion

Principal Findings

In both RCTs, patients in the intervention groups experienced fewer QALYs lost compared with those in the control groups. In the B-RCT, the quality of life of patients in the intervention group decreased significantly less during treatment compared with the control group; however, this was not observed in the P-RCT. The reduction in QALYs lost was achieved with a low intervention cost per patient. Unfortunately, while ICERs are particularly valuable for guiding decision makers, the ICERs from this study are somewhat difficult to interpret due to uncertainty, as illustrated in the cost-effectiveness planes. The variability in the ICERs arose from differences in patients' health care costs. When health care costs were excluded from the analysis, the RCTs showed ICERs slightly above the NBHW threshold for a low cost per QALY but still well below what the NBHW considers a high cost per QALY. These findings are encouraging and support the conceptual foundation of ePRO [48].

Comparison With Prior Work

Although the P-RCT showed a decrease in QALYs lost, the difference was relatively small. This finding is not uncommon. Snoswell et al [49] reviewed 25 cost-utility studies of telehealth interventions that reported costs from the health system perspective and changes in HRQOL. About one-third of these studies demonstrated cost savings and changes in effect, but most QALY improvements were marginal (range 0.0006-0.12). The authors concluded that this may be partly due to HRQOL instruments being neither sensitive nor appropriate for detecting the effects of changes in health service delivery. Demonstrating substantial cost savings from ePRO during curative cancer treatment may be challenging, given the relatively short time frame and the high variability in health care utilization, which necessitate large sample sizes. However, because productivity loss due to morbidity and mortality represents the most significant societal cost of cancer [50], further research should explore whether life quality improvements enable patients to continue working during treatment or return to work earlier and to a greater extent after treatment. Such a cost-effectiveness analysis could reveal societal cost savings.

There are a few studies available to compare with our findings, as CUAs of ePRO interventions remain limited [27]. We did not identify any studies evaluating the cost-effectiveness of ePRO during first-line curative cancer treatment. However, some studies have been conducted in the context of follow-up and advanced cancer care. For instance, Nixon et al [51] and Lizée et al [28] reported relatively low ICERs for ePRO in cancer survivors, whereas Van der Hout et al [52] found a small positive effect on HRQOL but no significant differences in direct or indirect medical costs among cancer survivors.

Evidence suggests that ePRO can reduce health care utilization [27]. For example, ePRO has been shown to positively impact outcomes such as emergency room visits, hospitalizations, and readmissions [27]. However, not all studies demonstrate these effects. Barbera et al [53], in a study conducted during adjuvant chemotherapy for breast cancer, did not observe a reduction in hospitalizations or readmissions. Similarly, Wheelock et al [54]

investigated the impact of ePRO during follow-up care after breast cancer treatment and found no reduction in health care resource use, including oncology-related appointments, physician visits, or medical tests. Lizée et al [28] observed a higher number of follow-up clinic visits in the ePRO intervention group compared with the control group. However, the intervention group also experienced longer overall survival, allowing more time for follow-up visits.

The study highlights the heterogeneity of the cancer population and the variation in health care use not only between but also within patient populations. For instance, nearly 104 of 149 (69.8%) patients treated for breast cancer made acute outpatient visits, whereas only about one-third (50/150) of patients with prostate cancer required such visits. This may be linked to the continuous health care contact that patients undergoing external RT maintain. In the context of older patients receiving cancer treatment, Nipp et al [55] demonstrated that age moderated the positive effects of ePRO on both ER visits and survival in patients with advanced cancer.

By analyzing ICD codes documented during health care visits to regional health care organizations, this study revealed that 5 of 75 (7%) intervention group patients and 6 of 75 (8%) control group patients undergoing treatment for prostate cancer had an acute outpatient visit for urological problems. Similarly, 4 of 74 (5%) intervention group patients and 11 of 75 (15%) control group patients treated for breast cancer had an acute outpatient visit for gastrointestinal symptoms. However, health care visits to general practitioners' clinics and health centers lacked ICD codes, meaning these figures may not fully capture the patients' health care utilization for those symptoms.

In this study, intervention group patients treated for breast cancer had more acute outpatient visits for fever/neutropenia, although the difference was not statistically significant. A similar increase in neutropenic events was observed by Absolom et al [10], who evaluated an intervention for patients undergoing chemotherapy, which aligns with national recommendations for managing chemotherapy patients presenting with this symptom [56]. In this study, the number of acute inpatient care episodes for fever/neutropenia was similar between the intervention and control groups.

Previous research has shown that health care utilization and costs during cancer treatment are complex [45]. This study examined whether age, comorbidity, and health status significantly influenced patients' health care utilization. As expected, the results suggest that health status has some impact on health care consumption. In the B-RCT, higher HRQOL before treatment was associated with reduced acute outpatient costs. In the P-RCT, higher HRQOL before treatment was associated with a lower likelihood of having an acute outpatient visit or inpatient care episode. Considering the results showing a smaller decline in quality of life among intervention group patients, these findings suggest that patients using the app receive timely and appropriate care, leading to more effective and prompt management of symptoms and adverse events associated with cancer treatment. This interpretation aligns with previously reported positive effects on health-related quality of life and symptom burden [11,19,20].

Limitations

The study presents unique and highly relevant findings for modern outpatient-based, personalized cancer care. A key strength is its randomized design, although some limitations should be noted. First, the ICERs must be interpreted with caution due to the uncertainty illustrated in the cost-effectiveness planes. Regarding costs, additional expenses for nurses handling alerts were not included, as staff interviews indicated that no increase in working hours was necessary (unpublished data). A similar assumption was made in the study by Nixon et al [51]. A recent study of a similar intervention also concluded that the intervention did not increase hospital clinicians' workload [10]. Finally, the Swedish valuation system assigns higher values to most conditions than the British system, presumably because it is based on patients' valuations of their conditions rather than, as in the British case, the public's valuations of hypothetical conditions [57]. Accordingly, the results regarding intervention effectiveness may have differed.

In the P-RCT, the dropout rate was notably high, potentially reducing the statistical power to detect significant differences. The reasons for nonresponse to outcome questionnaires remain unknown. Importantly, all patients used the app daily as instructed, with an adherence rate of 80% [6]. Although debated, imputation aims to accurately estimate the overall data distribution [58]. It is suggested that imputing missing values exceeding 10% increases the risk of bias [34,58]. By contrast, the use of ITT analysis is highly recommended in RCTs [34]. Although there is no specific threshold for missing values in health economic studies, it is emphasized that patterns of missing data should be reported [32]. The sample in our study is too small to analyze patterns, but the ITT principle presumably assumes missing data are random, though other mechanisms may also have contributed [59]. Based on the study design and sample size, a simple imputation method was applied in this study [57].

Health care costs were missing at random due to an administrative error, and values for no more than 2 patients per group were imputed. The risk of overestimating costs due to right-skewed data is therefore small. Given that the data on the EORTC dimension scores are approximately normally distributed, the imputation method appears to be accurate. Nevertheless, further studies are needed.

Conclusions

At a low weekly cost, the intervention reduced QALYs lost. The cost-effectiveness of the intervention, as defined by the ICER in relation to the Swedish NBHW, varied depending on the costs considered. For patients with breast cancer, the intervention was cost-effective when nonacute health care costs were excluded, whereas for patients with prostate cancer, cost-effectiveness was achieved when all health care costs were included. This suggests that the intervention has the potential to achieve cost-effectiveness. However, larger studies are needed, as there was considerable uncertainty regarding the ICERs due to significant variations in patients' health care costs.

Patients in the intervention group with breast cancer had more acute health care visits for neutropenia/fever, whereas more

patients in the control group were hospitalized for gastrointestinal symptoms. Only a few patients with prostate cancer were hospitalized for urological problems. These findings highlight the previously demonstrated positive effects on patients' symptom burden and suggest that the intervention may facilitate timelier and more effective symptom management. Future studies should assess cost-effectiveness from a societal perspective.

Acknowledgments

We thank Dr. Tracey A. Young and Dr. Clara Mukuria for kindly providing the original mapping algorithm syntax. We also extend our gratitude to the Region Stockholm Health Care Administration and the Confederation of Regional Cancer Centres for their supportive assistance with registry data. The study was supported by the Swedish Cancer Foundation (grant 160298), the Swedish Research Council (grant 521-2014-2723), the Kamprad Family Foundation for Entrepreneurship, Research, and Charity (grant 20150015), the Swedish Research Council for Health, Working Life and Welfare (grant 2014-04713), and Karolinska Institutet (internal grant).

Abstract

Background: Breast cancer screening plays a pivotal role in early detection and subsequent effective management of the disease, impacting patient outcomes and survival rates.

Objective: This study aims to assess breast cancer screening rates nationwide in the United States and investigate the impact of social determinants of health on these screening rates.

Methods: Data on mammography screening at the census tract level for 2018 and 2020 were collected from the Behavioral Risk Factor Surveillance System. We developed a large-scale dataset of social determinants of health, comprising 13 variables for 72,337 census tracts. Spatial analysis employing Getis-Ord Gi statistics was used to identify clusters of high and low breast cancer screening rates. To evaluate the influence of these social determinants, we implemented a random forest model, with the aim of comparing its performance to linear regression and support vector machine models. The models were evaluated using R^2 and root mean squared error metrics. Shapley Additive Explanations values were subsequently used to assess the significance of variables and direction of their influence.

Results: Geospatial analysis revealed elevated screening rates in the eastern and northern United States, while central and midwestern regions exhibited lower rates. The random forest model demonstrated superior performance, with an R^2=64.53 and root mean squared error of 2.06, compared to linear regression and support vector machine models. Shapley Additive Explanations values indicated that the percentage of the Black population, the number of mammography facilities within a 10-mile radius, and the percentage of the population with at least a bachelor's degree were the most influential variables, all positively associated with mammography screening rates.

Conclusions: These findings underscore the significance of social determinants and the accessibility of mammography services in explaining the variability of breast cancer screening rates in the United States, emphasizing the need for targeted policy interventions in areas with relatively lower screening rates.

Introduction

In the United States, breast cancer ranks as the second most prevalent form of cancer among women, surpassed only by skin cancer [1]. Annually, approximately 240,000 cases of breast cancer are diagnosed in women, and tragically, approximately 42,000 women succumb to this disease each year in the United States. This makes breast cancer the second leading cause of cancer-related mortality among women in the country, following lung cancer [2]. Screening for breast cancer serves as a crucial secondary prevention measure, aimed at identifying the disease at an early stage, prior to clinical manifestation. Early detection of breast cancer enables the implementation of less intensive treatment strategies, contributing to improved survival rates.

Mammography-based screening detects lesions before they achieved clinical visibility [3]. Evidence shows that high-quality routine screening programs have led to a 25% to 31% reduction in breast cancer–related mortality among women aged 50 to 69 years [4].

The US Preventive Services Task Force recommends mammography every two years for women aged 40 to 74 years [5]. Despite these recommendations, current research indicates disparities in mammography screening across different parameters, including variations among women residing in different regions and belonging to different races, with varying levels of median household incomes, health insurance statuses, and access to mammography services [6]. The 2022 Cancer Trends Progress Report revealed that 76% of women aged 50 - 74 years underwent mammogram testing, with rates varying from 74% among Hispanic women to 82% among non-Hispanic Black women [7]. Additionally, 64% of women with less than a high school education, 67.5% of women with incomes below 200% of the federal poverty level, and 75% of those who were Medicare beneficiaries underwent a mammogram test [7]. The Healthy People 2030 [8] has set a target to increase the proportion of breast cancer screenings to 80% [9].

Geospatial and machine learning models have proven effective in identifying the impact of social, natural, and built environments on health outcomes [10-12]. This study seeks to explain the geographical disparities in breast cancer screening across the United States and to explore the area-level socioeconomic factors associated with the rates of breast cancer screening. By examining these disparities, we seek to provide insights that can guide targeted interventions and policies aimed at improving equitable access to breast cancer screening services.

Methods

This cross-sectional study investigates the spatial and socioeconomic factors influencing mammography screening rates among women aged 50 to 74 years in the United States. The methodology section outlines the steps, including data collection, variable selection, descriptive analysis, spatial analysis, machine learning model implementation, and model performance evaluation.

Data Collection

Dependent Variables

The data for mammography screening rates in this study were sourced from the Centers for Disease Control and Prevention's (CDC) PLACES Project for the years 2018 and 2020, which used responses collected through the Behavioral Risk Factors Surveillance System (BRFSS) survey [13]. This survey specifically targeted female respondents aged 50-74 years, categorizing them as women who reported having undergone mammogram screenings and those who did not (excluding unknowns and refusals). Our data extraction process comprised two main stages. First, we extracted age-adjusted mammography screening rates at the county level for spatial analysis, facilitating the visualization of patterns across the entire country. Second, we obtained the crude rates (raw percentages) of mammography screening at the census tract level, a small geographic unit used by the US Census Bureau for collecting and analyzing statistical data, explanatory analysis, and prediction model development by machine learning methods.

Independent Variables

Based on a preliminary literature review, we selected independent variables for the study from various sources. We incorporated socioeconomic data from the CDC, the 2013 - 2017 American Community Survey, the United States Department of Agriculture, and the Health Resources and Services Administration. The analyzed variables encompass a range of factors, including urban-rural location, population density, the rate of older women (aged 55 to 74 years), poverty rate, ethnicity (Black and Hispanic), educational attainment, uninsured rate, median home value, social vulnerability index, and primary care shortage area.

To assess accessibility, we used data from the US Food and Drug Administration's Mammography Facility Database, which included geocoding the locations of 8706 mammography centers. The geodesic distance from each census tract to the nearest facility and the number of facilities within a 10-mile radius were calculated. Table 1 provides a comprehensive overview of the dependent and independent variables used in this study, including their names, sources, and definitions.

Table . Dependent and independent variables used in this study.

Variable name	Source	Unit	Definition
Dependent variables			
Mammography rate (2018)	CDC[a]	Percent	Crude percent of mammography use among women aged 50 - 74 years in 2018
Mammography rate (2020)	CDC	Percent	Crude percent of mammography use among women aged 50 - 74 years in 2020
Independent variables			
Urban-rural location	USDA[b]	Binary	Urban or rural tract as of 2019
Population density	2013 - 2017 ACS[c]	Per square mile	Number of people per square mile
Number of women aged ≥55 years	2013 - 2017 ACS	Percent	Estimated percent of the female population aged 55 or above
Poverty rate	Census ACS data	Percent	Estimated percent of all people that are living in poverty
Without health insurance	2013 - 2017 ACS	Percent	Estimated percent of the population without health insurance coverage
Higher education rate	2013 - 2017 ACS	Percent	Estimated percent of the population ≥25 years, with a bachelor's, graduate, or professional degree
Black population	2013 - 2017 ACS	Percent	Percent of the population that is Black or African American, by single census classification
Hispanic population	2013 - 2017 ACS	Percent	Percent of the population identified as Hispanic or Latino
Home value	2013 - 2017 ACS	Dollar	Estimated median value of an owner-occupied housing unit
Social vulnerability index	CDC	Index	Social vulnerability level as of 2020
Primary care shortage	HRSA[d]	Binary	Primary care health professional shortage area status as of 2020
Distance to nearest mammography facility	Calculated	Mile	Distance from the center of the census tract to the nearest accredited mammography facility
Number of mammography facilities	Calculated	Number	Number of mammography facilities within the 10-mile catchment of the census tract

Analysis

Preprocessing

The primary objective of preprocessing was to handle missing values of both dependent and independent variables within the dataset. Due to the complexity of accounting for both spatial and temporal correlations in imputing breast cancer screening rates, we opted to exclude any census tracts that lacked mammography screening data in the BRFSS dataset for the years 2018 and 2020. Missing independent variables were imputed using the mean values for numerical data and the mode for binary data from the 20 closest neighboring records.

Thematic Mapping and Spatial Clustering

The age-adjusted rates for breast cancer screening were integrated into a shapefile of ArcGIS containing 3143 counties across all 50 states and the District of Columbia. Subsequently, the data was visualized using the natural break method [14] to enhance clarity. Using the Getis-Ord Gi statistic [15], we identified hotspots indicating areas with either high or low mammography screening rates. This spatial analysis allowed us to discern localized patterns and trends of breast cancer screening behavior.

Machine Learning Analysis

While constructing the predictive model, the response variable was the mean value of mammography screening rates in 2018 and 2020 for each census tract. The dataset was randomly split into two parts: 75% was used for training the model, and the remaining 25% was reserved for testing. This division allowed us to develop the model using the training data and then assess its predictive performance on the unseen testing data.

In this study, an ensemble learning algorithm known as random forest (RF) was employed to model the relationship between geospatial factors and breast cancer screening rates. Ensemble learning combines multiple models to improve the overall prediction accuracy and robustness, which is the rationale for choosing RF [16].

To enhance the efficacy of the RF model, we conducted a systematic hyperparameter search, where a predefined grid of values for the number of trees and the number of variables sampled at each split were explored to identify the optimal configuration [17]. We defined a grid of values for the number of trees and the number of variables sampled at each split.

We utilized the 5-fold cross-validation to evaluate the RF model's performance across different combinations of hyperparameters. In a 5-fold cross-validation, the dataset is split into 5 subsets, with each subset serving as the validation set once, while the other 4 subsets are used for training. This process helps in assessing the model's generalization ability. The model's performance was fine-tuned by selecting the combination of hyperparameters that minimized the root mean squared error (RMSE), a metric indicating the average difference between observed and predicted values. The RMSE is critical as it directly relates to the model's prediction accuracy, with lower values indicating better performance [18].

To benchmark the performance of the RF model, we also implemented the linear regression (LR) and support vector machine (SVM) models. The LR provides a straightforward baseline, while SVM is known for its effectiveness in high-dimensional spaces. The inclusion of these three algorithms was motivated by their complementary strengths in handling different data characteristics, allowing for a comprehensive comparison of predictive accuracy.

The models were implemented using the Scikit-learn package in Python, a widely used library for machine learning that provides efficient tools for model training, evaluation, and hyperparameter optimization [19].

Following the training process, predictions of breast cancer screening rates were made on a separate testing set. Model accuracy was evaluated using metrics such as R^2 and RMSE. R^2 represents the proportion of variance in the dependent variable explained by the model, serving as an indicator of goodness-of-fit. RMSE, as previously mentioned, measures the average difference between predicted and observed values, providing insight into the model's prediction error [18].

To interpret the model's predictions, we calculated Shapley Additive Explanations (SHAP) values for each feature. SHAP values provide a detailed understanding of how each feature contributes to the model's predictions [20]. By examining the mean SHAP values, the most influential variables in predicting breast cancer screening rates were identified. For variables with average SHAP values exceeding 0.3, scatterplots were created to explore the direction and magnitude of their effects on screening rates [21].

Ethical Considerations

The Institutional Review Board at the University of Tennessee Health Science Center determined that this study (24 - 10240-NHSR) qualifies for Not Human Subjects Research status as it does not involve human subjects as defined by 45 CFR 46.102. The data used in this study were obtained from the publicly available BRFSS dataset provided by the CDC. All study data were aggregated at the census tract level, and no individual-level data were accessed or analyzed, ensuring participant anonymity and compliance with ethical standards.

Results

Summary Statistics About Data

Of the 72,337 census tracts nationwide, 49,118 were eligible for inclusion in our analysis, as they had available mammography screening data. The mean mammography screening rate within these census tracts was 77% (SD 3.62) in 2018 and 76.51% (SD 3.71) in 2020. Table 2 provides a detailed overview of summary statistics for all variables considered in our analysis, encompassing the 49,118 included census tracts.

Table . Summary statistics for all dependent and independent variables for 49,118 census tracts included in the analysis.

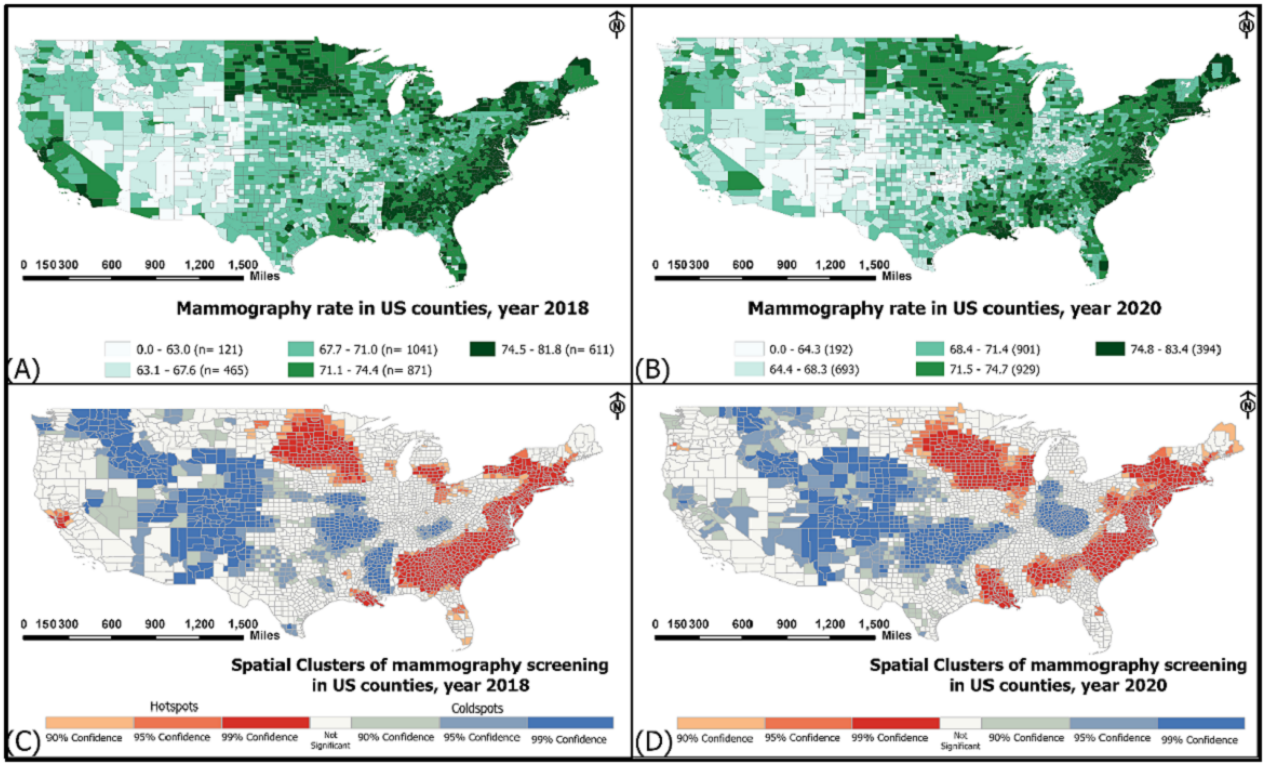
Variables	Missing values, n	Census tracts (N=49,118)
Mammography rate (2018) (%), mean (SD)	0	77 (3.6)
Mammography rate (2020) (%), mean (SD)	0	76.5 (3.7)
Location n (%)		
Rural	0	12,284 (25)
Urban	0	36,834 (75)
Population density (per square mile), mean (SD)	0	5,547.38 (13,334.53)
Women aged ≥55 years (%), mean (SD)	0	7.9 (4.0)
Poverty rate (%), mean (SD)	49	16.3 (12.5)
Without health insurance (%), mean (SD)	35	11.47 (7.83)
Higher education rate (%), mean (SD)	4	28.4 (18.6)
Black population (%), mean (SD)	1	15.2 (23.6)
Hispanic population (%), mean (SD)	1	12.7 (18.5)
Home value (US $), mean (SD)	727	203,834 (170,438)
Social vulnerability index, mean (SD)	82	0.59 (0.28)
Primary care shortage, n (%)		
Yes	0	28,031 (57.1)
No	0	21,087 (42.9)
Distance to nearest mammography (miles), mean (SD)	0	1.8 (3.2)
Number of mammography facilities, mean (SD)	0	18.1 (28.6)

Thematic Mapping and Spatial Clustering

Figures 1A and B illustrate the distribution of breast cancer screening rates across the 3143 US counties for the years 2018 and 2020, respectively. Regions in the eastern and northern parts of the country exhibited higher rates of breast cancer screening (>71%), while counties in the central, midwestern, and southern areas displayed comparatively lower rates (<63%). While these visual representations provide valuable insights, further confidence in the findings is derived from statistical and spatial analyses.

Figures 1C and D present the outcomes of Getis-Ord Gi statistics for the clustering of breast cancer screening rates across the United States in 2018 and 2020, respectively. The red areas (hotspots) on these maps represent spatial clusters characterized by high mammography rates, indicating that the screening rates and their neighboring values significantly surpass those in other regions. Conversely, the blue areas denote coldspots, representing spatial clusters with lower screening rates. The similarity in patterns between the two time points underscores the reliability of the observations and strengthens the robustness of the identified spatial clusters. The map also reveals certain disparities. For instance, counties along the western borders, such as California, experienced a decline in mammography rates from 2018 to 2020. Similarly, regions in Indiana, Texas, and Arkansas saw decreased rates of breast cancer screening during this period. Conversely, parts of Illinois and Louisiana showed reported mammography rates from 2018 to 2020.

Figure 1. Age-adjusted rates of breast cancer screening in US counties for (A) 2018 and (B) 2020. Spatial clusters in (C) 2018 and (D) 2020.



Machine Learning Analysis

Evaluation of the final RF model, along with the LR and SVM models, based on R^2 and RMSE of the testing dataset is presented in Figure 2. The results indicate that the RF model, with an optimal number of trees set to 500 and the number of nodes (m) set to 4, outperforms both LR and SVM. Specifically, the RF model achieved a higher R^2 value and a lower RMSE, indicating its superior ability to capture and predict the underlying patterns in the data. This performance underscores the suitability of the RF model for this analysis.

Figure 3 depicts the relative importance of each factor, as determined by SHAP values, at the census tract level in predicting the rate of breast cancer screening across the United States. The mean of SHAP values provides a measure of the overall contribution of each variable to the model's predictions. As evident from Figure 3, the proportion of the Black population is the most important factor, followed by the number of mammography facilities within a 10-mile distance and the higher education rate. For the subsequent analysis, we refined our focus to variables with SHAP values exceeding 0.3 (the top 6 variables) to assess the direction and magnitude of influence that each variable exerts on the prediction of breast cancer screening rates as the variables vary in value.

While assessing variable importance using mean SHAP values offers crucial insights into the most influential factors in predicting breast cancer screening rates, it does not elucidate the direction of their effects on the outcome variable across different variable values. To address this, we generated scatterplots of individual SHAP values for the selected six variables to examine the detailed changes in SHAP values across varying values of these variables. Figure 4 shows that higher proportions of the Black population, higher education levels, an increased number of mammography facilities, and a higher median home value exhibit positive associations with breast cancer screening rates. Conversely, a higher proportion of Hispanic ethnicity and a lack of health insurance demonstrate negative impacts on the screening rates.

Figure 2. Comparison of the performance of random forest, linear regression, and SVM models in predicting breast cancer screening rates. RMSE: root mean squared error; SVM: support vector machine.

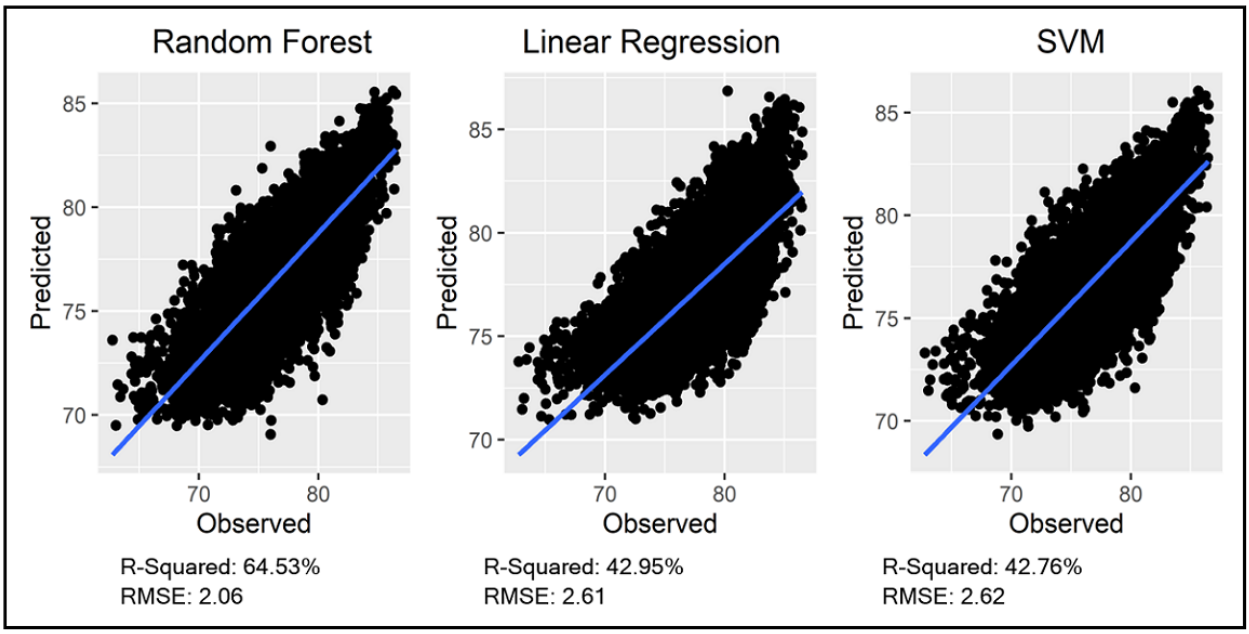


Figure 3. SHAP values of each census tract–level factor in predicting the rate of breast cancer screening across the United States. SHAP: Shapley Additive Explanations.

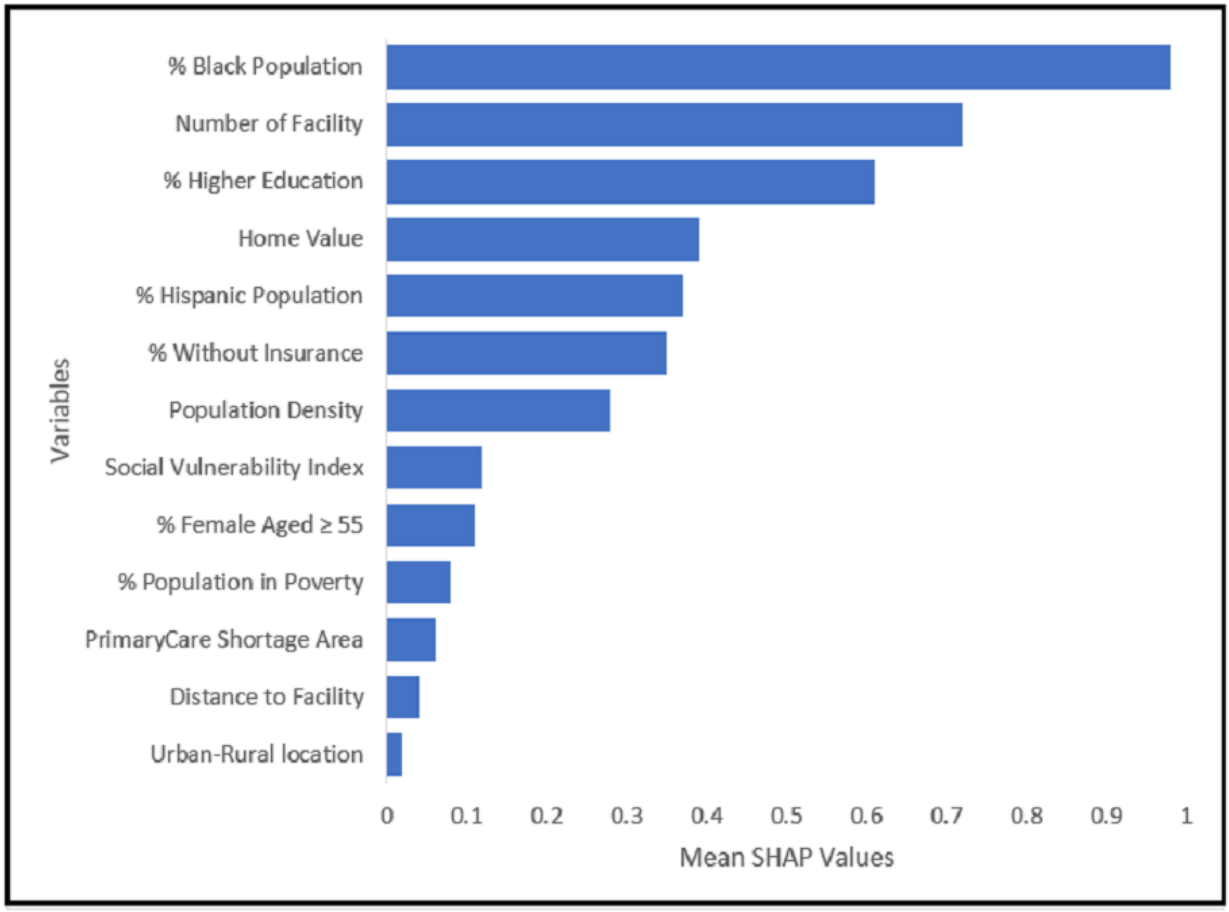

Figure 4. Direction of influence illustrated by individual SHAP values on the prediction of breast cancer screening rates for the selected six important variables. SHAP: Shapley additive explanations.

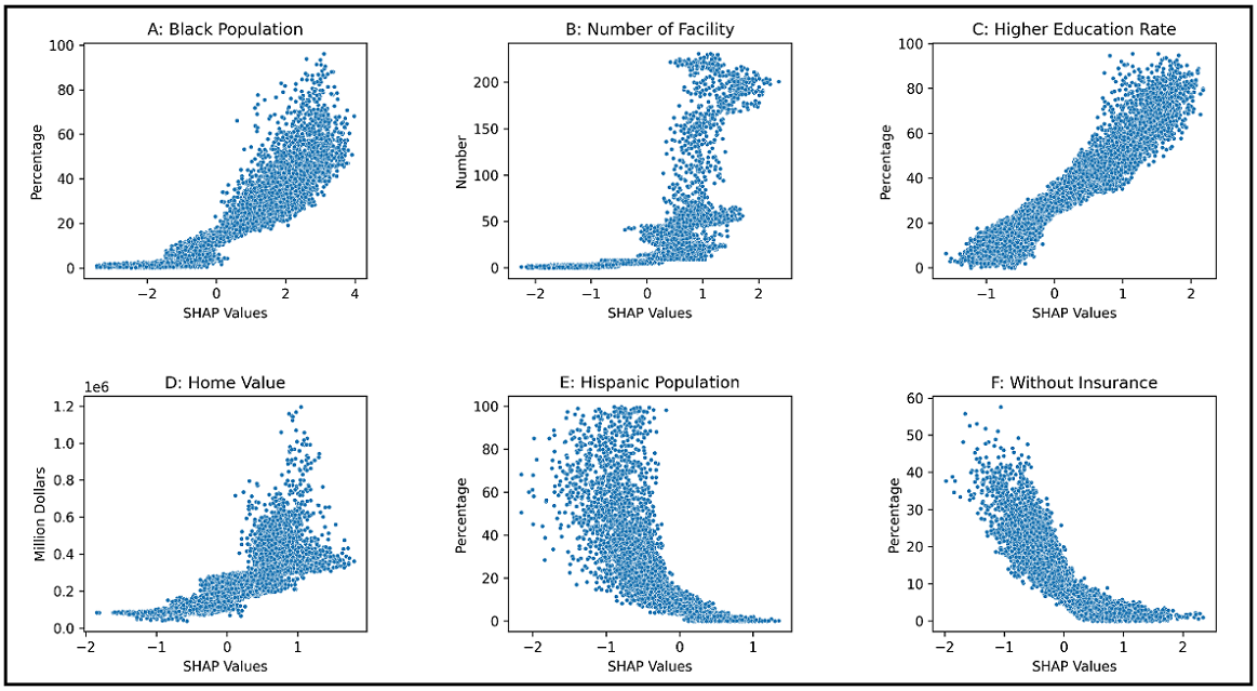

Discussion

Our research employed a combination of spatial analysis, statistical methods, and machine learning techniques to elucidate the disparities in breast cancer screening across the United States. Spatial patterns revealed clusters of low screening rates, particularly in central, midwestern, and southern regions, contrasted with hotspots of mammography rates, particularly evident along the east coast and in the northern parts of the United States. A predictive model for breast cancer screening rates was developed using the RF algorithm. Meanwhile, key influencing factors for predicting breast cancer screening rates were identified based on the mean SHAP values, including the proportion of the Black population, availability of mammography facilities, and higher education rates.

Spatial clustering identified through Getis-Ord Gi statistics reinforces the observed patterns and underscores their persistence across two distinct time points (2018 and 2020). The consistency of these spatial clusters suggests enduring factors influencing breast cancer screening behavior in specific areas, providing valuable information for policy makers and health care professionals seeking to implement targeted interventions.

It is crucial to acknowledge that the onset of the COVID-19 pandemic has significantly impacted various aspects of human life, including breast cancer screening [21]. The pandemic may have played a role in the decreased mean breast cancer screening rate of breast cancer from 77% in 2018 to 76.51% in 2020. The disruption of routine health care services and the challenges associated with social distancing could have affected mammography screening rates, particularly in urban areas with denser populations. However, it is important to consider that the BRFSS survey focuses on individuals who have undergone breast cancer screening in the last two years. Consequently, women who underwent mammography screening in the year prior to the COVID-19 pandemic could still respond affirmatively. The influence of COVID-19 on the average rate and pattern of breast cancer screening may vary significantly in 2022 and 2023, particularly in cities with higher disease prevalence. Additional investigations are warranted to understand the influence of COVID-19 on changes in breast cancer screening rates across the United States and globally.

Our machine learning analysis that uses an RF model contributes toward understanding the complex interplay of various factors influencing breast cancer screening rates. The RF model with optimal hyperparameters outperformed the LR and SVM models. The ability of RF to capture complex nonlinear relationships and interactions among influencing factors aligns with findings from other population-level studies, highlighting its superiority in predicting population health outcomes [22,23], which confirms our choice of RF as the primary model for our analysis.

While the RF model demonstrated superior performance in predicting breast cancer screening rates, there is a potential risk of overfitting, inherent to ensemble methods [24]. To mitigate this, we implemented cross-validation during the hyperparameter tuning process and evaluated the model's performance on a separate testing dataset to ensure that the RF model maintained its predictive accuracy on unseen data.

It is particularly noteworthy that a higher proportion of the Black population within a census tract was positively associated with increased mammography screening rates. This finding aligns with a 2022 cancer trends progress report, which revealed that 82% of Black women underwent mammography screening, while the screening rate was as low as 74% among other ethnic groups [1]. Possible explanations for this positive association

may include the effectiveness of targeted public health interventions and community-based outreach programs specifically designed to increase awareness and accessibility of breast cancer screening in these communities. Additionally, it may reflect a growing awareness and proactive behavior regarding breast cancer prevention among Black women, possibly influenced by public health campaigns and community support networks. Some studies also suggested that when access to health care is equitable, racial and ethnic minorities who are often more aware of their heightened risk, may be more likely to use preventive services like mammography [25]. However, despite the relatively higher mammography screening rates in areas with a larger Black population, it is crucial to underscore that Black women are 40% more likely to die from breast cancer compared to White women [26]. This disparity could be attributed to delays in diagnosis and treatment, particularly when a breast tissue abnormality is identified by mammography [27,28]

Our findings highlighted the importance of the number of available mammography facilities within a 10-mile radius, despite the relatively low SHAP value assigned to the distance to the nearest facility. A plausible explanation is that proximity to a facility may not always be a decisive factor, as various considerations such as affordability and type of insurance can significantly impact facility selection. Moreover, our research revealed that the education rate plays a pivotal role in determining breast cancer screening rates. This finding aligns with prior studies indicating that American women with lower educational attainment are less likely to undergo screening [29]. Educational attainment is closely linked to health literacy [27]; women with lower health literacy have a reduced likelihood of accessing health services, including breast cancer screening [28]. Moreover, women with lower educational attainment might face limited employment opportunities and a lack of jobs that offer access to employee health insurance, leading to a lower likelihood of consulting physicians who recommend mammography.

The variables of home value, rate of the Hispanic population, and rate of the uninsured population exhibited relatively similar and high SHAP values. Areas with higher home values and lower uninsured populations tend to have fewer financial barriers to accessing preventive services. According to existing literature, Hispanic women exhibit lower rates of breast cancer and mortality compared to non-Hispanic Black women and non-Hispanic White women [30]. This disparity could explain the lower screening rate in census tracts with higher proportions of Hispanic population.

Variables analyzed in this study are based on estimates from the CDC PLACES project, which uses a multilevel regression and poststratification approach. This method combines individual-level BRFSS data with demographic data from the US Census to produce reliable estimates at small geographic levels, including census tracts. The multilevel regression and poststratification method has been validated against direct survey data, ensuring that the aggregated rates at the census tract level are both stable and accurate for our analysis [31].

Our study has several limitations. The use of cross-sectional data restricts our capacity to establish causality, underscoring the importance of future research examining temporal changes in breast cancer screening rates. Moreover, as is inherent in all self-reported sample surveys, the BRFSS data may be susceptible to systematic errors stemming from noncoverage, nonresponse, or measurement bias. It is imperative to note that our study was conducted at an aggregate level; therefore, prudence is advised when extrapolating individual-level conclusions. The ecological fallacy, a key concern in population studies, underscores the necessity of avoiding assumptions about individual behaviors based solely on group-level observations.

This study provides a comprehensive analysis of breast cancer screening disparities in the United States, combining spatial, statistical, and machine learning approaches. The spatial patterns and influential factors identified in this study offer valuable insights for policy makers, health care professionals, and researchers striving to implement targeted interventions to reduce breast cancer screening disparities and improve overall public health outcomes. Ongoing research and targeted interventions are vital for achieving equitable access to breast cancer screening services and ultimately reducing the impact of this significant health issue.

Abstract

Background: Early-stage breast cancer has the complex challenge of carrying a favorable prognosis with multiple treatment options, including breast-conserving surgery (BCS) or mastectomy. Social media is increasingly used as a source of information and as a decision tool for patients, and awareness of these conversations is important for patient counseling.

Objective: The goal of this study was to compare sentiments and associated emotions in social media discussions surrounding BCS and mastectomy using natural language processing (NLP).

Methods: Reddit posts and comments from the Reddit subreddit r/breastcancer and associated metadata were collected using pushshift.io. Overall, 105,231 paragraphs across 59,416 posts and comments from 2011 to 2021 were collected and analyzed. Paragraphs were processed through the Apache Clinical Text Analysis Knowledge Extraction System and identified as discussing BCS or mastectomy based on physician-defined Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) concepts. Paragraphs were analyzed with a VADER (Valence Aware Dictionary for Sentiment Reasoning) compound sentiment score (ranging from −1 to 1, corresponding to negativity or positivity) and GoEmotions scores (0 - 1) corresponding to the intensity of 27 different emotions and neutrality.

Results: Of the 105,231 paragraphs, there were 7306 (6.94% of those analyzed) paragraphs mentioning BCS and mastectomy (2729 and 5476, respectively). Discussion of both increased over time, with BCS outpacing mastectomy. The median sentiment score for all discussions analyzed in aggregate became more positive over time. In specific analyses by topic, positive sentiments for discussions with mastectomy mentions increased over time; however, discussions with BCS-specific mentions did not show a similar trend and remained overall neutral. Compared to BCS, conversations about mastectomy tended to have more positive sentiments. The most commonly identified emotions included neutrality, gratitude, caring, approval, and optimism. Anger, annoyance, disappointment, disgust, and joy increased for BCS over time.

Conclusions: Patients are increasingly participating in breast cancer therapy discussions with a web-based community. While discussions surrounding mastectomy became increasingly positive, BCS discussions did not show the same trend. This mirrors national clinical trends in the United States, with the increasing use of mastectomy over BCS in early-stage breast cancer. Recognizing sentiments and emotions surrounding the decision-making process can facilitate patient-centric and emotionally sensitive treatment recommendations.

KEYWORDS

breast cancer; social media; patient decision-making; natural language processing; breast conservation; mastectomy

Introduction

Early-stage breast cancer has the complex challenge of carrying a favorable prognosis with multiple treatment options, including breast-conserving surgery (BCS) or mastectomy. Treatment decisions are therefore driven by patient preferences, making information gathering and decision analysis critical. Multiple randomized trials have shown that locoregional recurrence and survival rates are similar with breast-conserving therapy (BCT) or mastectomy, with recent data even suggesting improved survival with BCT [1,2]. Nonetheless, trends indicate that women with early-stage, nonhereditary breast cancer are increasingly choosing mastectomy [3].

Many factors contribute to patient decision-making for cancer therapy, including the growing influence of social media. Several previous studies have investigated the use of online forums and social media by patients with breast cancer [4-8]. As many as 77% of patients with breast cancer cite the internet as their primary information source [9]. Additionally, patients who are frequent users of online communication and social media tools experience increased decision-satisfaction [10]. Additionally, large language models, including ChatGPT, are being increasingly used by patients for medical decision making. As social media data, including that from Reddit, are used to train these models, these discussions are relevant to the information that patients receive [11,12].

There are limited data characterizing social media conversations surrounding the decision regarding BCS or mastectomy, which is important to understand to gain insights into national trends in the United States and inform the counseling process. We applied sentiment and emotion analyses with natural language processing (NLP) approaches to a popular breast cancer online community to compare the sentiments and associated emotions around conversations of BCS and mastectomy.

Methods

Data Source

The moderated Reddit subreddit r/breastcancer was created on December 3, 2011, and is self-described as “a support and information group for people who have been diagnosed with breast cancer and for their caregivers and loved ones.” As of January 2023, it had 13,700 subscribed members. Out of all internet users, 8% of men and 4% of women used Reddit; of those, 11% were aged 18 - 29 years, 7% were aged 30 - 39 years, 2% were aged 50 - 64 years, and 2% were aged 65+ years [13]. We selected Reddit for social and technical reasons, as it is anonymous, public, open, and interaction-centric. Reddit text is also frequently used to train NLP algorithms, reducing concerns about model applicability.

All posts, comments, and metadata from r/breastcancer from 2011 to 2021 were collected using pushshift.io [14]. Pushshift.io is a public social media archiving platform with real-time Reddit data for social media research. As of March 20, 2024, it has 908 citations according to Google Scholar. Data from Pushshift.io were accessed on February 4, 2022.

Data Preprocessing and Topic Identification

These posts and comments were separated into paragraphs based on line breaks to separate topics for analysis. We applied the Apache cTAKES (Clinical Text Analysis Knowledge Extraction System) v. 4.0.0 default clinical pipeline to identify mentions of BCS- or mastectomy-related terms mapped to the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT). cTAKES is an NLP software with multiple parts designed to process clinical free text. It had a sentence boundary detector, tokenizer, normalizer, part-of-speech tagger, shallow parser, and a named entity recognition annotator with negation. SNOMED keywords related to BCS or mastectomy were identified by a physician author (DYS). Examples of SNOMED words or phrases used in this analysis include *simple mastectomy*, *bilateral mastectomy*, and *modified radical mastectomy* as mastectomy keywords and *lumpectomy*, *excision biopsy*, and *segmental mastectomy* as BCS keywords. Analyses of paragraphs were based on references to BCS or mastectomy, nonexclusively. Paragraphs containing mentions of both were attributed to both treatments in the analysis.

Sentiment Analysis

Paragraphs (as a whole) were analyzed using VADER (Valence Aware Dictionary for Sentiment Reasoning) to generate compound sentiment scores from −1 to 1 (negative to positive). VADER is a popular sentiment analysis model trained on social media text, with performance comparable to more complex approaches and advantages of computational efficiency, explainability, and domain agnosticism or generalizability [12].

Emotion Classification

GoEmotions is the largest human-annotated dataset of fine-grained emotions, with 58,000 Reddit comments labeled for 27 emotions and neutrality [11]. We applied a publicly available BERT (Bidirectional Encoder Representations from Transformers) model from Google Research [15]. GoEmotions generates a score from 0 to 1 based on the intensity of the detected emotion. A paragraph was considered to express an emotion if its score was >0.5, as used in intensity annotations in the original GoEmotions benchmark studies [11].

Statistics were aggregated longitudinally for summary statistics per year. Years 2011 to 2014 had less than 100 posts discussing BCS or mastectomy; years 2011 - 2017 were pooled due to limited sample size. Sentiment scores were compared between BCS and mastectomy using a 2-tailed Student *t* test. Emotions across treatments were visualized using radar charts.

Ethical Considerations

The study data used in this analysis are anonymous, public, and open source. Therefore, there is minimal risk to performing these analyses. This study was approved by the University of San Francisco institutional review board, where the data collection and analyses were performed (IRB #21 - 35353).

Results

A total of 59,416 posts with 105,231 paragraphs on r/breastcancer, which were posted by 5845 users, were analyzed. There were 2729 mentions of BCS and 5476 mentions of

mastectomy, nonexclusively. Post volume increased over time (5282 in 2011 - 2017 to 44,235 in 2021). Words per paragraph had a slight increase over time, from a median of 28 (IQR 11 - 53) words per line in 2011 - 2017 to 26 (IQR 11 - 49) in 2018, 28 (IQR 12 - 50) in 2019, 30 (IQR 14 - 55) in 2020, and 30 (IQR 14 - 54) in 2021. The median number of comments per user was 2 (IQR 1 - 7).

Discussion of both BCS and mastectomy increased over time, but BCS outpaced mastectomy, with an increasing ratio of BCS to mastectomy mentions (0.312 in 2011 - 2017 to 0.583 in 2021). The median (IQR) sentiment score for all discussions became more positive annually: 0 (IQR –0.361 to 0.624) in 2011 - 2017 to 0.288 (–0.223 to 0.701) in 2021. Positive sentiments for mastectomy generally increased over time: median of 0 (IQR –0.599 to 0.726) in 2011 - 2017 to a median of 0.178 (IQR –0.511 to 0.73) in 2021. Similarly, the proportion of positive mastectomy-related discussions increased annually from 48.1% (151/314) in 2011 - 2017 to 53.3% (1107/2076) in 2021. Discussion of BCS remained neutral—median 0 (IQR –0.494 to 0.523) to median 0.039 (IQR –0.511 to 0.642)—and the proportion of positive BCS discussions did not show a similar trend year-to-year: 43.9% (43/98) in 2011-2017 to 52.3% (139/266) in 2019, and stable in 2021 to 50.7% (614/1211). Compared to BCS, conversations about mastectomy were more positive (P=.02), driven primarily by differences in 2021—median 0.178 (IQR –0.511 to 0.73) for mastectomy vs median 0.039 (IQR –0.511 to 0.642) for BCS, with P=.049.

The most common emotions across r/breastcancer were neutrality, gratitude, caring, approval, and optimism. The most common emotions for both BCS and mastectomy were similar: neutrality (BCS: 1001/2729, 36.68%; mastectomy: 1973/5476, 36.03%), caring (BCS: 242/2729, 8.87%; mastectomy: 547/5476, 9.99%), approval (BCS: 267/2729, 9.78%; mastectomy: 492/5476, 8.98%), realization (BCS: 284/2729, 10.41%; mastectomy: 542/5476, 9.9%), and curiosity (BCS: 237/2729, 8.68%; mastectomy: 459/5476, 8.38%) (Figure 1). Six emotions increased over time for all posts: approval (2011 - 2017: 354/5282, 6.7%; 2021: 4176/44,235, 9.44%), amusement (2011 - 2017: 34/5282, 0.64%; 2021: 677/44,235, 1.53%), desire (2011 - 2017: 37/5282, 0.7%; 2021: 552/44,235, 1.25%), disappointment (2011 - 2017: 64/5282, 1.21%; 2021: 787/44,235, 1.78%), excitement (2011 - 2017: 23/2729, 0.44%; 2021: 477/44,235, 1.08%), and realization (2011 - 2017: 259/5282, 4.9%; 2021: 2902/44,235, 6.56%). Fear (2011 - 2017: 203/5282, 3.84%; 2021: 1223/44,235, 2.76%) and neutrality (2011 - 2017: 2144/5282, 40.59%; 2021: 14,514/44,235, 32.81%) decreased over time (Table 1).

Figure 1. Radar chart of average emotion score across breast-conserving surgery (BCS) and mastectomy posts, respectively.

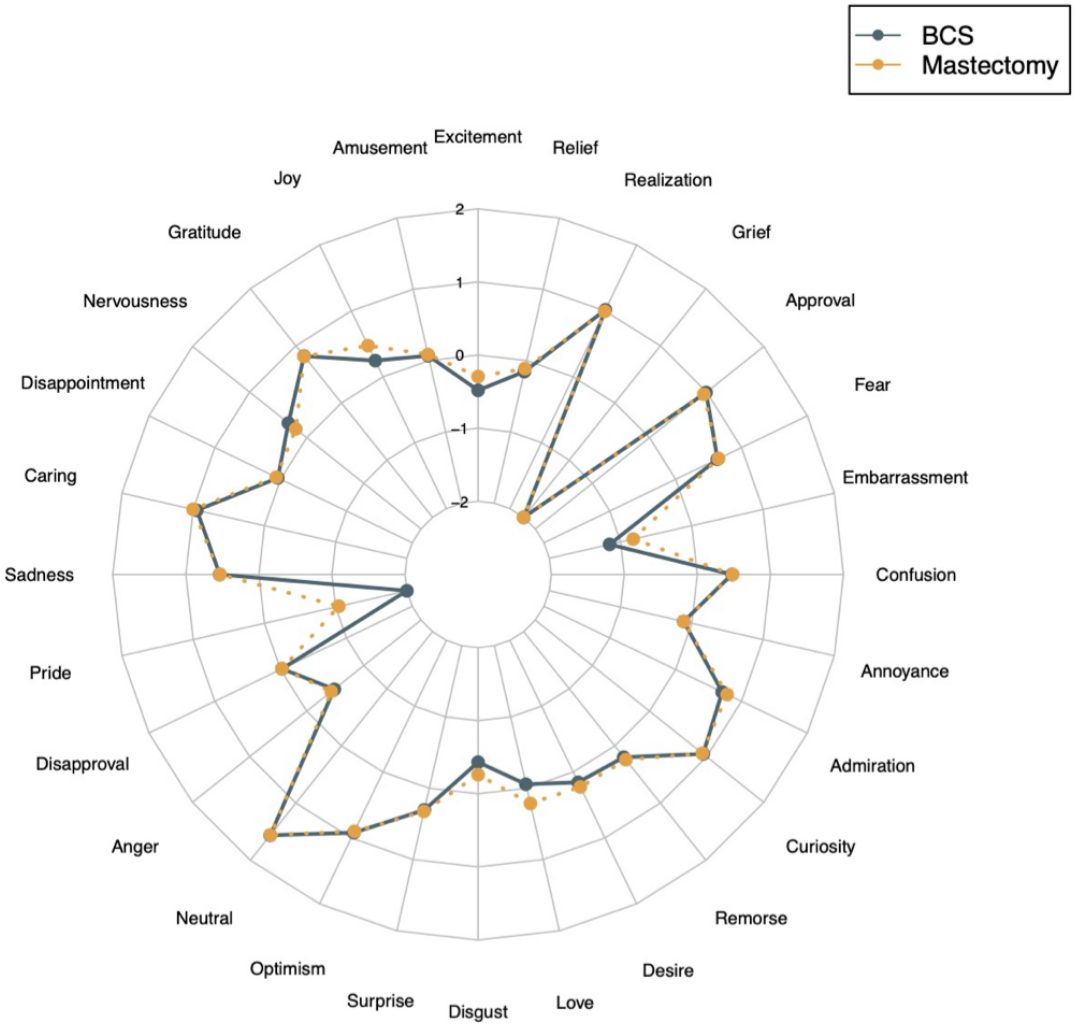

Table . Comparison of emotion trends.[a]

Emotion		All messages, n/N (%)	Breast conservation, n/N (%)	Mastectomy, n/N (%)
Amusement				
	Overall	1379/105,231 (1.31)	32/2729 (1.17)	67/5476 (1.22)

[a]Comparison of emotion trends overall and over time across all paragraphs and separated by breast conservation or mastectomy, nonexclusively, in r/breastcancer.

Five emotions became increasingly prevalent for BCS, although they were rare: anger (2011 - 2017: 0/98, 0%; 2021: 5/1211, 0.41%), annoyance (2011 - 2017: 0/98, 0%; 2021: 15/1211, 1.24%), disappointment (2011 - 2017: 0/98, 0%; 2021: 18/1211, 1.49%), disgust (2011 - 2017: 0/98, 0%; 2021: 5/1211, 0.41%), and joy (2011 - 2017: 0/98, 0%; 2021: 24/1211, 1.98%). No emotions showed a consistent trend for mastectomy-related posts (Table 1). Additionally, after 2017, realization and nervousness were more common for BCS than mastectomy annually. Realization, approval, and caring were the most strongly expressed emotions across both BCS (top decile scores: 0.52, 0.48, and 0.43, respectively) and mastectomy (top decile scores: 0.49, 0.41, and 0.5), with breast conservation being more associated with optimism (top decile score: 0.33).

Discussion

Principal Findings

Building upon past research in sentiment analysis of online discussions about breast cancer [4,5,16], NLP identified differences in social media discussions across BCS and mastectomy, reflecting trends reported clinically. Compared to previous studies [4,5,16] conducting sentiment analyses of online forums discussing cancer, our work focused specifically on surgical management options for patients with breast cancer. Our distinct NLP approaches identified that discussions surrounding mastectomy became increasingly positive over time, corresponding with concordant emotions. These findings are consistent with multiple studies that have found a growing trend of patients with early-stage breast cancer choosing mastectomy over BCS [3,17]. While it is not feasible to determine the reason for the observed increase in positive sentiments for mastectomy mentions based on the data available in this study, it does indicate a parallel with real-world patient decision-making.

Discussion in this breast cancer–specific forum increased substantially over time, confirming that patients are increasingly using social media as a resource. BCS and mastectomy-related posting increased, emphasizing trends in content-specific information. In a recent survey study, patients reported that their cancer diagnosis prompted them to join social media platforms, and over 80% of respondents reported using social media to gather information online [9]. The predominance of objectivity (neutrality emotion) and informative (realization and curiosity) emotions supports these findings.

Evidence surrounding treatment choice for early-stage breast cancer suggests the decision to pursue mastectomy over BCS is often driven by fear of recurrence and secondary cancers [18]. Our application of NLP identifies this in the online setting, with BCS posts more likely to express nervousness. Negative emotions such as anger, annoyance, disappointment, and disgust also became increasingly prevalent over time in BCS posts.

This study is limited by confounders. While VADER and GoEmotions are specifically developed for social media text and based on complementary approaches, they also may reflect inaccuracies and biases based on limitations in their training. Moreover, sentiments cannot be explicitly attributed to the topics themselves, but rather to the paragraphs associated with specific treatments. Nevertheless, these paragraphs likely reflect related discussions around each of these treatments or some aspect of related care.

These findings provide unique insight into patient decision-making. Social media reflects real-time discussions in a natural setting with less filtered discussion of patient concerns and experiences. Recognizing the sentiments and emotions expressed surrounding the treatment, the decision-making process can help clinicians create patient-centric recommendations.

Conclusion

As social media becomes more pervasive, patients are increasingly discussing options for breast cancer therapy online. NLP can characterize these candid online patient discussions at scale and help clinicians identify barriers to treatment decisions and strengthen counseling for patients. Additional studies will be required to see if ongoing social media sentiment trends continue to track patient decisions.

Abstract

Background: Breast cancer is a major health concern in various countries. Routine mammography screening has been shown to reduce breast cancer mortality, and Japan has set national targets to improve screening participation and increase public attention. However, collecting nationwide data on public attention and activity is not easy. Google Trends can reveal changes in societal interest, yet there are no reports on the relationship between internet search volume and nationwide participation rates in Japan.

Objective: This study aims to reveal and discuss the relationship between public awareness and actual behavior in breast cancer screening by examining trends in internet search volume for the keyword “breast cancer screening” and participation rates over a decade-long period.

Methods: This time-series study evaluated the association between internet search volume and breast cancer screening participation behavior among women aged 60 - 69 years in Japan from 2009 to 2019. Relative search volume (RSV) data for the search term “breast cancer screening (nyuugan-kenshin)” were extracted from Google Trends as internet search volume. Breast cancer screening and further assessment participation rates were based on government municipal screening data. Joinpoint regression analyses were conducted with weighted BIC to evaluate the time trends. An ethics review was not required because all data were open.

Results: The RSV for “breast cancer screening (nyuugan-kenshin)” peaked in June 2017 (100) and showed clear spikes in June 2016 (94), September (69), and October (77) 2015. No RSVs above 60 were observed except around these three specific periods, and the average RSV for the entire period was 30.7 (SD 16.2). Two statistically significant joinpoints were detected, rising in December 2013 and falling in June 2017. Screening participation rates showed a temporary increase in 2015 in a slowly decreasing trend, and no joinpoints were detected. Further assessment participation rates showed a temporary spike in 2015 in the middle of an increasing trend, with a statistically significant point of slowing increase detected in 2015. Post hoc manual searches revealed that Japanese celebrities’ breast cancer diagnoses were announced on the relevant dates, and many Japanese media reports were found.

Conclusions: This study found a notable association between internet search activity and celebrity cancer media reports and a temporal association with screening participation in breast cancer screening in Japan. Celebrity cancer media reports triggered internet searches for cancer screening, but this did not lead to long-term changes in screening participation behavior. This finding suggests what information needs to be provided to citizens to encourage participation in screening.

Introduction

Breast cancer is a major health concern that affects large numbers of women in various countries. It is the most common cancer in women, with approximately 2.3 million new cases diagnosed and 680,000 deaths reported in 2020 [1,2]. The disease burden of breast cancer is also high in Japan. The age-adjusted incidence rate of breast cancer continues to increase every year, and it has been reported that breast cancer accounts for about 20% of all cancers in women in Japan [3,4]. As Japan’s

population ages, the burden of breast cancer is predicted to increase [5].

Several studies have indicated the efficacy of mammography screening for breast cancer in reducing the burden of breast cancer. Routine mammography screening has been shown to reduce breast cancer mortality by 25% - 31% [6,7]. The long-term effects of mammography have also been shown in a 30-year follow-up study [8]. In Japan, national policy recommends biennial mammography for breast cancer screening in women older than 40 years [9]. Therefore, screening is a practical approach to reducing the long-term burden of breast cancer, and its importance is increasing in Japan.

Cancer screening programs in Japan are divided into two main types: municipal screening and workplace screening. Municipalities conduct screenings, and information is collected by the Ministry of Health, Labor, and Welfare and made available to the public. This is the only data on cancer screening for all regions in Japan for which the government reports actual statistics annually. This report includes data on screening and further assessment participation. The participation rate is the proportion of the target population that receives the primary screening test, which in the case of breast cancer screening is mammography. The further assessment participation rate is the proportion of women who, after a positive screening test result, receive the following test to confirm the diagnosis: fine needle aspiration cytology or core needle biopsy in breast cancer screening. Even if a person participates in screening, the effectiveness of cancer screening will not be fully realized unless the screening-positive person receives a further assessment. The further assessment participation rate is an important indicator, as is the screening participation rate. Japan has set national targets to improve screening participation, further assessment participation, and increase public attention to the importance of cancer screening [10]. Understanding the public's attention and behavior around cancer screening is critical to improving screening participation rates. However, it is not easy to collect nationwide data on public attention and activity to assess the association with screening participation.

Internet search volume has recently become one of the most valuable tools for exploring human interests and behavior. Google Trends is a popular open web-based tool that quantifies changes in internet search volume for a given term based on actual Google search history [11,12]. Google Trends is used for academic research in fields as diverse as social science, economics, language, and medicine and can also reveal changes in societal interest in public health issues [13]. Google Trends initially focused on detecting infectious disease outbreaks, and past studies have reported early detection of influenza outbreaks [14].

Google Trends is now expected to be used in noncommunicable disease areas such as mental health and preventive behaviors and is a potential source of information for understanding the public's interest in and behaviors around cancer screening [15]. Malaysia reported a significant correlation between Google Trends search patterns and Pink Ribbon Month, a breast cancer awareness campaign [16]. Among several internet search engines, Google was also shown to have the best search validity (regarding whether a web page could be opened) for breast cancer screening information [17]. In contrast, a previous Japanese study analyzed trends in cervical cancer and reported no change in public interest during the cervical cancer awareness month [18].

Therefore, there is considerable interest in the relationship between internet search activity and cancer screening. In Japan, it would be valuable to determine the relationship between public attention to cancer screening and participation rates at the national level to understand public awareness and behavior. However, there are no reports on the relationship between changes in internet search volume and long-term trends in nationwide participation rates in Japan.

This study examined the relationship between public awareness and actual behavior in breast cancer screening at the national level. This study is the first report in Japan to reveal and discuss the background of the relationship between trends in internet search volume for the keyword "breast cancer screening" and participation rates over a decade-long period. As an example of the application of epidemiologic research using internet search volume, this approach could provide knowledge for promoting cancer screening and providing appropriate information.

Methods

Study Design

This time-series study uses internet search volume and national cancer screening statistics. Internet search volume targets those who conducted searches in Japanese using Google in Japan. Cancer screening data targets municipal screening in Japan. Both data are openly available on the web.

Data Sources (Internet Search Volume)

Google Trends is a data tool that publishes the volume of keyword searches worldwide in Google Search, an internet search engine, since 2004. This tool allows users to access the relative search volume (RSV) but not the absolute number of searches. RSV is calculated on a scale of 0 to 100 based on the volume with the most searches per unit of time in the defined region, period, category, and search term. For example, RSV=30 means 30% of the highest search volume observed within a given condition. RSVs can assess changes in interest in a particular term by showing the relative value of search volume trends over time.

The search term was "nyuugan-kenshin," which means "breast cancer screening" in Japanese. Monthly RSV data from the Google Trends platform were retrieved on September 17, 2023. Since the Japanese term "nyuugan-kenshin" is written as one continuous word without any spaces, we did not enclose it in quotes when using it in Google Trends. Because Google Trends does not provide a "Topic" option for the Japanese term "nyuugan-kenshin," we used the "Search Term" option instead. It was set to Japan as the target region and 2009 - 2019 as the target period. To ensure that all possible contexts in which the term might appear were captured, we set "All categories" as the "Category" and "Web Search" as the "Search Type."

If a significant trend increase was observed, a post hoc manual search was conducted using the "Related Keywords" feature of Google Trends to see if any socially essential media reports might be related to the increase.

Data Sources (Cancer Screening)

For cancer screening, this study included screening participation rates and further assessment participation rates in municipal screening for breast cancer in Japan from 2009 to 2019. Municipal screening does not include individuals who participate in workplace screening. Consequently, when calculating screening participation rates for ages 40 years and older using the population as the denominator, workplace screening participants are excluded from the numerator. This omission can lead to fluctuations in time-series data, for example, if there is a change over time in the proportion of working individuals. Furthermore, when participation rates differ by age group, they are also affected by changes in the age distribution over time. To eliminate this effect as much as possible and to improve the time-series analysis's validity, the calculation of participation rates was restricted to women aged 60 - 69, who are mainly retired. The number of participants in screening, positive cases in screening, and further assessment participants were obtained from the "Report on Regional Public Health Services and Health Promotion Services" by the Ministry of Health, Labor, and Welfare [19]. Population data were obtained from the Statistics Bureau of the Ministry of Internal Affairs and Communications [20]. Screening participation rates were calculated by dividing the number of screening participants by the population of women in the target age group. The further assessment participation rates were calculated by dividing the number of further assessment participants by the number of positive screening cases. The recommended interval for breast cancer screening in Japan is once every two years, and the original "screening participation rates" are calculated by considering the number of participants screened for two years. However, this calculation method equalizes two years of information and may not detect sensitive value changes. As this study aimed to detect changes over time rather than absolute assessments, "screening participation rates" were defined as calculated values per one-year period and used in the analyses.

Statistical Analysis

Joinpoint regression analyses were performed to assess RSV trends quantitatively. This analysis is an appropriate way to examine data over time and statistically detect points of change in gradient [21]. The software used was the Joinpoint Regression Program (version 5.0.2, Statistical Research and Applications Branch, National Cancer Institute) [22]. The statistical method used for joinpoint detection was weighted BIC, a standard method in Program version 5.0 and later. Weighted BIC is the most flexible and adaptable method for various situations in this software. Joinpoint regression analysis requires many computing resources, and the calculation time depends on the maximum number of detectable joinpoints set before the calculation. This analysis's maximum number of joinpoints was set to 3 due to calculation time. Changing the maximum number of joinpoints can alter the significance level for individual tests and potentially change the number of joinpoints in the optimal model [22]. When no joinpoints were detected in the initial analysis, we conducted additional analyses with the maximum number set to two and one. The statistical significance level for joinpoint detection was set to 0.05.

Ethical Considerations

This study was conducted per the principles of the Declaration of Helsinki. An ethics review was not required because all data used in this study were open. For this type of study, formal consent is not required.

Results

Internet Search Volume

Figure 1 shows the trend of RSVs for the search term "breast cancer screening (nyuugan-kenshin)" from 2009 to 2019. The RSV peaked in June 2017 (100) and showed clear spikes in June 2016 (94), September 2015 (69), and October 2015 (77). No RSVs above 60 were observed except around these three specific periods. The average RSV for the entire period was 30.7 (SD 16.2). Figure 2 shows the results of the joinpoint regression analysis for RSVs. Two statistically significant joinpoints were detected, rising in December 2013 and falling in June 2017.

Figure 1. Monthly “breast cancer screening (nyuugan-kenshin)” relative search volumes in Japan from 2009 to 2019, based on Google Trends. The black arrows show the timing of media reports on the celebrities’ breast cancer diagnoses or passing.

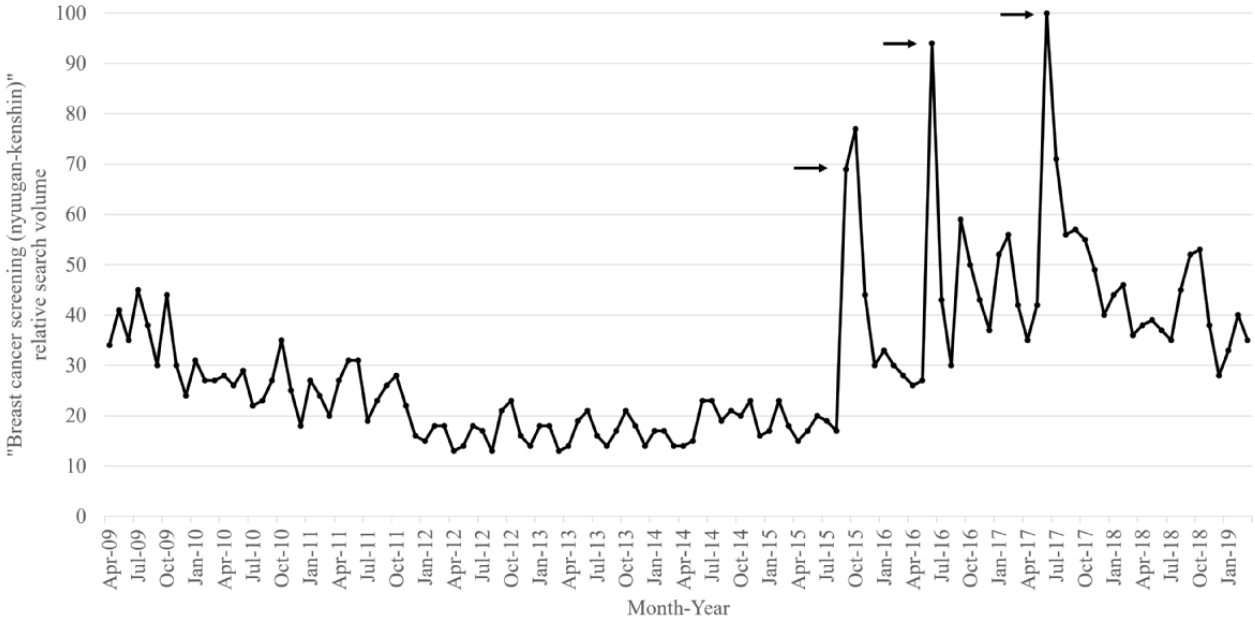

Figure 2. Joinpoint regression analysis of the monthly “breast cancer screening (nyuugan-kenshin)” relative search volumes in Japan from 2009 to 2019. Two significant joinpoints were detected (December 2013 and June 2017). The black arrows show the timing of media reports on the celebrities’ breast cancer diagnoses or passing.

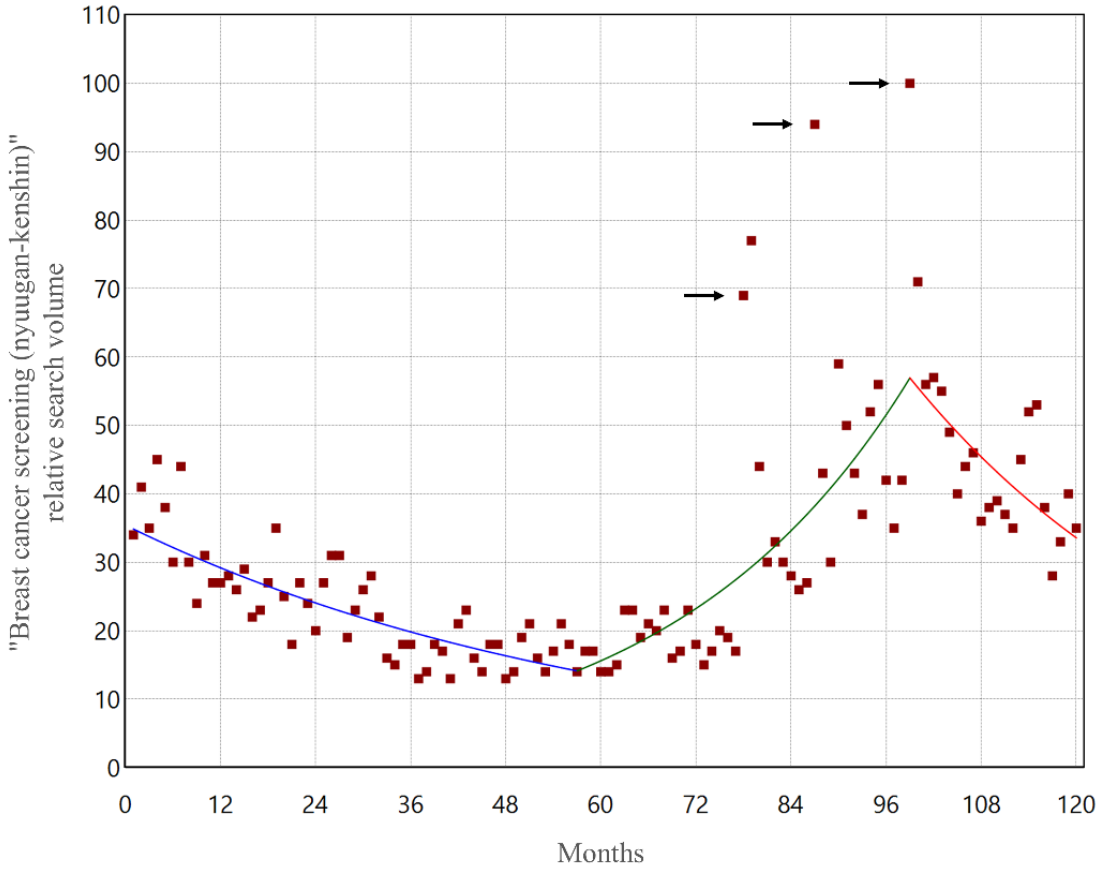

Cancer Screening Participation

Figure 3 shows the trend of breast cancer screening participation rates from 2009 to 2019. Visual observation shows a temporary increase in 2015 in the slowly decreasing trend. Figure 4 shows the results of the joinpoint analysis for screening participation rates. No joinpoints were detected. Even in additional analyses with the maximum number set to two or one, no joinpoints were detected.

Figure 3. Annual breast cancer screening participation rates (mammography) among Japanese women aged 60 - 69 years from 2009 to 2019, based on municipal screening data. The rate is the proportion of screening participants in the target population.

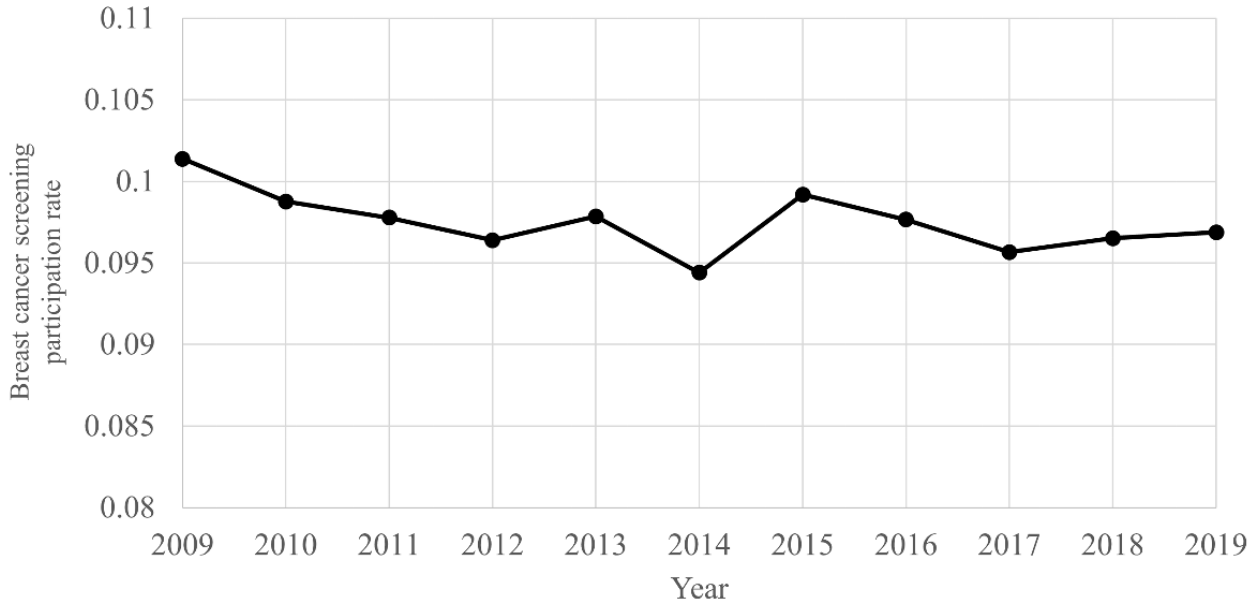

Figure 4. Joinpoint regression analysis of the annual breast cancer screening participation rates (mammography) among Japanese women aged 60 - 69 years from 2009 to 2019. No joinpoints were detected.

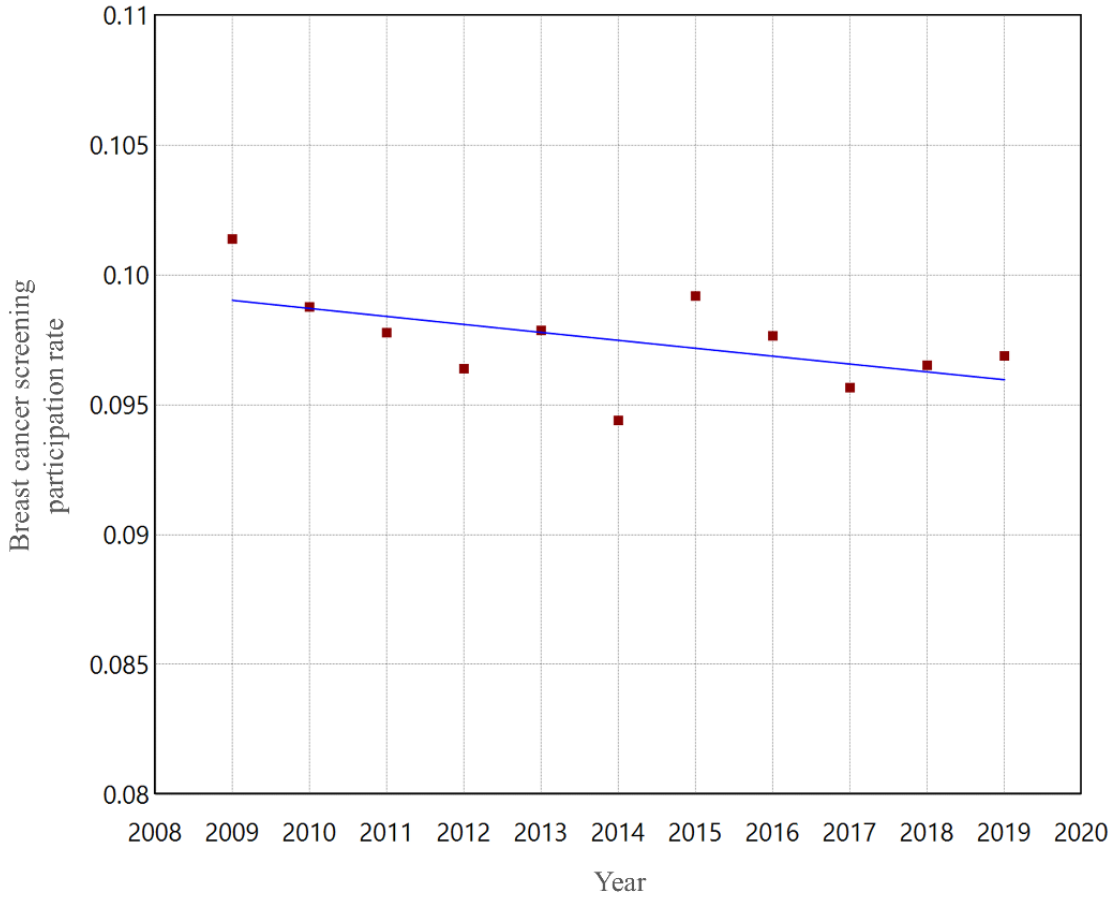

Figure 5 shows the trend of further assessment participation rates for breast cancer screening from 2009 to 2019. Visual observation shows a temporary spike in 2015 in the middle of an increasing trend. Figure 6 shows the result of the joinpoint analysis for further assessment participation rates. While the trend has been increasing for the entire period, a statistically significant point of slowing increase was detected in 2015. The year 2015 was the maximum for screening and further assessment participation rates, except for 2009 and 2019, the two ends of the period covered.

Figure 5. Annual breast cancer screening further assessment participation rates among Japanese women aged 60 - 69 years from 2009 to 2019, based on municipal screening data. The rate is the proportion of women who received fine needle aspiration cytology or core needle biopsy following a positive screening result.

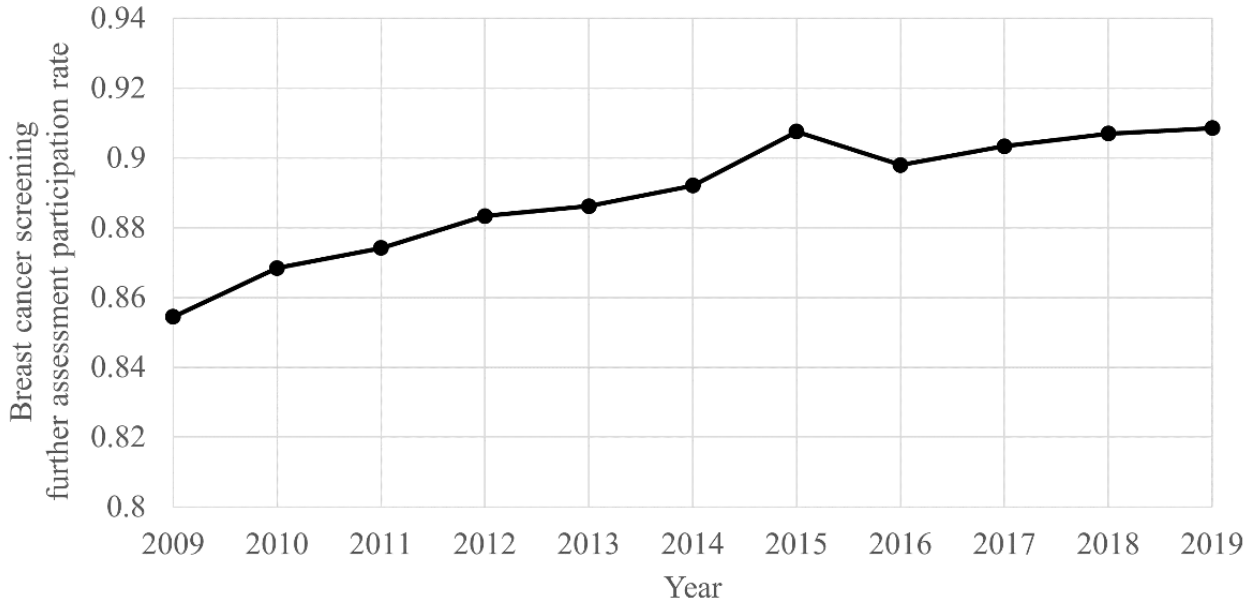

Figure 6. Joinpoint regression analysis of the annual breast cancer screening further assessment participation rates among Japanese women aged 60 - 69 years from 2009 to 2019. One significant joinpoint was detected in 2015.

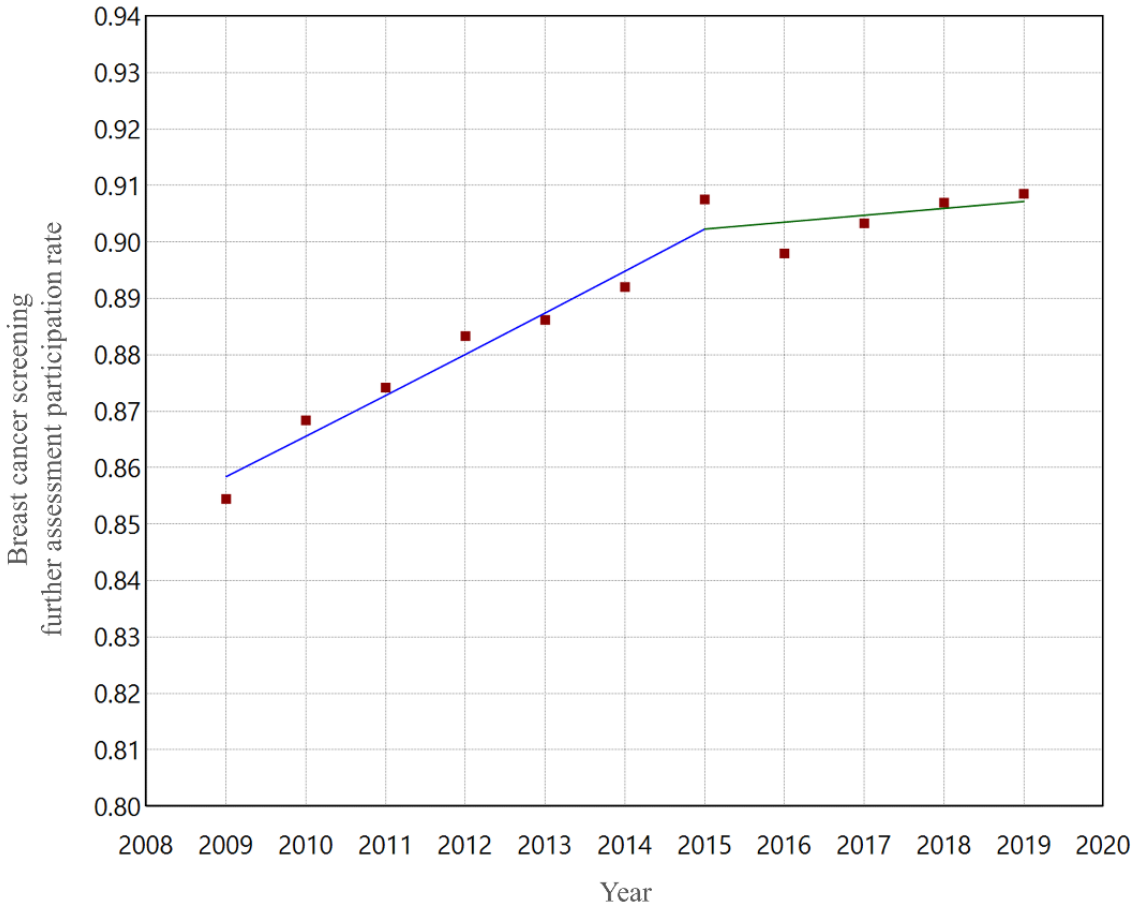

Post Hoc Manual Search

When RSV spiked in 2015, 2016, and 2017, three periods were explored post hoc. A detailed review of the RSV data downloaded from Google Trends, restricting the period specified, revealed a notable spike on September 23 and 24, 2015, June 9, 2016, and June 23, 2017. The day's news and Google Trends "Related Keywords" were manually searched for these three periods. For the term "nyuugan-kenshin," only general keywords such as "examination," "cost," "mammography," "breastfeeding," and "symptoms" were suggested on each of the relevant dates. In contrast, as "Related Keywords" for "nyuugan (breast cancer)" on September 23 and 24, 2015, a Japanese celebrity, AH, was suggested as a nonmedical term. A Google search limited to the same period revealed that her breast cancer incidence was announced on September 23, 2015, and many Japanese media reports were found. In the same way, the Japanese celebrity MK's breast cancer incidence was announced on June 9, 2016, and her passing on June 23, 2017, confirmed many media reports.

Discussion

General Interpretation of the Results

We conducted a time-series study for 2009 - 2019 on Japanese internet search volume and breast cancer screening data for 60 - 69-year-olds. Internet search RSVs for "breast cancer screening" spiked notably in three specific periods in September 2015, June 2016, and June 2017. The joinpoint analysis for RSVs revealed two joinpoints in December 2013 and June 2017, showing an increase over the period, including the spikes mentioned above. The 10-year trend in internet searches for breast cancer screening was dynamically changing, down, up, and down. The joinpoint of screening data was not detected for screening participation rates but was detected in 2015 for further assessment. Upon examination of Figure 5, it might be reasonable to interpret this as a temporary increase in 2015 and a return to the original trend from 2016 onwards. Indeed, the screening and further assessment participation rates reached their maximum in 2015, except for 2009 and 2019, the two ends of the period covered. A post hoc search for the timing of the three RSV spikes from 2015 to 2017 was consistent with the dates of media reports of breast cancer incidences and the passing of Japanese celebrities.

It is worth noting that 2015 marked the timing of the first media reports on celebrities, the first notable increase in RSVs, and the short-term maximum in the screening and further assessment participation rates. In particular, the consistency of the three dates between celebrity media reports and search trends is evident. RSV provided by Google Trends is not an absolute number of searches but a relative measure of the maximum number of searches scaled to 100 within a defined period. Therefore, if there is even one moment of drastic increase in search, RSV for the rest of the period will be relatively low. The fact that the average volume for the entire period in this analysis was 30.7 (SD 16.2) highlights the magnitude of the three spikes. Many individuals became interested in breast cancer screening when AH and MK were featured in the media, which probably triggered internet search behavior. Additionally, screening and further assessment participation rates increased temporarily in 2015, suggesting some individuals may have engaged in screening participation behaviors. Celebrity media reports may have influenced individuals, leading to search and screening participation behavior. This contrasts with a previous Japanese study that showed no association between cervical cancer awareness months and RSVs for "cervical cancer" [18].

However, screening and further assessment participation rates showed only a temporary spike in 2015 and did not increase the long-term trend. RSVs also declined after the 2017 joinpoint. These findings provide insight into the mechanisms necessary for citizens to be concerned about, act on, and maintain their health. To interpret this study's results, referring to the findings of established behavioral models and previous studies would be appropriate.

Interpretation Based on the Health Belief Model

Participation behavior in cancer screening has been a critical subject of study in the Health Belief Model (HBM). HBM is a theoretical model in the behavioral sciences that aims to explain, predict, and promote individual health behaviors. This model was developed in the 1950s to understand the factors determining participation in immunization and screening [23-25]. HBM considers that individual health behaviors are determined by the interaction of six factors: "perceived susceptibility," "perceived severity," "perceived benefits," "perceived barriers," "self-efficacy," and "cues to action." The model is widely used to design education and promotion programs for health activities. In cancer screening, the model has been primarily used to improve participation in colorectal cancer screening and has been validated in several randomized controlled trials [26,27]. Recently, there has been much research on breast cancer screening [28-33].

It would be meaningful to interpret the results of this study based on HBM. In the media reports, AH was 48 years old, and MK was 32 when they were diagnosed. Consecutive media reports of breast cancer in young celebrities may have caused "perceived susceptibility" among the public. MK passed away about a year after her diagnosis was announced. The sad outcome of the celebrity, which had been worrying through media reports, would have caused "perceived severity" for the public. Indeed, the RSV peaked on June 23, 2017, when MK's passing was announced. MK's weblog about her fight against breast cancer has attracted attention in Japan and around the world, and she was named one of the BBC's 100 Women of the Year in 2016 [34,35]. Citizen exposure to a series of media reports may have fulfilled these elements in the HBM. Additionally, for those who were already aware of "susceptibility" and "severity," media reports on the cancer of celebrities may have become "cues to action" to help them take action.

There have been several reports on the impact of celebrity cancer media reports on the behavior of citizens [36,37]. In Australia, mammography screening appointments increased by 40% in the two weeks following media reports of singer Kylie Minogue's breast cancer diagnosis [38]. In the United States, Angelina Jolie's decision to share her experience with the increased risk of breast and ovarian cancer due to BRCA1 gene

mutations has improved public awareness of the disease and increased genetic testing and breast cancer screening. In particular, Angelina Jolie's influence was reported to be related to "perceived susceptibility" and "cues to action," which are elements of HBM [39,40].

These reports illustrate the appropriateness of interpreting the impact of personal cancer experiences and narratives on people's emotions and behaviors based on the HBM. The findings on these effects support the validity of the interpretation that the two celebrities' media reports were elements of "perceived susceptibility," "perceived susceptibility," and "cues to action" in the HBM.

Importance of Removing Barriers

Conversely, information that provides "perceived benefits" or "self-efficacy" for screening or removes "perceived barriers" is not directly included in the celebrity cancer media reports. In contrast to the case of Angelina Jolie, where there is a direct link between her actions and the benefits of preventive behavior, there is a gap in logic between media reports of celebrity breast cancer and the benefits of screening participation. For internet users, there are few barriers to search action. However, there are significant barriers to screening participation on an entirely different level than internet searches. To participate in screening, citizens must confirm the possible dates, times, locations, and costs, make an appointment, and go to mass screening sites or hospitals. Media reports and internet search activity showed a direct relationship, while screening participation behavior showed a limited response. This suggests that information from media reports and internet searches did not remove barriers to screening participation. Some citizens who participated in screenings triggered by the media reports may not have continued to behave because they were unaware of the benefits. This finding of limited participation versus notable search activity highlights the importance of removing "perceived barriers" in the HBM component. This study's post hoc manual search was limited to breast cancer information for 10 years. In today's Japan, where approximately half of the population will be diagnosed with some form of cancer in their lifetime, media reports on celebrities provide citizens with many opportunities to perceive the susceptibility and severity of cancer. Nonetheless, information to remove barriers does not occur unless someone intends it. The importance of "perceived barriers" in HBM elements has long been recognized [41]. A meta-analysis of 18 communication campaigns shows that "perceived benefits" and "perceived barriers" were consistently the most robust predictors [42]. This study supports the idea that removing barriers is an essential public action to encourage healthy behaviors.

Limitations and Strengths of This Study

There are several limitations to this study. First, there is a restriction due to the time-series analysis design. It is unknown whether specific individuals were exposed to media reports, performed search actions, or participated in screening because this is a comparison through time for the whole population. It is important to note that the results indicate only an association, and do not necessarily imply a causal relationship among celebrity news, search spikes, and screening uptake. Various real-world factors, such as concurrent public health campaigns or medical policies, could have influenced the keyword search volume, the screening participation rate, or both. Even if there is a match between exposure and outcome for an individual, it does not prove causation because confounding by unknown factors cannot be ruled out. Given this study's data sources and design, directly evaluating causality is complex and remains an issue for future research.

Second, there is a lack of data on workplace screening. Japan's cancer screening programs are divided into municipal screening and workplace screening. Due to incomplete legislation on workplace screening, data have not been collected and published for the entire country, and it was necessary to use only municipal screening data. In this study, to remove the effect of the lack of workplace screening data as much as possible, the age range for calculating participation rates was restricted to 60 - 69 years so that retirees would represent most of the population. Due to this restriction, the generalizability of the screening data is limited. In the future, once workplace screening data becomes available, it will be necessary to include those data in the analysis to more accurately evaluate trends in screening participation rates among the working population.

Third, the coverage of Google Trends data. Given that the RSV is based on Google search data, it does not reflect the interests of populations that do not use Google or internet search. The percentage of Japanese aged 60 - 69 years using the internet increased from 71.6% (60-64) and 58% (65-69) in 2009 to 90.5% (60-69) in 2019 [43]. This percentage and time change may have affected the results. Even if internet use was high enough in the age group 60s, RSV is an indicator that includes all ages and does not necessarily reflect search activity in the 60s. Furthermore, even if they use internet search, they may use a search engine other than Google. As of 2019, Google accounted for 92% of the global market share for internet search engines, 93% in Europe and 89% in North America, whereas in Japan, it was 75% [44]. While there is no doubt that Google holds the top market share in Japan, unlike Baidu in China or Yandex in Russia, its relatively lower share compared to Western regions could influence the validity of Google Trends data [45]. Further, an absolute assessment is impossible since RSV is a relative measure for a given period and search term.

Fourth, some of the methods and interpretations of this study were post hoc. In the analysis phase of this study, we found a marked increase in the RSV data for the keyword "breast cancer screening" in three specific periods. To explore background information, we performed a post hoc manual search and found that the media reports of the celebrity matched the RSV spikes. This manual search was not planned at the time the study was designed. Because these manual searches and discussions involve the arbitrariness of the researcher, careful attention should be paid to the validity of the interpretation of the results.

Furthermore, one possible reason that no joinpoints were detected for screening participation rates is that the limited number of data points may not have provided sufficient statistical power. To analyze one or more joinpoints, at least seven data points need to be observed [22]. Although this study had 11 data points for both screening and further assessment

participation rates, exceeding seven, the number of data points may still have been insufficient for detecting any joinpoints.

Despite these limitations, there are strengths to this study. Google Trends, an internet search volume, is a limited source of information that directly reflects changes in the preferences and interests of the entire population over time. Media reports related to changes in internet search volume will be revealed after data analysis. Therefore, the type of study that follows participants prospectively cannot discuss what this study did. Retrospective studies that question about past exposures may cause recall or information bias due to the validity of the questionnaire. Internet search volume has none of these biases and selection biases for study enrollment, so it directly reflects citizens' actual preferences. The screening data also have no self-reporting bias because they are actual values reported to the government by municipalities. This study design is conducive to exploring what influences public interest in cancer screening and leads to participation behavior.

Practical Considerations and Future Implications

We found that internet search volume for "breast cancer screening" was notably associated with media reports of the celebrity's cancer and was temporally associated with participation in screening. Although caution is needed in interpreting causal relationships, it is worth noting that the three periods in which the spike in internet search volume occurred match the media reports of the celebrities. It is reasonable to assume that media reports clearly impacted search activity. The results also showed barriers to screening participation and limitations to explaining behavior only by internet search volume. Established "model" and "effect" in behavioral medicine could describe these associations and limitations. Importantly, pragmatic data without educational intervention or questionnaire surveys supported these effects. This finding suggests that internet search volume is valuable for deciphering individuals' behavior. Internet search volume can also help verify the effectiveness of efficacy findings confirmed by exploratory methods, such as intervention trials, with real-world data. Although it is essential to evaluate various potential biases in internet search volume, with an understanding of its limitations, using it for epidemiologic studies will continue to be beneficial and may suggest improvements in public health policy and risk communication.

Conclusions

The public impact of celebrity cancer media reports found in this study will lead to the development of information and awareness methods to improve and sustain participation in cancer screening. A colorectal cancer awareness campaign conducted on television by Katie Couric, a well-known American television anchor, was associated with an increase in colonoscopy use [46]. The results of this study support the potential for such celebrity publicity for preventive health programs to be temporarily effective in Japan. If doing so, information on removing barriers should be included to maximize and sustain the effect.

Abstract

Background: Breast cancer is prevalent among females in the United States. Nonmetastatic disease is treated by partial or complete mastectomy procedures. However, the rates of those procedures vary across practices. Generating real-world evidence on breast cancer surgery could lead to improved and consistent practices. We investigated the quality of data from the *All of Us* Research Program, which is a precision medicine initiative that collected real-world electronic health care data from different sites in the United States both retrospectively and prospectively to participant enrollment.

Objective: The paper aims to determine whether *All of Us* data are fit for use in generating real-world evidence on mastectomy procedures.

Methods: Our mastectomy phenotype consisted of adult female participants who had CPT4 (Current Procedural Terminology 4), *ICD-9* (*International Classification of Diseases, Ninth Revision*) procedure, or SNOMED (Systematized Nomenclature of Medicine) codes for a partial or complete mastectomy procedure that mapped to Observational Medical Outcomes Partnership Common Data Model concepts. We evaluated the phenotype with a data quality dimensions (DQD) framework that consisted of 5 elements: conformance, completeness, concordance, plausibility, and temporality. Also, we applied a previously developed DQD checklist to evaluate concept selection, internal verification, and external validation for each dimension. We compared the DQD of our cohort to a control group of adult women who did not have a mastectomy procedure. Our subgroup analysis compared partial to complete mastectomy procedure phenotypes.

Results: There were 4175 female participants aged 18 years or older in the partial or complete mastectomy cohort, and 168,226 participants in the control cohort. The geospatial distribution of our cohort varied across states. For example, our cohort consisted of 835 (20%) participants from Massachusetts, but multiple other states contributed fewer than 20 participants. We compared the sociodemographic characteristics of the partial (n=2607) and complete (n=1568) mastectomy subgroups. Those groups differed in the distribution of age at procedure (P<.001), education (P=.02), and income (P=.03) levels, as per χ^2 analysis. A total of 367 (9.9%) participants in our cohort had overlapping CPT4 and SNOMED codes for a mastectomy, and 63 (1.5%) had overlapping *ICD-9* procedure and SNOMED codes. The prevalence of breast cancer–related concepts was higher in our cohort compared to the control group (P<.001). In both the partial and complete mastectomy subgroups, the correlations among concepts were consistent with the clinical management of breast cancer. The median time between biopsy and mastectomy was 5.5 (IQR 3.5-11.2) weeks. Although we did not have external benchmark comparisons, we were able to evaluate concept selection and internal verification for all domains.

Conclusions: Our data quality framework was implemented successfully on a mastectomy phenotype. Our systematic approach identified data missingness. Moreover, the framework allowed us to differentiate breast-conserving therapy and complete mastectomy subgroups in the *All of Us* data.

Introduction

Breast cancer is one of the most common forms of cancer in females worldwide and has a lifetime prevalence of 13%. The incidence in the United States is estimated to be greater than 297,000 women annually and increases with patient age [1,2]. In addition to patient age, breast cancer risk factors include BMI, early age of menarche, late age of menopause, family history or genetic risk, and environmental exposures [3].

Nonmetastatic breast cancer is treated surgically, and approximately 30% of patients have a complete mastectomy. An alternative to a complete mastectomy is breast-conserving therapy (BCT), which consists of breast-conserving surgery and radiation therapy [4]. In multiple randomized controlled trials, BCT has been shown to have similar long-term disease-free survival to a complete mastectomy [5-8].

A recent systematic review found that patients' choice of surgical treatment was multifaceted. Some factors that were associated with patients choosing a mastectomy over BCT were related to tumor characteristics and pathology. Others were sociodemographic or individual belief factors, such as body image, aversion to radiation, and physician preference [9]. In a prospective study of 180 patients, surgeons' preference was the strongest predictor of surgical treatment [10]. Accordingly, there is a need to compare a complete mastectomy to a partial mastectomy, the surgical component of BCT that encompasses lumpectomy, quadrantectomy, and other BCT-related surgical interventions.

We believe that a robust characterization of partial and complete mastectomy patients with data from the *All of Us* Research Program could generate valuable real-world evidence regarding breast cancer treatment and be used to provide evidence towards best practices for patients with the disease. The *All of Us* Research Program has electronic health records (EHRs) on more than 287,000 patients from 50 health care organizations within the United States. The program does targeted enrollment of groups that are underrepresented in biomedical research. Because the *All of Us* Research Program is one of the most comprehensive and diverse observational health care databases worldwide, those findings would represent real-world data associated with partial or complete mastectomy procedures [11].

Accordingly, to date, we are unaware of a study assessing the fitness for the use of *All of Us* and focusing on mastectomy as a treatment modality. Accordingly, the primary objective of this study is to determine whether the *All of Us* data are fit for an analysis of women who had a mastectomy.

Methods

Observational Medical Outcomes Partnership Common Data Model

The Observational Medical Outcomes Partnership Common Data Model (OMOP CDM) is the data standard used by the *All of Us* Research Program. The OMOP CDM consists of standardized concepts and relationships, allowing for harmonizing data from different sources. OMOP CDM concepts use codes from structured medical terminologies as the source (eg, CPT4 [Current Procedural Terminology 4], *ICD-9* [*International Classification of Diseases, Ninth Revision*], and LOINC [Logical Observation Identifiers Names and Codes]). The schema consists of standardized concept relationships across data tables [12-14].

We created partial and complete mastectomy phenotypes by manual selection. First, we selected CPT4, *ICD-9* procedure, and SNOMED (Systematized Nomenclature of Medicine) codes for those procedures manually. We chose CPT4, *ICD-9* procedure, and SNOMED source codes because these are the standards that are used by the OMOP CDM. Then, we searched ATHENA for the corresponding OMOP CDM concepts [15]. The partial and complete mastectomy OMOP CDM concept sets were the basis for our phenotype queries. Additionally, we restricted the phenotype to the earliest occurrence of a procedure and to female participants who were at least 18 years or older at the time of the procedure.

Primary Outcomes and Variables

Overview

We developed a data quality dimensions (DQD) framework and evaluation matrix that was adapted from Kahn et al [16]. The framework comprises 5 mutually exclusive and parsimonious dimensions that can be operationalized and applied to a mastectomy cohort as primary outcome variables: conformance, completeness, concordance, plausibility, and temporality. A prior study applied these dimensions to a ductal carcinoma in situ cohort data quality analysis [17].

DQD Framework

Concomitantly, we evaluated the application of the DQD framework to a mastectomy cohort. Each framework element was evaluated with respect to concept selection, internal verification, and external validation. The overarching principles of assessing the DQD include internal characteristics, described by Kahn et al [16] as verification; comparing external benchmarks as validation; and applying descriptive, inferential, and agreement statistics and data visualization. In practice, a researcher would decide whether the data associated with their constructed cohort meets their expectations for fitness of use based on the rating matrix [18]. For the DQD analysis, we selected OMOP CDM concepts related to risk factors and the medical management of breast cancer. Specifically, we included concepts that included but were not limited to breast cancer diagnoses, breast biopsies, screening and diagnostic breast imaging, endocrine therapy, anti–human epidermal growth factor receptor 2 (anti-HER2) therapy, tyrosine kinase inhibitors, chemotherapy, radiation therapy, laboratory measurements, and genetic risk factors [19,20]. Many of our codes had been validated in a prior ductal carcinoma in situ study [17]. Furthermore, a surgical oncologist (SLG) reviewed those codes, confirmed their appropriateness, and recommended additional codes for our analysis. Representative codes are shown in the supplemental appendix (Tables S1-S8 in Multimedia Appendix 1).

Sociodemographic Characterization and Geospatial Analysis

We characterized the geospatial distribution of the mastectomy cohort participants based on state address at the time of enrollment. Also, we characterized the mastectomy cohort, the partial and complete mastectomy subgroups, and control cohort according to sex at birth, race or ethnicity, age group, education, and income.

Analysis

All of Us participants enrolled between May 6, 2017, and July 1, 2022, provided consent to participate and had the option to authorize sharing of their EHRs. Upon enrollment, participants were required to fill out a basic self-reported survey, which includes information on sociodemographic characteristics, and could also consent to have additional data submitted to the program, including data from biospecimens, genomic sequences, and wearable data. All analyses presented in this paper used the *All of Us* Controlled Tier Dataset v7, released on April 20, 2023. The source data were formatted to be compatible with OMOP CDM (version 5.3.1) [21]. Additionally, the data curation team modified some of the drug table schemas for optimal use with *All of Us* data. Accordingly, we modified our queries to maximize the capture of drug exposure data. Missing data were not included in the analysis and we did not make statistical adjustments for missingness.

All programming and statistical analyses were performed in Python (version 3.7.12) and were implemented in a Jupyter Notebook (version 6.5.4). We used chi-squared statistics to test for independent association, Spearman coefficients to measure bivariate correlations, and data visualization to explore the application of the DQD. The level of significant differences was set at $P<.05$.

Ethical Considerations

The *All of Us* Research Program complies with multiple ethical considerations. First, it has an institutional review board (IRB) that reviews the protocol, informed consent, and other participant-facing materials for the *All of Us* Research Program. The IRB follows the regulations and guidance of the Office for Human Research Protections for all studies [22]. The *All of Us* IRB determined that the data that were used in this analysis were considered non–human subjects' research. Second, participants are provided with information on how the program operates, reasonable expectations, and participants' rights. Participants who agree to enroll sign consent forms [23]. Third, *All of Us* participants' data are removed of identifiers and coded to protect their privacy before they are made available to researchers. Reidentification or recontacting of participants is prohibited, and governance mechanisms ensure protection against reidentification or recontact of participants [24]. Fourth, *All of Us* participants who give blood, saliva, or urine samples receive a one-time compensation of US $25 [25]. Otherwise, no direct compensation is provided. Fifth, this paper is not focused on imaging, and thus we have not included any images in the supplemental material. In addition, we censor counts that are less than or equal to 20 to comply with program requirements for minimizing disclosure risk. Data and code used in this study are available as a featured workspace to registered researchers of the *All of Us* Researcher Workbench [26].

Results

Sample

In the *All of Us* database, 249,565 participants consented to participate in the study, were at least 18 years old, and selected assigned as female at birth in the *All of Us* "Basics" self-reported questionnaire. Of those, 172,401 (69%) signed an authorization to share clinical data and had at least one data record in a participating EHR. We created a cohort of 4175 (2.4%) patients with mastectomy procedures and a control cohort of 168,226 (97.6%) female participants who did not have a mastectomy. Out of the 4175 female participants who had mastectomy procedures, 316 (7.6%) had both partial and complete mastectomy procedures. The first occurrence of the procedure code was used for subgroup assignment.

We plotted the mastectomy (partial or complete) cohort's geospatial distribution to assess whether our cohort was distributed equally across the United States (Figure 1). A total of 835 (20%) participants of our cohort had medical records from Massachusetts, 656 (15.7%) from Arizona, 547 (13.1%) from Wisconsin, 468 (11.2%) from California, 386 (9.3%) from New York, 369 (8.8%) from Illinois, 245 (5.9%) from Florida, and 197 (5.9%) from Michigan. Many states had mastectomy cases for fewer than 20 participants in our cohort and were not reported due to disclosure risk guidelines.

Figure 1. Geospatial analysis of a mastectomy cohort (partial or complete). States with a white-gray fill color contributed no participants to the cohort. Data source: The *All of Us* research program.

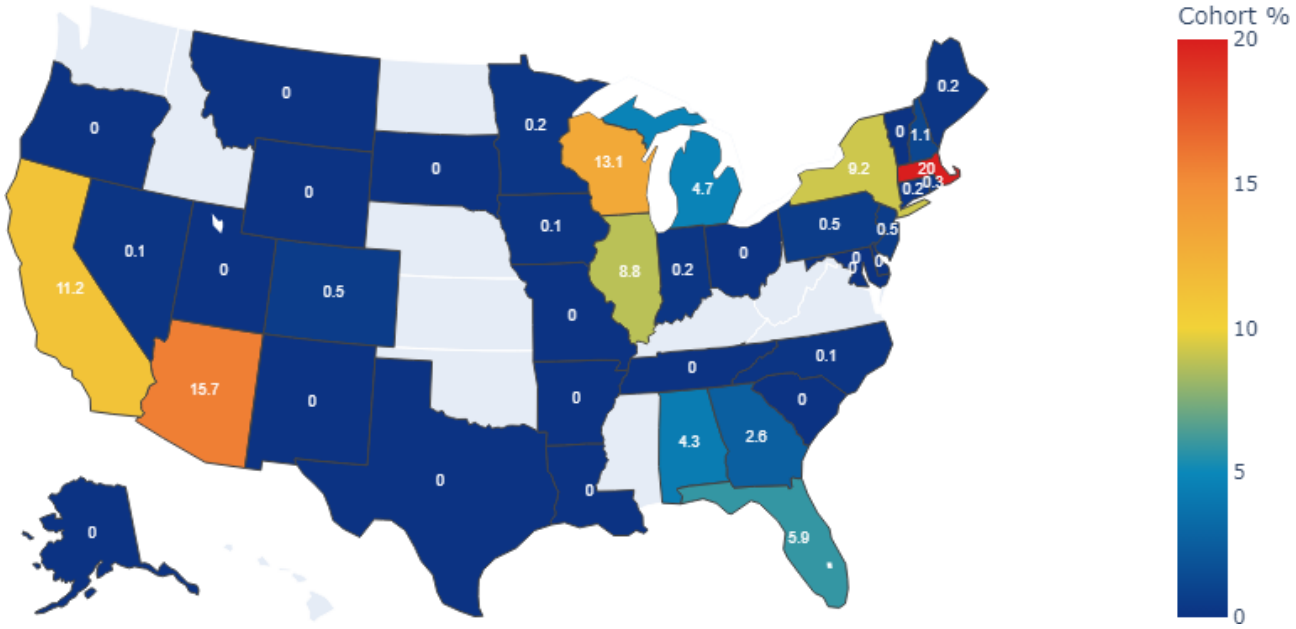

Table 1 provides a breakdown of the cohort by sex at birth, race or ethnicity, age group, education, and income by partial (n=2607) and complete (n=1568) mastectomy. Among the participants who underwent partial or complete mastectomy, the majority were white (66.9% and 70.4%, respectively), with procedures peaking between 40 and 79 years (89.5% and 82.6%, respectively), differ in achieving college or higher degree (52.2% and 58%, respectively), and household income greater or equal to 100k (27% and 32.3%, respectively). A similar sociodemographic comparison was performed for the mastectomy cohort and the control group (Table S8 in Multimedia Appendix 1).

Table . Sociodemographic characteristics of *All of Us* partial and complete mastectomy cohorts.

Demographic category	Partial mastectomy, n (%)	Complete mastectomy, n (%)	*P* value
Assigned sex at birth			—[a]
Female	2607 (100)	1568 (100)	
Race or ethnicity[b]			.14

[a]Not applicable.

[b]More than one race or ethnicity category could have been selected.

[c]GED: General Educational Development.

Conformance

Data elements can be assessed according to standards. The *All of Us* Program uses SNOMED as a standard vocabulary. We created a butterfly plot to determine the overlap between CPT4, *ICD-9* procedure, and SNOMED procedure codes, as shown in Figure 2. Of the 4175 female participants in our cohort, 3376 (80.9%) had CPT4 codes only, 313 (7.5%) had both CPT4 and SNOMED codes, 176 (3.2%) had CPT4 and *ICD-9* procedure codes, and 63 (1.5%) had *ICD-9* procedure and SNOMED codes. A total of 54 (1.3%) female participants had overlapping CPT4, SNOMED, and *ICD-9* procedure codes (Figure 2). Thus, the overlap among standards was low.

To characterize the source data variance in the standards, we calculated the counts of the partial or complete mastectomy CPT4 codes in our cohort (Table 2). Of the 50 EHR-contributing *All of Us* sites, 24 reported mastectomy CPT4 codes. CPT4 code 19301 ("mastectomy, partial") was reported the most frequently by every site that contributed data to our cohort. The sets of distinct CPT4 codes that each site reported varied substantially, with the median site using 6 different CPT4 codes. We used data from within our cohort to verify conformance. However, we did not validate this dimension against an external benchmark because one was not available.

Figure 2. The butterfly plot of CPT4 (left), SNOMED (top right), and *ICD-9* (bottom right) mastectomy procedure codes. CPT4: Current Procedural Terminology 4; *ICD-9*: *International Classification of Diseases, Ninth Revision*; SNOMED: Systematized Nomenclature of Medicine. Data source: The *All of Us* research program.

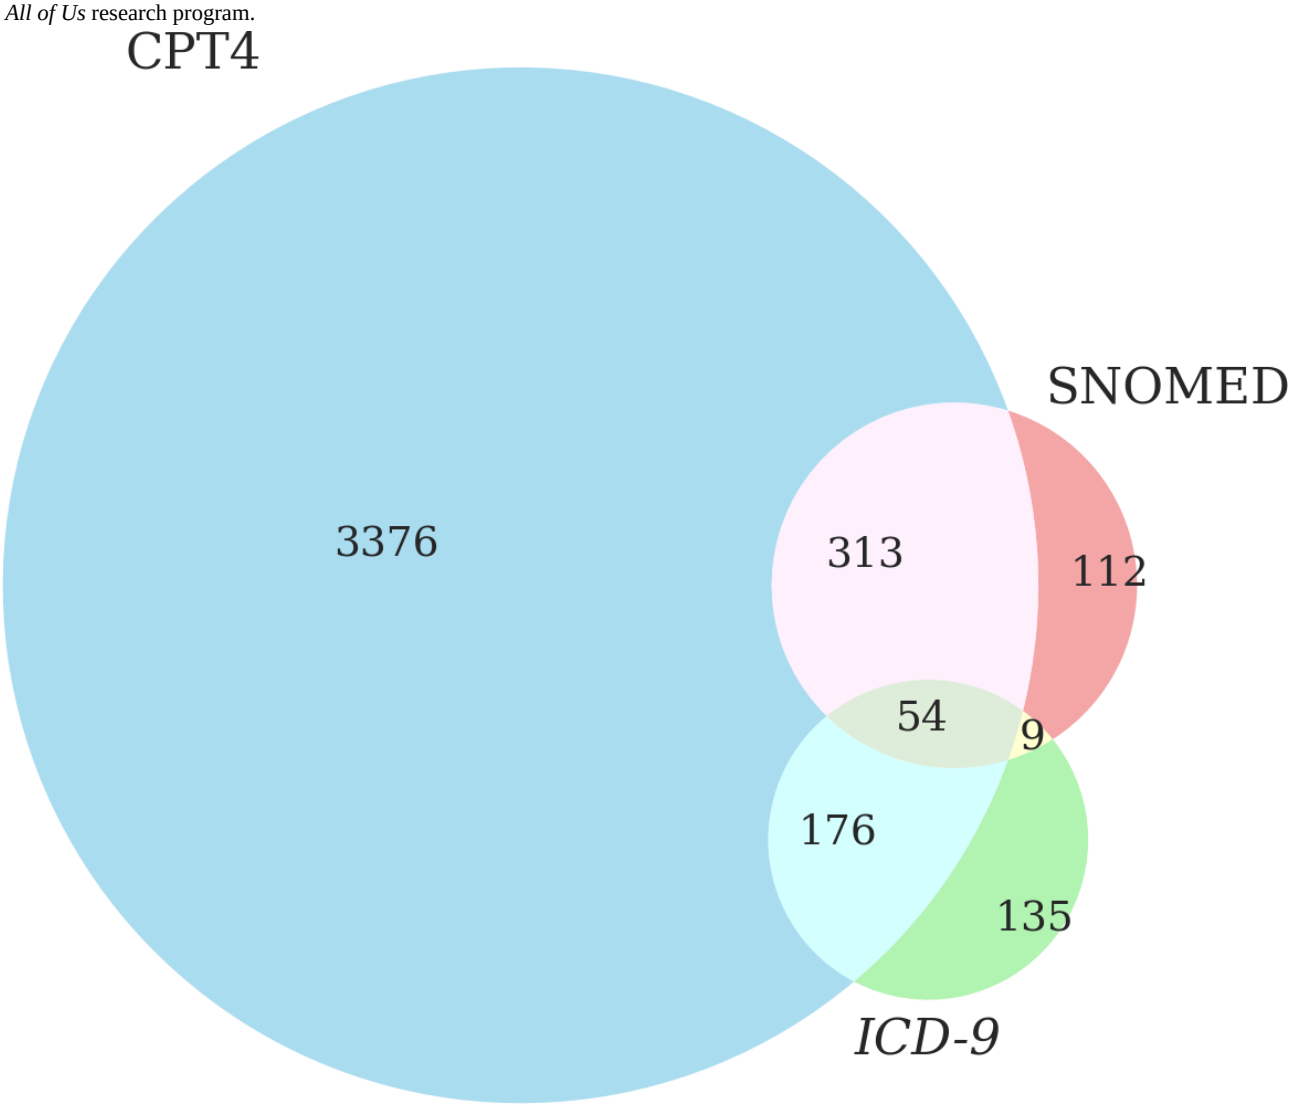

Table . Mastectomy Current Procedural Terminology 4 (CPT4) counts by code. Codes with ≤10 counts were omitted. Data source: The *All of Us* research program.

CPT4 code	Count
19301[a]	2366
19303[b]	1304
19307[c]	358
19302[d]	160
19160[e]	126
19180[f]	53
19162[g]	48
19304[h]	44
19240[i]	35

[a]CPT4 code 19301=mastectomy, partial (eg, lumpectomy, tylectomy, quadrantectomy, and segmentectomy).

[b]CPT4 code 19303=mastectomy, simple, complete.

[c]CPT4 code 19307=mastectomy, modified radical, including axillary lymph nodes, with or without pectoralis minor muscle, but excluding pectoralis major muscle CPT4.

[d]CPT4 code 19302=mastectomy, partial (eg, lumpectomy, tylectomy, quadrantectomy, segmentectomy); with axillary lymphadenectomy.

[e]CPT4 code 19160=mastectomy, partial.

[f]CPT4 code 19180=mastectomy, simple, complete.

[g]CPT4 code 19162=mastectomy, partial, with axillary lymphadenectomy.

[h]CPT4 code 19304=mastectomy, subcutaneous.

[i]CPT4 code 19240=mastectomy, modified radical, including axillary lymph nodes, with or without pectoralis minor muscle, but excluding pectoralis major muscle.

Completeness

We used concept prevalence within our cohort to evaluate data completeness. Table 3 shows the counts and percentages of female participants who did and did not have partial or complete mastectomy procedures, for which each specific clinical measure and intervention was present in the *All of Us* EHR at least once. The participants in our partial or complete mastectomy cohort had a higher prevalence of breast cancer associated OMOP CDM concepts compared to female control cohort participants who did not have a partial or complete mastectomy code. Specifically, comparing females who had a partial or complete mastectomy to females who had neither showed increased prevalence of diagnostic mammography (70.7% vs 13.5%), biopsy (61.2% vs 3.3%), or endocrine therapy (51% vs 1.8%), or chemotherapy (25.1% vs 4.3%). A χ^2 test indicated that partial or complete mastectomy procedures were associated with clinical measures and interventions (P<.001).

Table . Clinical measures and interventions for female participants who had a mastectomy and who did not have a mastectomy. Data source: The *All of Us* research program.

Clinical measure	Mastectomy cohort, n (%)	Nonmastectomy cohort, n (%)	*P* value
Procedures			<.001
Breast biopsy	2554 (61.2)	5625 (3.3)	
Diagnostic mammography	2951 (70.7)	22,731 (13.5)	
Radiation therapy	1656 (39.7)	1644 (1.0)	
Screening mammography	2143 (51.3)	45,071 (26.8)	
Surgery	4175 (100.0)	0 (0)	
Medications			<.001
Anti-HER2[a]	221 (5.3)	151 (0.1)	
CDK[b] 4/6 inhibitors	60 (1.4)	138 (0.1)	
Chemotherapy	1046 (25.1)	7152 (4.3)	
Endocrine therapy	2130 (51.0)	3109 (1.8)	
Goserelin	106 (2.5)	91 (0.1)	
Olaparib	≤20	41 (<0.1)	
Pembrolizumab	≤20	162 (0.1)	
Tyrosine kinase inhibitor	50 (1.2)	277 (0.2)	
Conditions			<.001
Breast cancer gene mutation	435 (10.4)	903 (0.5)	
Estrogen receptor status	235 (5.7)	180 (0.1)	

[a]anti-HER2: anti–human epidermal growth factor receptor 2.

[b]CDK: cyclin-dependent kinase.

Table 4 shows the counts and percentages for the partial and complete mastectomy subgroups. Each specific clinical measure and intervention was in the *All of Us* EHR at least once. The partial mastectomy subgroup, compared to the complete mastectomy subgroup, had a greater proportion of radiation therapy (49.4% vs 23.5%), endocrine therapy (54.7% vs 44.9%), screening mammography (58.8% vs 39%), and diagnostic mammography (77.5% vs 59.3%). By contrast, the complete mastectomy group when compared to the partial mastectomy subgroup had a greater proportion of breast cancer gene (BRCA) mutations (18%vs 5.8%). A χ^2 test indicated that partial and complete mastectomy subgroup categories were associated with clinical measures and interventions (*P*<.001).

Table . Clinical measures and interventions for female participants who had a partial mastectomy and who had a complete mastectomy. Data source: The *All of Us* research program.

Clinical measure	Partial mastectomy, n (%)	Complete mastectomy, n (%)	*P* value
Procedures			<.001
Breast biopsy	1728 (66.3)	826 (52.7)	
Diagnostic mammography	2021 (77.5)	930 (59.3)	
Radiation therapy	1288 (49.4)	368 (23.5)

Estrogen receptor status	162 (6.2)	73 (4.7)	

[a]anti-HER2: anti–human epidermal growth factor receptor 2.

[b]CDK: cyclin-dependent kinase.

To further characterize completeness, we used UpSet plots (Figures 3 and 4) to assess which combinations of clinical measurements and interventions were prevalent among participants in the partial and complete mastectomy subgroups. The plots show the counts of the concept sets on the left-hand side, and the counts of concept set combinations at the top. The makeup of the combinations is indicated by the dotted lines below. The most frequent combinations in the partial mastectomy subgroup are presented in Textbox 1.

Textbox 1. The most frequent combinations in the partial mastectomy subgroup.

- Combination 1: Surgery, diagnostic mammography, biopsy, screening mammography, endocrine therapy, and radiation therapy (298 cases)
- Combination 2: Surgery, diagnostic mammography, biopsy, screening mammography, and endocrine therapy (188 cases)
- Combination 3: Surgery, diagnostic mammography, biopsy, and screening mammography (174 cases)

Figure 3. Bar chart (top) and UpSet plot (bottom) of breast cancer–related diagnosis codes, procedures, medications, and genetic tests in female participants who had a partial mastectomy. Data source: The *All of Us* research program. anti-HER2: anti–human epidermal growth factor receptor 2; BRCA: breast cancer gene; CDK: cyclin-dependent kinase.

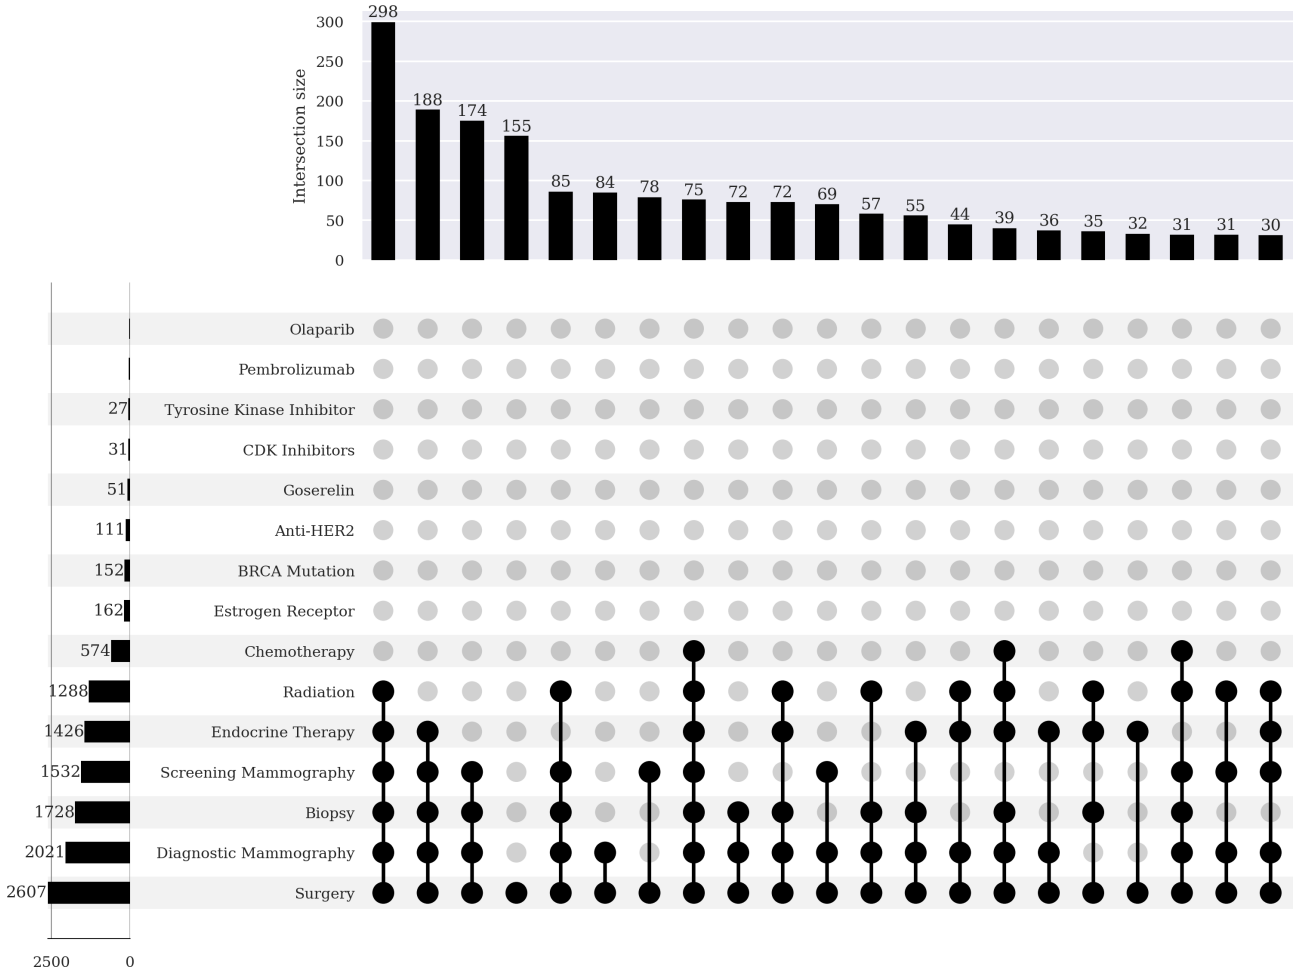

Figure 4. Bar chart (top) and UpSet plot (bottom) of breast cancer–related diagnosis codes, procedures, medications, and genetic tests in female participants who had a complete mastectomy. Data source: The *All of Us* research program. anti-HER2: anti–human epidermal growth factor receptor 2; BRCA: breast cancer gene; CDK: cyclin-dependent kinase.

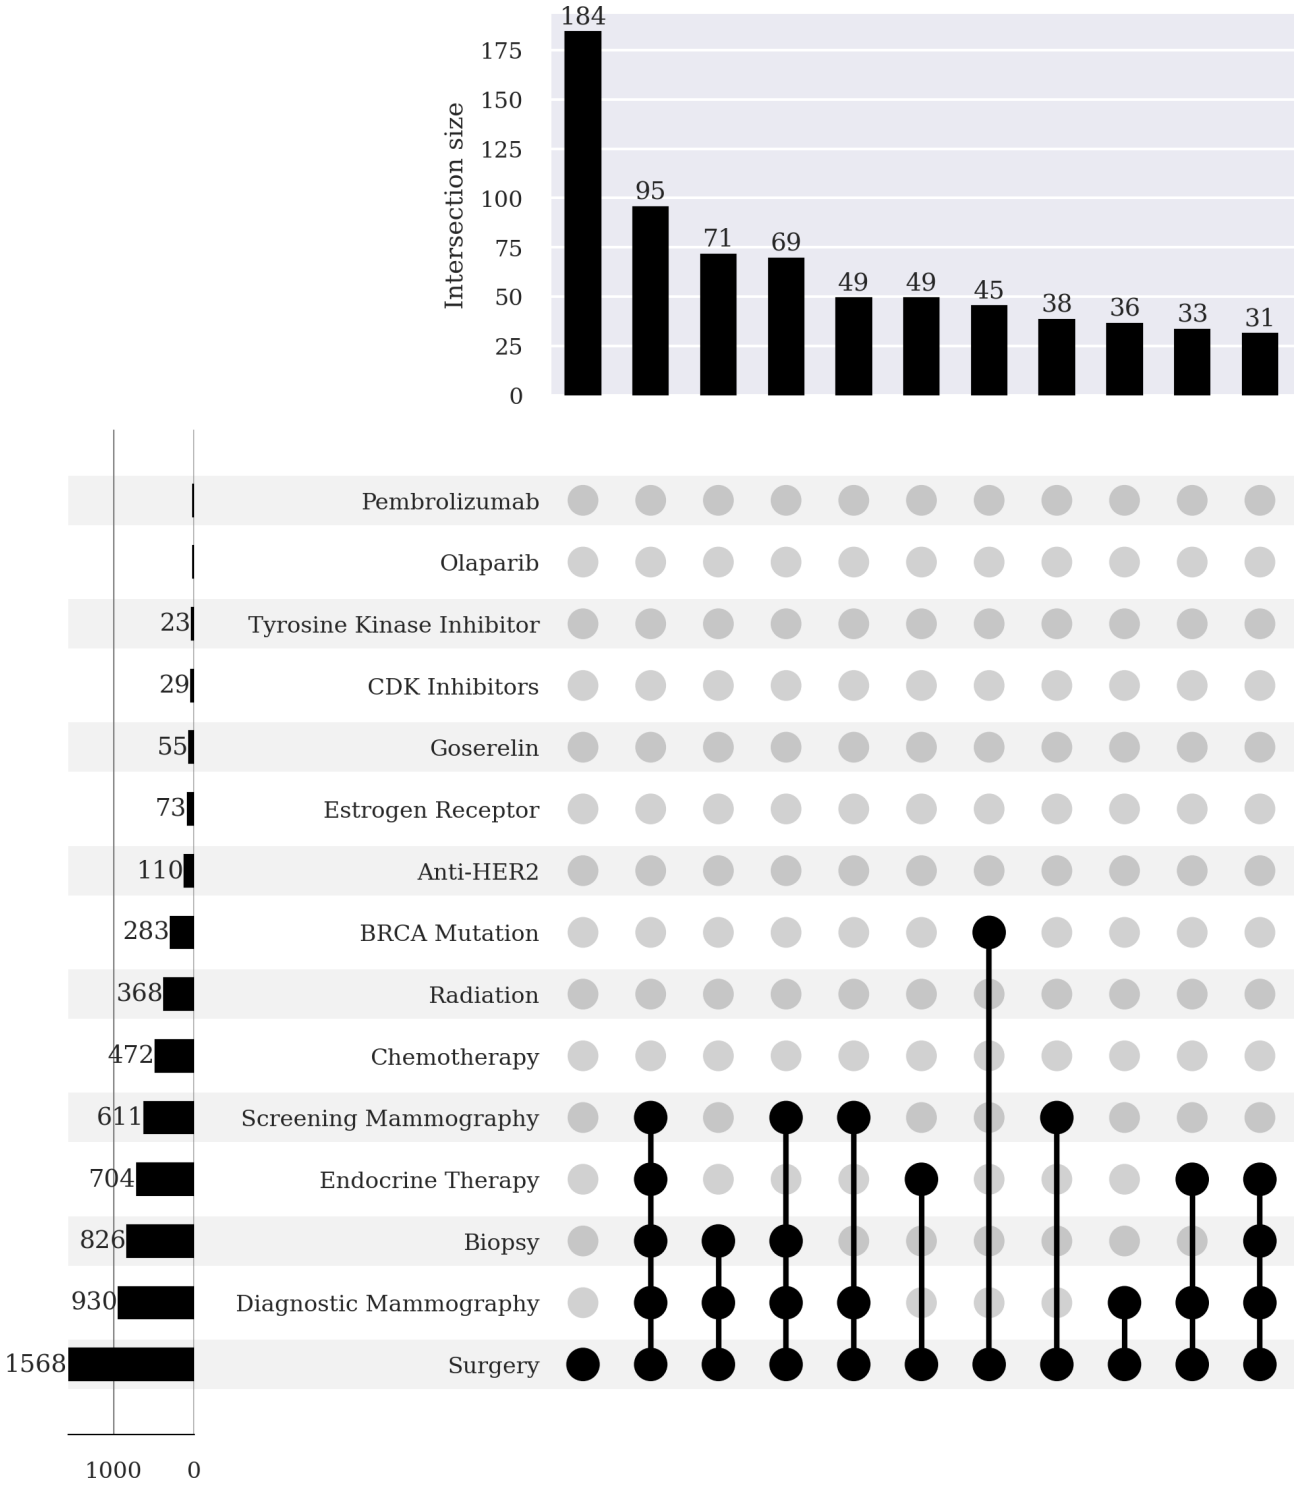

We did not validate completeness because external benchmarks were not available.

The most frequent combinations in the complete mastectomy subgroup are presented in Textbox 2.

Textbox 2. The most frequent combinations in the complete mastectomy subgroup.

- Combination 1: Surgery (184 cases)
- Combination 2: Surgery, diagnostic mammography, biopsy, screening mammography, and endocrine therapy (95 cases)
- Combination 3: Surgery, diagnostic mammography, and biopsy (71 cases)

Concordance

We calculated the bivariate correlations between OMOP CDM concepts for clinical measures and interventions in the partial and complete mastectomy subgroups to measure concordance (Figures 5 and 6). The highest bivariate correlations for the partial mastectomy subgroup were between biopsy and diagnostic mammography (r=0.36) and chemotherapy and anti-HER2 therapy (r=0.36). We also calculated the bivariate correlations for the complete mastectomy subgroup; the highest bivariate correlations were between biopsy and diagnostic mammography (r=0.43), radiation therapy and chemotherapy (r=0.38), screening mammography and diagnostic mammography (r=0.37), and chemotherapy and anti-HER2 therapy (r=0.34).

Figure 5. Correlogram of medications, procedures, and genetic tests in the subgroup of partial mastectomy patients. Data source: The *All of Us* research program. anti-HER2: anti–human epidermal growth factor receptor 2; BRCA: breast cancer gene; CDK: cyclin-dependent kinase.

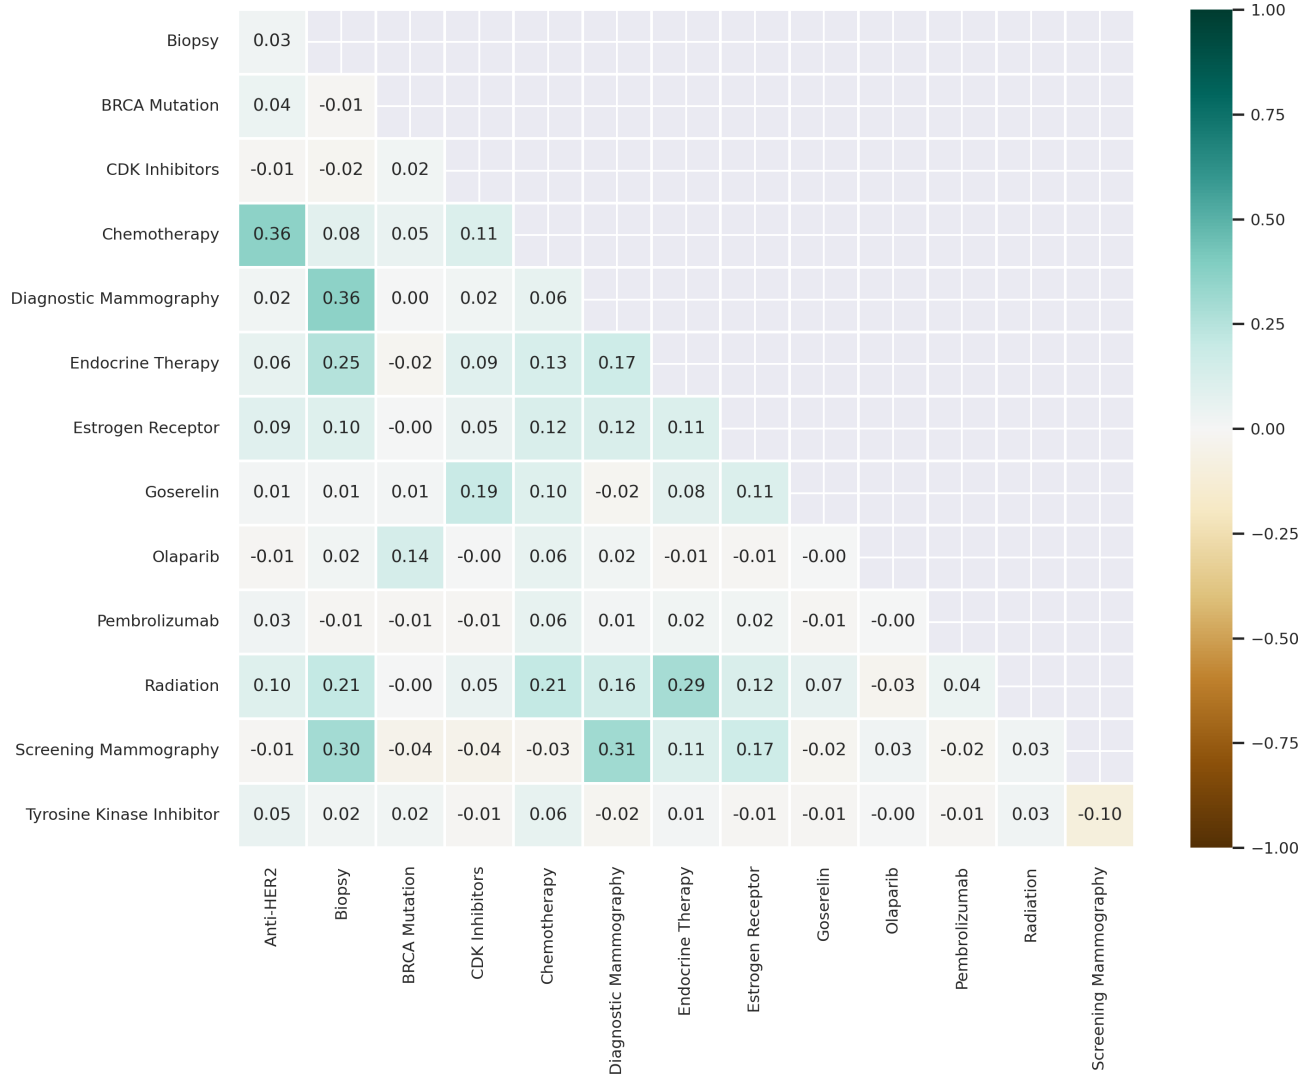

Figure 6. Correlogram of medications, procedures, and genetic tests in the subgroup of complete mastectomy patients. Data source: The *All of Us* research program. anti-HER2: anti–human epidermal growth factor receptor 2; BRCA: breast cancer gene; CDK: cyclin-dependent kinase.

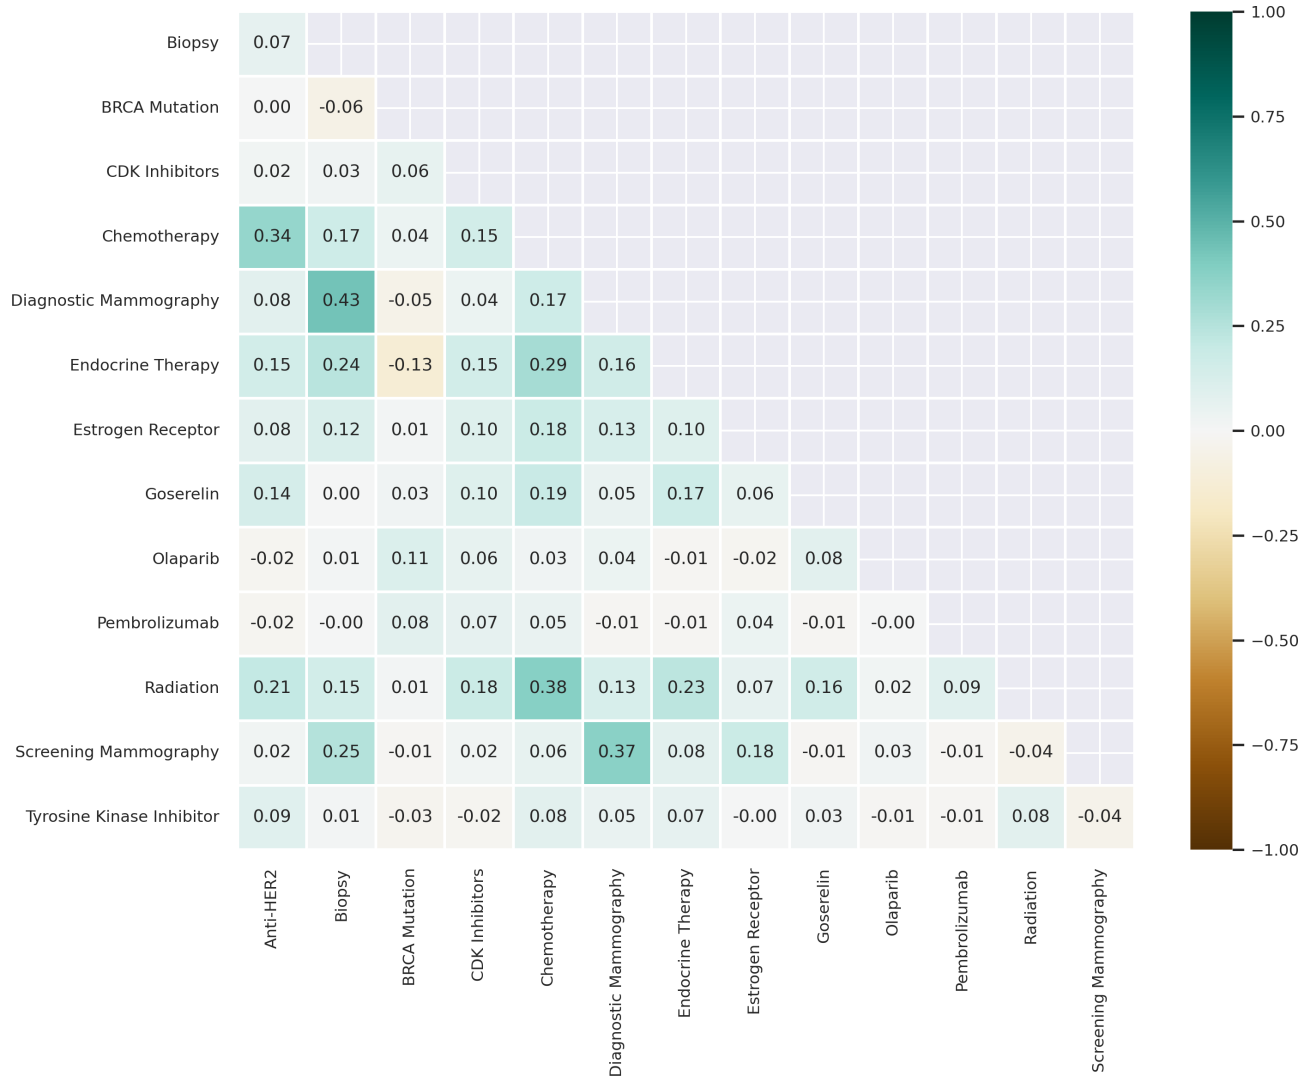
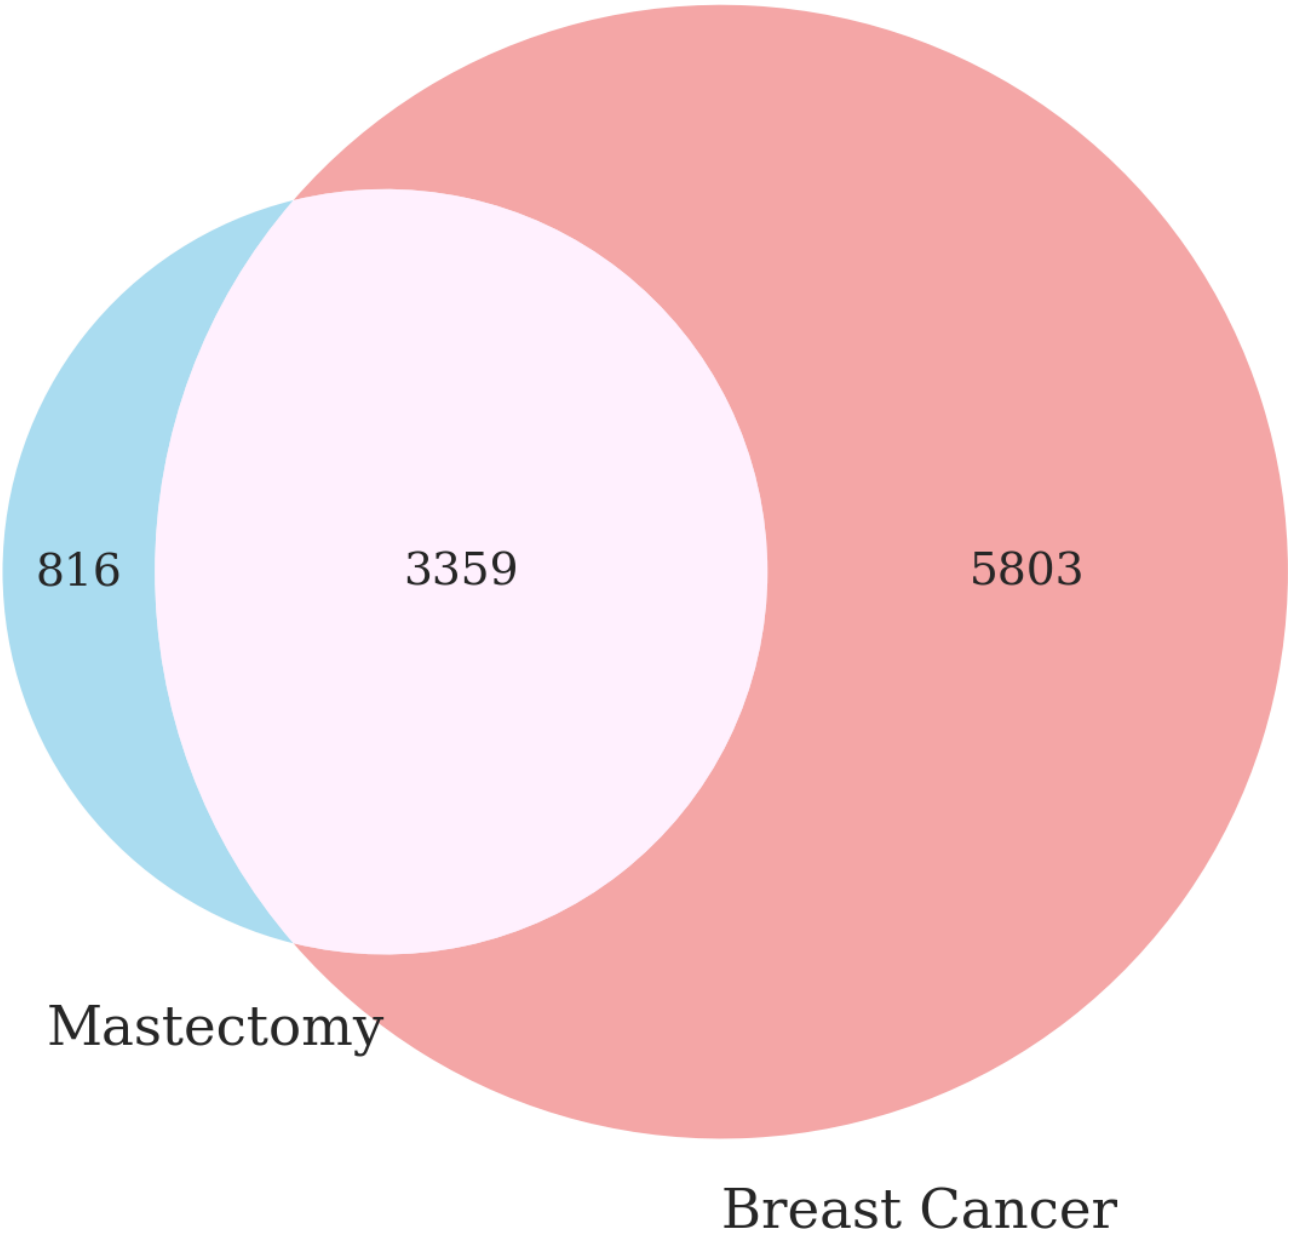


The overlap of patients who had a mastectomy procedure and breast cancer diagnosis (eg, SNOMED 254837009 “Malignant Neoplasm of Breast”) is shown in Figure 7. Of the 816 (19.5%) of female participants who had a mastectomy code only, 277 (33.9%) had diagnosis codes for physical or radiographic findings (eg, breast lump, mammographic calcification of breast), premalignant disease, or benign disease within 1 year before the procedure.

We did not validate concordance because external benchmarks were not available.

Figure 7. The butterfly plot of the mastectomy procedure (left) and the breast cancer diagnosis (right) codes. Data source: The *All of Us* research program.



Plausibility

We assessed plausibility by characterizing distributions of clinical measurement and intervention concepts by age group. We stratified the analysis by partial and complete mastectomy procedures (Figures 8 and 9). We used the age at which a participant's surgical procedure was recorded in EHR rather than other internal characteristics. Our data support a clear association between age patterns and the rate of mastectomy surgery (see Table 1) and the literature [3].

Figure 8. Bar chart of clinical measures and interventions for female participants who had a partial mastectomy. Data source: The *All of Us* research program. anti-HER2: anti–human epidermal growth factor receptor 2; BRCA: breast cancer gene; CDK: cyclin-dependent kinase.

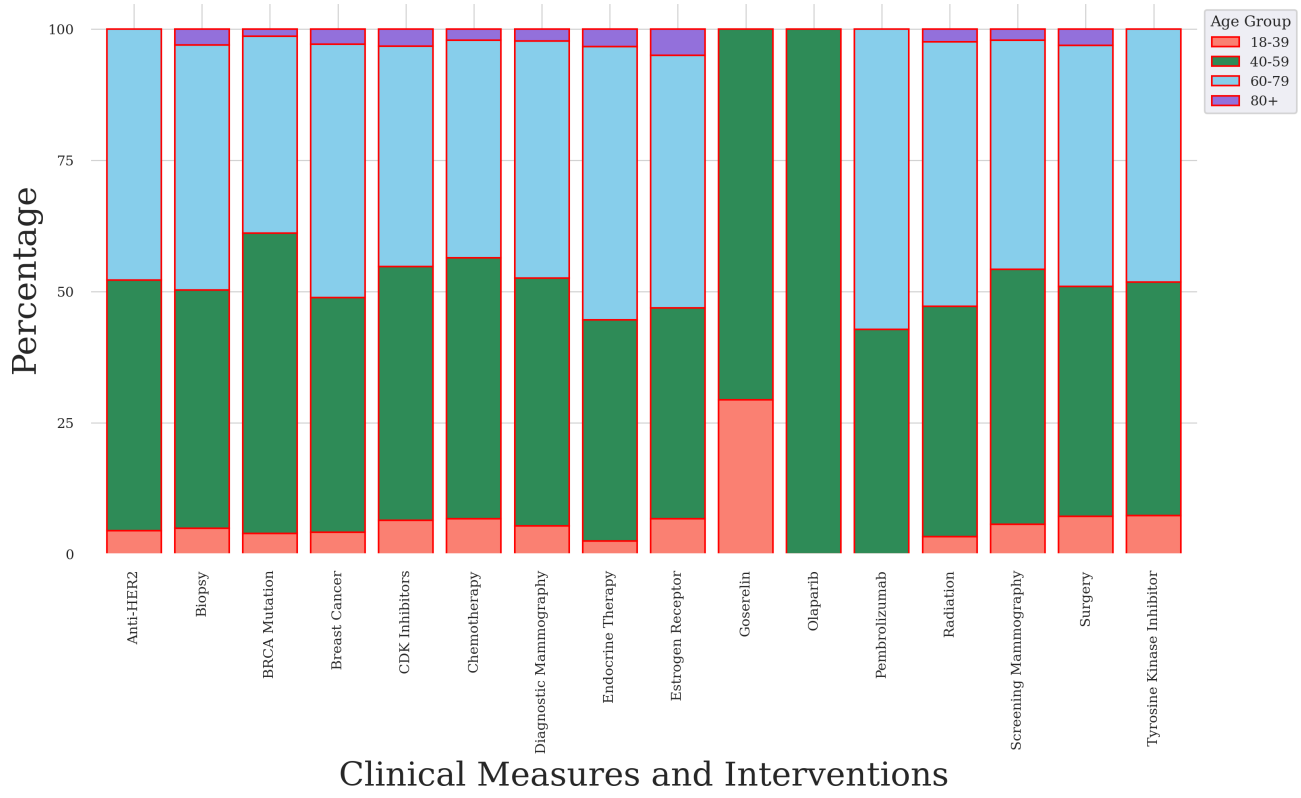


Figure 9. Bar chart of clinical measures and interventions for female participants who had a complete mastectomy. Data source: The *All of Us* research program. anti-HER2: anti–human epidermal growth factor receptor 2; BRCA: breast cancer gene; CDK: cyclin-dependent kinase.

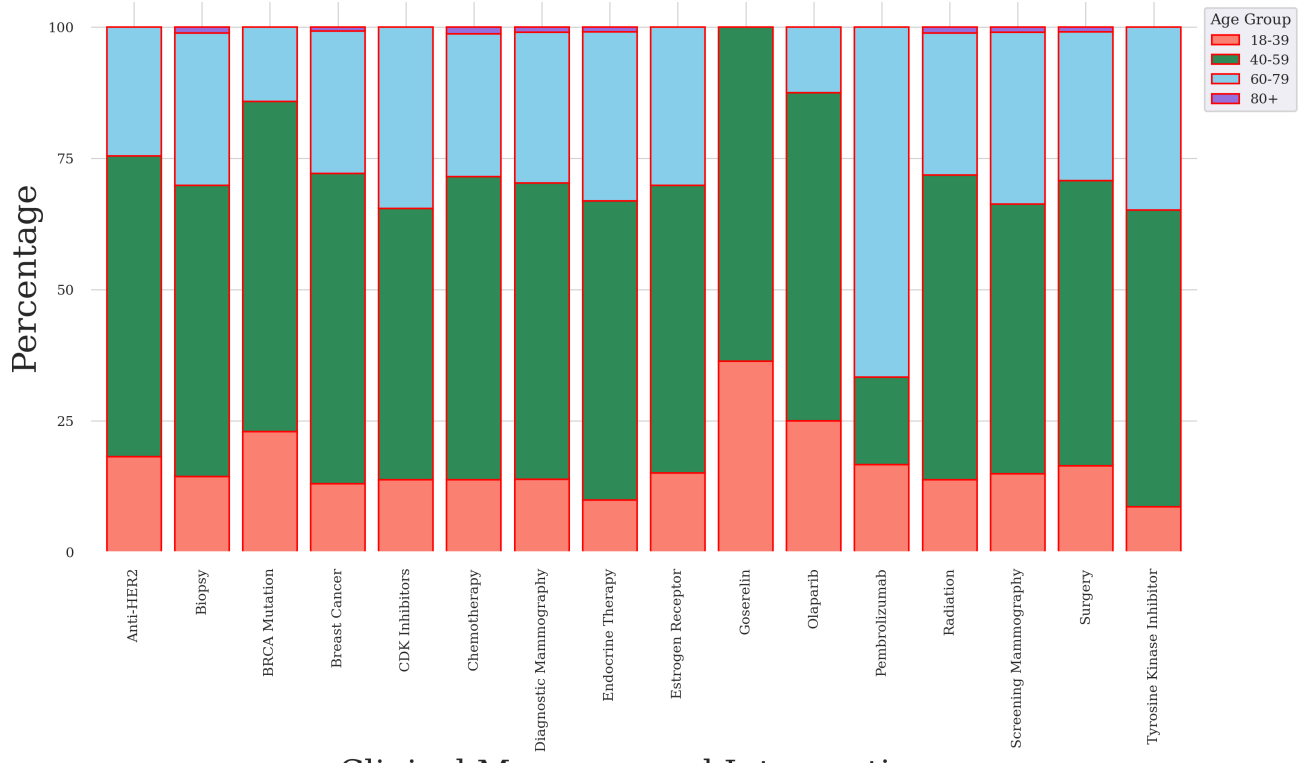

For the partial mastectomy subgroup, clinical measures and interventions were most frequent in for adult female participants who were between 40 and 79 years of age (Figure 8). Specifically, BRCA mutation (57.2%) was most frequent in the 40 - to 59-year-old group. Biopsy (46.7%), radiation therapy (50.4%), surgery (45.9%), and endocrine therapy (52%) were most frequent in the 60 - to 79-year-old group. A χ^2 test indicated that age categories were associated with clinical measures and interventions (P<.001).

For the complete mastectomy subgroup, the frequencies of clinical measures and interventions were highest for adult female participants who were between 40 and 79 years of age (Figure 9). Specifically, BRCA mutation (62.9%), diagnostic mammography (56.5%), biopsy (55.4%), surgery (54.3%), endocrine therapy (56.9%), radiation therapy (58%), screening mammography (51.3%), and estrogen receptor status (54.8%) concepts were most frequent in the 40 - to 59-year-old age group. A χ^2 test indicated that age categories were associated with clinical measures and interventions (P<.001).

We did not validate plausibility because external benchmarks were not available.

Temporality

To assess temporality, we examined the time intervals between biopsy and mastectomy. A biopsy procedure was available for 2354 (56.4%) female participants in the partial or complete mastectomy cohort. There was a skewed time distribution from biopsy to surgery (right positive skew=9.9). Therefore, the median (5.5, IQR 3.5-11.2 weeks) better represents the distribution than the mean (18.4 weeks) for the time difference between biopsy and surgery.

We did not validate temporality because external benchmarks were not available.

Discussion

Principal Findings

The primary objective of this study is to determine whether the *All of Us* EHR data are fit for analyzing female participants who had a mastectomy. Indeed, this study provides valuable information to researchers on the quality of EHR data by operationalizing 5 DQD to the procedure-driven selection of the mastectomy cohort clinical measurements and interventions. We implemented concept selection and internal verification on all domains but were unable to validate them because external benchmarks were not available. Each domain provided unique information about data quality. In this study, our conformance analysis evaluated the overlap of procedure codes from different source vocabularies. The low overlap with SNOMED implies that there may be suboptimal linkage of procedure concepts with concepts from other domains because the standardized relationships may be underused. Furthermore, our method for evaluating conformance may be applicable to quantifying the amount of overlap between nonstandardized and standardized codes. The completeness DQD analysis can be used to identify disease-specific missingness in our data. The concordance analysis measures associations among concepts, which have implications for their relative missingness. The plausibility and temporality analyses are an effort to make the data quality issues transparent and comparable to existing clinical knowledge.

Despite the incompleteness of EHRs, breast cancer–related concepts were prevalent in our cohort. The correlations among those concepts were logical and consistent with the practice of treating breast cancer. For example, concepts for radiation therapy, which is an essential part of BCT, were more prevalent in the partial mastectomy subgroup. The completeness and correlations of our data allowed us to differentiate patients who had BCT from patients who had a complete mastectomy. Our cohort consisted of *All of Us* participants who had a mastectomy procedure at one of the participating sites. However, a greater number of participants may have had a mastectomy procedure at a site that was not part of our research network. Alternatively, diagnosis code-based phenotypes may have higher sensitivity and more false positives than procedure-based phenotypes.

This DQD paper is the first OMOP CDM study to evaluate the quality of partial or complete mastectomy procedure data with procedure-based phenotypes using *All of Us* EHR data. There are several distinct advantages to using a procedure-based phenotype over a diagnosis code-based phenotype. First, in the United States, procedure codes tend to be submitted by experts and can be subject to more rigorous quality checks than codes from other domains, which makes them more likely to be accurate. Second, a mastectomy is a disease-specific intervention for breast cancer. Therefore, a mastectomy phenotype should have a strong association with breast cancer. Third, procedure codes are well-defined and map to granular OMOP CDM concepts. Furthermore, the granularity of codes allows for differentiating partial from complete mastectomy procedures. Fourth, procedures are concrete events synchronizing a cohort to a point in the disease course. Synchronizing the cohort can be especially valuable for performing a treatment pathway analysis, a population-level estimation, or a patient-level prediction.

Comparisons to Prior Work

The relative proportions of the mastectomy cohort who had partial and complete mastectomy procedures were similar to the national averages [27]. However, we found that the frequencies of multiple concepts were lower than expected in our analysis. For example, 51% of our mastectomy cohort had endocrine therapy concepts, and only 5.6% had estrogen receptor status concepts.

Limitations

Our study had several limitations. First, the OMOP CDM breast cancer concepts had minimal information on the breast cancer stage, grade, pathology, laterality, and quadrant of a tumor. Consequently, adopting guidelines from other research networks, such as the National Comprehensive Cancer Network, was not feasible for our use because National Comprehensive Cancer Network guidelines are associated with specific tumor, node, and metastasis characteristics. Health Care Common Procedure Coding System and *International Classification of Diseases* procedure codes can help provide some information on mastectomy status; however, they are limited by their granularity and frequency in the dataset. Second, we wrote custom code to implement our phenotype and selected our concepts manually. Also, evaluating phenotypes with software packages such as CohortDiagnostics and Phevaluator is a possible future area of research. Third, our geospatial analysis was based on the participant's location at the time of enrollment. Some participants could have had surgical treatment in another state. Because our data does not identify the site, variation in practice patterns by institution or provider was unknown. These issues are potential sources of selection bias. Notwithstanding, we

recognize that institution and provider preferences can influence whether a patient undergoes a partial or complete mastectomy for breast cancer [9]. Future development with the *All of Us* Center for Linkage and Acquisition of Data may enable the effects of those preferences on patient procedure choice to be analyzed through the acquisition of health care claims data. Fourth, we restricted our analysis to female participants to reduce errors attributed to misclassification of participants' assigned sex at birth. A study that also includes males with breast cancer, who make up 1% of the breast cancer population, would be more generalizable [28]. Fifth, there was minimal data available for an external validation comparison.

Future Directions

Our study has shown that our data quality framework is systematic and comprehensive and can be implemented in a mastectomy use case. The results of our analysis could inform investigators about the feasibility of using *All of Us* data for follow-up studies. Furthermore, we encourage continued procedure-based phenotyping with our data. In summary, our methods can continue to assess data quality in the *All of Us* Research Program and they may lead to precision medicine studies applicable to diverse patient populations.

Conclusions

We successfully implemented a data quality framework to evaluate whether a mastectomy phenotype that uses *All of Us* data is fit for observational health care research. Our procedure-based phenotype overcame many EHR limitations. In a subgroup analysis, we achieved reasonable differentiation of BCT from complete mastectomy patients. We encourage the continued use of procedure-based phenotypes to evaluate data quality.

Acknowledgments

We gratefully acknowledge *All of Us* participants for their contributions, without whom this research would not have been possible. We also thank the National Institutes of Health's (NIH) *All of Us* Research Program for making available the participant data examined in this study. This study used data from the *All of Us* Research Program's Controlled Tier Dataset V7, available to authorized users on the Researcher Workbench. The implementation of the program is supported by awards through the NIH Office of the Director. We did not use large language models to produce this manuscript. We did not use generative AI to produce any part of this work.

Data Availability

Data and code used in this study are available as a featured workspace to registered researchers of the *All of Us* Researcher Workbench [26].

Abstract

Background: Melanoma currently ranks as the fifth leading cancer diagnosis and is projected to become the second most common cancer in the United States by 2040. Melanoma detected at earlier stages may be treated with less-risky and less-costly therapeutic options.

Objective: This study aims to analyze temporal and spatial trends in melanoma incidence by stage at diagnosis (overall, early, and late) in Texas from 2000 to 2018, focusing on demographic and geographic variations to identify high-risk populations and regions for targeted prevention efforts.

Methods: We used melanoma incidence data from all 254 Texas counties from the Texas Cancer Registry (TCR) from 2000 to 2018, aggregated by county and year. Among these, 250 counties reported melanoma cases during the period. Counties with no cases reported in a certain year were treated as having no cases. Melanoma cases were classified by SEER Summary Stage and stratified by the following four key covariates: age, sex, race and ethnicity, and stage at diagnosis. Incidence rates (IRs) were calculated per 100,000 population, and temporal trends were analyzed using joinpoint regression to determine average annual percentage changes (AAPCs) with 95% CIs for the whole time period (2000 - 2018), the most recent 10-year period (2009 - 2018), and the most recent 5-year period (2014 - 2018). Heat map visualizations were developed to assess temporal trends by patient age, year of diagnosis, stage at diagnosis, sex, and race and ethnicity. Spatial cluster analysis was conducted using Getis-Ord Gi* statistics to identify county-level geographic clusters of high and low melanoma incidence by stage at diagnosis.

Results: A total of 82,462 melanoma cases were recorded, of which 74.7% (n=61,588) were early stage, 11.3% (n=9,352) were late stage, and 14% (n=11,522) were of unknown stage. Most cases were identified as males and non-Hispanic White individuals. Melanoma IRs increased from 2000 to 2018, particularly among older adults (60+ years; AAPC range 1.20%-1.84%; all *P* values were <.001), males (AAPC 1.59%; *P*<.001), and non-Hispanic White individuals (AAPC of 3.24% for early stage and 2.38% for late stage; *P*<.001 for early stage and *P* = .03 for late state). Early-stage diagnoses increased while the rates of late-stage diagnoses remained stable for the overall population. The spatial analysis showed that urban areas had higher early-stage incidence rates (*P*=.06), whereas rural areas showed higher late-stage incidence rates (*P*=.05), indicating possible geographic-based differences in access to dermatologic care.

Conclusions: Melanoma incidence in Texas increased over the study time period, with the most-at-risk populations being non-Hispanic White individuals, males, and individuals aged 50 years and older. The stable rates of late-stage melanoma among racial and ethnic minority populations and rural populations highlight potential differences in access to diagnostic care. Future prevention efforts may benefit from increasing access to dermatologic care in areas with higher rates of late-stage melanoma at diagnosis.

KEYWORDS

melanoma incidence; melanoma screening; geographic disparity; geospatial analysis; joinpoint regression; demographic variation; temporal trend analysis; stage at diagnosis

Introduction

Melanoma currently ranks as the fifth leading cancer diagnosis overall and is projected to become the second most diagnosed cancer in the United States by 2040 [1]. Nationally, melanoma incidence rates (IRs) have shown distinct temporal trends across age, sex, race, and ethnicity. Since 2006, IRs have decreased for adolescents and young adults but increased for older adults, with an annual percent change (APC) of 2.5% for individuals older than 65 years between 2006 and 2015 [2,3]. From 2006 to 2021, IRs have increased for non-Hispanic White and Hispanic individuals (APC of 1.7% and 0.6%, respectively) but decreased for non-Hispanic Black individuals (APC of –1.2%) [3]. Non-Hispanic White males older than 50 years have maintained the highest incidence over the last 2 decades [3].

Previous studies have reported that the areal-level social determinants of health (SDoH) are associated with disparities in melanoma incidence, stage at diagnosis, and survival outcomes. For example, using spatial cluster analysis and a multinomial logistic regression model, a study in Florida found that patients with melanoma who live in census tracts with higher percentage of poverty are more likely to have a late-stage diagnosis [4]. Another study examining the national cancer database from 2011 to 2020 used a chi-square test and found that patients from urban areas are more likely to have an early-stage melanoma (P<.001) [5]. Similarly, a study in Texas using a multinomial logistic regression model found that patients from counties with persistent poverty (≥20% of residents at or below the federal poverty level for the past two decennial censuses) have higher incidence-based melanoma mortality [6]. Melanoma survival rates vary dramatically depending on stage at diagnosis, with nearly guaranteed 5-year survival for early-stage (localized) diagnoses [3]. However, racial and ethnic minority groups are more likely to be diagnosed with melanoma at advanced stages when compared with stage-matched White patients (chi-square tests with P<.001) [3,7,8]. Therefore, understanding how stage-specific melanoma incidence varies across time by patient demographics and geographic location can inform data-driven early detection efforts to improve melanoma morbidity and mortality.

Although Texas had lower all-stage melanoma IRs compared with the national average during 2017 and 2021 (14.9 vs 22.7 cases per 100,000 population), it reported the highest percentage of late-stage cutaneous melanoma diagnoses in the contiguous United States (18.2% in Texas vs 14.1% nationally) [9]. One strategy to shift melanoma detection from late to earlier stages is to increase screening via dermatologists. However, many regions of Texas lack access to dermatologists [10,11]. Alternatively, primary care providers (PCPs) may provide essential skin-cancer detection services [12], yet significant training barriers often preclude early skin cancer diagnosis by PCPs [13]. Geographically targeted education and telementoring efforts to support PCP melanoma diagnosis [14] could potentially enhance early melanoma detection, particularly in areas with a high late-stage melanoma IR. However, the spatial and temporal distribution of stage-based melanoma incidence in Texas has yet to be thoroughly explored to identify these critical locations.

In this study, we analyzed Texas Cancer Registry (TCR) melanoma cases from 2000 to 2018. Using novel data visualizations, we identified trends in melanoma incidence by year of diagnosis, patient demographics, and stage at diagnosis. We also investigated county-level geographic patterns of melanoma incidence across Texas over time. Understanding these trends can guide the development of risk-based interventions to improve melanoma outcomes at the population level.

Methods

Data

Melanoma incidence data from 2000 to 2018 were obtained from the TCR and aggregated by 254 Texas counties and year. Among these, 250 counties reported melanoma cases during the period. Counties with no cases reported in a certain year were treated as having no cases. Melanoma cases were categorized by stage at diagnosis using the Surveillance, Epidemiology, and End Results (SEER) summary stage system, which differs from the more clinically oriented National Comprehensive Cancer Network melanoma-specific staging guidelines [10]. While SEER summary stage data categories have changed over time, we organized TCR melanoma cases into three groups: early stage (SEER stages 0 [in situ], 1 [localized], and 2 [regional by direct extension only]), late stage (SEER stages 3 to 5 [regional] and stage 7 [distant]), and unknown (SEER stage 9: unknown, unstaged, and unspecified).

For demographic stratification, we considered 7 age groups (18 - 29, 30 - 39, 40 - 49, 50 - 59, 60 - 69, 70 - 79, and ≥80 years old), 2 sex groups (female and male), and 4 racial and ethnic groups (non-Hispanic White, non-Hispanic Black, Hispanic, and non-Hispanic Others). Annual county-level population estimates stratified by age, sex, and race and ethnicity were obtained from the National Institutes of Health (NIH) SEER county population data [15].

Patient county of residence at the time of diagnosis was classified as rural or urban using the 2013 US Department of Agriculture Rural-Urban Continuum Codes (RUCCs) [16]. RUCCs 1 - 3 were classified as urban and RUCCs 4 - 9 were classified as rural. Counties were also classified as either with or without persistent poverty using the US Economic Development Administration's 2021 persistent poverty data [17].

Incidence Calculation and Trend Analysis

Annual melanoma incidence-based rates were calculated by sex, age, and racial and ethnic groups as described in the "Data" section. Given the substantial variation in melanoma incidence across different age groups, with higher rates typically observed in older age groups, previous analyses often reported age-adjusted rates to allow for more comparable temporal trends across different populations. However, in this study, we adopted a novel data visualization approach using temporal heat maps, which effectively incorporate known confounders such as age and provide a clearer and more intuitive representation of trends [18]. The heat maps display the year of diagnosis (x-axis), age at diagnosis (y-axis), and calculated stage-specific incidence per 100,000 population as a blue (lower rates) to red (higher rates) color gradient. The heat maps used the Akima interpolation method [19] to generate a smoothed surface from observed data points, providing a visually coherent presentation of temporal trends in IRs.

Spatial Cluster Analysis

We calculated the annual melanoma incidence-based rate for each county in Texas (n=254) using county-specific population data. Spatial cluster analyses were then performed using Getis-Ord Gi* statistics. The Gi* statistic indicates the degree of spatial clustering: positive values indicate that a county and its neighboring areas have higher-than-average rates, while negative values suggest lower-than-average rates. Statistical significance was assessed via Monte Carlo simulation, comparing the observed Gi* values to a reference distribution generated from simulated spatial data. The results categorize counties' spatial clustering significance as follows: Very High (Gi* stat>0 and $P<.01$), High (Gi* stat>0 and $0.01 \leq P<.05$), Somewhat High (Gi* stat>0 and $0.05 \leq P<.10$), Insignificant ($P>.10$), and Low (Gi* stat<0 and $P<.10$). These categorizations allow for the identification of counties with significantly higher or lower melanoma IRs than would be expected by random chance and represent successive thresholds for interpreting spatial clusters without implying a strict ranking of significance. Chi-square tests were used to examine the relationship between spatial clustering categories and urban-rural or poverty status. All data analyses and visualizations were conducted in R (version 4.2.1; R Core Team) [20].

Joinpoint Trend Analysis

To assess temporal changes in melanoma IR, we performed a state-level joinpoint trend analysis to identify years when significant shifts in trends occured. We calculated the APC in IR using the weighted least-squares method, stratified by stage at diagnosis and among different demographic groups [21]. The APC represents the annual rate of change in IR over a specified period, assuming a constant percentage change each year. For instance, an APC of 2% would indicate that an IR of 100 per 100,000 would increase to 102 per 100,000 in the following year. We allowed for a maximum number of two joinpoints over the 19-year study period. Using the Joinpoint Trend Analysis Software (Joinpoint Regression Program; version 5.3.0.0) from SEER [22], we identified specific years with significant changes in the temporal trends and determined the final number of joinpoints using permutation tests. In addition, we derived a summary measure, the average annual percentage change (AAPC), over three fixed time periods: 2000 - 2018 (entire study period), 2009 - 2018 (most recent 10 y), and 2014 - 2018 (most recent 5 y), based on the joinpoint regression model for the full period from 2000 to 2018. For example, an AAPC of 2% for the 2010 - 2018 period would indicate that the IR increased by an average of 2% annually during these years. The 95% CIs for both APC and AAPC were derived using empirical quantile methods.

Ethical Considerations

The study was approved by the institutional review board (IRB) at the University of Texas Health Science Center at Houston (IRB: HSC-SPH-23 - 0483). Melanoma TCR data were obtained from the Texas Department of State Health Services (DSHS) via a formal data request that included an IRB application. Upon IRB approval from the DSHS, a waiver of informed consent was granted because study constitutes secondary research using existing data, involves no more than minimal risk to the participants, and therefore does not require additional consent.

To protect participants' privacy and confidentiality, all data were de-identified prior to analysis. The dataset included only non-identifiable variables such as year of diagnosis, county of residence at diagnosis, demographic characteristics (e.g., sex, race/ethnicity), and birth year. No names, contact information, or medical record numbers were included. The research team adhered to all DSHS data use agreements and institutional data security protocols. Access to the data was limited to approved study personnel and stored on encrypted, password-protected servers within secure institutional networks.

Results

Overview

From 2000 to 2018, the TCR reported 82,462 melanoma cases (Table 1). Among these, 61,588 (74.7%) were diagnosed at an early stage, 9352 (11.3%) at a late stage, and 11,522 (14%) had an unknown stage at diagnosis. The demographic subgroups with the most cases included individuals aged 60 - 69 years (18,959 cases, 23.0%), males (49,058 cases, 59.5%), and non-Hispanic White individuals (74,943 cases, 90.9%). The demographic distribution of melanoma cases by stage largely mirrored these overall trends. The racial and ethnic distribution showed that non-Hispanic White individuals dominated both early- and late-stage cases, although their proportion was slightly lower in late-stage cases.

Figure 1 presents temporal heat maps of stage-specific population-adjusted melanoma IRs (cases per 100,000 population) across demographic subgroups (sex, age, and race and ethnicity) from 2000 to 2018 in Texas. When considering all stages, melanoma IRs slightly increased over time to around 90 per 100,000 population. The highest increase was observed in the 80+ age group from 79 in 2000 to 104 in 2018 (AAPC 1.84%, 95% CI 1.27-2.40), while the 70 - 79 age group saw the highest increase from 2014 - 2018 (AAPC 2.75%, 95% CI 1.84-5.03). Conversely, IRs for the 18 - 29 age group declined from 6 in 2014 to 4.6 per 100,000 in 2018 (AAPC 3.05%, 95% CI –3.66 to –2.46). IRs for those aged 30 - 49 years remained

stable at approximately 10 throughout the study period (Figure 1and Multimedia Appendix 1).

Table . Summary of patient demographics by Surveillance, Epidemiology, and End Results (SEER) summary stage system groupings at diagnosis.

Variable	Early stage[a] (N=61,588), n (%)	Late stage[b] (N=9,352), n (%)	Unknown stage[c] (N=11,522), n (%)	All cases (N=82,462), n (%)
Age group (years)				
18 - 29	2,196 (3.6)	391 (4.2)	536 (4.7)	3,123 (3.8)
30 - 39	4,466 (7.3)	758 (8.1)	927 (8.0)	6,151 (7.5)
40 - 49	7,599 (12.3)	1,287 (13.8)	1,589 (13.8)	10,475 (12.7)
50 - 59	11,822 (19.2)	2,049 (21.9)	2,149 (18.7)	16,020 (19.4)
60 - 69	14,412 (23.4)	2,108 (22.5)	2,439 (21.2)	18,959 (23.0)
70 - 79	13,027 (21.2)	1,712 (18.3)	2,156 (18.7)	16,895 (20.5)
≥80	8,066 (13.1)	1,047 (11.2)	1,726 (15.0)	10,839 (13.1)
Sex				
Male	36,300 (58.9)	6,016 (64.3)	6,742 (58.5)	49,058 (59.5)
Female	25,288 (41.1)	3,335 (35.7)	4,780 (41.5)	33,403 (40.5)
Race and ethnicity				
Non-Hispanic White	56,250 (91.3)	8,247 (88.2)	10,446 (90.7)	74,943 (90.9)
Non-Hispanic Black	304 (0.5)	122 (1.3)	109 (0.9)	535 (0.6)
Hispanic	3,294 (5.3)	924 (9.9)	784 (6.8)	5,002 (6.1)
Non-Hispanic Others	340 (0.6)	56 (0.6)	63 (0.5)	459 (0.6)
Unknown	1,400 (2.3)	3 (0.0)	120 (1.0)	1,523 (1.8)

[a]Early stage: SEER stages 0 (in situ), 1 (localized), and 2 (regional by direct extension only).

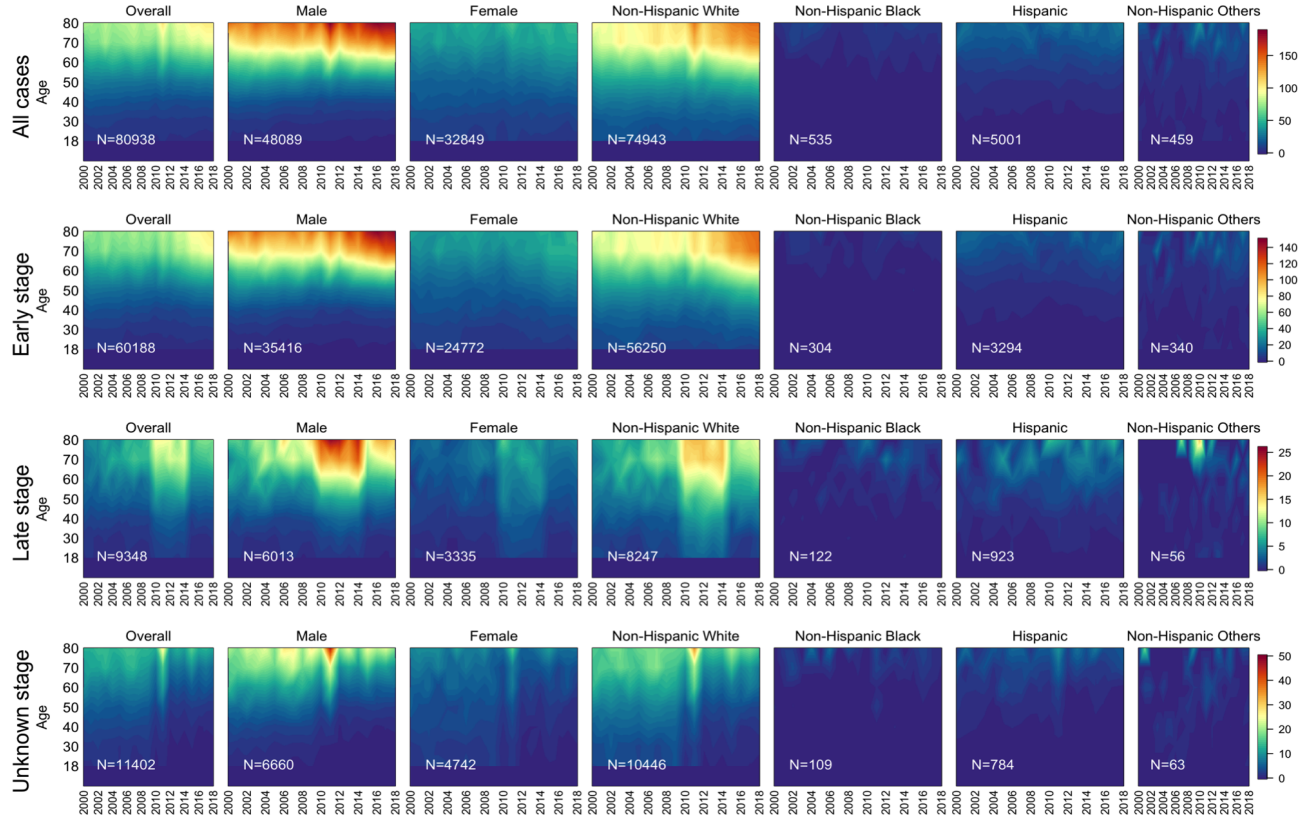
[b]Late stage: SEER stages 3 to 5 (regional) and stage 7 (distant).

[c]Unknown stage: SEER stage 9: unknown, unstaged, unspecified.

IRs for males appear much higher than females among 50+ years, reaching over 140 per 100,000 in the 70+ age group and over 180 per 100,000 in the 80+ age group by 2018 (Figure 1). In contrast, among younger age groups (18-49), females showed slightly higher rates than males over time. In addition, melanoma incidence increased at a more rapid rate for males from 2009 to 2018, with an AAPC of 3.48% (95% CI 2.49-5.19) compared with 2.47% (95% CI 1.89-3.26) for females (Multimedia Appendix 1).

Stratifying by race and ethnicity, non-Hispanic White individuals displayed the highest rates across all age groups, with noticeable increases over the study period for those aged 50 years and older. The older non-Hispanic White patients (70+ years) showed rates over 130 per 100,000 by 2018. For the 18 - 29 age group, non-Hispanic White patients had a slight decrease in IRs from 16.5 per 100,000 in 2000 to 11.4 per 100,000 in 2018. Other racial and ethnic groups, such as non-Hispanic Black and Hispanic individuals, maintained much lower IRs mostly below 30 per 100,000 across all age groups and years (Figure 1).

Figure 1. Temporal heat maps presenting melanoma incidence rates (per 100,000 population) by columns of overall population, sex, and racial and ethnicity groups. Each row panel shows a different stage at diagnosis: all cases, early stage, late stage, and unknown stage. Numbers in the lower left corner of each panel indicate the total number of melanoma cases in Texas from 2000 to 2018.



To facilitate comparison with national statistics, age-adjusted IRs (to the 2000 US standard population) are presented by stage at diagnosis, age, gender, and race and ethnicity in Multimedia Appendix 2.

The incidence of early-stage melanoma has increased more rapidly than late-stage melanoma incidence (Figure 1). Early-stage melanoma temporal trends mirrored those of overall cases, with the highest rates for non-Hispanic White males older than 70 years, reaching 114 cases per 100,000 by 2018. Other racial and ethnic groups displayed minimal variation over time, with rates remaining low throughout the study period (under 10 cases per 100,000 for non-Hispanic Black individuals and under 25 per 100,000 for Hispanic individuals). Late-stage melanoma IRs were lower than early-stage incidence across all demographics. The overall population showed rates below 15 cases per 100,000, with a slight increase over time in older males, peaking around 25 per 100,000 between 2011 - 2014 (refer to additional details in Discussion). Non-Hispanic White patients had the highest rates (maximum 16 per 100,000 in the 80+ age group), while non-Hispanic Black and Hispanic patients had consistently low late-stage IRs (mostly below 5 cases per 100,000). The IRs for unknown stage cases remained relatively stable over time across all demographic groups.

When investigating stage by race and ethnicity, early-stage diagnoses predominated across all races and ethnicities. However, Hispanic and non-Hispanic Black individuals had proportionately more late stage at diagnosis melanomas than non-Hispanic White patients (Multimedia Appendix 3). The AAPC for late-stage melanoma cases was similar for Hispanic (AAPC 2.38%, 95% CI 0.53-3.73) and non-Hispanic White patients (AAPC 2.66%, 95% CI –0.98 to 7.17) and higher for non-Hispanic Black patients (AAPC 5.79%, 95% CI 2.61-9.01; Multimedia Appendix 1).

Spatial Cluster Analysis

Maps showing high- and low-melanoma incidence spatial clusters are presented in Figure 2. When considering all melanoma cases, spatial clusters with significantly higher-than-average melanoma incidence (median IR 42 per 100,000, IQR 23-62) were primarily in northwestern Texas from 2000 to 2006, with a shift to central Texas between 2007 and 2015, and then to counties surrounding Dallas by 2018. Spatial clusters with lower-than-average melanoma incidence were clustered near southern and western Texas (median IR 11, IQR 0-24). The spatial patterns for early-stage and overall melanoma cases were similar with median IRs of 35 per 100,000 (IQR 19-52) in high-incidence spatial clusters, and 6 per 100,000 (IQR 0-17) in low-incidence spatial clusters. However, the spatial clusters for higher-than-average late-stage cases showed distinct patterns with localization to northwestern Texas from 2000 to 2007, a shift toward southeast Texas between 2010 and 2014, and a return to central-northern Texas in 2015.

Overlaying the 2018 spatial clusters with rural counties (hatched lines), we observed that clusters of higher-than-average late-stage melanoma incidence significantly overlap with rural areas (P=.05; Figure 3A). Similarly, clusters of higher-than-average early-stage melanoma incidence appear to overlap with urban areas (P=.06; Figure 3A). In contrast, clusters of lower-than-average incidence for overall, early-stage, and

late-stage melanoma appear to overlap with persistent poverty counties (all *P* values were <.001; Figure 3B).

Figure 2. Spatial cluster analysis of melanoma incidence rates (cases per 100,000 population) by melanoma stage at diagnosis (all cases, early stage, and late stage) and selected years from 2000 to 2018 using Gi* statistics. Classifications were defined as follows: very high (Gi*>0 and *P*<.01), high (Gi*>0 and 0.01 ≤ *P*<.05), somewhat high (Gi*>0 and 0.05 ≤ *P*<.10), insignificant (*P*>.10), and low (Gi*<0 and *P*<.10). Red-shaded areas represent high-incidence clusters, depicting clusters of counties with significantly higher incidence rates compared with the statewide average incidence rate. Blue-shaded areas highlight clusters of counties with significantly lower incidence rates compared with the state average.

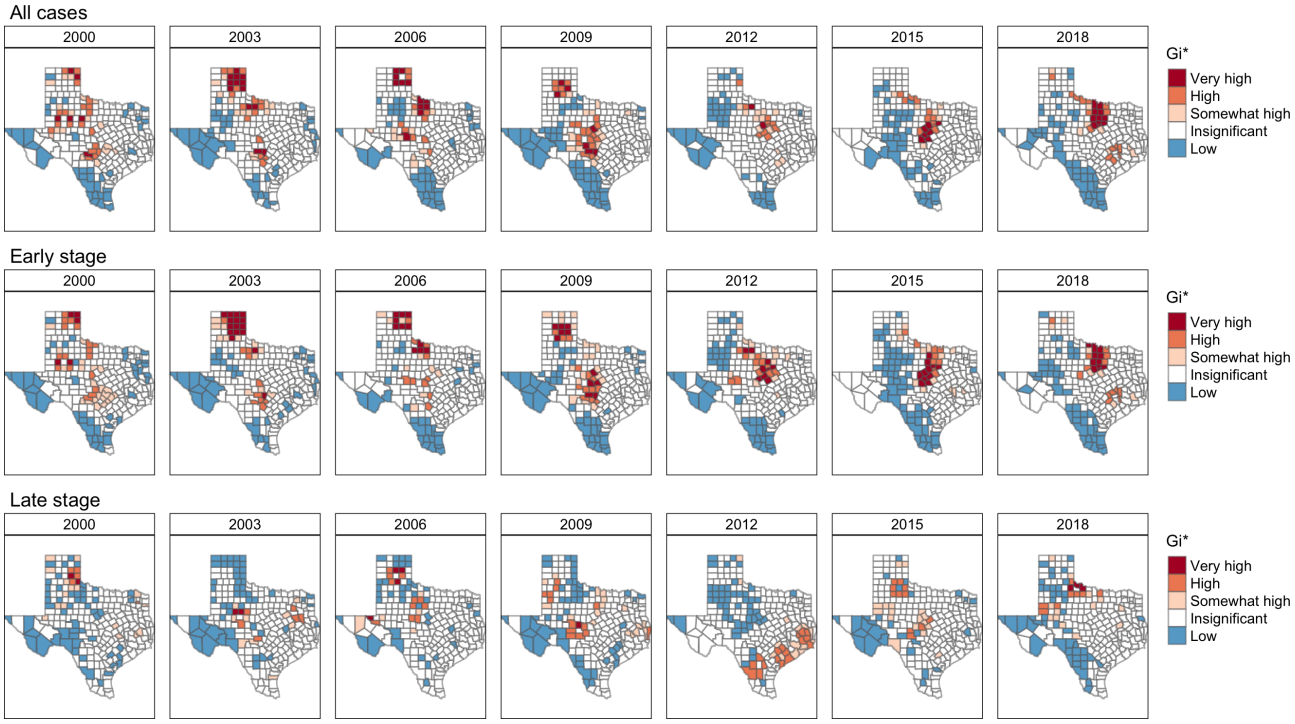


Figure 3. Spatial clusters of melanoma incidence rates overlaid with (A) rural counties and (B) persistent poverty counties in 2018. Classifications were based on Gi* statistics as follows: very high (Gi*>0 and P<.01), high (Gi*>0and 0.01 ≤ P<.05), somewhat high (Gi*>0 and 0.05 ≤ P<.10), insignificant (P>.10), and low (Gi*<0 and P<.10).

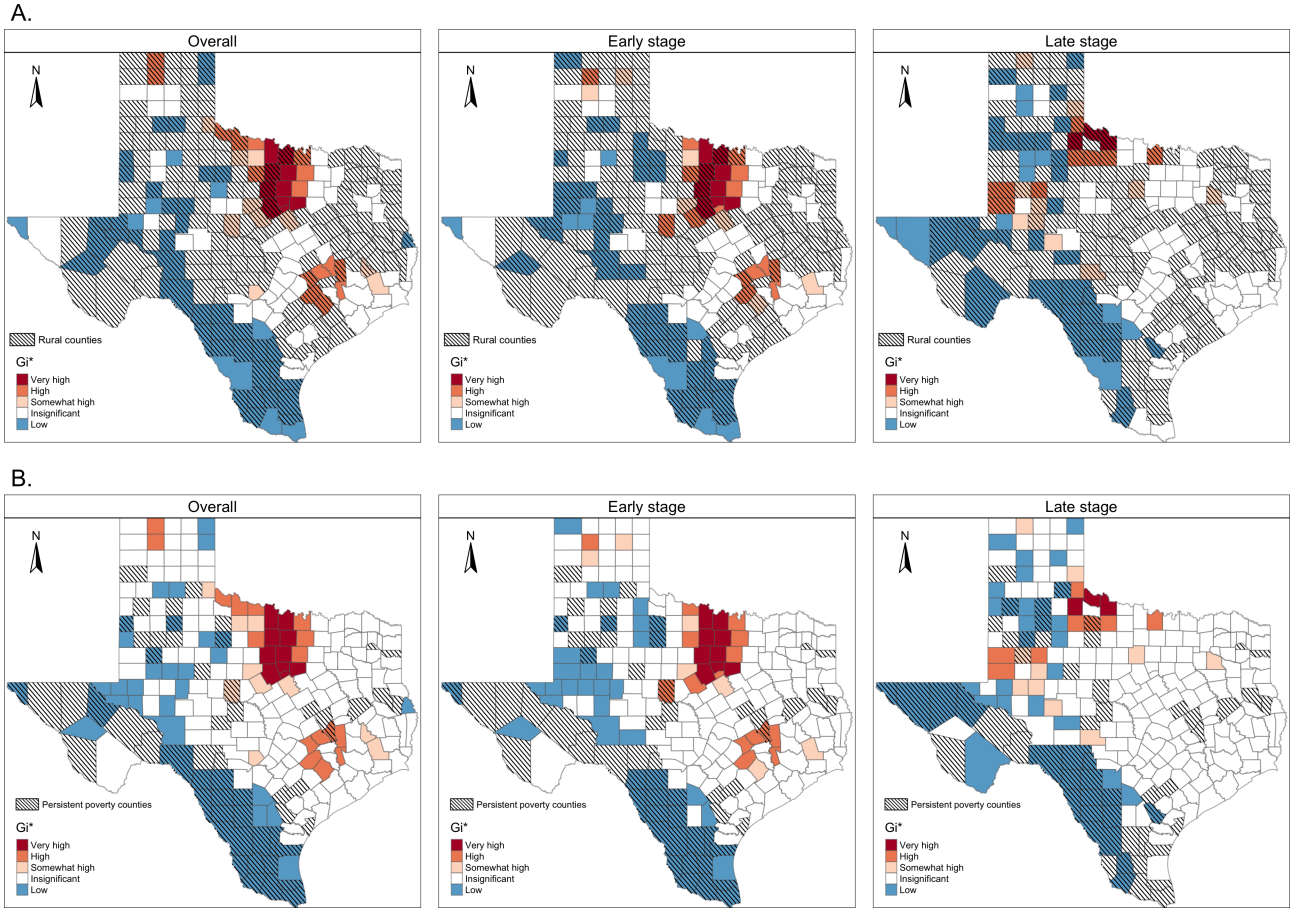

Discussion

Principal Findings

Texas has the highest proportion of late-stage melanoma cases relative to the total number of reported melanoma cases in the contiguous United States and is the second most populated state. Identifying the regions and patient populations that disproportionately bear the burden of late-stage melanoma at diagnosis is crucial for developing targeted early detection efforts. Our spatial clustering analysis of Texas revealed that high-incidence clusters of early-stage melanoma were primarily localized in urban, well-resourced areas, whereas high-incidence clusters of late-stage melanoma were concentrated in rural areas . This disparity may be partly explained by the lower density of dermatologists in rural areas [11,23]. Patients with melanoma living in these areas may experience delayed diagnosis [24], need to travel longer distances to receive surgical management, and have decreased melanoma-specific survival [25]. These findings, while observational, highlight the importance of addressing structural disparities in health care access. Therefore, any early detection intervention must be tailored to be feasible in rural, lower-resourced settings.

Melanoma IRs exhibit substantial variation by age, with older patients experiencing significantly higher rates compared with younger patients. Because the age distribution of the population often shifts over time, age-adjusted rates are commonly used to compare trends across different time periods and geographic regions. These adjustments typically use a fixed reference year for the age distribution, which may lack the robustness to fully capture ongoing demographic change. As the population continue to age and shift in age structure, a static reference year may obscure important trends and fail to accurately reflect the current risk landscape. In this study, we used a novel visualization approach using temporal heat maps that directly incorporate age as a variable, providing a more adaptive and precise method for identifying shifts in melanoma incidence trends over time. This visualization highlighted pronounced incidence variations, particularly among late-stage male and non-Hispanic White patients from 2010 to 2014. We identified two TCR data sources which may explain this variation: Texas Health Care Information Collection (THCIC) and eMaRC Plus (Centers for Disease Control and Prevention [CDC]). THCIC, established by the Texas legislature, collects data on health care activities in hospitals and health maintenance organizations [26]. During a pilot from 2010 to 2013, THCIC identified melanoma cases not otherwise reported to TCR, leading to the inclusion of 559 cases in the TCR database, most of which were categorized as unknown stage at diagnosis. The second data source, eMaRC Plus, a software developed by the CDC to receive and process Health Level Seven files from pathology laboratories, was used from 2010 to 2018. eMaRC Plus identified 8,786 cases, with 93.1% being early-stage and 6.8% unknown stage. The peaks in early-stage and unknown-stage

incidence observed in 2011 and onward may be attributed to these two data sources. However, the increase in late-stage incidence from 2010 to 2014 could not be fully explained by these data sources, suggesting that temporary reporting inconsistencies may warrant further investigation to fully understand their impact on the identified temporal trends.

Despite these data source differences, descriptive trends also revealed that older non-Hispanic White men comprise the majority of late-stage melanoma cases at diagnosis. This specific demographic provides a clear target cohort for refining early melanoma detection efforts. Given that older men generally have lower rates of skin self-awareness [27], promoting early detection through their family members or PCPs may offer greater opportunity. Our analysis of race and ethnicity revealed that, while most melanoma cases were diagnosed at early stages across all groups, Hispanic and non-Hispanic Black patients experienced proportionately more late stage at diagnosis melanomas than non-Hispanic White counterparts. Although the absolute number of melanoma cases is small compared with other cancers, these findings reinforce the concept that melanoma can impact individuals of all races and ethnicities.

Strengths and Limitations

This study has several strengths and limitations. A key strength is the innovative visualization approach, which enabled a comprehensive analysis of temporal trends, stratified by age, sex, race and ethnicity, and stage at diagnosis. The use of TCR data allowed for the inclusion of patient residential information at the time of diagnosis, as well as additional data captures from pilot studies that would otherwise be unavailable. Furthermore, the geospatial analysis provided a comprehensive examination of patterns across all cases and by specific stages, offering valuable insights that could guide future interventions and educational efforts. The study also presents several limitations, particularly the large proportion of cases with an unknown stage at diagnosis. More precise data on these cases would enable better stage classification and improve the stage-specific analyses. In addition, the TCR data has limitations in capturing SDoH, which, if included, could provide a deeper understanding of the health disparities associated with melanoma outcomes.

Conclusions

Our study provides valuable guidance for future early melanoma detection efforts. Such efforts must be feasible in rural, lower-resourced areas of the state and focus on patients at highest risk of late-stage melanoma at diagnosis. Multimodal approaches, which combine foundational dermatology training for interested PCPs [14], telementoring to support PCP incorporation of skin cancer detection examinations into practice [28], and efficient store-and-forward eConsults [29] to reduce dermatology access gaps, offer promising pathways to improve early melanoma detection in low-resource settings.

Acknowledgments

Abstract

Background: The noninvasive imaging examinations of mammography (MG), low-dose computed tomography (CT) for lung cancer screening (LCS), and CT colonography (CTC) play important roles in screening for the most common cancer types. Internet search data can be used to gauge public interest in screening techniques, assess common screening-related questions and concerns, and formulate public awareness strategies.

Objective: This study aims to compare historical Google search volumes for MG, LCS, and CTC and to determine the most common search topics.

Methods: Google Trends data were used to quantify relative Google search frequencies for these imaging screening modalities over the last 2 decades. A commercial search engine tracking product (keywordtool.io) was used to assess the content of related Google queries over the year from May 1, 2022, to April 30, 2023, and 2 authors used an iterative process to agree upon a list of thematic categories for these queries. Queries with at least 10 monthly instances were independently assigned to the most appropriate category by the 2 authors, with disagreements resolved by consensus.

Results: The mean 20-year relative search volume for MG was approximately 10-fold higher than for LCS and 25-fold higher than for CTC. Search volumes for LCS have trended upward since 2011. The most common topics of MG-related searches included nearby screening locations (60,850/253,810, 24%) and inquiries about procedural discomfort (28,970/253,810, 11%). Most common LCS-related searches included CT-specific inquiries (5380/11,150, 48%) or general inquiries (1790/11,150, 16%), use of artificial intelligence or deep learning (1210/11,150, 11%), and eligibility criteria (1020/11,150, 9%). For CTC, the most common searches were CT-specific inquiries (1800/5590, 32%) or procedural details (1380/5590, 25%).

Conclusions: Over the past 2 decades, Google search volumes have been significantly higher for MG than for either LCS or CTC, although search volumes for LCS have trended upward since 2011. Knowledge of public interest and queries related to imaging-based screening techniques may help guide public awareness efforts.

KEYWORDS

lung cancer; lung cancer screening; breast cancer; mammography; colon cancer; CT colonography; Google search; internet; Google Trends; imaging-based; cancer screening; search data; noninvasive; cancer; CT; online; public awareness; big data; analytics; patient education; screening uptake

Introduction

Worldwide, an estimated 20 million new cancer diagnoses and 9.7 million deaths occurred in 2022. The 3 most common types of newly diagnosed malignancies were lung cancer (12.4%), female breast cancer (11.6%), and colorectal cancer (9.6%). Lung cancer and colorectal cancer were the most common causes of cancer-related mortality, with breast cancer in fourth place after liver cancer [1]. Noninvasive imaging, such as mammography (MG), low-dose computed tomography (CT) for lung cancer screening (LCS), and CT colonography (CTC), plays important roles in the early detection of the most common cancer types and has demonstrated efficacy in reducing cancer-related and all-cause mortality rates [2,3]. Encouraging results from large screening trials in several countries [4-6] have

driven global interest in imaging-based lung, breast, and colorectal screening [7-12] and have prompted efforts to initiate and optimize screening worldwide [13-15].

A 2013 Pew Research Center survey found that 72% of adults had pursued web-based health information over the past year, with 77% performing an initial search using an internet search engine [16]. Analysis of internet search volumes for topics related to these imaging examinations may identify opportunities for improved patient outreach and education. Google search trends have been shown to correlate with both epidemiological data and public interest [17-19]. However, few studies have looked at general search volumes for each screening method [20-22], and to our knowledge no publication has documented a detailed topic-level analysis comparing all 3 types of image-based screening.

Methods

Overview

Google Trends was used to assess long-term variation in worldwide relative search volumes for the terms "mammography," "lung cancer screening," and "CT colonography" for the period January 1, 2004 (the earliest date for which Google Trends data were retrievable) to April 1, 2023. Google was chosen, as it is the most frequently used internet search engine, consistently capturing more than 80% of the worldwide internet search market [23].

Keyword tool (keywordtool.io), a commercial search engine tracking product, was used to query average volumes of monthly Google searches in English worldwide for the period May 1, 2022, to April 30, 2023 [24]. Keyword tool uses the output of the Google autocomplete tool to extract the most common entries at the search prompt, which made it optimal to use for this study design [24]. All questions and question-like queries entered at the Google search prompt relating to the terms "mammography," "lung cancer screening," and "CT colonography" were extracted. Two of the authors (ZDZ and BPL) used an iterative process to agree upon a list of thematic categories for queries. Search results with at least 10 monthly searches were independently assigned to the most appropriate category by the 2 graders, with disagreements resolved by consensus.

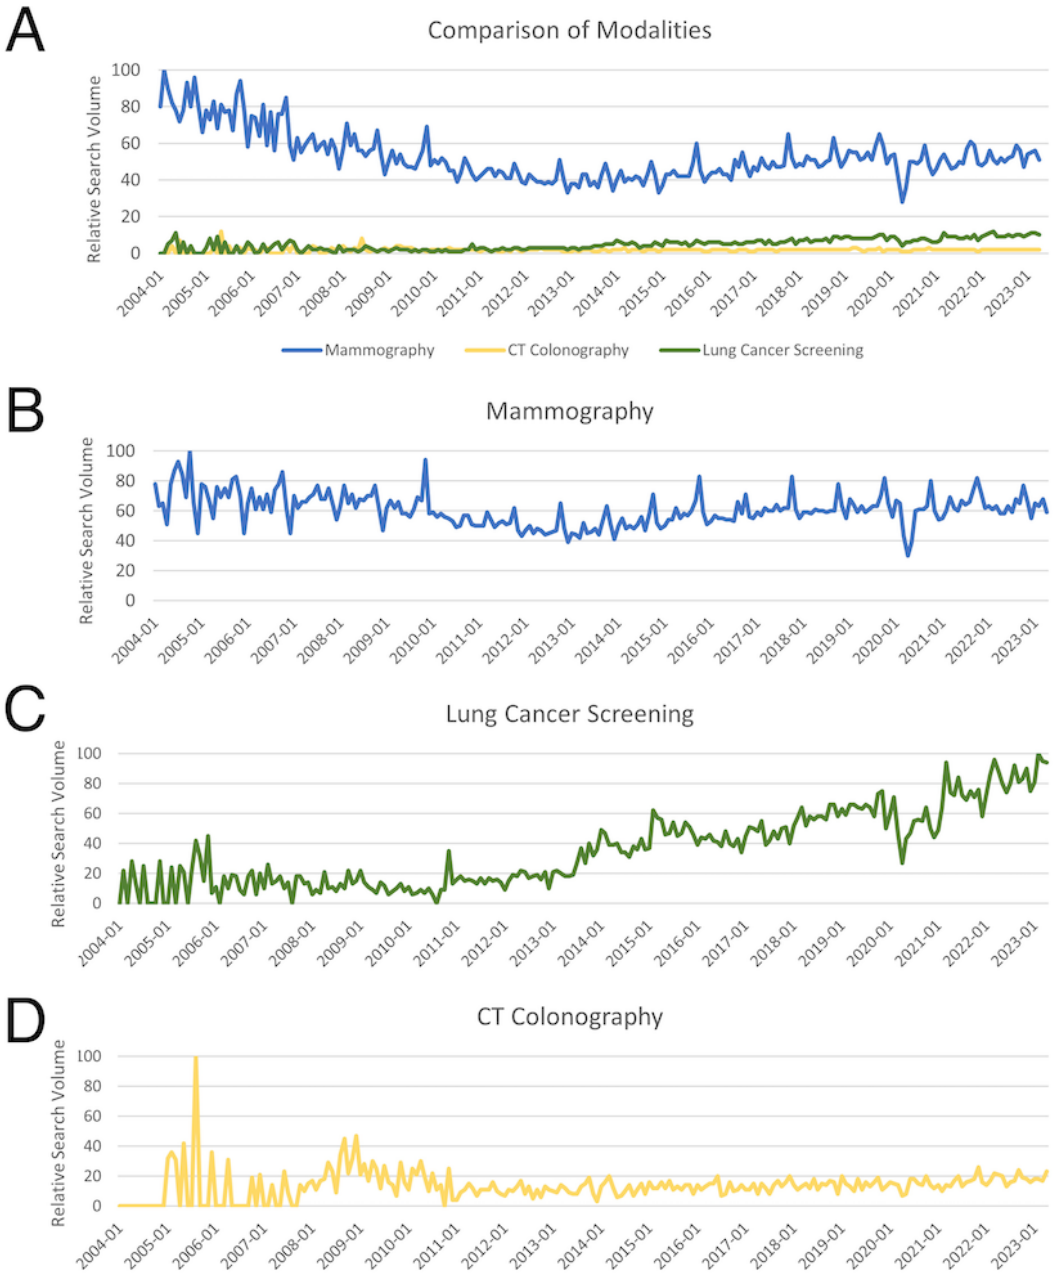
Data Analysis

Search volumes for each screening type were plotted as normalized values (relative search volumes comprising the format of Google Trends data output), with 100 representing the highest relative search volume and 1 representing the lowest, with 0 representing a search volume of zero or insufficient search volume to calculate. Average monthly search volumes for each category were grouped by screening modality and presented in tabular format as the number of searches and as a percentage of total searches for the corresponding modality.

Results

A plot of Google Trends data from 2004 to 2023 comparing MG, LCS, and CTC Google searches is shown in Figure 1. The median 20-year relative search volume was 50 (SD 13; IQR 43-57) for MG, 5 (SD 3; IQR 2-7) for LCS, and 2 (SD 1.2; IQR 1-2) for CTC. On average, the search frequency for LCS was only one-tenth of that for MG, and CTC search volume was only one–twenty-fifth of MG search volume. Search volumes for LCS steadily increased from 2011 to 2023, while searches for MG and CTC plateaued.

Figure 1. Relative worldwide monthly Google search volumes for imaging-based screening examinations. Graph A compares the relative average worldwide monthly search volumes for mammography, lung cancer screening, and CT colonography from January 1, 2004, to April 1, 2023. Graphs B, C, and D illustrate search volumes for the modalities taken independently. All data were obtained from Google Trends for worldwide searches in English. CT: computed tomography.



The relative search volumes for MG alone (Figure 1) across the period ranged from 30 to 100 (median 60; IQR 54-67); there was an overall decrease in relative search volume from the high in 2004 (100) to 2013 (39), followed by an overall increase from 2013 to 2019 (82), with the nadir in 2020 (30) corresponding to the onset of the COVID-19 pandemic. Relative search volumes for LCS alone ranged from 0 to 100; there was an overall decrease in relative search volumes from 2005 (90) to 2010 (0), and a subsequent uptrend after 2011, culminating in a high of 100 in 2019. Relative search volumes for CTC alone ranged from 0 to 100 with the highest volume in 2005, with a secondary peak in 2008 (47), and a plateau from 2010 to 2023 with an average of 14.

Topic analysis using Keyword tool data for the period from May 1, 2022, to April 30, 2023, showed that MG-related topics had the highest total monthly search volume (621,810 searches/month), followed by those related to LCS (23,250 searches/month), and CTC (17,690 searches/month). From these searches, a total of 751 queries classified as questions or question-like queries by the Keyword tool interface were extracted as follows: 442 for MG, 178 for LCS, and 131 for CTC. Of these, 332 had a search volume of >10 per month. The reviewers identified 39, 14, and 11 thematic categories for MG, LCS, and CTC, respectively. The most common categories of queries for MG were nearby screening locations (60,850/253,810, 24%), general inquiries (52,460/253,810, 21%), pain associated with screening (28,970/253,810, 11%), and eligibility criteria (ages) (16,160/253,810, 6%) (Table 1). For LCS, the most frequent categories of queries were CT-specific inquiries (5380/11,150, 48%), general inquiries (1790/11,150, 16%), artificial intelligence (AI) or deep learning use in lung screening (1210/11,150, 11%), screening eligibility criteria (ages or pack-years) (1020/11,150, 9%), and nearby screening locations (750/11,150, 7%) (Table 1). The most common categories of queries related to CTC were CT-specific inquiries (1800/5590, 32%), screening procedural details (1380/5590, 25%), performance compared with colonoscopy (870/5590, 16%), and screening preparation (such as colon preparation and sedation) (720/5590, 13%) (Table 1). Examples of the most common queries for each image-based screening are presented in Table 2.

Table . Average monthly search volumes for imaging-based screening examinations by search topic category. The table displays the average monthly Google search volumes for imaging-based screening examinations from May 1, 2022, to April 30, 2023. All data were obtained from Keyword tool (keywordtool.io) for worldwide searches performed in English. The top 10 thematic categories of search topics are listed for each modality.

Imaging-based cancer screening search query categories	Average monthly search volume, n (%)
MG[a] (n=253,810)	
Nearest screening locations	60,850 (24)
General inquiries	52,460 (21)
Pain associated with screening	28,970 (11)
Cancer imaging characteristics	28,890 (11)
Screening eligibility criteria	16,160 (6)
Screening procedural details	11,810 (5)
Comparison of screening modalities (MG vs MRI[b])	9120 (4)
General screening inquiries	8180 (3)
Opportunities for no-cost screening	6810 (3)
Breast tomosynthesis	6770 (3)
Other categories (combined)	23,790 (9)
LCS[c] (n=11,150)	
CT[d]-specific inquiries	5380 (48)
General inquiries	1790 (16)
Artificial intelligence and deep learning in LCS	1210 (11)
Screening eligibility criteria	1020 (9)
Nearest screening locations	750 (7)
Opportunities for no-cost screening	420 (4)
Screening procedural details	230 (2)
Insurance coverage	150 (1)
LCS trials	90 (0.8)
Imaging accuracy	40 (0.4)
Other categories (combined)	70 (0.6)
CTC[e] (n=5590)	
CT-specific inquiries	1800 (32)
Screening procedural details	1380 (25)
Imaging modality comparison (colonoscopy vs CTC)	870 (16)
Prescreening procedural preparation	720 (13)
Coding (*ICD*[f]/CPT[g])	230 (4)
Nearest screening locations	230 (4)
Pain associated with screening	220 (4)
Opportunities for no-cost screening	60 (1)
Diagnostic capabilities	60 (1)
Insurance coverage	10 (0.2)
Other categories (combined)	10 (0.2)

[f]CPT: current procedural terminology.

Discussion

Principal Findings

Overview

Our study revealed much higher Google search volumes for MG topics over the past 2 decades than for LCS and CTC. The average search frequency for LCS was only approximately one-tenth of that for MG, and CTC search volume was only one–twenty-fifth of MG search volume. LCS average search volumes increased from 2011 to 2023, while searches for MG and CTC plateaued. MG-related topics had the highest total monthly search volume, followed by those related to LCS and CTC. Frequently searched topics varied across modalities and included nearby screening locations, procedural details or associated pain, and eligibility criteria.

MG consistently exhibited higher levels of search interest compared with LCS or CTC, possibly reflecting the longer history of MG and various longstanding initiatives focused on breast screening and women's health [25,26]. Despite the higher

absolute mortality for lung cancer than for breast cancer globally, search volumes for topics related to LCS have remained much lower than those for MG, although LCS search volumes have experienced an uptrend since 2011, when the National Lung Screening Trial was published [3]. MG was first established in 1913 and fully adopted in the 1970s [25], in contrast to low-dose CT for LCS, which gained widespread recognition in 2011. The early peak of interest in LCS in the 2004‐2006 period coincides with attention generated by early CT LCS programs, followed by a decline in interest until 2011 [27,28]. The relative search volumes for CTC have been persistently low over the last 2 decades, especially compared with MG (2%). While CTC is recognized by the national medical societies and formal guidelines of several countries as a viable screening option [29-31], other organizations have raised concerns regarding the strength of evidence supporting CTC or cost-effectiveness compared with colonoscopy [32,33]. The low search volumes might reflect a lack of awareness or desire for this screening option among the public.

Our topic analysis of recent volumes for queries related to image-based screening techniques showed both similarities and differences across imaging modalities. For example, in the case of MG, a substantial portion of searches (60,850/253,810, 24%) involved the nearest screening center, a topic with substantial although lower percentages of search volumes for LCS (750/11,150, 7%) and CTC (230/5590, 4%), highlighting a possible target of increased or more effective publicity. A relatively high volume of searches related to procedural aspects of CTC (1380/5590, 25%) may suggest a relative unfamiliarity with details of this specific imaging modality. A common topic of searches was potential procedural discomfort or pain in MG (28,970/253,810, 11%), with a lower percentage for CTC (220/5590, 1%), suggesting an opportunity for providers to better address procedural comfort that might otherwise decrease screening uptake. Cost or insurance coverage for screening was in the top 10 most-searched topics for all 3 screening modalities but comprised a minority of searches in terms of percentage; although cost and coverage pose concerns for some individuals, it is notable that several other topics, such as the nearest screening locations, procedural pain, and eligibility criteria, had on average 2- to 3-fold higher search volumes. AI and deep learning were common search topics for LCS (1210/11,150, 11%) but were not common queries for MG or CTC; this is somewhat surprising, as AI in the form of computer-aided detection is commonly used in MG.

Comparison to Prior Work

Previous research has examined internet search trends for cancer screening examinations. Snyder et al [20] examined Google search volume trends for cancer screening terms during the first stages of the COVID-19 pandemic, finding a temporary decline in searches for terms related to MG, LCS, colonoscopy, and pap smear. Rosenkrantz and Prabhu [22] performed a Google Trends analysis of the relative frequency of Google searches for MG, LCS, CTC, and prostate magnetic resonance imaging from 2004 to 2014, finding a slight progressive decline over the decade in searches for MG, a decrease from 2004 to 2010 in searches for LCS, followed by a persistent increase beginning in 2011, and an overall decade-long decline in searches for CTC; these findings are consistent with our analysis, although we show that searches for LCS continued to rise from 2014 to 2023 and that searches for MG and CTC have continued to plateau. Our analysis also has the advantage of comparing both the relative and absolute volumes of searches across modalities (MG, LCS, and CTC) instead of relying solely on relative search volumes, showing that searches related to MG greatly exceeded those related to LCS and CTC.

A variety of other methods have been used to assess public interest in and knowledge of cancer screening, including interviews, focus group discussions, questionnaires, and news coverage analysis [10,34,35]. Raju et al's [34] survey of LCS-eligible individuals who chose not to participate in screening found that 19% of individuals had concerns about the distance to the screening site, and 14% of individuals had concerns about insurance coverage, recalling some of the frequent search topics for LCS in our study. In a Google News analysis of news coverage of MG from 2006 to 2015 [21], the most frequently covered topics included screening MG controversies (29%), new breast imaging technology (23%), imaging of dense breasts (11%), and public screening initiatives (11%), topics that were not among the most common MG searches in our study.

Strengths and Limitations

To our knowledge, our study is the first to use internet search engine data to gauge both general and topic-level public interest across imaging-based screening modalities by providing both relative search frequencies and estimates of absolute search volumes. We examined 2 decades of Google search volumes across 3 key imaging-based cancer screening examinations and documented the most common themes of recent related search queries.

Our study had several limitations. First, there are limitations inherent in any method of search volume estimation. Google Trends reports search data in relative terms and may report a value of 0 when search frequencies are low. For topic analysis, we captured data representing a snapshot of queries over a year, while queries may change over time. Search volumes were also estimated through a proprietary tool that uses Google autocomplete as a proxy for search volumes, as actual absolute search volumes are not available from Google Trends. However, our goal was not to measure exact search volumes but rather to analyze and compare trends across modalities and to discern the topics of the most frequent searches. Second, the analysis of thematic categories is intrinsically subjective; we attempted to mitigate this by using 2 observers, with final decisions rendered by consensus. Third, we analyzed worldwide Google searches in English and did not perform a country or region-specific analysis; while such comparative analyses are potentially of interest because of differences in screening guidelines and behavior across countries, our main objectives were to provide a general and comprehensive analysis of search interest across modalities and to determine the main topics of search queries. Future studies may incorporate comparisons of search queries across countries. Finally, internet search volumes may not directly translate to individual concerns, real-world behaviors, or screening uptake; however, individuals frequently

turn to the internet as a source of medical information [16], and internet searches have often been used as a proxy of public interest in a wide variety of health-related topics [17-20,22].

Conclusions

In conclusion, MG has generated consistently higher Google search volumes over the past 2 decades than LCS and CTC, but search interest in LCS has been on an upward trend since 2011. Frequently searched topics varied across modalities and included nearby screening locations, procedural details or associated pain, and eligibility criteria. These search trends might inform the development of communication strategies related to screening and aid in addressing frequently asked questions from the public.

Acknowledgments

Generative artificial intelligence was not used for any portion of the study or for any portion of manuscript writing.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the proprietary nature of one of the search analysis tools used but are available from the corresponding author on reasonable request.

Authors' Contributions

ZDZ and BPL contributed to data curation, formal analysis, and methodology. ZDZ, IOC, RAG, EMJ, MRM, PJM, SKS, JTS, and BPL were involved in conceptualization, drafting the original manuscript, and reviewing and editing the final version.

Abstract

Background: Esophageal and gastric cancer were among the top 10 most common cancers worldwide. In addition, sex-specific differences were observed in the incidence. Due to their anatomic proximity, the 2 cancers have both different but also shared risk factors and epidemiological features. Exploring the potential correlated incidence pattern of them, holds significant importance in providing clues in the etiology and preventive strategies.

Objective: This study aims to explore the spatiotemporal correlation between the incidence patterns of esophageal and gastric cancer in 204 countries and territories from 2010 to 2019 so that prevention and control strategies can be more effective.

Methods: The data of esophageal and gastric cancer were sourced from the Global Burden of Disease (GBD). Spatial autocorrelation analysis using Moran I in ArcGIS 10.8 (Esri) was performed to determine spatial clustering of each cancer incidence. We classified different risk areas based on the risk ratio (RR) of the 2 cancers in various countries to the global, and the correlation between their RR was evaluated using Pearson correlation coefficient. Temporal trends were quantified by calculating the average annual percent change (AAPC), and the correlation between the temporal trends of both cancers was evaluated using Pearson correlation coefficients.

Results: In 2019, among 204 countries and territories, the age-standardized incidence rates (ASIR) of esophageal cancer ranged from 0.91 (95% CI 0.65-1.58) to 24.53 (95% CI 18.74-32.51), and the ASIR of gastric cancer ranged from 3.28 (95% CI 2.67-3.91) to 43.70 (95% CI 34.29-55.10). Malawi was identified as the highest risk for esophageal cancer (male RR=3.27; female RR=5.19) and low risk for gastric cancer (male RR=0.21; female RR=0.23) in both sexes. Spatial autocorrelation analysis revealed significant spatial clustering of the incidence for both cancers (Moran I>0.20 and P<.001). A positive correlation between the risk of esophageal and gastric cancer was observed in males (r=0.25, P<.001). The ASIR of both cancers showed a decreasing trend globally. The ASIR for esophageal and gastric cancer showed an AAPC of −1.43 (95% CI −1.58 to −1.27) and −1.76 (95% CI −2.08 to −1.43) in males, and −1.93 (95% CI −2.11 to −1.75) and −1.79 (95% CI −2.13 to −1.46) in females. In addition, a positive correlation between the temporal trends in ASIR for both cancers was observed at the global level across sexes (male r=0.98; female r=0.98).

Conclusions: Our study shows that there was a significant spatial clustering of the incidence for esophageal and gastric cancer and a positive correlation between the risk of both cancers across countries was observed in males. In addition, a codescending incidence trend between both cancers was observed at the global level.

Introduction

Globally, cancer is a leading cause of mortality, with its significance continually rising [1-4]. It was estimated that in 2019, cancer accounted for 250 million disability-adjusted life years [3]. Concurrently, according to the Global Cancer Statistics 2020, esophageal and gastric cancer were among the top 10 most common cancers worldwide [5]. In addition, sex-specific differences were observed in the incidence [5]. Due to their anatomic proximity, esophageal and gastric cancer have both different but also a number of shared risk factors and epidemiological features [6-8]. Several published articles have demonstrated that frequent consumption of hot beverages and poor oral hygiene are risk factors for esophageal cancer [9,10], while a high-sodium diet and *Helicobacter pylori* infection are risk factors for gastric cancer [11,12]. Smoking and heavy alcohol consumption are associated with the incidence of both esophageal and gastric cancer [13,14]. There are also some pathological injuries involving both esophagus and stomach, such as gastroesophageal reflux disease and Barrett esophagus, which is related to reflux [15,16]. Furthermore, the high-incidence regions for esophageal cancer are primarily distributed in East Asia, Southeastern Africa, and Northern Europe, while the high-incidence regions for gastric cancer are mainly distributed in East Asia and Eastern Europe [5]. The spatial distribution of these 2 cancers exhibits certain overlapping patterns. However, there has been no global-level spatiotemporal correlation analysis simultaneously examining the incidence of both esophageal and gastric cancer [17-22]. Therefore, systematic exploring the spatiotemporal correlation in the incidence of esophageal and gastric cancer holds significant importance.

Through the spatiotemporal correlation analysis of global incidence of esophageal and gastric cancer, we aim to provide insightful information that would contribute to the prevention and control of these cancers worldwide and the rational allocation of global public health resources.

Methods

Data Sources

The Global Burden of Diseases, Injuries, and Risk Factors Study 2019 (GBD 2019), coordinated by the Institute for Health Metrics and Evaluation (IHME) offers comprehensive and comparable data on the epidemiological burden of esophageal and gastric cancer, which includes age-standardized incidence rates (ASIR) recorded annually spanning from 1990 to 2019 [4]. The data of esophageal and gastric cancer were sourced from the Global Health Data Exchange (GHDx) query tool [23]. The GHDx query tool in the GBD 2019 database includes data from 204 countries and territories by sex from 1990 to 2019. Furthermore, according to the geographic location, the world was divided into 21 regions such as East Asia in GBD 2019 database. The quality and integrity of data can be significantly influenced by advancements in medical records and data collection technologies. Therefore, we extracted data on the ASIR (per 100,000 person-years) with 95% uncertainty interval (UI) of esophageal and gastric cancer from 2010 to 2019 due to the higher quality and integrity of recent data in our study. The ASIR was calculated by the direct method. Standardization was crucial in this study as it eliminates the bias when comparing rates. The 95% UI is a range of values that reflects the certainty of an estimate. The sociodemographic index (SDI) is a composite indicator developed by GBD researchers to characterize the developmental status of countries and territories, and it is closely associated with health outcomes. It is the geometric mean of 0 to 1 indices of total fertility rate under the age of 25, mean education for those ages 15 and older, and lag distributed income per capita [24]. The IHME provides publicly available SDI Reference Quintiles and the SDI values for all locations from 1950 to 2020 [24]. Based on the provided SDI Reference Quintiles, all locations can be classified into 5 categories, including low SDI (SDI≤0.46), low-middle SDI (0.46<SDI≤0.61), middle SDI (0.61<SDI≤0.69), high-middle SDI (0.69<SDI≤0.81), and high SDI (SDI>0.81).

Statistical Analysis

Spatial Distribution and Correlation of Esophageal and Gastric Cancer

In the analysis of spatial distribution and correlation of the ASIR of esophageal and gastric cancer, we used ArcGIS 10.8 (Esri) to calculate Global Moran I [25,26], which was used to evaluate whether the incidence of each cancer exhibited spatial clustering. Global Moran I measure spatial autocorrelation based on both feature locations and feature values simultaneously, where the feature here refers to different countries and territories. The tool calculates the Moran I value and both a zI-score and *P* value to evaluate the significance of that Index. The Moran I statistic for spatial autocorrelation was given as Multimedia Appendix 1.

Moran I values range between −1 and +1. For the Global Moran I statistic, the null hypothesis states that the attribute being analyzed is randomly distributed among the features in the study area. When the *P* value is statistically significant, we may reject the null hypothesis, and a positive value indicates the spatial distribution of high values and low values in the dataset is more spatially clustered than would be expected if underlying spatial processes were random; a negative value indicates the spatial distribution of high values and low values in the dataset is more spatially dispersed than would be expected if underlying spatial processes were random. A dispersed spatial pattern often reflects some type of competitive process—a feature with a high value repels other features with high values, and it is similar in a feature with a low value. When the *P* value is not statistically significant, we cannot reject the null hypothesis, indicating a random spatial distribution. In spatial autocorrelation analysis, the conceptualization of spatial relationships adheres to the Inverse_Distance rule.

In addition, by comparing the ASIR levels of esophageal and gastric cancer in each country and territory against those of the global ASIR levels, we obtained the corresponding risk ratio (RR) to quantify the level of relative risk. Countries and territories with an RR value≤0.50 were classified as low-risk area, while an 0.50<RR value<2.00 and RR value≥2.00 were classified as medium-risk area and high-risk area, respectively.

We then used the Pearson correlation coefficient to evaluate the correlation between the RR of esophageal and gastric cancer in both sex groups. We also evaluated the relationship between SDI quintiles and the distribution of different risk areas.

Temporal Trend and Correlation of Esophageal and Gastric Cancer

In the analysis of temporal trends and correlation of the ASIR of esophageal and gastric cancer, we used the National Cancer Institute Joinpoint Regression Program (version 5.0.2) to calculate the average annual percent change (AAPC) of the ASIR for esophageal and gastric cancer across 204 countries and territories during 2010 - 2019. The CI was set at 95%. AAPC is a statistical indicator used to describe the average annual change rate of the ASIR over a certain period. It provides a comprehensive assessment of the overall trend of ASIR over the entire study period by weighting the annual percentage change over multiple time periods. If both the estimation of AAPC and its lower boundary of 95% CI were >0, the ASIR was considered to be in an increasing trend; if both the estimation of AAPC and its upper boundary of 95% CI were <0, the ASIR was considered to be in a decreasing trend. Otherwise, the ASIR was considered to be stable over time. In the correlation analysis, the Pearson correlation coefficient was used to evaluate the correlation between the temporal trends in the ASIR of esophageal and gastric cancer. A Pearson correlation coefficient >0 with a *P* value less than the specified significance level indicated a significant positive correlation, while a coefficient <0 with a *P* value less than the specified significance level indicated a significant negative correlation. In addition, we assessed the correlation between the temporal trends in the ASIR of both cancers across SDI quintiles.

Given the significant sex differences in the incidence of esophageal and gastric cancer [27,28] and the lifestyle disparities, all analyses were stratified by sex. ArcGIS (version 10.8) and Joinpoint Regression Program (version 5.0.2) were used for spatial autocorrelation analysis and temporal trend analysis of ASIR respectively. All data analyses were conducted in software R (version 4.3.2; R Foundation for Statistical Computing) and R Studio (Posit). A *P* value of less than .05 was considered statistically significant.

Ethical Considerations

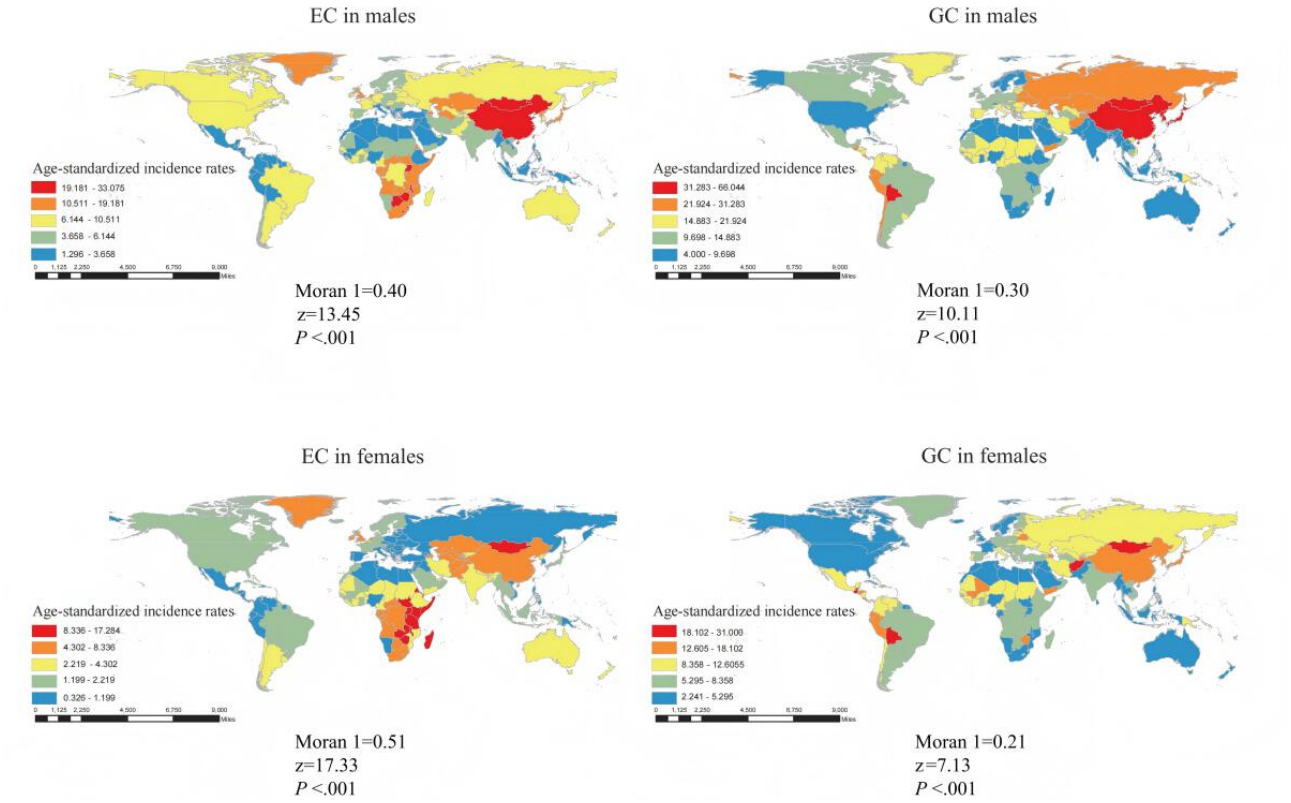
This study did not involve human participants and animals. Ethics approval was not applicable for this study, as this study used existing good quality data that were aggregated at the population level. Data available for download on IHME websites are publicly available and can be used, shared, modified or built upon by noncommercial users in accordance with the IHME Free-of-Charge Non-Commercial User Agreement [29].

Results

Spatial Distribution and Correlation Between the Esophageal and Gastric Cancer Incidence in 2019

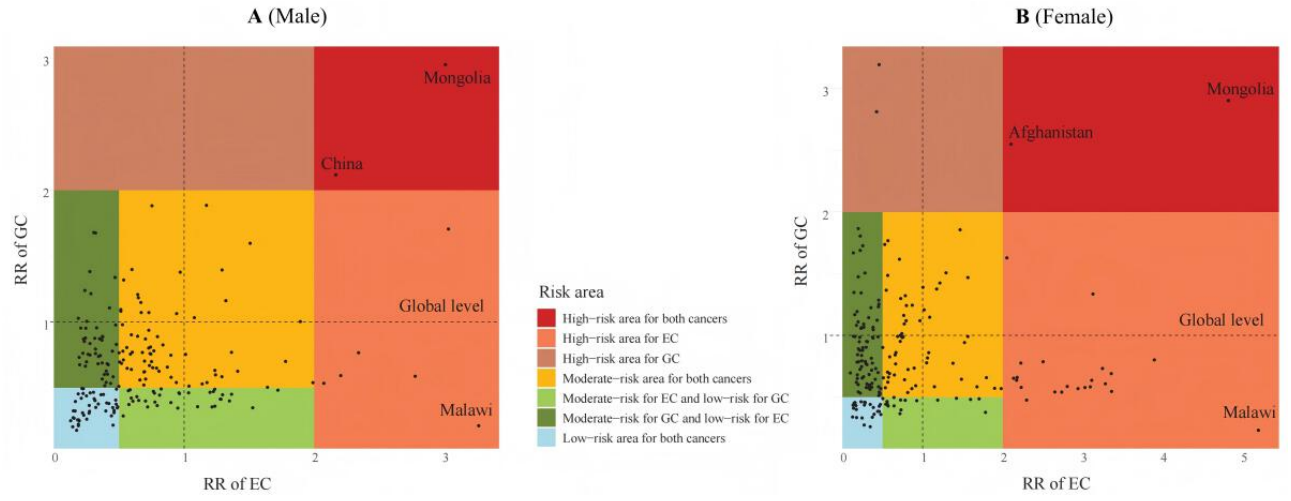
The study included data on the incidence of esophageal and gastric cancer from 204 countries and territories and 21 geographic regions. In 2019, the global ASIR of esophageal and gastric cancer were 6.51 (95% CI 5.69-7.25) and 15.59 (95% CI 14.11-17.15) per 100,000 person-years, respectively, with considerable variation observed across regions and sex groups. Among the 204 countries and territories provided by the GBD dataset, the ASIR of esophageal cancer ranged from a minimum of 0.91 (95% CI 0.65-1.58) in Nigeria to a maximum of 24.53 (95% CI 18.74-32.51) in Malawi, while the ASIR of gastric cancer ranged from a minimum of 3.28 (95% CI 2.67-3.91) in Malawi to a maximum of 43.70 (95% CI 34.29-55.10) in Mongolia. Overall, the ASIR of esophageal and gastric cancer was significantly higher in males than in females, and within the sex group, the ASIR of gastric cancer was significantly higher than that of esophageal cancer at the global level (Figure 1). In 2019, Malawi had the highest ASIR of esophageal cancer in both sexes (male: 33.08, 95% CI 24.44-44.43; female: 17.28, 95% CI 12.64-23.50), and Mongolia was ranked the top 5 for both esophageal (male: 30.48, 95% CI 22.58-37.90; female: 16.03, 95% CI 7.50-21.37) and gastric cancer (male: 66.04, 95% CI 51.50-82.68; female: 28.18, 95% CI 21.53-36.56) in both sexes (Table S1 in Multimedia Appendix 2). In a broader scale, among males, the ASIR of esophageal and gastric cancer in East Asia, Central Asia and high-income Asia Pacific all ranked within the top 6 among 21 geographic regions. Among males, East Asia had the highest ASIR for both esophageal (21.70, 95% CI 16.37-26.61) and gastric cancer (46.67, 95% CI 37.63-56.82), while High-income Asia Pacific ranked fifth for esophageal cancer (10.68, 95% CI 8.87-12.89) and second for gastric cancer (41.91, 95% CI 35.58-49.40), and Central Asia ranked sixth (9.51, 95% CI 8.37-11.53) and fifth (24.08, 95% CI 21.82-26.57), respectively. Similarly, in females, the regions with the top 6 ASIR for esophageal and gastric cancer were East Asia and Central Asia. East Asia ranked second for esophageal cancer (6.67, 95% CI 4.39-8.38) and third for gastric cancer (15.65, 95% CI 12.80-19.05), while Central Asia ranked fifth (4.70, 95% CI 4.19-5.29) and sixth (10.76, 95% CI 9.81-11.87), respectively (Figures S1 and S2 in Multimedia Appendix 2). The spatial autocorrelation analysis also showed that there was a significant clustering phenomenon in the spatial distribution of the incidence of esophageal and gastric cancer in both sex groups (all Moran I>0.20 and *P* value <.001; Figure 1).

Figure 1. ASIR of esophageal cancer (EC) and gastric cancer (GC) in 204 countries and territories in 2019, by sex. EC: esophageal cancer; GC: gastric cancer; ASIR: age-standardized incidence rate.



The 2019 risk area classification results were shown in Figure 2. In 2019, China and Mongolia belonged to the high-risk area for both esophageal and gastric cancer in males (Figure 2), while Afghanistan and Mongolia belonged to the high-risk area for both cancers in the females (Figure 2). Mongolia was identified as an overlapped high-risk area for both esophageal cancer and gastric cancer in males and females. In addition, the number of countries and territories belonging to the high-risk area for esophageal cancer alone was significantly higher in females than in males, and the number of countries and territories belonging to the low-risk area for both esophageal and gastric cancer was much lower in females than in males. Furthermore, no country or territory in males belonged to the high-risk area for gastric cancer alone, while in females, there were 2 countries (Guatemala and Bolivia). It is noteworthy that Malawi had the highest RR value for esophageal cancer (male RR=3.27; female RR=5.19) and a low RR value for gastric cancer (male RR=0.21; female RR=0.23) in both males and females. We further conducted Pearson correlation analysis for the RR values of esophageal and gastric cancer, and found that there was a positive correlation between the RR values of esophageal and gastric cancer in males (r=0.25; P<.001), but no significant correlation was found in females (r=0.02; P=.77).

Figure 2. Risk area classification map of esophageal cancer (EC) and GC (gastric cancer) for 204 countries and territories in 2019, by sex. A. Risk area classification map of EC and GC for 204 countries and territories in males. B. Risk area classification map of EC and GC for 204 countries and territories in females. EC: esophageal cancer; GC: gastric cancer; ASIR: age-standardized incidence rates; RR: risk ratio; obtained by comparing the ASIR levels of esophageal and gastric cancer in each country and territory against those of the global ASIR levels.



Temporal Trend and Correlation Between Esophageal and Gastric Cancer Incidence From 2010 to 2019

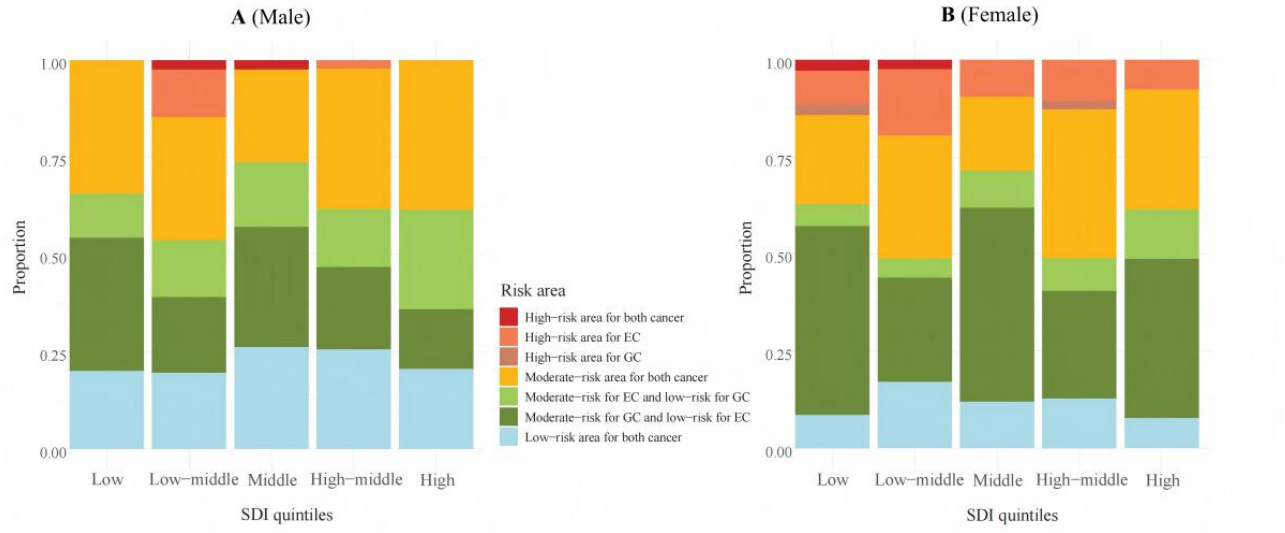
From 2010 to 2019, at the global level, the ASIR of esophageal cancer ranged from a peak of 7.50 (95% CI 6.10-8.02) in 2010 to a lowest point of 6.44 (95% CI 5.79-7.00) in 2017, while the ASIR of gastric cancer ranged from a peak of 18.25 (95% CI 17.14-19.22) in 2010 to a lowest point of 15.59 (95% CI 14.11-17.15) in 2019. And the ASIR of esophageal and gastric cancer decreased significantly in both sex groups globally. The AAPC for esophageal and gastric cancer in males was −1.43 (95% CI −1.58 to −1.27) and −1.76 (95% CI −2.08 to −1.43), respectively, while in females, the AAPC for esophageal and gastric cancer was −1.93 (95% CI −2.11 to −1.75) and −1.79 (95% CI −2.13 to −1.46), respectively. We selected all the high-risk countries and territories which had the top 5 ASIR of esophageal or gastric cancer in 2019 in both sex groups (14 countries and territories were finally presented in the table due to partial overlap; Table S2 in Multimedia Appendix 3). In males, the ASIR for esophageal and gastric cancer both showed a decreasing trend in 10 countries and territories, while in females, this trend was observed in 11 countries and territories. Furthermore, in all countries and territories except Bolivia, there was a strong positive correlation between the temporal trends in the ASIR of esophageal and gastric cancer (Pearson correlation coefficient>0.5). In addition, it is noteworthy that despite Cabo Verde being among the top 5 countries for ASIR of esophageal and gastric cancer in males, the ASIR for these cancers continued to show a significant increasing trend in males, with an increasing trend also observed in females.

We also performed Pearson correlation analyses for the temporal trends between esophageal and gastric cancer ASIR at the global level and across all 204 countries and territories. At the global level, the Pearson correlation coefficient (r) for the temporal trends in the ASIR for both cancers were 0.98 in males and 0.98 in females. The results also showed that a positive correlation between temporal trends in the ASIR of the 2 cancers was observed in most countries and territories, regardless of sex (Figure 3 in Multimedia Appendix 3). A normality test on the distribution of Pearson correlation coefficients across 204 countries and territories for both males and females indicated that the distributions were not normal. Wilcoxon rank-sum test results showed that there were differences (P<.001) in the distribution of Pearson correlation coefficient data between males and females in these 204 countries and territories, and the median Pearson correlation coefficient was higher for females than for males.

The Correlation Between SDI and Both Risk Areas and Temporal Trend

Based on the SDI Reference Quintiles publicly provided by the IHME and the SDI values for all locations since 1950 [24], we collected the SDI for 204 countries and territories in 2019, and classified these countries and territories into different SDI quintiles according to the SDI Reference Quintiles. The composition of risk areas for different SDI quintiles was shown in Figure 3. As shown in Figure 3, the high-risk area for both cancers all distributed in the middle and below SDI quintiles. In males, high-risk areas were distributed only in the low-middle, middle, and high-middle SDI quintiles (Figure 3), while high-risk areas were distributed across all SDI quintiles in females (Figure 3). The chi-square test results show that there was no difference in the composition ratio of risk areas among various SDI quintiles in both sex groups.

Figure 3. Stacked bar plot of sociodemographic index (SDI) quintiles and different risk areas, by sex. (A) The stacked bar plot of SDI quintiles and different risk areas in males. (B) The stacked bar plot of SDI quintiles and different risk areas in females. EC: esophageal cancer; GC: gastric cancer; SDI: sociodemographic index.



As shown in Table 1, the ASIR of esophageal and gastric cancer both showed a downward trend in all SDI quintiles from 2010 to 2019, with all 95% CI excluding 0. In both sexes, the average annual percentage decrease in ASIR for esophageal and gastric cancer in the middle SDI quintile was both substantial. In addition, the decrease in ASIR for esophageal cancer in this quintile over the past decade was significantly more substantial than in other SDI quintiles. In the middle SDI quintile, the average annual percentage decrease in ASIR for esophageal cancer over the decade was more substantial than that for gastric cancer across both sexes. Conversely, in other SDI quintiles except for females in the low-middle SDI, the decrease in ASIR

for esophageal cancer was less substantial than that for gastric cancer. Pearson correlation analysis indicated that the correlation between the temporal trends in the ASIR for esophageal and gastric cancer was high in all SDI quintiles (Table 1 and Figure S4 in Multimedia Appendix 4). Since the distributions of Pearson correlation coefficients in each SDI quintile was nonnormal in both sex groups after normality test, the Kruskal-Wallis test was used to assess the differences in correlation coefficients among these SDI quintiles. The Kruskal-Wallis test indicated no significant differences in the correlation between the temporal trends in the ASIR of esophageal and gastric cancer across various SDI quintiles in both sex groups.

Table . Average annual percent change (AAPC) in age-standardized incidence rates (ASIR) of esophageal cancer (EC) and gastric cancer (GC) among different sociodemographic index (SDI) quintiles, 2010 - 2019 (AAPC, %).

Location	Male (95% CI)	*r* [a]	Female (95% CI)	*r* [a]
Low SDI		0.85		0.94
EC	−0.27[b] (−0.42 to −0.12)		−0.39[b] (−0.46 to −0.33)	
GC	−1.37[b] (−1.53 to −1.21)		−0.74[b] (−0.84 to −0.65)	
Low−middle SDI		0.88		0.95
EC	−0.21[b] (−0.34 to −0.09)		−0.43[b] (−0.74 to −0.12)	
GC	−1.19[b] (−1.41 to −0.98)		−0.67[b] (−0.82 to −0.52)	
Middle SDI		0.87		0.94
EC	−2.56[b] (−2.77 to −2.35)		−3.79[b] (−4.04 to −3.53)	
GC	−1.90[b] (−2.13 to −1.67)		−2.26[b] (−2.64 to −1.88)	
High−middle SDI		0.76		0.94
EC	−0.95[b] (−1.28 to −0.62)		−1.58[b] (−1.84 to −1.31)	
GC	−1.66[b] (−1.84 to −1.48)		−2.13[b] (−2.28 to −1.97)	
High SDI		0.88		0.95
EC	−0.92[b] (−1.07 to −0.76)		−0.79[b] (−0.88 to −0.69)	
GC	−2.46[b] (−2.68 to −2.23)		−1.94[b] (−2.31 to −1.56)	

[a]Median Pearson correlation coefficients between temporal trends in the ASIR of esophageal and gastric cancer for countries and territories in each SDI quintile from 2010 to 2019.

[b]Indicates that 95% CI did not include 0.

Discussion

Principal Results

This study is the first to simultaneously report on the global temporal trends and spatial distribution of the ASIR for esophageal and gastric cancer, as well as their correlation based on GBD 2019 data. Our results show that there was a significant spatial clustering of the incidence for both cancers and a positive correlation between the risk of esophageal and gastric cancer across countries was observed in males. In addition, a codescending incidence trend between both cancers was observed in most countries and territories.

Due to the significant differences in the incidence of esophageal and gastric cancer between males and females [27,28], and the disparities in lifestyle, sex stratification was conducted in all analysis. In consistent with the previous studies, the risk of both esophageal and gastric cancer was high in Asia (especially East Asia and Central Asia) [5,30,31]. In addition, among Asian countries, the incidence of esophageal and gastric cancer was particularly serious in Mongolia (in 2019, the ASIR of both esophageal and gastric cancer ranked in the top 5 among both sexes). For Mongolia, the high incidence of esophageal cancer may be associated with high levels of fluoride in drinking water or drinking hot milk tea [32]. In addition, local cooking and heating mainly rely on coal and wood, resulting in high levels of fine particulate matter (diameter<2.5 μm), may also be one of the main reasons for the high incidence of esophageal cancer [33]. The spatial clustering phenomenon and the variation of geographical distribution in ASIR of esophageal and gastric cancer may be due to different lifestyles and environmental factors caused by differences in geographical and socioeconomic factors, as well as different histological subtypes of both cancers [34]. Compared with gastric cancer, there were more countries and territories with extremely high ASIR for esophageal cancer relative to the global level, which may be the reason why there were more countries and territories classified as the high-risk area for esophageal cancer than gastric cancer in this study. Although females were generally considered to have a lower risk of esophageal and gastric cancer than males, there were more countries and territories where females were at extremely high risk of esophageal and gastric cancer relative to the global

level. Those countries and territories, where the risk of esophageal and gastric cancer was much higher than the global level should be taken seriously. In addition, it is noteworthy that Malawi exhibited the highest risk for esophageal cancer alongside a very low risk for gastric cancer in both sex groups. The previous studies found that African countries with a higher incidence of esophageal cancer tend to have a lower estimated supply of selenium in their diets [35]. Therefore, the generally low selenium intake of the population in Malawi mainly caused by the reduced soil-to-crop selenium transfers in the local typical low pH soils may be one of the reasons for this phenomenon [35-37]. Since Malawi is one of the major tobacco producers in Africa, smokers have easier access to self-rolled tobacco (without filters), which will lead to smokers of this form of tobacco receive a higher dose of the carcinogenic products within the tobacco in comparison to store-bought cigarettes, thereby increasing the risk of developing esophageal cancer [38]. In addition, it has been reported that mycotoxins such as fumonisin B-1 stored in grain are fairly common in maize samples from Malawi, and although a direct causal relationship has not been established, this may be one of the reasons for the high incidence of esophageal cancer there [38]. The main source of energy in Malawian households is wood burning, which produces incomplete combustion products such as polycyclic aromatic hydrocarbons and may also be responsible for the high incidence of esophageal cancer [39]. In Pearson correlation analysis on the RR values for esophageal and gastric cancer among males and females, a positive correlation between the risk of incidence for esophageal and gastric cancer was observed in males, whereas no such correlation was found in females. Taking into account the possibility that the results may be influenced by a greater number of extreme values in females, we conducted a correlation analysis after removing some outliers. Nevertheless, no statistically significant correlation was found. One possible explanation is that smoking, as a primary common risk factor for both esophageal and gastric cancer, occurs at a significantly higher prevalence in males than in females (about 4 - 5 times higher) [40].

From 2010 to 2019, there was a global trend of decline in the ASIR for both esophageal and gastric cancer among males and females. The decline in the incidence of both cancers may be attributed to the improvements in the socioeconomic level and population health awareness in recent years [41-43]. It is worth mentioning that there were still some countries and territories, even some high-risk countries and territories including Cabo Verde, exhibited an increasing trend in the ASIR of esophageal and gastric cancer from 2010 to 2019. Although the significant increase of cancer registers compared with the past may be one of the reasons, it is necessary to actively control the incidence of esophageal and gastric cancer for those countries and territories showing an increasing trend. The reason for the stronger positive correlation between the temporal trends of esophageal and gastric cancer in females compared to that in males is unclear. However, it is certain that a significant positive correlation exists, which may be related to the shared risk factors due to their anatomic proximity.

When exploring the correlation between SDI and risk areas classified by RR values of esophageal and gastric cancer, no statistically significant difference was found in the composition ratio of risk areas across various SDI quintiles. This may be related to the low number of countries and territories belonging to the high-risk area for both cancers and gastric cancer alone. Consistent with the global trend, all SDI quintiles exhibited a decreasing trend in the ASIR of esophageal and gastric cancer, which indicated that, overall, the incidence of esophageal and gastric cancer had been improving in regions with different SDI quintiles from 2010 to 2019. Compared with other quintiles, the ASIR of esophageal and gastric cancer in middle SDI quintile both showed a substantial decreasing trend, which may be related to the high ASIR of both esophageal and gastric cancer in middle SDI quintile. Although the ASIR of gastric cancer was significantly higher than that of esophageal cancer, in contrast to other SDI quintiles, the decreasing trend in ASIR for esophageal cancer over the decade was more substantial than that for gastric cancer in middle SDI quintile. This opposite phenomenon, observed in the middle SDI quintile, calls for more rational public policies to strengthen the control of gastric cancer related risk factors. The correlation between the temporal trends in the incidence of esophageal and gastric cancer was strong among different SDI quintiles, and no statistically significant difference of this correlation was found across various SDI quintiles.

Strengths and Limitations

Our study has numerous strengths, including the ability to visually display the risk of both esophageal and gastric cancer in various countries and territories through risk area classification. This aids in developing prevention strategies tailored to shared or distinct risk factors of the 2 digestive cancers, while also considering local characteristics. Our study also has some limitations. First, the data we analyzed is sourced from the GBD 2019, the quality of some data, especially that from low-income or low SDI countries, is difficult to be guaranteed. Second, esophageal cancer includes 2 histological subtypes—esophageal squamous cell carcinoma and esophageal adenocarcinoma [44,45], while gastric cancer includes cardia gastric cancer and noncardia gastric cancer subtypes [46,47]. There are analogous and distinct etiologies with modifiable risk factors between these subtypes, as well as epidemiological characteristics [48-51]. However, due to the limitations of the GBD database, our study did not differentiate the subtypes of esophageal cancer and gastric cancer. Third, the results of Moran I are highly dependent on the choice of the conceptualization of spatial relationships. For global analysis, selecting an appropriate conceptualization is challenging, especially when regions are separated by natural barriers such as oceans. Contiguity measure may fail to capture spatial relationships across such barriers, while distance measure requires careful consideration of distance thresholds. In addition, Moran I is typically calculated for a single time point, which does not account for dynamic changes in spatial patterns over time. Furthermore, more detailed work is required to identify the primary modifiable risk factors in high-risk areas for each cancer, which will aid in more precisely reducing the global incidence of esophageal and gastric cancer.

Conclusions

This spatiotemporal correlation study simultaneously investigates esophageal cancer and gastric cancer, which share many risk factors. The results shows that there was a significant spatial clustering of the incidence for esophageal and gastric cancer and a positive correlation between the risk of both cancers across countries was observed in males. In addition, a codescending incidence trend between both cancers was observed at the global level. Despite the overall declining trend in the incidence rates of both esophageal and gastric cancer, they still pose a heavy disease burden worldwide. Analyzing the correlations in the global distribution and temporal trends of the incidence of esophageal and gastric cancer can help to gain a deeper understanding of the homogeneity and heterogeneity in the incidence pattern of these 2 cancers to optimize the allocation of global public health resources.

Acknowledgments

We sincerely appreciate the works by the Global Burden of Disease study 2019 collaborators and thank all the researchers and collaborators who were involved in this study for their efforts and contributions. Abstract

Background: Cancers of the bladder, kidney, and prostate are the 3 major genitourinary cancers that significantly contribute to the global burden of disease (GBD) and continue to show increasing rates of morbidity and mortality worldwide. In mainland China, understanding the cancer burden on patients and their families is crucial; however, public awareness and concerns about these cancers, particularly from the patient's perspective, remain predominantly focused on financial costs. A more comprehensive exploration of their needs and concerns has yet to be fully addressed.

Objective: This study aims to analyze trends in online searches and user information–seeking behaviors related to bladder, kidney, and prostate cancers—encompassing descriptive terms (eg, "bladder cancer," "kidney cancer," "prostate cancer") as well as related synonyms and variations—on both national and regional scales. This study leverages data from mainland China's leading search engine to explore the implications of these search patterns for addressing user needs and improving health management.

Methods: The study analyzed Baidu Index search trends for bladder, kidney, and prostate cancers (from January 2011 to August 2023) at national and provincial levels. Search volume data were analyzed using the joinpoint regression model to calculate annual percentage changes (APCs) and average APCs (AAPCs), identifying shifts in public interest. User demand was assessed by categorizing the top 10 related terms weekly into 13 predefined topics, including diagnosis, treatment, and traditional Chinese medicine. Data visualization and statistical analyses were performed using Prism 9. Results revealed keyword trends, demographic distributions, and public information needs, offering insights into health communication and management strategies based on online information-seeking behavior.

Results: Three cancer topics were analyzed using 39 search keywords, yielding a total Baidu Search Index (BSI) of 43,643,453. From 2011 to 2015, the overall APC was 15.2% (P<.05), followed by –2.8% from 2015 to 2021, and 8.9% from 2021 to 2023, with an AAPC of 4.9%. Bladder, kidney, and prostate cancers exhibited AAPCs of 2.8%, 3.9%, and 6.8%, respectively (P<.05). The age distribution of individuals searching for these cancer topics varied across the topics. Geographically, searches for cancer were predominantly conducted by people from East China, who accounted for approximately 30% of each cancer search query. Regarding user demand, the total BSI for relevant user demand terms from August 2022 to August 2023 was 676,526,998 out of 2,570,697,380 (15.74%), representing only a limited total cancer-related search volume.

Conclusions: Online searches and inquiries related to genitourinary cancers are on the rise. The depth of users' information demands appears to be influenced by regional economic levels. Cancer treatment decision-making may often involve a family-centered approach. Insights from internet search data can help medical professionals better understand public interests and concerns, enabling them to provide more targeted and reliable health care services.

KEYWORDS

bladder cancer; kidney cancer; prostate cancer; Baidu Index; infodemiology; public interest; patients' concern

Introduction

Cancer poses a significant burden on global public health [1]. In urology, bladder, kidney, and prostate cancers are the 3 primary genitourinary cancers contributing to the global burden of disease (GBD), with persistently high morbidity and mortality rates [1,2]. According to a GBD report from 2019, the annual global incidence rates of bladder, kidney, and prostate cancers have risen by 154.78%, 123.34%, and 169.11%, respectively, over the past 2 decades, making them the most prominent cancers in the field of urology [3,4]. In mainland China, the incidence rates of bladder, kidney, and prostate cancers in 2019 had doubled compared with 1990 and are projected to triple by 2030 [2], with 192,390 cases of bladder cancer, 126,980 cases of kidney cancer, and 315,310 cases of prostate cancer. Therefore, precautionary measures are essential in addition to gathering information and assessing the disease burden using real-world data.

Infodemiology was defined as "The framework for an emerging set of public health informatics methods to analyze search, communication and publication behavior on the Internet." It has been shown to effectively highlight public health issues, assess the impact of health care policies, and uncover public concerns during global pandemics, as well as in chronic and contagious diseases, along with related public acceptance [5-9]. Examining underlying trends in user behavior and the specific demands associated with major genitourinary cancers could potentially provide insights into regional health information–seeking behaviors and population-level interests.

Cancer imposes a significant burden on patients and their families, typically measured in terms of financial costs and clinical outcomes [10,11]. However, there is limited understanding of its broader impacts, such as public awareness, emotional well-being, and social participation. In China, previous studies have examined prevalent noncancer urological issues and their online visibility using data from the Baidu Index [6,12,13], a tool that analyzes search behaviors to reflect public interest in health topics. While prior research has explored general cancer-related searches, these studies primarily focused on incidence correlations and population-level disparities across 28 cancer types [14], offering limited insights into specific user demands or temporal and geographic patterns.

This study aims to address this gap by focusing on 3 major genitourinary cancers: bladder cancer, kidney cancer, and prostate cancer. Using Baidu Index data, we analyzed internet search trends, user needs, and associated geospatial and temporal patterns. By identifying search behaviors and topics of interest, we seek to provide actionable insights into public health awareness and address unmet needs, potentially contributing to the improvement and guidance of health care strategies.

Methods

Keyword Selecting and Data Retrieving

Baidu (Baidu, Inc.), the leading search engine in mainland China, accounts for 92.1% of the search volume and 93.1% of user coverage [15]. Its analytics platform, Baidu Index, allows for tracking keyword popularity trends and analyzing related user demands [6,7,14]. Comparable to Google's platform on a global scale, Baidu has been validated as a reliable tool for studying online search trends and user behavior in infodemiology research within China [16,17].

This study primarily focuses on analyzing the temporal search trends of cancer-related terms associated with kidney, bladder, and prostate cancers. Based on defined criteria, these terms are characterized as compounds [6], combining morphemes denoting a urological organ with those indicating tumor-related concepts. The key morphemes identified were (1) "肾脏" or "肾" (the kidney), (2) "膀胱" (the bladder), (3) "前列腺" (the prostate), and (4) "肿瘤" (the tumor). The Baidu Index platform automatically matched these combinations with all available search keywords, including synonyms and complex derivatives. Measures were implemented to prevent duplication and omissions, following approaches detailed in previous studies [6,18]. Synonyms and complex derivatives were screened and selected to minimize ambiguity and bias arising from language habits, as previously described [6,13]. All available search keywords related to these 3 cancer types were categorized based on their connotations and are listed in Multimedia Appendix 1.

The Baidu Index platform consists of 3 key modules: (1) the search trend module, (2) the user demand module, and (3) the demographic portrait module. These modules enable the analysis of search demand from multiple perspectives, including popularity trends, topic-related concerns, and geodemographic features [6,13]. Search popularity is quantified using the Baidu Search Index (BSI), a key metric based on daily recorded search demand. With integrated data on location, gender, age, and other elements, trends and demographic profiles of the population can be visualized and retrieved [6,13]. Search trend data, available since 2011, were retrieved from the search trend module of the Baidu Index platform [14]. Data at both provincial and national scales were collected for the period from January 1, 2011, to July 31, 2023. The most recent data from the geodemographic and user demand modules were obtained from the user demand module on the Baidu Index official website [9,19].

Data Processing and Statistical Analysis

The Baidu Index is a data-sharing platform that leverages extensive user behavior data to measure search trends. By tracking the frequency of unique keyword searches and their weighting within Baidu's overall search volume, it provides a metric for keyword popularity. This study collected data on a daily, weekly, monthly, and yearly basis to capture a

comprehensive view of cancer-related search patterns. Sequential plotting of BSI data for each term was conducted to illustrate trends in public interest. Changes in trends over time were analyzed using the Joinpoint Regression Model (program version 4.7.0.0; Statistical Research and Applications Branch, National Cancer Institute). This model, well-suited for time-series analysis of large data sets, identifies statistically significant shifts in trends. The annual percentage change (APC) was calculated to summarize yearly trends within specified intervals, measuring year-over-year percentage changes. The average APC (AAPC) was used to evaluate trends over extended periods, providing a more stable estimate of the overall trend direction and rate of change [20,21]. For each topic—bladder cancer, kidney cancer, and prostate cancer—the public demand trend was illustrated through sequentially plotted BSI data. Intergroup differences were analyzed using the Student *t* test and Kruskal-Wallis test, as appropriate. A *P* value of <.05 was considered statistically significant.

In the user demand section, the top 10 most frequently mentioned words related to each search keyword were listed weekly and sorted by cancer type. This allowed for the identification and analysis of the most prominent and commonly discussed topics for each cancer type. In line with previous findings, we used a 13-topic system to categorize user demand–related terms, helping to clarify users' main concerns and implied intentions [13]. Aside from some random or off-topic terms, these categories were defined as follows: (1) complaint, (2) inquiry, (3) treatment and decision, (4) health issue, (5) diagnosis, (6) hospital and service, (7) symptom confirmation, (8) tests and examinations, (9) prognosis, (10) traditional Chinese medicine (TCM) complaint, (11) TCM inquiry, (12) TCM ingredient, and (13) TCM regimen.

All databases were constructed using Excel 2019 (Microsoft Corporation). The APC was calculated with the Joinpoint Regression Model, program version 4.7.0.0 (Statistical Research and Applications Branch, National Cancer Institute). Statistical analysis and figure creation were performed using Prism 9 for macOS (version 9.5.0 (525); GraphPad Software).

Ethical Considerations

We used publicly available, anonymized data that can be accessed without special permissions. As the data are aggregated and publicly accessible, IRB approval or exemption was not required.

Results

Available Trends Data in Urology Cancer Topics

We identified and confirmed 39 valid search keywords on the Baidu Index platform. These keywords are theme-based synonyms and moderate derivative terms that convey specific motives or demands. Among these, 13 keywords pertained specifically to bladder cancer, while 15 and 11 keywords were related to kidney cancer and prostate cancer, respectively. For theme categorization, 4 topics were identified: (1) complaint, with 9 keywords; (2) inquiry, with 23 keywords; (3) treatment, with 4 keywords; and (4) prognosis, with 3 keywords. All available search keywords related to these 3 urological cancers, along with their English equivalent translations, are listed in Multimedia Appendix 1.

The general search volume for all 3 urological cancers increased to a mean of 10,737.74 (SD 1026.29) from an initial mean of 5975.68 (SD 770.42). Specifically, the average daily search volume for bladder cancer rose to 3453.09 (SD 337.44) in 2023 from an initial average of 2275.72 (SD 302.17). For kidney cancer, the average daily search volume increased to 2976.78 (SD 319.64) from an initial average of 1706.84 (SD 262.95). Similarly, the search volume for prostate cancer grew to a mean of 4307.87 (SD 417.68) from 1993.12 (SD 297.99). According to the trend module, the total BSI for these top 3 urological cancers was 43,643,453. Specifically, the 13-year summed BSI ratio was 37.37% (15,972,271/43,643,453) for bladder cancer, 28.27% (12,079,106/43,643,453) for kidney cancer, and 34.36% (15,592,076/43,643,453) for prostate cancer (Figure 1). Regarding topic preferences for each cancer, the BSI ratio for complaint and inquiry was dominant, accounting for 90.26%, 96.10%, and 79.53% across all 4 topics for bladder cancer, kidney cancer, and prostate cancer, respectively (Figure 2).

To illustrate search trends over time since January 1, 2011, the daily request–based BSI for each cancer was analyzed both overall and by specific topics. The significance of these trends was evaluated using the APC model, as shown in Figures 1 and 2.

Based on the average annual BSI counts, a general growth in search requests for all 3 urological cancers was observed. The overall APC was 15.2% (*P*<.05) from 2011 to 2015, –2.8% from 2015 to 2021, and 8.9% from 2021 to 2023, resulting in an AAPC of 4.9%. For bladder cancer, the APC was 8.3% (*P*<.05) from 2011 to 2019, –11.7% from 2019 to 2021, and 7.4% from 2021 to 2023, with an AAPC of 2.8%. For kidney cancer, the APC was 8.0% (*P*<.05) from 2011 to 2019, –9.6% from 2019 to 2021, and 11.4% from 2021 to 2023, resulting in an AAPC of 3.9%. For prostate cancer, the APC was 17.7% (*P*<.05) from 2011 to 2015, –3.1% from 2015 to 2020, and 10.4% from 2021 to 2023, yielding an AAPC of 6.8% (*P*<.05).

Specifically within the bladder cancer theme, the APCs for the *complaint* topic were 8.0% (*P*<.05) from 2011 to 2021 and –5.1% from 2021 to 2023, with an AAPC of 1.2%. For the *inquiry* topic, the APCs were 20.8% (*P*<.05) from 2011 to 2014 and 1.2% from 2014 to 2023, with an AAPC of 4.8% (*P*<.05). For the *prognosis* topic, the APCs were –20.8% (*P*<.05) from 2011 to 2014, 15.6% from 2014 to 2018, and –6.9% from 2018 to 2023, resulting in an AAPC of –4.4%. For the *treatment* topic, the APCs were –5.4% from 2011 to 2016, 7.6% from 2016 to 2019, and –23.9% (*P*<.05) from 2019 to 2023, with an AAPC of –9.4%.

In the kidney cancer theme, the APCs for the *complaint* topic were 6.8% (*P*<.05) from 2011 to 2019 and –3.6% from 2019 to 2023, with an AAPC of 3.2% (*P*<.05). For the *inquiry* topic, the APCs were 14.0% (*P*<.05) from 2011 to 2017, –9.2% (*P*<.05) from 2017 to 2021, and 17.8% from 2021 to 2023, resulting in an AAPC of 6.2% (*P*<.05). For the *prognosis* topic, the APCs were –19.0% (*P*<.05) from 2011 to 2019 and 15.7% from 2019 to 2023, with an AAPC of –11.0% (*P*<.05). For the *treatment* topic, the APCs were 2.5% from 2011 to 2014,

–47.1% from 2014 to 2018, and 42.6% from 2019 to 2023, with an AAPC of –12.2% (*P*<.05). In the prostate cancer theme, the APCs for the *complaint* topic were 25.4% (*P*<.05) from 2011 to 2013, 3.1% from 2013 to 2017, and –1.4% from 2017 to 2023, resulting in an AAPC of 4.2%. For the *inquiry* topic, the APCs were 21.2% (*P*<.05) from 2011 to 2015, –4.6% from 2015 to 2020, and 11.8% from 2020 to 2023, with an AAPC of 11.8%. For the *prognosis* topic, the APCs were –6.2% (*P*<.05) from 2011 to 2018 and 2.5% from 2018 to 2023, with an AAPC of –3.0% (*P*<.05). For the *treatment* topic, the APCs were 41.6% (*P*<.05) from 2011 to 2015, –5.8% from 2015 to 2018, and 17.4% (*P*<.05) from 2018 to 2023, resulting in an AAPC of 18.2% (*P*<.05).

Figure 1. Online search trends in bladder, kidney, and prostate cancer topics since 2011. (A) Searching trend of each cancer topic; (B) Sum BSI proportion of each cancer topic. APC: annual percentage change; BSI: Baidu Search Index.

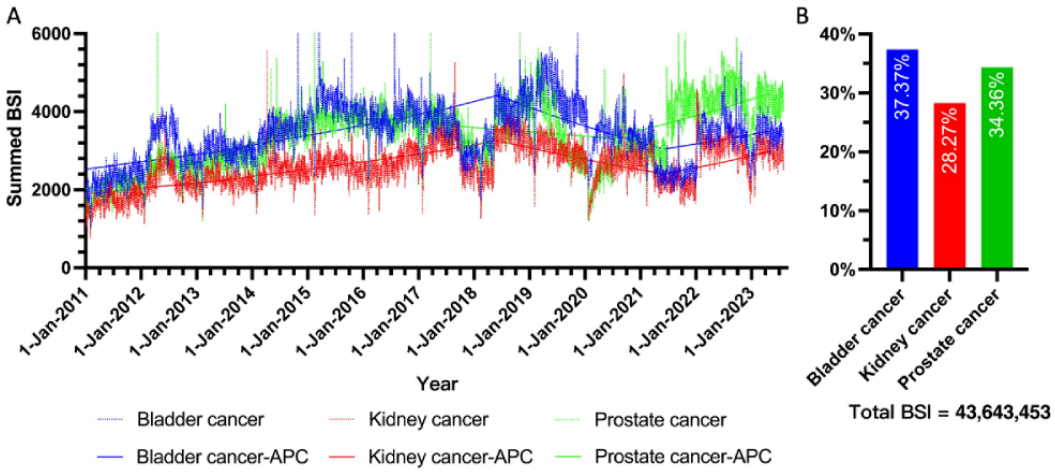

Figure 2. Online search trends for specific topics related to bladder, kidney, and prostate cancer since 2011. (A) Searching trend of specific topics in bladder cancer. (B) Sum BSI proportion of specific topics in bladder cancer. (C) Searching trend of specific topics in kidney cancer. (D) Sum BSI proportion of specific topics in kidney cancer. (E) Searching trend of specific topics in prostate cancer. (F) Sum BSI proportion of specific topics in prostate cancer. APC: annual percentage change; BSI: Baidu Search Index.

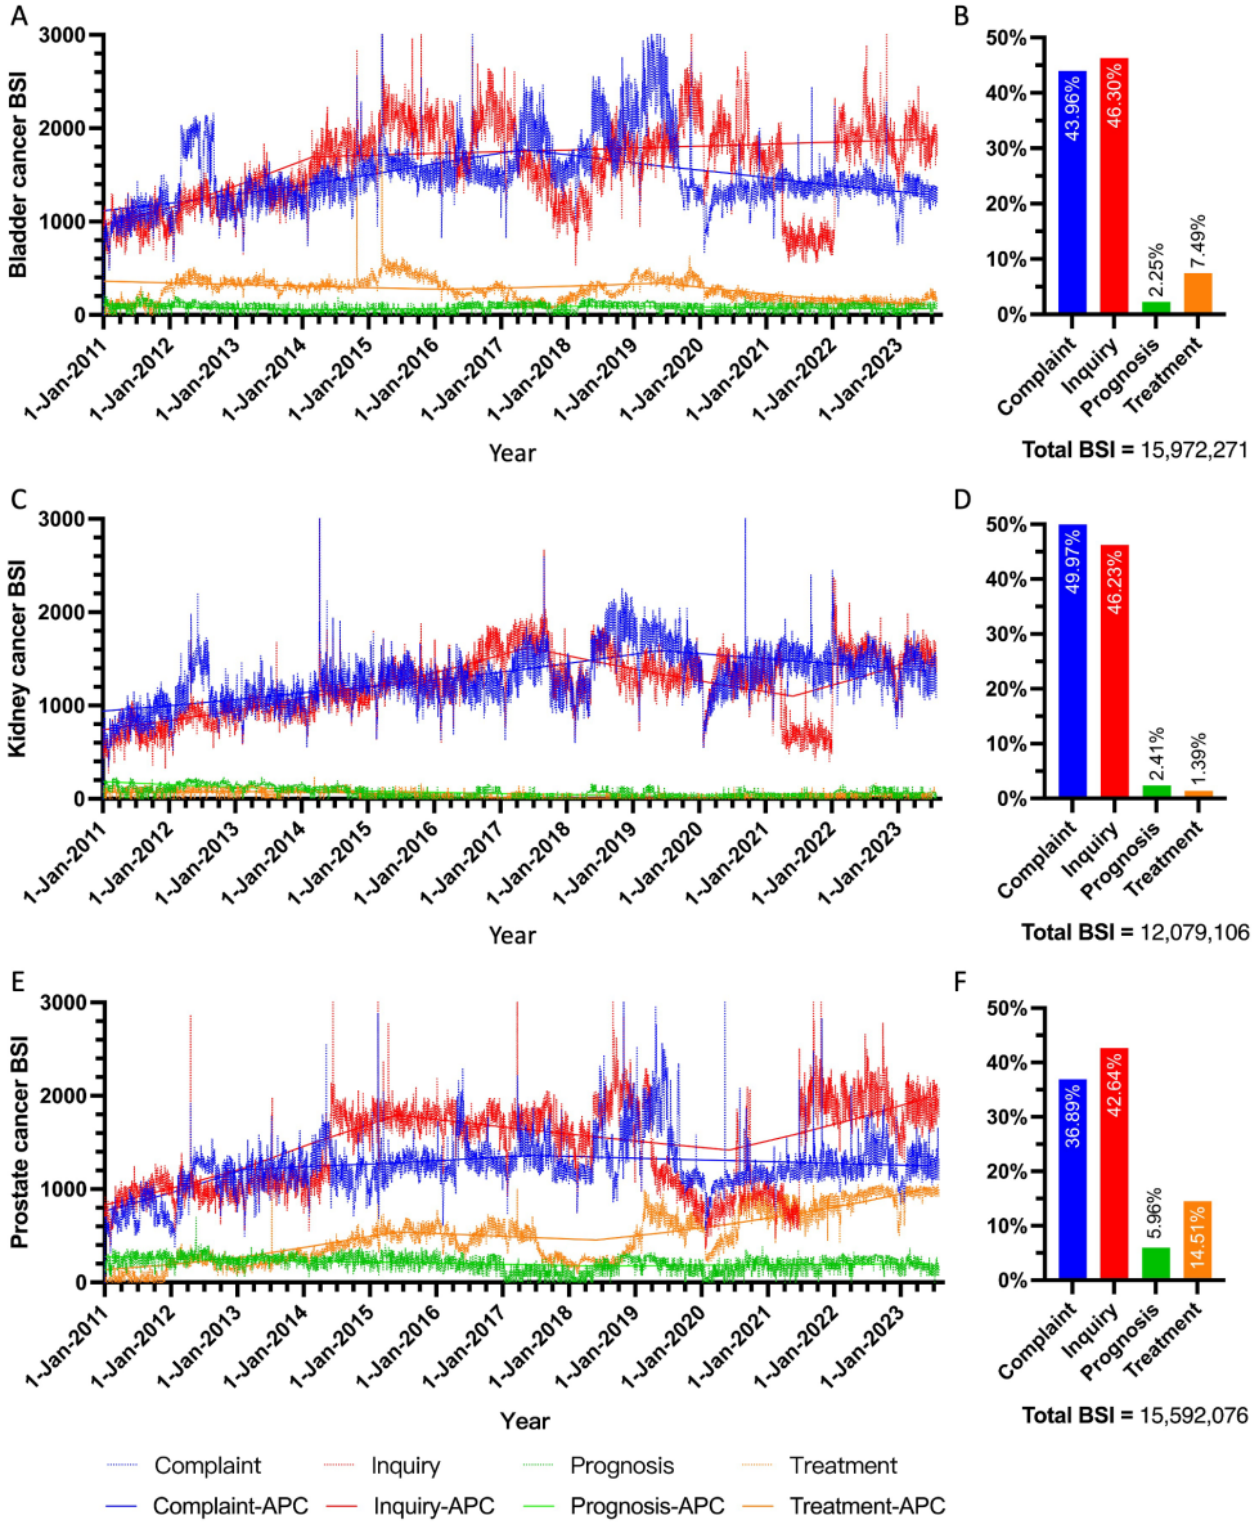
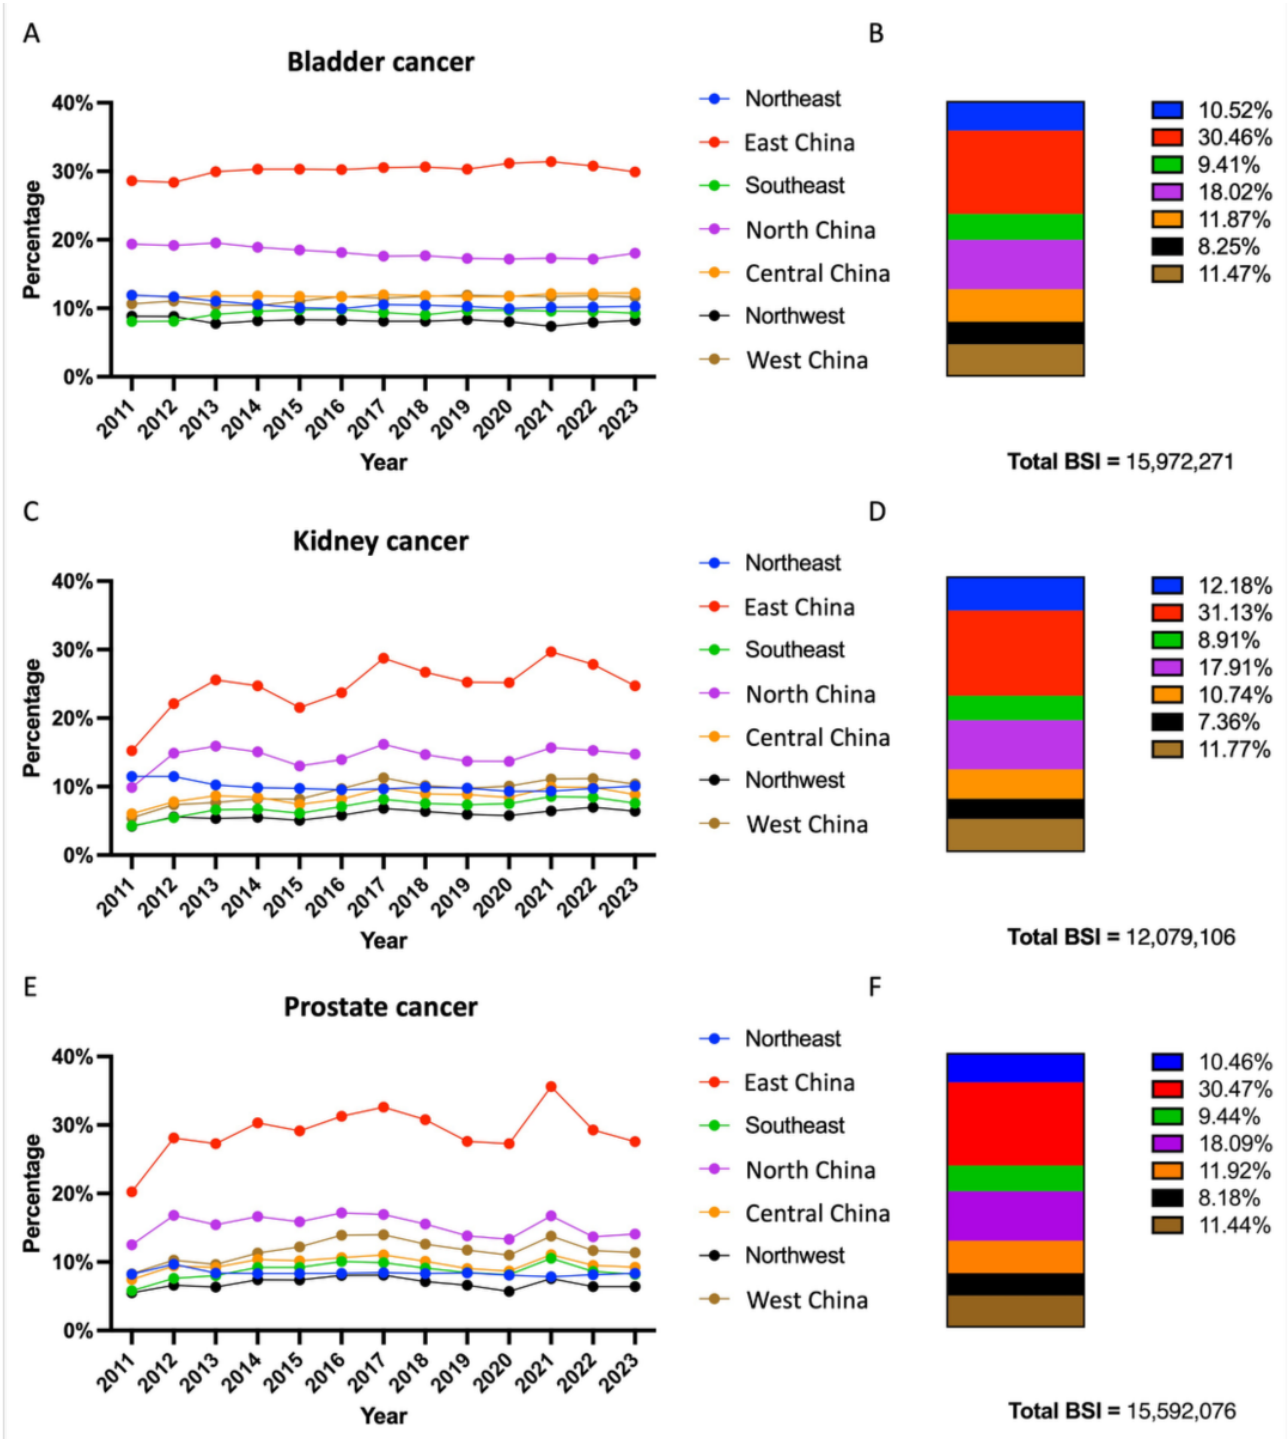


Geographic Differences

The geographic distribution of each cancer type was calculated based on provincial BSI data and categorized according to the 7 Chinese administrative divisions [6]. Figure 3 shows the 13-year regional BSI proportions for each cancer type with valid search records. Search requests were predominantly from East China, accounting for 30.46%, 31.13%, and 30.47% of bladder, kidney, and prostate cancer searches, respectively, followed by North China. Search demand from Central China, South China, and West China was comparable, each contributing around 11%. The Northeast and Northwest regions ranked the lowest, collectively accounting for approximately 8% of searches for each urological cancer.

Figure 3. Regional distribution of online search in bladder, kidney, and prostate cancer topics. (A) Annual BSI trend for each region in the topic of bladder cancer. (B) Total search rates for each region on the topic of bladder cancer. (C) Annual BSI trend for each region in the topic of kidney cancer. (D) Total search rates for each region on the topic of kidney cancer. (E) Annual BSI trend for each region in the topic of prostate cancer. (F) Total search rates for each region on the topic of prostate cancer. BSI: Baidu Search Index.



Demographic Differences

From the demographic distribution analysis, variations in age and gender distribution were observed across each cancer theme and specific topic. In the bladder cancer theme, search requests for each topic were primarily made by individuals aged 20-29 and 30-39 years. For kidney cancer, the topics of complaint, inquiry, and prognosis were predominantly searched by the 20-29-year age group, whereas the topic of treatment was mainly searched by individuals aged 40-49 years. In the prostate cancer theme, the topics of inquiry and treatment were primarily requested by the 30-39-year age group, while searches for prognosis were mainly made by those aged 40-49 years. Notably, no dominant age group was identified for searches in the complaint topic for prostate cancer (Table 1).

Table 1. Demographic differences in each cancer topic.

Theme and topic	≤19 years	20-29 years	30-39 years	40-49 years	≥50 years	Female	Male
Bladder cancer							
Complaint, n/N (%)	2447/40,701 (6.01)	12,411/40,701 (30.49)	14,187/40,701 (34.86)	6954/40,701 (17.09)	4702/40,701 (11.55)	22,332/40,701 (54.87)	18,369/40,701 (45.13)

Keywords, Related Terms, and Search Frequency

During the data-providing period from August 15, 2022, to August 13, 2023, 27,065 out of 31,200 words were identified as in-topic, representing valid user demand. The total BSI for these relevant user demand terms was 676,526,998, accounting for only 676,526,998 of 2,570,697,380 (15.74%) total search requests. Detailed distributions of these relevant terms and their search frequencies are shown in Figure 4. The valid search ratio and demand distribution were also summarized overall (Figure 4) and specifically for each cancer theme (Figures 5 and 6). Additionally, the 3 most representative user-demand issues were identified and ranked based on frequency and search popularity (Tables 2 and 3).

Figure 4. erm categories related to all cancers (bladder, kidney, and prostate) in the Baidu Index user demand module (August 2022 to August 2023). (A) The most frequently appearing related words (word units) in Baidu Index searches related to bladder, kidney, and prostate cancers. (B) The most searched related words in Baidu Index inquiries related to bladder, kidney, and prostate cancers. BSI: Baidu Search Index; TCM: traditional Chinese medicine.

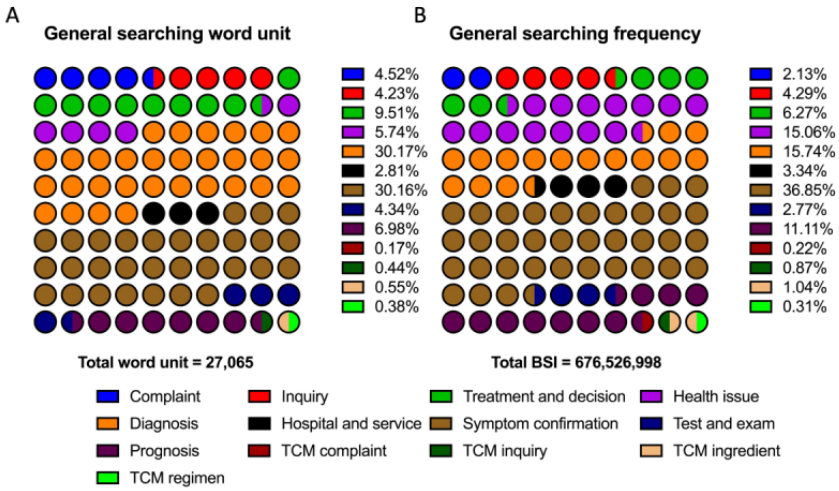

Figure 5. Term categories of the most frequently appearing related words for each cancer (August 2022 to August 2023). (A) Most frequently appearing related words (word units) in Baidu Index searches related to (A) bladder cancer, (B) kidney cancer, and (C) prostate cancer. TCM: traditional Chinese medicine.

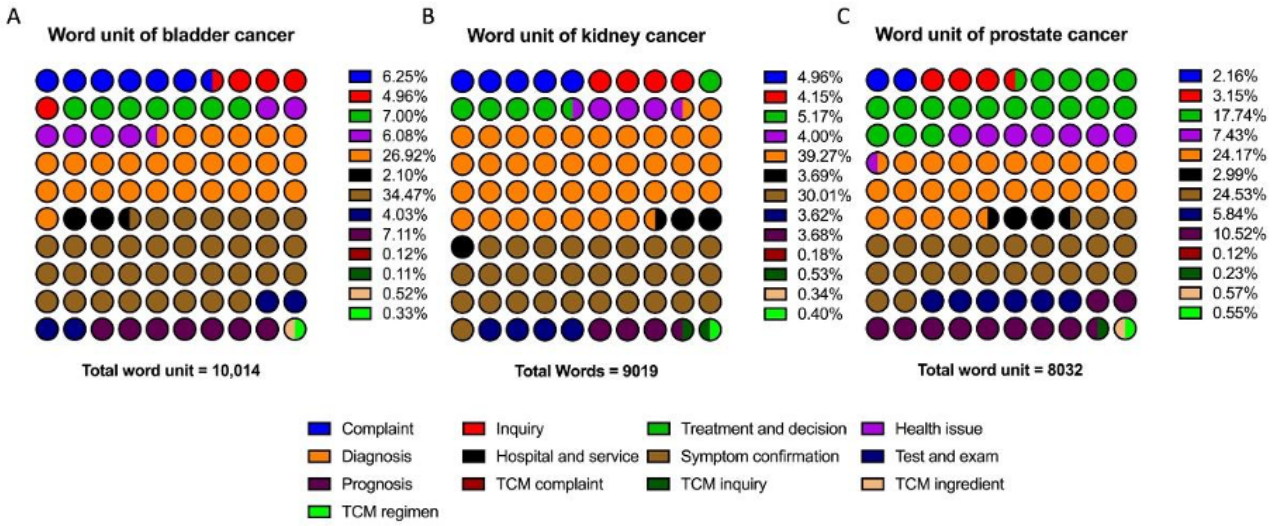

Figure 6. Term categories related to the most searched related words for each cancer (August 2022 to August 2023). Most searched related words (word units) in Baidu Index searches related to (A) bladder cancer, (B) kidney cancer, and (C) prostate cancer. BSI: Baidu Search Index; TCM: traditional Chinese medicine.

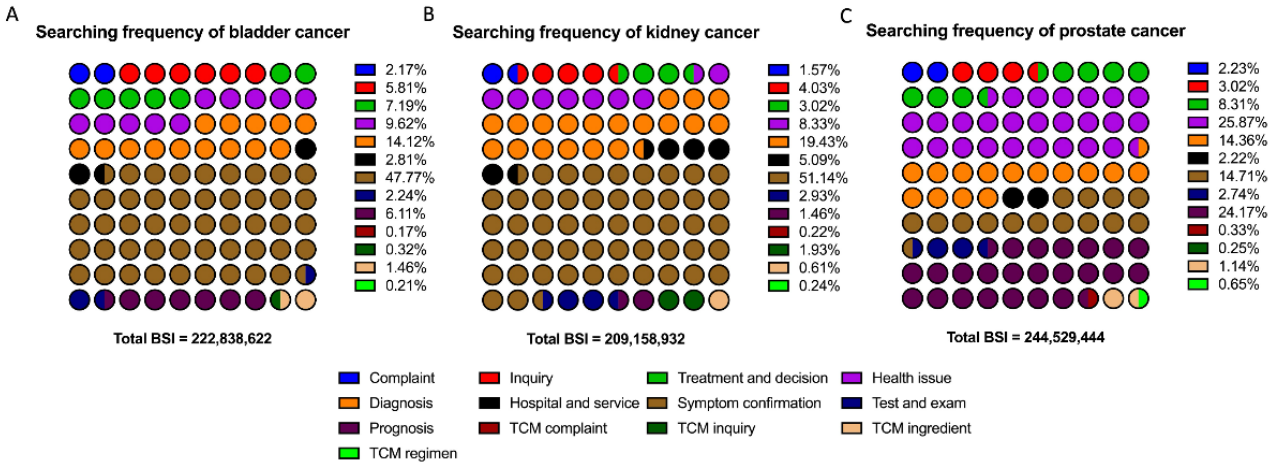

Table 2. The top 3 most frequently appearing related words (word units) searched in the Baidu Index for each type of cancer.

Category and term	Bladder cancer	Count, n	Kidney cancer	Count, n	Prostate cancer	Count, n
Complain						
Term 1	血尿(Hematuria)	96	血尿 (Hematuria)	51	尿潴留 (Urinary retention)	19
Term 2	尿血 (Urinate with blood)	79	无痛血尿 (Painless hematuria)	40	血精 (Hemospermia)	9
Term 3	无痛血尿 (Painless hematuria)	74	尿血 (Urinate with blood)	33	前列腺痛 (Prostatic pain)	7
Etiology and causes						
Term 1	小便时尿出血是怎么回事 (What is urinate with blood)	81	肾肿瘤分类 (Phenotypes in kidney cancer)	19	前列腺钙化是什么意思 (What is prostatic calcification)	34
Term 2	尿频尿急尿不尽是什么原因造成的 (What caused urinary frequency, urgency, and incomplete urinate)	26	肾积水是什么原因造成的怎么治疗 (What caused the hydronephrosis)	13	前列腺钙化灶是什么意思 (What does prostatic calcification mean)	26
Term 3	尿频繁是什么原因 (What caused frequently urination)	19	小便时尿出淡红色是怎么回事 (What caused reddish urination)	10	前列腺炎怎么引起的 (What caused prostatitis)	11
Treatment and pharmaceutical						
Term 1	膀胱癌治疗 (Treatment for bladder cancer)	115	肾癌的治疗 (Treatment for kidney cancer)	19	前列腺癌治疗 (Treatment for prostate cancer)	129
Term 2	膀胱炎怎么治疗 (Treatment for cystitis)	21	肾囊肿怎么治疗 (Treatment for renal cyst)	11	前列腺增生的最佳治疗方法 (Best treatment for prostate cancer)	96
Term 3	前列腺癌治疗 (Treatment for prostate cancer)	13	肾肿瘤切除 (Nephrectomy for kidney cancer)	10	前列腺癌的治疗 (Prostate cancer treatment)	74
Health care–related terms						
Term 1	膀胱 (Bladder)	169	肿瘤 (Tumor)	24	前列腺 (Prostate)	174
Term 2	四种癌已经不是癌了 (4 no longer diseases defined as cancer)	117	肾脏 (Kidney)	23	四种癌已经不是癌了 (4 no longer diseases defined as Cancer)	165
Term 3	芳香胺 (Aromatic amines)	28	肾癌饮食 (Diet for kidney)	17	前例腺 (“Prastate”)	7
Diagnosis						
Term 1	膀胱癌 (Bladder cancer)	499	肾癌 (Kidney cancer)	395	前列腺癌 (Prostate cancer)	422
Term 2	膀胱肿瘤 (Bladder tumor)	180	肾囊肿 (Renal cyst)	242	前列腺癌骨转移 (Prostate cancer with bone metastasis)	115
Term 3	膀胱炎 (Cystitis)	169	肾肿瘤 (Tumors in kidney)	230	前列腺炎 (Prostatitis)	108
Health care services and commodities						
Term 1	北京大学第一医院 (The first affiliate Hospital of PKU)	4	中国最好的肾病医院 (The best hospital for treating kidney diseases)	42	海外医疗 (Oversee medication service)	15
Term 2	泌尿外科哪个医院好 (What is the best urology hospital)	4	治疗肾癌最好的医院 (The best hospital for treating kidney cancers)	30	麻省总医院 (Massachusetts General Hospital)	14
Term 3	吴阶平 (Prof Jiepin Wu)	3	肿瘤医院全国排名一 (National NO.1 Oncology Hospital)	10	厚朴方舟 (Hopenoak.com)	7
Diagnosis confirmation						
Term 1	膀胱癌早期是什么症状 (Early symptoms of bladder cancer)	431	肾癌早期的五个表现 (Early symptoms of bladder cancer)	376	前列腺癌症状有哪些 (What are the symptoms of prostate cancer)	356

Category and term	Bladder cancer	Count, n	Kidney cancer	Count, n	Prostate cancer	Count, n
Term 2	膀胱炎是什么症状表现 (What are the symptoms of cystitis)	204	肾癌症状 (Symptoms of kidney cancer)	134	前列腺癌症状 (Symptoms of prostate cancer)	149
Term 3	膀胱癌症状 (Symptoms of bladder cancer)	202	肾衰竭的早期症状表现 (Early symptoms of kidney cancer)	123	前列腺癌的症状 (Prostate cancer symptoms)	226
Test and examination						
Term 1	膀胱镜 (Cystoscope)	140	肾钙化 (Renal calcification)	12	前列腺特异性抗原 (Prostate specific antigen)	98
Term 2	膀胱检查 (Bladder examination)	19	肾功能检查哪些项目 (Items of renal function test)	10	PSA (PSA)	72
Term 3	尿常规能检查出什么 (What can routine urinary test tell)	10	肾穿刺 (Renal puncturing)	10	前列腺炎一杯水自测 (Confirming prostatitis with a cup of water)	30
Prognosis						
Term 1	膀胱癌能活多久 (How long one can live with diagnosed bladder cancer)	210	肾癌晚期能活多久 (How long one can live with diagnosed late-stage kidney cancer)	51	前列腺癌能活多久 (How long one can live with diagnosed prostate cancer)	342
Term 2	膀胱癌晚期 (Late-stage bladder cancer)	125	晚期肾癌 (Late-stage kidney cancer)	17	前列腺炎有什么症状和危害性 (Symptoms and hazard of prostatitis)	213
Term 3	前列腺癌能活多久 (How long one can live with diagnosed prostate cancer)	67	肺癌晚期能活多久 (How long one can live with diagnosed late-stage lung cancer)	16	前列腺癌晚期 (Late-stage prostate cancer)	122
TCM[a] diagnosis						
Term 1	疾在腠理 (Disease sign on the skin)	1	肾虚 (Insufficiency in “Shen” essence)	3	湿热症疹状 (Rashes of the humid heat symptoms)	2
Term 2	肾精亏耗 (Depletion of “Shen” essence)	1	肾阳虚 (Insufficiency in “Shen” essence of “Yang”)	2	五心烦热 (Sphoria with feverish sensation in chest, palms, and soles)	1

Discussion

Principal Findings

To the best of our knowledge, this study is the first infodemiology research to explore patients’ awareness and demand for primary urologic cancers (bladder, kidney, and prostate) within China’s vast population, particularly from clinical and health care perspectives [12,22]. By analyzing the most widely used local search platform, with billions of daily active queries, we identified consistent shifts in search trends, dominant regions for searches, and key demographic groups. Furthermore, we examined the most sought-after topics, reflecting user-initiated care-seeking behaviors and decision-making patterns [13].

We observed that while the overtime search trends fluctuate, the overall search volume for each cancer type has shown a general increase, as indicated by the overtime AAPC. Across all urologic cancer themes, the 4 main topics—“complaint,” “inquiry,” “treatment,” and “prognosis”—remain consistent, indicating that user queries focus on key aspects of disease-related decision-making. Notably, there is a strong demand for information on diagnostic criteria, etiology, treatment options, and realistic expectations for each cancer. Among tumor-related keywords, symptom-related searches account for 43.95%, 49.97%, and 36.89% of the total search volume for bladder, kidney, and prostate cancers, respectively. Inquiries, comprising 23 search keywords, account for 46.30%, 46.23%, and 42.64% of the total search volume for bladder, kidney, and prostate cancers, respectively. In terms of treatment-related searches, prostate cancer leads with 14.51% of the total search volume, followed by bladder cancer at 7.49% and kidney cancer at 2.41%. The prominence of searches related to complaints and inquiries is unsurprising, as the complaint

category primarily includes diagnostic keywords, reflecting users' initial, exploratory searches when they are uncertain about the specific information they require [22].

The main concerns in user inquiries revolve around early signs, primary indications, etiologies, specific symptoms, and other cancer-related issues. These topics represent a comprehensive collection of the most common challenges patients face during health care–seeking sessions, particularly in cancer-related scenarios.

In bladder cancer, search keywords frequently reflect concerns about symptoms, particularly in the early or late stages, with hematuria being a primary focus [23]. While hematuria does not definitively indicate bladder cancer, prompt attention to this visible symptom facilitates early detection and diagnosis.

For prostate cancer, user queries often center on symptoms, staging, and metastasis. Lower urinary tract symptoms are commonly reported but frequently stem from benign causes, making symptom-based identification challenging. Prostate cancer detection primarily relies on prostate-specific antigen-magnetic resonance imaging-biopsy combinations, though the screening sensitivity (0.93) and specificity (0.20) underscore limitations and adherence challenges [24-27]. Furthermore, concerns about skeletal metastasis and staging highlight the importance of enhanced education and communication strategies.

Kidney cancers, characterized by diverse carcinomas, are often identified through imaging as "space-occupying lesions," resulting in ambiguous search terms like "mass (肿物)." Compared with bladder and prostate cancers, users frequently lack precise diagnostic information [28]. Advances in imaging technology have increased renal cell carcinoma detection rates by 3.1% annually over the past decade [29,30]. However, diagnostic accuracy remains limited by tumor size and the high cost of imaging. Emerging machine learning systems offer promise, with diagnostic precision ranging from 84.18% to 90.83%, supporting cancer identification and surgical decision-making [29,30]. Addressing misdiagnosis and delays in renal carcinoma detection remains a critical priority for health care providers.

Life expectancy is a primary concern in users' inquiries about the 3 cancers. The standard query, "How long can one live with the diagnosis?" highlights that the most significant need for patients with cancer, in terms of treatment or intervention, is to minimize the negative impact of cancer on life expectancy. Currently, the growing population in Mainland China exacerbates the challenges posed by the morbidity and mortality of urologic cancers, affecting both the national health care system and personal lives [2]. As of 2019, the death rates for bladder cancer, kidney cancer, and prostate cancer in China were 50.39/1000, 40.09/1000, and 23.95/1000, respectively, with mortality rates gradually increasing with age [2]. Predictive models suggest that the morbidity and mortality rates for these 3 genitourinary cancers will continue to rise, although health care facilities are becoming more accessible in traditionally less-developed regions [31]. With improvements in perioperative management and increasing proficiency among surgeons in primary health care facilities, internet users have expressed concerns that could be addressed more promptly and validated by local health care professionals [31,32].

The search trend patterns across each cancer theme showed similarities, with an overall upward trend primarily driven by the topics of complaint and inquiry. The demand for cancer treatment and prognosis has generally declined, with the only exception being observed in prostate cancer treatment topics. Specifically, the search trends for bladder and kidney cancers increased until 2019, followed by a decline until a resurgence in 2021. For prostate cancer, turning points occurred in 2015 and 2020. The rising search trends may partly reflect real-world cancer incidence. Data from the GBD 2019 database indicated that the counts for bladder, kidney, and prostate cancers in 2019 were at least four times higher, with age-standardized incidence rates at least double those of 1990 [2]. This period also marked Baidu's "golden age," during which it became the primary source of information for internet users [13]. Although Baidu's marketing strategies for channeling information have been criticized, they do not appear to have affected its dominant role in providing cancer-related information to users [13].

Despite the COVID-19 pandemic's significant impact on regular medical activities and the shift in public attention toward outbreak management, online demand for information on tumor diseases, including genitourinary cancers, persisted and even increased in 2019 [6,33]. This demand was temporarily suppressed during the 2020-2021 pandemic peak but rebounded as government policies and health care responses evolved [34,35]. Search terms highlighted unresolved issues and user concerns about genitourinary cancers, emphasizing Baidu's role as a trusted source of health-related information. These trends underscore the need to address user-identified health care gaps in future health policy optimization.

Geographically, searches for the 3 cancers were led by East China, accounting for approximately 30%, followed by North China at around 18%. Other regions showed similar levels of interest, each at approximately 10%, while the northwest region ranked last with about 8%.

Socioeconomic inequalities significantly influence health-seeking behavior and online health information searches [33,36]. In China, disparities in medical center density, health care costs, social security policies, and household finances shape patients' decisions, with individuals from disadvantaged backgrounds often hesitating to seek treatment due to financial constraints [37]. Similarly, socioeconomic and educational factors affect online search behavior: higher-income individuals tend to exhibit greater digital literacy, use precise medical terminology, and seek reliable sources [38,39]. By contrast, lower-income groups face barriers such as limited internet access and lower trust in online information, often relying on symptom-based searches [40]. These differences underscore the impact of socioeconomic status on health awareness and access to accurate medical information [39,41].

Demographic data revealed similar interest in cancer topics across genders, though females expressed greater concern about kidney cancer prognosis. Bladder and kidney cancers have significantly higher incidence rates in males, at 5-fold and 2.5-fold, respectively. Interest in prostate cancer, despite being

male-specific, indicates engagement extending beyond patients alone [2]. Agewise, searches for bladder and kidney cancers were common among users aged 20-39 years, with kidney cancer treatment queries peaking in the 40-49-year age group. Prostate cancer searches followed a similar pattern, except prognosis-related queries, which were predominantly from users aged 40-49 years. Bladder and kidney cancer incidence rates in individuals aged 20-39 years (25.48/100,000 and 1.51/100,000, respectively) were half of those observed in the 40-59-year age group, while prostate cancer incidence peaked in individuals over 60 years [2].

The disparity between incidence rates and concern levels across gender and age groups highlights the importance of health consciousness and awareness. The high cost, complex nursing requirements, and strict follow-up schedules associated with cancer treatment underscore that the disease burden affects not only individuals but also entire families [42]. Research indicates that women play a prominent leadership role within families, making approximately 80% of health care–related decisions [43-45]. The concerns and demands of women, as key decision makers within families, should not be underestimated. Although older adults are increasingly integrating internet technology into their daily routines, including health care–seeking activities, the persistent digital divide among older users remains a significant challenge [46]. Therefore, joint decision-making involving family members, rather than focusing solely on the patients' needs, should be taken into account.

Our study found that only 15.74% of user search queries were categorized as relevant, reflecting a focus on trending topics, nonhealth issues, or vague terms, such as medication-related words. This low percentage suggests that public attention often shifts toward less scientifically grounded information, driven by societal trends, misinformation, or curiosity about lifestyle, diet, or alternative medicine [47,48]. The findings highlight the need for more effective dissemination of accurate cancer information and targeted educational campaigns to enhance public understanding of critical cancer issues. Furthermore, many users rely on general or indirect language in their searches, which may prevent their queries from being classified as relevant. This underscores the importance of promoting more precise health communication.

Overall, frequency, diagnosis, and symptom confirmation issues ranked among the top categories, accounting for 30.17% and 30.16%, respectively. Regarding popularity, interest in symptom confirmation ranked first, followed by diagnosis and health-related issues, each comprising approximately 15%. Similar patterns were observed in bladder and kidney cancers. However, in prostate cancer, while interest in diagnosis and symptom confirmation was dominant in terms of frequency, health care–related issues in prognosis garnered the most actual popularity.

In the topics of complaints and etiology inquiries, the most common concerns related to bladder and kidney cancers were hematuria and questions about its causes. As a marker of cancer risk, hematuria is often associated with underlying urologic malignancies. The standardized incidence ratio for overall urologic cancer risk peaks within the first 3 months following a hematuria diagnosis, reaching 14.15% [49]. Specifically, the standard incidence ratios for bladder, kidney, and prostate cancers at 3 months are 186.43%, 81.40%, and 14.18%, respectively [49]. Reports indicate that delayed responses to initial hematuria often lead to missed cancer diagnoses. Therefore, heightened awareness and timely investigation of its causes are recommended to prevent delays in cancer diagnosis [50,51].

We observed that several differential diagnoses were listed within the diagnosis topic. For bladder cancer, cystitis and prostate cancer were frequently mentioned. In the context of kidney cancer and prostate cancer, the most commonly referred differential diagnoses included renal cysts, renal kidney disease, prostatitis, and benign prostatic hyperplasia. These conditions must be ruled out before confirming a tumor diagnosis, suggesting the potential for users to engage in self-assisted cyber diagnosis [52].

Accurate evidence is essential for the correct diagnosis of cancer, as it helps identify tumor characteristics. In some cancer cases, even experienced experts may find judgment and decision-making complicated due to varying test results [53]. The risk of internet self-diagnosis in cancer warrants greater attention, as diagnosis delays and misleading treatments can have serious consequences [52]. For users with limited medical knowledge, it becomes even more challenging to identify accurate and useful information while maintaining reasonable and objective expectations [54]. Therefore, online health care information should be more instructive, neutral, and objective, enabling potential patients to better follow guidance from medical professionals [55].

Limitations

Several limitations of this study should be acknowledged. First, although Baidu is the largest search engine in mainland China, its dominance is increasingly challenged by emerging search platforms and social media, which restricts the scope of online search behavior captured. Consequently, the daily BSI may not fully reflect the demands of all internet users. Second, regional differences in user preferences and political regulations result in the exclusion of searches by individuals legally accessing international platforms. Furthermore, as Baidu is a Chinese platform, searches conducted in foreign languages or by ethnic minorities may be systematically omitted, potentially introducing bias. Third, the absence of a real-time public cancer database is a significant limitation, as it prevents the integration of search data with clinical data for more accurate disease prediction and forecasting. These factors underscore biases in internet access and usage across different demographic groups, which should be considered when interpreting the results in the context of broader cancer awareness and digital health information–seeking behavior.

Future Directions

This study is the first to address public concerns regarding the 3 major genitourinary cancers within the Chinese-speaking population. These cancers were selected due to their complexity and subtle onset, which often lead to delayed diagnoses and severe outcomes. By analyzing online search trends, this

research provides valuable insights into patient perceptions and needs, offering a broader understanding of public demand. Future infodemiology studies should incorporate data from multiple search engines, social media platforms, and multilingual or minority groups to achieve a more comprehensive analysis of public health trends. Integrating such a system into a national cancer database could significantly enhance disease tracking, forecasting, and public health decision-making.

Conclusions

Online searches and inquiries related to genitourinary cancers are on the rise. The depth of users' information demands appears to be influenced by regional economic levels. Cancer treatment decision-making may often involve a family-centered approach. Insights from internet search data are potentially beneficial for medical professionals to better understand public interests and concerns, enabling them to provide more targeted and reliable health care services.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author upon reasonable request.

Use of Artificial Intelligence

Artificial intelligence or chatbot tools were used exclusively for language editing in this manuscript. No content generation or ideation was performed by the artificial intelligence tools or chatbot.

Authors' Contributions

Conceptualization was carried out by SZW. Formal analysis was performed by XW and XDX. The investigation was conducted by XDX and SQL, while methodology was developed by SZW and XW. Project administration was handled by SZW and XBL, with resources provided by HCC and XDX. The original draft of the manuscript was written by HCC, XDX, and SZW, Administration support was provided by LXB, and all authors contributed to reviewing and editing the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Androgen receptor axis-targeting reagents (ARATs) have become key drugs for patients with castration-resistant prostate cancer (CRPC). ARATs are taken long term in outpatient settings, and effective adverse event (AE) monitoring can help prolong treatment duration for patients with CRPC. Despite the importance of monitoring, few studies have identified which AEs can be captured and assessed in community pharmacies, where pharmacists in Japan dispense medications, provide counseling, and monitor potential AEs for outpatients prescribed ARATs. Therefore, we anticipated that a named entity recognition (NER) system might be used to extract AEs recorded in pharmaceutical care records generated by community pharmacists.

Objective: This study aimed to evaluate whether an NER system can effectively and systematically identify AEs in outpatients undergoing ARAT therapy by reviewing pharmaceutical care records generated by community pharmacists, focusing on assessment notes, which often contain detailed records of AEs. Additionally, the study sought to determine whether outpatient pharmacotherapy monitoring can be enhanced by using NER to systematically collect AEs from pharmaceutical care records.

Methods: We used an NER system based on the widely used Japanese medical term extraction system MedNER-CR-JA, which uses Bidirectional Encoder Representations from Transformers (BERT). To evaluate its performance for pharmaceutical care records by community pharmacists, the NER system was first applied to 1008 assessment notes in records related to anticancer drug prescriptions. Three pharmaceutically proficient researchers compared the results with the annotated notes assigned symptom tags according to annotation guidelines and evaluated the performance of the NER system on the assessment notes in the pharmaceutical care records. The system was then applied to 2193 assessment notes for patients prescribed ARATs.

Results: The F_1-score for exact matches of all symptom tags between the NER system and annotators was 0.72, confirming the NER system has sufficient performance for application to pharmaceutical care records. The NER system automatically assigned 1900 symptom tags for the 2193 assessment notes from patients prescribed ARATs; 623 tags (32.8%) were positive symptom tags (symptoms present), while 1067 tags (56.2%) were negative symptom tags (symptoms absent). Positive symptom tags included ARAT-related AEs such as “pain,” “skin disorders,” “fatigue,” and “gastrointestinal symptoms.” Many other symptoms were classified as serious AEs. Furthermore, differences in symptom tag profiles reflecting pharmacists’ AE monitoring were observed between androgen synthesis inhibition and androgen receptor signaling inhibition.

Conclusions: The NER system successfully extracted AEs from pharmaceutical care records of patients prescribed ARATs, demonstrating its potential to systematically track the presence and absence of AEs in outpatients. Based on the analysis of a large volume of pharmaceutical medical records using the NER system, community pharmacists not only detect potential AEs but also actively monitor the absence of severe AEs, offering valuable insights for the continuous improvement of patient safety management.

Introduction

According to the International Agency for Research on Cancer, 20 million new cancer cases were reported in 2022 [1]. In particular, an increasing number of patients are receiving chemotherapy at home [2], driven by the increasing availability of oral anticancer drugs over the past 20 years [3]. Outpatient chemotherapy offers advantages such as reduced invasiveness of administration and fewer hospital visits. However, compared with inpatient chemotherapy, the lack of direct and frequent observation by health care professionals can present safety challenges. In practice, ensuring the safety of oral anticancer drugs prescribed to patients is never easy for treating physicians [4,5]. Additionally, for patients, the adverse events (AEs) experienced after the initiation of treatment may be more burdensome than those reported in clinical trials [6]. Therefore, continuous medical support is essential, extending beyond the hospital setting and involving collaboration with community health care services. Community pharmacies, as the most accessible health care providers, play a crucial role in monitoring AEs in outpatients using oral anticancer drugs [7].

Among outpatient chemotherapy options, endocrine therapy is a common treatment for patients with prostate cancer. In particular, for patients with castration-resistant prostate cancer (CRPC), androgen receptor axis-targeting reagents (ARATs)—abiraterone acetate, apalutamide, darolutamide, and enzalutamide—are taken long term in outpatient settings. Therefore, effective AE monitoring can contribute to prolonged treatment duration [8]. Furthermore, ARATs exhibit distinct AE profiles depending on their pharmacological mechanisms [9,10]. Abiraterone acetate, an androgen synthesis inhibitor, has been reported to cause AEs such as hypertension, gastrointestinal symptoms, fatigue, and liver dysfunction [11]. On the other hand, apalutamide, darolutamide, and enzalutamide, which act through androgen receptor (AR) signaling inhibition, have been associated with AEs such as fatigue and dermatologic disorders [12-15].

In Japan, outpatients prescribed ARATs typically have their prescriptions filled at community pharmacies. Pharmacists at these pharmacies dispense medications, provide patient counseling, monitor for potential AEs, and document pharmaceutical care records. Pharmaceutical care records are commonly written in the SOAP (subjective, objective, assessment, and plan) format [16]. In particular, the assessment section contains pharmacists' evaluations related to the patient's pharmacotherapy and thus may be a fruitful source of information about AEs experienced by patients. By systematically collecting and analyzing the AEs and pharmacists' assessments accumulated in pharmaceutical care records, it could be possible to clarify the AEs experienced outside the hospital by outpatients prescribed ARATs.

However, pharmaceutical care records comprise huge amounts of unstructured text data, including medical terms, accumulated over time for individual patients, making them difficult to analyze manually. Therefore, natural language processing technology, particularly named entity recognition (NER), offers a solution by enabling the extraction of patients' illnesses and symptom data from unstructured medical records [17,18]. Although studies using the NER system to analyze medical texts in hospital inpatients have been reported in the past, few studies have focused on outpatient care, especially in community pharmacy settings, where pharmacists contribute to the safe delivery of pharmacotherapy.

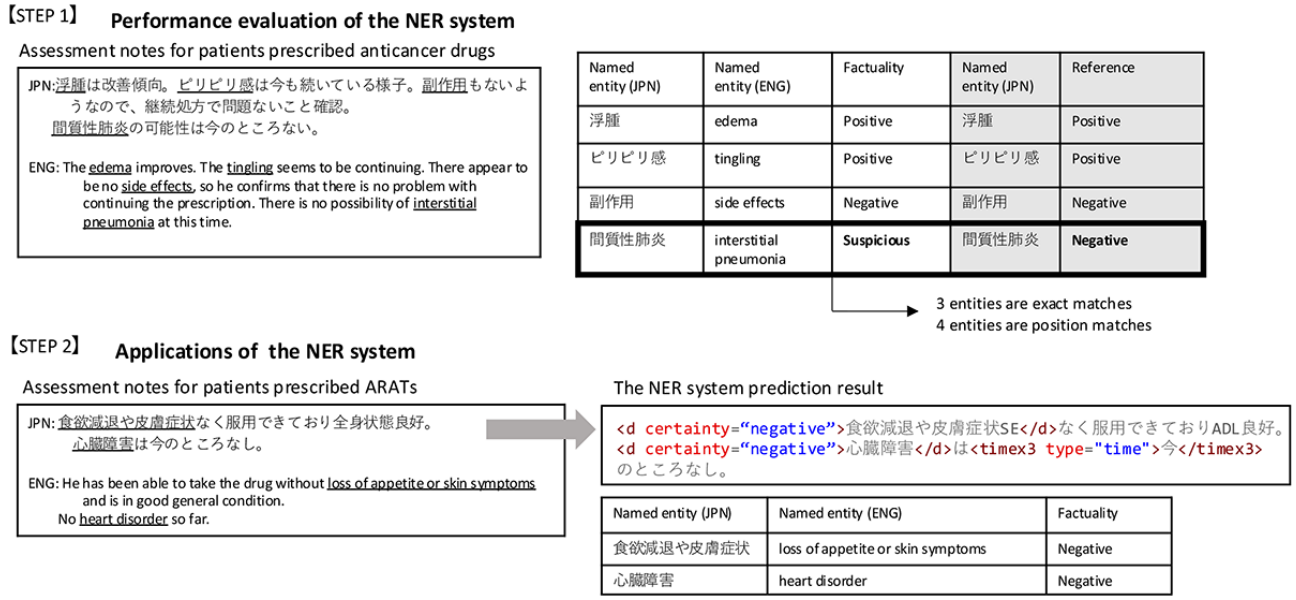
This study aimed to determine whether pharmacotherapy monitoring of outpatients prescribed ARATs can be carried out using NER to systematically collect AEs from pharmaceutical care records, with a particular focus on assessment notes, which may contain detailed records of AEs experienced by patients.

Methods

Outline

An overview of the experimental method is shown in Figure 1. First, we evaluated the performance of the NER system using assessment notes from pharmaceutical care records (STEP 1). The NER system was then used to extract symptoms from the pharmaceutical care records of patients prescribed ARATs (STEP 2).

Figure 1. Outline of the experimental method, including manual annotation on a data set, examination of the model's performance in terms of "position match" and "exact match," and use of the named entity recognition (NER) system to extract symptoms from the pharmaceutical care records of patients prescribed androgen receptor axis-targeting agents (ARATs). ENG: English; JPN: Japanese.



Model Description

System

Our objective was to evaluate the utility of pharmacist-assessed symptoms extracted from pharmaceutical care records kept by community pharmacies. To extract terms, we applied MedNER-CR-JA, an existing Japanese medical term-extraction system based on Bidirectional Encoder Representations from Transformers (BERT) and that was trained using Japanese case reports [19]. Given the input (pharmaceutical care records), the NER system output the symptoms with the factuality (e.g., positive symptom, negative symptom). The factuality was classified into 4 categories as shown in Table 1.

Table 1. Certainty attributes of symptom tags.

Symptom tags	Definition
Positive	The symptom is observed in the patient.
Suspicious	The symptom is suspected to be present in the patient.
Negative	The symptom is not observed in the patient.
General	The symptom is described without reference to the patient's condition.

Materials

This study used data from patients at community pharmacies (n=291,150) belonging to the Nakajima Pharmacy Group in Japan from April 2020 to December 2021. The patients' data consisted of medication orders (structured data) and pharmaceutical care records written in Japanese (unstructured data, n=2,180,902).

First, to evaluate the performance of the NER system (STEP 1), we selected pharmaceutical care records of patients with at least one prescription for anticancer drugs according to the structured data, using the drug codes (YJ codes). YJ codes starting with "42" in Japan indicate anticancer drugs. To evaluate the NER system, we took data recorded during October 2021 through December 2021 at 11 randomly selected pharmacies from the pharmacies with a history of anticancer drug prescriptions. Second, to apply the NER system to pharmaceutical care records (STEP 2), we extracted data for patients prescribed ARATs at least once from April 2020 through December 2021 using individual YJ codes (Multimedia Appendix 1) and used their assessment notes.

In both experiments (STEP 1 and STEP 2), we input the preprocessed text into the NER system. For text preprocessing, we removed line breaks and full-width and half-width spaces from the target text and normalized the text (Unicode). Furthermore, structured sections with template-based input were excluded, and only free-text sections were used.

Performance Evaluations and Metrics for Pharmaceutical Care Records

To evaluate the performance of the NER system on the assessment notes in the pharmaceutical care records, we performed manual annotation on a data set. We verified that the NER system was able to assign symptom tags according to existing annotation guidelines [20] with manual annotation performed by 3 pharmaceutically proficient researchers (SY, YY, KS). These researchers were selected based on their pharmaceutical expertise. Two of them were licensed pharmacists with over 5 years of experience in hospitals or

pharmacies, while the third was a pharmacy student who had completed a clinical internship in both a hospital and a pharmacy. To ensure consistency and reliability in the study, all researchers were expected to be familiar with the existing guidelines regarding the study objectives, task procedures, and evaluation criteria. The existing guidelines were standardized to enable annotation even by nonmedical professionals. To evaluate the consistency and generalizability of the annotation guidelines across annotators, we randomly extracted 100 cases from the target data, and these were annotated. Label agreement was evaluated using the Fleiss kappa (κ) coefficient to assess the concordance rate among the 3 researchers. Let *Po* be the mean of the raters' agreement and *Pe* the degree of concentration for each rating, then the calculation formula is as follows:

For a difficult task like NER, a score of around 0.6 is considered a substantial match, and the obtained evaluations are considered reasonably reliable [21].

After evaluating their agreement, the 3 researchers (SY, YY, KS) annotated the entire data set. The model's performance was evaluated using "position match" and "exact match." Position match is a method that accepts a match with the correct data if the tag's position and name are correct, while exact match requires the tag's position, name, and attributes to match with the correct data. In the position match evaluation, if the position is correct but the predicted tag name is different from the correct tag name, it is considered incorrect. Therefore, in the exact match, we calculated evaluation metrics separately for tags and attributes, while in the position match, we calculated metrics only for the tags. In both methods, the performance was evaluated in terms of precision, recall, and F_1-score:

Ethical Considerations

This study was conducted with anonymized data following approval by the ethics committee of the Keio University Faculty of Pharmacy (approval number: 240618-1) and was conducted in accordance with the relevant guidelines and regulations and the Declaration of Helsinki. Informed consent specific to this study was waived due to the retrospective observational design of the study based on the approval by the ethics committee of the Keio University Faculty of Pharmacy. To respect the will of each stakeholder, however, we provided patients and pharmacists of the pharmacy group with an opportunity to refuse the sharing of their pharmaceutical care records by posting an overview of this study at each pharmacy store or on their websites.

Results

Model Performance and Statistics

The data set used to evaluate the performance of the NER system consisted of 1008 assessment notes. The average word count per text in the target data was 48.3 words, with a median of 42.0 words and minimum and maximum values of 4 and 292 words, respectively. The κ coefficient among the 3 annotators for 100 randomly extracted texts was 0.62.

The F_1-score (NER excluding position matches and attribute classification) was 0.72. This score is the macro-average of the F_1-scores for all attribute classifications (positive, suspicious, negative, and general). For positive and negative symptom tags, the F_1-scores were 0.70 and 0.78, respectively (Table 2). The F_1-scores for all attribute classifications are shown in Multimedia Appendix 2. The position matches showed an excellent F_1-score of 0.86 (Multimedia Appendix 2).

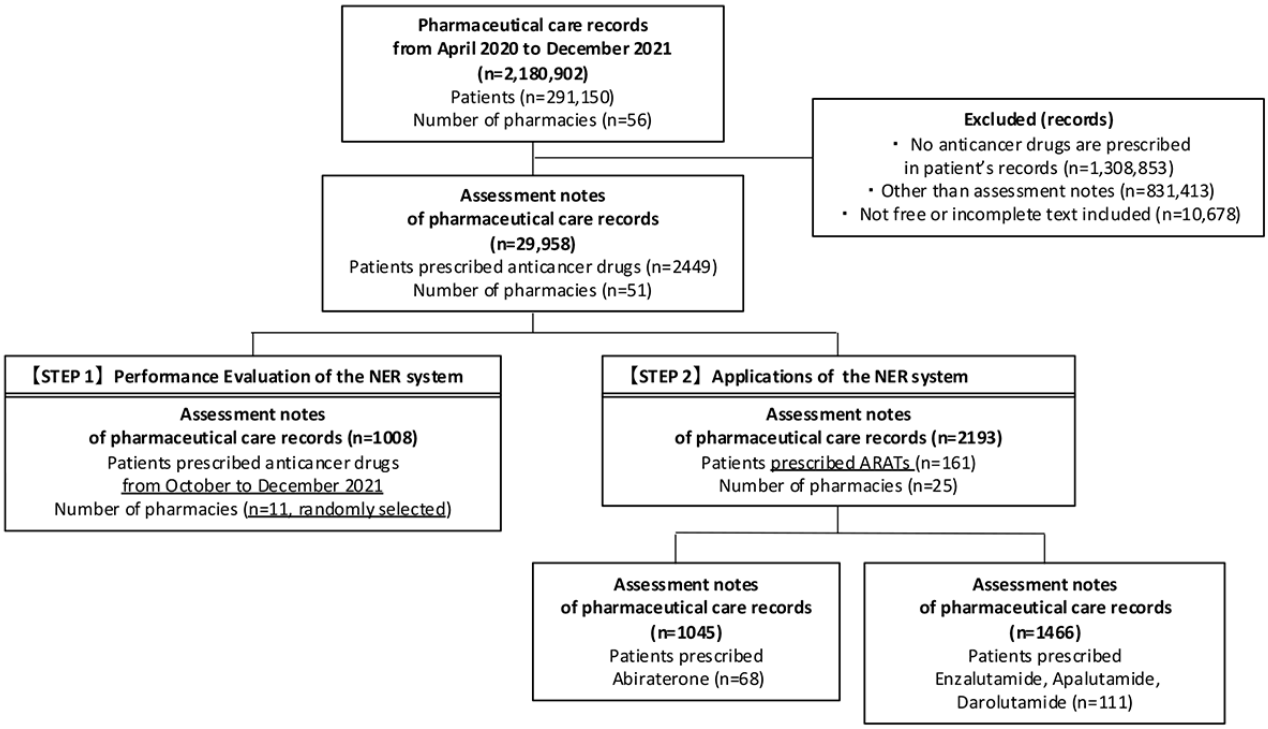
Table 2. Exact matches between the named entity recognition system and annotators.

Tags	Precision	Recall	F_1-score
All symptom tags	0.66	0.78	0.72
Positive symptom tags	0.60	0.85	0.70
Negative symptom tags	0.73	0.83	0.78

Assessment Notes for Patients Prescribed Antiandrogens

Figure 2 shows the flowchart of the procedure for selecting pharmaceutical care records. From April 2020 through December 2021, 161 patients had at least one ARAT prescription and corresponding assessment notes in their pharmaceutical care records. There were 2193 assessment notes recording pharmacists' assessments. Additionally, 68 patients had a history of prescriptions for the androgen synthesis inhibitor abiraterone acetate, with 1045 assessment notes. There were 111 patients with a history of prescription for AR signal transduction inhibitors enzalutamide, apalutamide, and darolutamide, with 1466 assessment notes. On average, each extracted assessment note contained 39.8 words.

Figure 2. Flowchart for selecting pharmaceutical care records to evaluate the performance of the named entity recognition (NER) system (STEP 1) and apply the NER system to pharmaceutical care records (STEP 2). ARAT: androgen receptor axis-targeting agent.



Prediction by the NER System

From 2193 assessment notes of patients prescribed ARATs, the NER system automatically assigned 1900 symptom tags. Among these 1900 symptom tags, 623 (32.8%) were positive symptom tags, predicting the presence of symptoms, while the majority, 1067 (56.2%), were negative symptom tags, predicting the absence of symptoms. Additionally, of the 1900 symptom tags, there were 131 (6.9%) general symptom tags and 79 (4.2%) suspicious symptom tags. Specifically, the positive symptom tags were commonly assigned to notes describing "pain," "skin disorders," "fatigue," and "gastrointestinal symptoms." The negative symptom tags frequently appeared in descriptions indicating general side effects such as "SE" or "side effects," accounting for 13.9% (148/1067) of the total. Furthermore, entities with nonpositive symptom tags were AE expressions related to ARATs, such as gastrointestinal symptoms, neuropsychiatric symptoms, and cardiovascular symptoms (Table 3). Other extracted symptoms included seizures and other neuropsychiatric symptoms, cardiovascular symptoms, and hepatic dysfunction. There were also descriptions of severe AEs, including myelosuppression, interstitial pneumonia, and rhabdomyolysis.

Next, the results were examined according to the pharmacological mechanism of action of the ARATs. For patients prescribed the androgen synthesis inhibitor abiraterone acetate, 876 symptom tags were automatically assigned to 1045 assessment notes. The most common symptom tag was negative, with 488 tags (488/876, 55.7%), while 283 positive symptom tags were assigned (283/876, 32.3%; Multimedia Appendix 3). Of the 876 tags, there were 64 (7.3%) general symptom tags and 41 (4.7%) suspicious symptom tags. Regarding characteristic expressions for patients taking abiraterone acetate, "congestive heart failure" was frequently noted among the positive symptom tags. Entities related to skin disorders, which occur frequently in patients taking AR signal transduction inhibitors, appeared infrequently in the top 20 entities. Additionally, entities such as "congestive heart failure," "drug-induced liver injury," and "hyperglycemia" were extracted among nonpositive symptom tags.

For patients prescribed the AR signal transduction inhibitors enzalutamide, apalutamide, and darolutamide, 1466 symptom tags were automatically assigned to 1274 assessment notes. Negative symptom tags were most common, amounting to 692 (692/1466, 47.2%), while positive symptom tags amounted to 438 (438/1466, 29.9%; Multimedia Appendix 4). Of the 1466 tags, there were 96 (6.5%) general symptom tags and 48 (3.3%) suspicious symptom tags. Among the positive symptom tags, characteristic entities for AR signal transduction inhibitors such as "skin disorders" and "fatigue" were frequently noted. Additionally, entities such as "seizures," "psychiatric symptoms," and "cardiovascular diseases" were extracted among the nonpositive symptom tags.

The differences in symptom entities collected based on the pharmacological mechanism of prescribed ARATs are illustrated in Figure 3.

Table 3. Application of the named entity recognition (NER) system to assessment notes of patients prescribed androgen receptor axis-targeting agents (ARATs), showing the top 20 entities.

Entity (Japanese)	Results, n (%)
Positive symptom tags (n=623)	
Pain (痛み)	22 (3.5)
Skin disorders (皮膚障害)	22 (3.5)
Fatigue (倦怠感)	16 (2.6)
Loss of appetite (食欲不振)	15 (2.4)
Pain (疼痛)	12 (1.9)

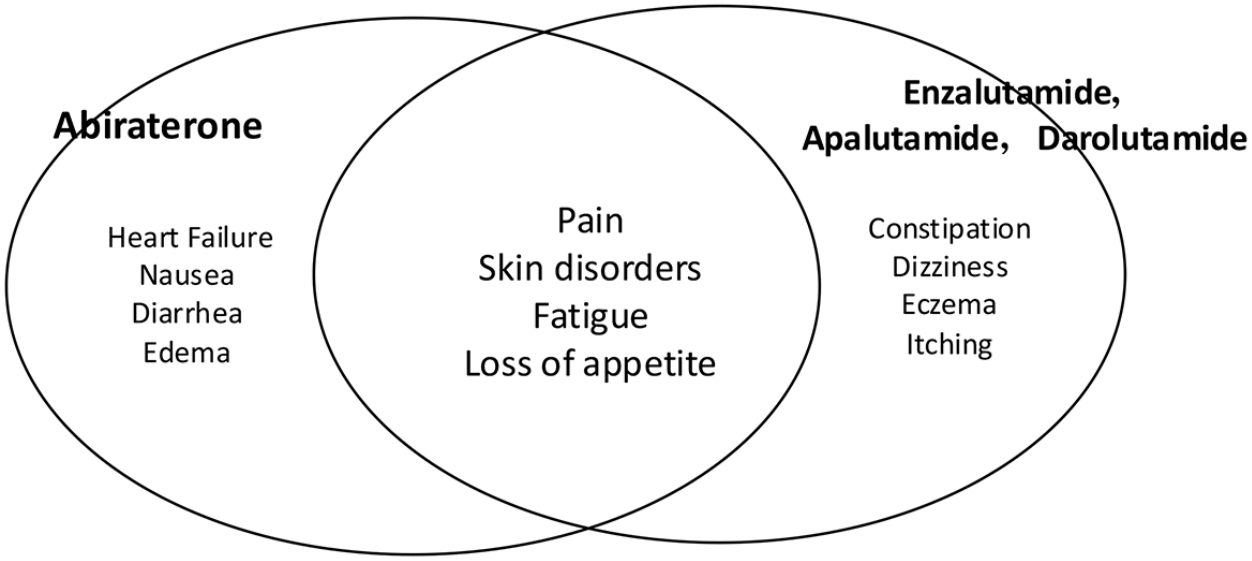
Bleeding tendency (出血傾向)	11 (1)
Hypoglycemia (低血糖)	11 (1)
Pain (疼痛)	11 (1)

Entity (Japanese)	Results, n (%)
Elevated PSA (PSA上昇)	11 (1)

[a]PSA: prostate-specific antigen.

[b]SE (SE): Side effects.

Figure 3. Main symptom entities extracted as positive for agents with different pharmacological mechanisms of action, including androgen synthesis inhibitors (abiraterone acetate) and androgen receptor signaling inhibitors (enzalutamide, apalutamide, darolutamide), shown in order of the number of adverse events extracted.



Discussion

Overview

We evaluated the performance of the NER system on pharmaceutical care records and successfully extracted symptoms, including AEs, from the free-text assessment notes of community pharmacists. This study is the first to report the use of the NER system to systematically identify AEs from pharmaceutical care records of patients prescribed ARATs.

Predictive Performance of the NER System

The NER system exhibited robust performance on the pharmaceutical care records analyzed. Although the kappa statistics for annotation (0.62) indicate substantial agreement, the following factors were considered to have contributed to the decrease in the kappa. The most common type of disagreement among annotators was related to the selection range of the entity. Specifically, the annotation guidelines [16] we referenced set the standard for selecting the entire range when symptoms were expressed in parallel. However, discrepancies in the interpretation of the range occurred among the annotators. For example, for text such as “gastrointestinal symptoms, hypoglycemia present,” disagreements arose over whether to annotate this as “gastrointestinal symptoms” and “hypoglycemia” or as “gastrointestinal symptoms, hypoglycemia.”

The F_1-score for symptom tagging (NER and attribute classification) was 0.72, and the F_1-scores for positive and negative predictive performance ranged from 0.70 to 0.78. These results indicate that the system is effective for analyzing the pharmaceutical care records used in this study. Notably, the system outperformed prior work by Ohno et al [22], who reported an F_1-score of 0.64 for assessment notes among the SOAP format descriptions in Japanese hospital-based pharmaceutical care records using MedNER-J (NER and positive and negative classification). The NER evaluation method used in this study assumed that entities that completely matched the annotations were correct. In addition, many types of tags were used, and the evaluation was conducted under more stringent conditions.

Several factors may have affected model performance. In particular, there were specific expressions in pharmaceutical care records that we recognized as causing frequent errors in NER predictions during the performance evaluation. First, pharmacist assessment records often include descriptions related to medication adherence. The NER system sometimes incorrectly recognized terms such as “adherence” and “compliance” as symptom entities (for example, the entity “adherence” was predicted as a symptom expression). Second, pharmacist assessment records frequently included descriptions related to AE confirmation, often using nuanced expressions characteristic of Japanese, such as “no suspicion of XX.” As a result, the NER system occasionally predicted “suspicious” for negative symptom expressions (for example, the entity “interstitial pneumonia” was predicted as suspected in the sentence “no suspicion of interstitial pneumonia,” whereas the correct status should be negative). Additionally, the system showed low extraction rates for entities related to hypertension,

which is a side effect specific to enzalutamide acetate, as well as blood glucose–related expressions associated with concomitant corticosteroids and expressions related to hypokalemia, possibly because vital sign–related terms like "blood pressure" and "blood glucose" were treated as test values rather than symptoms. Another challenge was interpreting negation patterns, such as "No symptoms: XX (Symptoms)" and "Symptoms (-)," which may have led to incorrect symptom tagging.

AEs Identified in Pharmaceutical Care Records for Patients Prescribed ARATs

Our analysis of pharmacists' assessment records for outpatients prescribed ARATs revealed that over 90% of the records contained symptom tags. The extracted entities predominantly indicated symptoms related to AEs commonly seen in patients treated with ARATs. Common positive symptom entities included "pain," "skin disorders," "fatigue," "anorexia," and other typical side effects of ARATs. "Pain" was the most frequently identified symptom, reflecting the high prevalence of bone metastases in patients with CRPC requiring ARAT therapy. A study using the Frankfurt Metastatic Cancer Database of the Prostate reported that 78% of patients with CRPC had bone metastases [23].

On the other hand, the fact that the top 20 entities accounted for less than one-third of the total positive symptom tags suggests that many symptoms occur with low frequency, resulting in a long-tail distribution. This indicates that a large portion of symptom tags is dispersed across numerous less-frequent entities. This distribution indicates that the NER system has the sensitivity to capture a wide range of symptoms. However, it also suggests the need for standardization if the aim is to extract specific symptom expressions.

Entities other than positive symptom tags were serious AEs such as "interstitial pneumonia," "myelosuppression," and "rhabdomyolysis." Interestingly, many of the negative symptom tags indicated the absence of severe AEs, suggesting that pharmacists were actively monitoring for signs of AEs and documenting the absence of signs. These negative assessments, particularly for rare but serious AEs, highlight the thoroughness of pharmacists in ensuring the safety of outpatient pharmacotherapy.

Drug-Specific Monitoring by Community Pharmacists

There are two types of ARATs with different pharmacological mechanisms of action: androgen synthesis inhibition and AR signaling inhibition. Each category is associated with distinct AEs, which require tailored care. Despite the common indication for ARATs, this study highlights the differences in pharmacists' monitoring based on drug type.

The most characteristic positive symptom extracted for abiraterone acetate, an androgen synthesis inhibitor, was "heart failure," a critical AE requiring close monitoring. In addition, "cardiovascular symptoms," "congestive heart failure," "rhabdomyolysis," and "drug-induced liver injury" were also identified as nonpositive symptoms.

For patients prescribed AR signaling inhibitors (enzalutamide, apalutamide, darolutamide), the most frequently extracted positive symptoms included "skin problems," "fatigue," and "gastrointestinal symptoms," which are common AEs that are important to monitor. "Skin disorder" was more frequently reported as a symptom for AR signaling inhibitors, whereas it was less commonly reported for abiraterone acetate, an androgen synthesis inhibitor. In addition, "gastrointestinal symptoms" and "neuropsychiatric symptoms" were extracted from the nonpositive symptom tags. "Seizures" were also extracted from the nonpositive symptom tags. Seizures are a serious AE specifically associated with AR signaling inhibitors [15,24,25].

These results indicate that, even though ARATs are used for the same purpose, pharmacists should pay particular attention to certain AEs depending on the pharmacological mechanism of each type of ARAT.

Comparison With Prior Work

The NER system used in this study has previously been reported to be applicable to medical records documented in electronic medical records within hospitals in Japan [22,26,27]. For example, Ohno et al [22] reported an F_1-score of 0.64 for an NER system applied to hospital-based pharmaceutical records. In contrast, this study applied the NER system to pharmaceutical records documented in community pharmacies outside hospitals and achieved an F_1-score of 0.72 under more stringent evaluation conditions.

A key feature of this study is its focus on pharmaceutical care records by community pharmacists, which tend to include more diverse and nuanced expressions of outpatients than electronic medical records. Furthermore, our previous studies have demonstrated that patients with hand-foot syndrome and serious AEs can be identified using NLP applied to pharmaceutical care records by community pharmacies [28]. In this study, the NER system enabled the extraction of a wide range of AEs, not limited to specific side effects. These results highlight advancements in NER methodologies and underscore their applicability in real-world outpatient settings.

Limitations

This study has several limitations. First, the content of pharmaceutical care records may vary depending on the pharmacists' experience, the role of each pharmacy, and the condition of the patients. Second, this study focused on the extraction of AEs and did not include symptom normalization. As a result, synonymous entities such as "pain" were counted separately. Third, the pharmacies included in this study were part of a single pharmacy group, which may limit the generalizability of the findings to other pharmacy settings.

Prospects

The NER system used in this study enabled the automated analysis of a large volume of records accumulated by community pharmacists. This system can extract symptoms from text, determine their factuality, and monitor patients' symptoms over time. Additionally, error analysis of the NER system applied to pharmaceutical medical records by community pharmacists

can contribute to the appropriate and effective use of NER systems in the future.

Our findings support the idea that NER technology offers the potential for real-time and longitudinal monitoring of patients' symptoms through the seamless integration of local health care systems, including community pharmacies. In hospital electronic health records, it has been demonstrated that the accuracy of detecting AEs improves when physicians' notes are combined with records from nurses and pharmacists [23]. Similarly, for outpatients, AEs identified by community pharmacists may play a key role in effective monitoring. This approach would extend beyond the confines of hospital-based electronic medical record systems. By using NER technology, it should be possible to gain detailed insights into drug efficacy and the progression of AEs. Moreover, it should enable earlier interventions and timely adjustments to treatment plans, particularly for outpatients who may otherwise have limited direct interaction with health care providers

Conclusions

We evaluated the performance of the NER system on Japanese medical text, focusing on pharmaceutical care records by community pharmacists. The NER system successfully extracted AEs from pharmaceutical care records. This is the first study to apply NER to the pharmaceutical care records of patients prescribed ARATs in community settings. Our analysis of pharmacists' assessment records for outpatients prescribed ARATs revealed that over 90% of the records contained symptom tags. Notably, ARATs have distinct pharmacological mechanisms and exhibit different AE profiles, and the NER system successfully captured these variations. Furthermore, it highlights the role of community pharmacists in monitoring specific AEs related to ARAT therapy and, importantly, in documenting the absence of severe AEs as well. This study demonstrates that NER can effectively capture symptoms reported by outpatients and documented by community pharmacists, complementing hospital records and contributing to a more comprehensive understanding of AEs in outpatient settings. The NER system is expected to be a valuable tool for enhancing pharmacotherapy monitoring in outpatient settings.

Abstract

Background: For patients with cancer, the pathway to diagnosis will most often begin in general practice. In the absence of strong diagnostic features or in patients with nonspecific symptoms, delays in diagnosis can occur. Initial presentations and routine blood tests are important in determining whether a patient requires further investigation. Quality improvement interventions, including auditing tools and clinical decision support (CDS), have been developed for use in general practice to support this diagnostic process. We conducted a process evaluation of a pragmatic, cluster-randomized trial that evaluated the effectiveness of a new technology, Future Health Today (FHT), implemented in general practice to assist with the appropriate follow-up of patients at risk of undiagnosed cancer.

Objectives: This study aims to understand implementation gaps, explore differences between the general practices involved, provide context to the trial effectiveness outcomes, and understand the mechanisms behind the intervention successes and failures.

Methods: The trial intervention consisted of the FHT tool (with CDS, audit, recall, and quality improvement components), training and educational sessions, benchmarking reports, and ongoing practice support. The 21 general practices in the intervention arm of the trial were included in the process evaluation. Process data were collected using semistructured interviews, usability and educational session surveys, engagement with intervention components, and technical logs. The Medical Research Council's Framework for Developing and Evaluating Complex Interventions was used to analyze and interpret the data.

Results: The uptake of the supporting components of the intervention (training and education sessions, benchmarking reports) was low. Most practices only used the CDS component of the tool, facilitated by active delivery, with general practitioners reporting acceptability and ease of use. Complexity, time, and resources were reported as barriers to the use of the auditing tool. Access to a study coordinator and ongoing practice support facilitated the sustained involvement of practices in the trial, while contextual factors, such as the COVID-19 pandemic and staff turnover, impacted their level of participation. The relevance of the intervention varied between practices, with some practices reporting very low numbers of patients who were flagged for further investigation.

Conclusions: While some components of the intervention, such as the CDS tool, were considered to be acceptable and useful, this process evaluation highlighted barriers such as time and resources, practice differences, and considerations around the optimal amount of support needed when delivering the intervention. Addressing these in future studies may optimize the implementation process. Further work is needed to determine if a scaled-back approach, which meets the time and resource availability of a busy general practice, can effectively facilitate the implementation of CDS tools. Given the variation seen between practices, the use of the FHT cancer module may be better targeted to certain practices based on size, location, and patient demographics.

Introduction

Diagnosing cancer early can improve patient outcomes and quality of life [1,2]. But, in general practice, the timely detection of cancer can be challenging in the absence of strong diagnostic features, often resulting in prolonged diagnostic intervals [3-5]. In patients presenting to general practice with nonspecific symptoms, the use of routine blood tests can guide decision-making [6]. There is strong evidence that supports the diagnostic utility of abnormal blood tests (eg, iron-deficiency anemia and raised platelets) for multiple cancer types [7-9]. However, suboptimal follow-up and management of abnormal test results have been shown to contribute to delays in diagnosis [10].

Inadequate follow-up of abnormal test results may occur in the case of diagnostic errors, but is also influenced by the general practitioners' (GPs) experience and training; perceptions of cancer care and investigations; patient characteristics; and health system pressures [11,12]. For example, controversy and confusion about prostate-specific antigen (PSA) testing, coupled with changing guidelines and revised thresholds for what is abnormal, contribute to lower follow-up rates in men who have a raised PSA. Surprisingly, there are very few trials that look at modifying the practitioner- and practice-level barriers to following up abnormal results [11].

The general practice electronic medical record (EMR) allows for the integration of novel technologies, where algorithms apply epidemiological data on the underlying risks of undiagnosed cancer based on symptoms and test results to monitor and identify patients who may benefit from further investigation [13]. Clinical decision support (CDS) systems assist in clinical decision-making, where such tools are linked to patient data to produce patient-specific recommendations or prompts for the GP to consider [14,15]. Similarly, auditing tools that use patient information from the EMR enable practice population-level management and review and have the potential to capture patients who are at risk of being lost to follow-up [16,17]. Evidence suggests that tools that highlight patients for review, referral, or further investigation based on evidence-based guidelines can improve patient care, but many of these tools designed to support diagnosis in general practice are met with low uptake and implementation difficulties [18-20].

Complex interventions are used to assess the effectiveness and utility of such tools in general practice. Yet implementing complex interventions can be distinctly difficult, as they involve multiple interrelated components and there are often multiple levels where change is required [21]. Process evaluation can aid in the understanding of the factors that influence how or why a complex intervention succeeds or fails. This study presents the results of a process evaluation of a pragmatic trial, Future Health Today (FHT). This complex intervention consisted of a novel CDS and auditing software, education, quality improvement (QI), and practice support. The pragmatic trial evaluated whether the intervention, which flagged patients with an abnormal blood test that may be indicative of undiagnosed cancer (FHT cancer module), increased the proportion of patients receiving guideline-based care. By gaining process information, we aim to better understand the implementation gaps, explore differences between the general practices involved, understand the interactions between intervention components, and provide context to understand the effectiveness of the intervention.

Methods

Intervention Description and Study Population

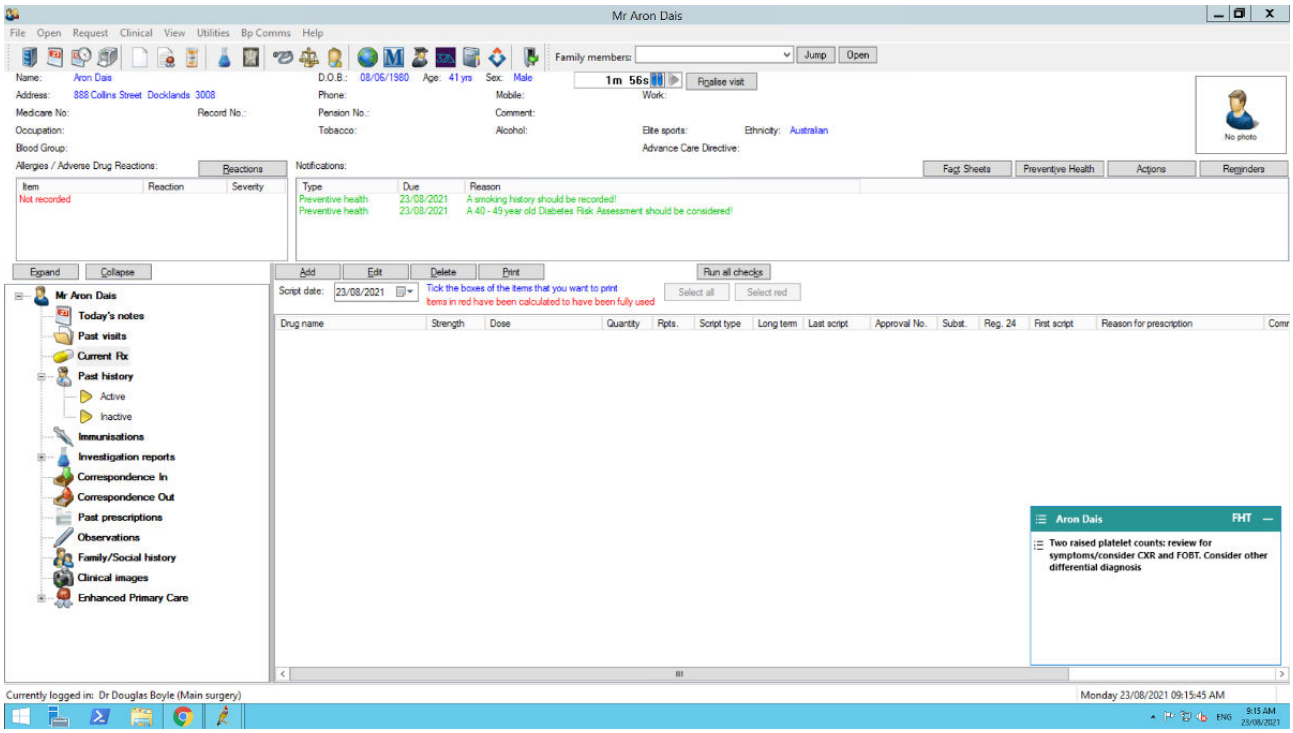
The FHT study was a pragmatic cluster-randomized controlled trial that evaluated the effectiveness of a QI intervention [22]. Pragmatic trials, by definition, are trials that evaluate an intervention in everyday practice, with the aim of measuring the effectiveness of the intervention in routine clinical practice rather than under ideal conditions [23,24]. The implementation of the FHT software and the trial components (including implementation strategies) were applied and adapted to real-world conditions to understand and evaluate how the tool would be used in routine general practice.

The components of the complex intervention included the FHT software, training and educational sessions, benchmarking reports, and practice support. The trial was conducted between October 2021 and September 2022. Practices were randomly allocated to participate in either the intervention (follow-up of patients with abnormal blood test results associated with the risk of undiagnosed cancer) or the active control (which had access to a different FHT module). As the aim of this process evaluation was to explore the factors critical to the implementation of the cancer module, our study population comprises the 21 intervention arm practices only; results for the active control intervention will be reported separately. The study protocol has been published on the Australia and New Zealand Clinical Trial Registry (ACTRN12620000993998) [25].

FHT was integrated within the general practice EMR and consisted of a CDS tool, a web-based audit and feedback tool, and the capacity for general practices to monitor their QI activities [26]. Disease-specific modules were developed for use in FHT. The cancer module used patient information in the EMR (age, sex, previous cancer diagnosis) and results of abnormal tests associated with undiagnosed cancers. The FHT cancer module consisted of 3 central algorithms, designed to assist GPs by flagging patients with abnormal blood test results that are associated with an increased risk of undiagnosed cancer: markers of iron deficiency and anemia, raised PSA, and raised platelet count). The CDS component of the tool activates when the GP or general practice nurse (GPN) opens the patients' medical record, displaying a prompt on screen with guideline-concordant recommendations, such as the review of relevant symptoms or appropriate investigations (Figure 1).

There is also a web-based portal, containing an auditing tool; a QI monitoring tool; and access to resources, guidelines, education, and training, which can be accessed on any computer with FHT installed. Algorithms run each night, extracting data from the practice management software database (eg, Best Practice or Medical Director), processing the data locally by applying FHT algorithms (the data does not leave the practice), and categorizing the results. Examples of a CDS prompt and the audit tool are presented in Multimedia Appendix 1. Further details on the development of the tool and the cancer module explored in this study have been described elsewhere [27-29].

Figure 1. An example of the clinical decision support tool as it appears in the medical record. Simulated patient data are used in this image.



In the pragmatic trial, FHT was installed on general practice computers before study initiation. On the first day of the trial, practices were asked to create 3 cohorts of patients using the FHT auditing tool, one for each abnormal blood test (raised PSA, raised platelets, and markers of anemia). The cohorts included all patients identified by the FHT cancer module who had recommendations for guideline-based follow-up (as part of the trial, practices could then review the patient cohorts and determine if further follow-up was necessary). Cohorts were created again at the 6-month mark, using the audit tool, so that benchmarking information could be determined. After generating the cohorts, practices were invited to use FHT as they chose during the trial.

Implementation of the software was supported by a number of additional intervention components. This multifactorial implementation strategy was informed by the Reach, Effectiveness, Adoption, Implementation, and Maintenance framework, with strategies that were relevant and useful to general practice [30]. These components have previously been shown to increase reach; they are low intensity and high impact, with the purpose of limiting implementation workload while promoting continued engagement with the intervention [31,32]. Training on the use of FHT was offered regularly in the lead up to and in the first month of the trial, and then monthly thereafter. Each practice was assigned a study coordinator, who conducted the Zoom-based training sessions on how to use FHT, assisted with any technological queries, and facilitated requests for support throughout the trial. Practices had access to short training videos on YouTube and a range of short- and long-form written training guides. In addition, 6 Project ECHO (Extension for Community Healthcare Outcomes) [33] educational sessions were run on the topics of cancer diagnosis and QI, each consisting of a 10-minute didactic session, a 10-minute case discussion, followed by an open discussion for approximately 20 - 30 minutes. The ECHO sessions were delivered via a webinar, and general practice staff were invited to attend. Quarterly benchmarking reports were provided to practices to review their progress in the follow-up of patients who had been flagged by the tool, and to compare their progress to other practices in the trial. All practices were required to nominate a practice champion to lead the implementation of FHT in their practice and to be the primary point of contact with the study coordinator during the trial, managing the installation and technical queries, facilitating ongoing use of the tool, identifying staff for process evaluation interviews and to disseminating trial related information to the practice. The goal of the practice champion in this study was to mirror the pragmatic approach of the intervention (eg, they were asked to filter and disseminate information to the practice using an approach that best reflects their individual practice needs and current processes).

Ethical Considerations

The study was approved by the Faculty of Medicine, Dentistry and Health Sciences Human Ethics Sub-Committee at the University of Melbourne (ID:2056564). While practices consented on behalf of all practice staff to participate in the

wider trial, additional written consent was obtained for all interviews. Interview participants were compensated A $100 (US $64.83) for their time. Practice champions also consented separately and were compensated A $200 (US $129.66) for their role as practice champions. All participant data were deidentified and kept anonymous.

Data Collection

Data were collected via qualitative interviews, usability surveys, technical queries, engagement logs, and educational session surveys. For the semistructured interviews, all practice champions were contacted via phone and email to participate in an interview in the first and last months of the trial. The practice champion was most commonly a practice manager (PM) or GPN, but GPs occasionally took on this role during the trial (eg, due to staff changes). The semistructured interviews were conducted over the phone. The interviews were conducted by study researchers (SC, NL, and BH; see the following section on researcher characteristics). The duration of the interviews ranged between 15 and 42 minutes. The interview guides were developed using the Clinical Performance Feedback Intervention Theory framework [34] and were pilot-tested during earlier optimization work on the FHT cancer module [27]. The interviews explored installation, intervention delivery, implementation barriers and facilitators, goals, and usability (see Multimedia Appendix 2 for interview schedule). The interviews explored similar themes at each timepoint, although earlier interviews included questions around goals and intention, and the final interviews explored long-term implementation and sustainability. GPs and GPNs were also recruited for interviews in month 6 of the trial. These interviews have been reported separately [35], as the purpose of the clinical interviews was to explore the acceptability of the clinical recommendations and impact on clinical practice, rather than explore the implementation of the wider intervention.

Usability surveys were sent to practice champions in months 1 and 12 of the trial, with the request to distribute them to the rest of the practice. The survey was delivered via web using REDCap (Research Electronic Data Capture; Vanderbilt University) [36] and included 30 questions (multichoice or free text). This survey was anonymous but captured general demographic information about the user and the general practice in which they work. The survey then explored the use and experience with the intervention (eg, length of time using the tool, what components have been used, and feedback and engagement with the intervention components). The survey also included a System Usability Scale (SUS) a 5-point Likert scale that quantifies the perceived usability of FHT [37]. The usability survey was developed by the study implementation team and is available in full in Multimedia Appendix 3).

Postsession ECHO surveys were sent to all ECHO session participants via REDCap after each educational session and collected both demographic information and feedback on the specific learning outcomes of each webinar. The survey consisted of 23 multiple-choice or free-text questions. An example survey from one of the webinars is included in Multimedia Appendix 4.

Information on the number of installations in each practice, the number of individual users, and recommendation queries (submitted through the technology by the practice) was collected using the FHT technology. Technical reports, including any technical queries by the practice throughout the trial, were recorded by the study coordinator. All engagements between the practice and the study team (study coordinator and technical team), were recorded by the study coordinator and categorized by content (eg, technical queries, training, and administrative items). Implementation diaries were kept by study coordinators to record contextual information (eg, changes in COVID-19 pandemic guidelines, immunization rollout, and general practice initiatives) throughout the trial.

Researcher Characteristics

SC is a PhD candidate at the Department of General Practice and Primary Care, University of Melbourne. BH, a senior qualitative research fellow in the department is the implementation lead for the FHT trial. NL is a postdoctoral research fellow who was the study coordinator for the active control arm of the trial. All are female and experienced in qualitative research and conducting semistructured interviews. Some interview participants were known to the interviewer, given their position in delivering the intervention and supporting the implementation in practices throughout the trial.

Data Analysis

Recorded interviews were transcribed and imported into NVivo (version 12; Lumivero). Process evaluation data were analyzed independently (SC and BH), prior to trial effectiveness outcomes, so as not to bias the interpretation of the results. Each researcher independently conducted a structured, deductive content analysis of the interview transcripts to extract key themes in the data. The results of the content analysis were collated, and themes were presented to the research team. To promote trustworthiness, analytical codes and emerging concepts and categories were discussed at multiple points in the analysis. Positionality was discussed by the coding team, including how established relationships, biases, and experiences may influence their relationship to the study data, and reflexive notes were kept [38,39]. The interpretation of the key findings and discrepancies in interpretations was discussed with the wider team. The results of the evaluation were then mapped onto the UK Medical Research Council (MRC) framework [40,41].

While several frameworks are available to explore and evaluate the implementation of an intervention, the MRC framework was chosen as it is designed for evaluating complex interventions. It has previously been shown to be useful in evaluating the delivery of new technologies in complex environments and in instances of a multi-faceted implementation approach [42,43]. The framework includes overarching themes of context, implementation, and mechanisms of impact and provides a mechanism for understanding the implementation successes and failures (Figure 2) [40,41]. In the figure, the data sources from the trial are mapped onto the 4 process evaluation components as outlined by the MRC framework (implementation, context, mechanisms of impact, and outcomes). The figure outlines the core components and

questions underpinning each theme, and the process data used to answer these questions.

Results

Overview

A total of 21 practices participated in the process evaluation. Characteristics of the participating practices are described in Table 1. Characteristics of the interview participants are outlined in Table 2. Participation in other components of the process evaluation (usability survey, ECHO surveys) and additional general practice details are outlined in Multimedia Appendix 5. In summary, 25 interviews were conducted with 19 practice champions in the first and last months of the trial. A total of 12 usability surveys were completed, and 13 post-ECHO session surveys. Usability survey responses included a mix of PMs (n=4), GPNs (n=4), and GPs (n=3), as well as one receptionist (n=1).

Results have been mapped onto the 3 themes of implementation, context, and mechanisms of impact.

Trial Results Summary

The results of the cluster randomized controlled trial did not demonstrate a significant improvement in follow-up in the intervention arm [22]. At 12 months, 76.2% (2820/3709) of patients with abnormal test results in the intervention arm had been followed up compared with 70% in the control arm, with an estimated difference of 2.6% (95% CI −2.8% to 7.9%). No significant differences were identified in the secondary analyses or in the time to follow-up of abnormal tests for patients flagged by the tool. The following results of the process evaluation provide some context for the null outcome of the trial and suggest areas for improvement in the development and

implementation of CDS and audit software for cancer diagnosis in general practice.

Implementation

There were 3 core themes on implementation: intervention delivery, installation, and general practice characteristics, each underpinned by different evaluation data sources. Intervention delivery was supported by data from engagement logs and educational session surveys, installation and general practice characteristics were supported by data from technical reports, and all 3 drew from qualitative interview data.

Intervention Delivery

The intervention consisted of multiple components: the FHT software components (CDS, an auditing tool, and QI monitoring) and the supporting trial components (educational ECHO sessions, zoom-based training sessions, benchmarking reports, and other web-based learning components that practices could opt-in to use). The uptake of the supporting elements of the trial was generally low, except for the initial formal training sessions. GPs, GPNs, and PMs from all intervention practices were invited to the Project ECHO sessions, yet attendance ranged from 2 to 9 people per session, a mix of GPs and GPNs. Three key barriers were assessed as driving the low uptake of these trial components. First, the supporting components of the intervention were promoted via phone calls, newsletters, and regular emails to the practice champion, so it is possible that the knowledge of each session may not have reached the whole practice, dependent on how the practice champion decided to distribute this information to the practice (eg, internal email systems). The second barrier is the time and resource cost associated with each component. For example, attendance at training sessions and ECHO sessions (1 h each), during or after work hours, was not feasible for many clinical staff. The final barrier relates to recognized need and usability, with many practices reporting that they could use the CDS tool and the cancer recommendations adequately, without the need for additional education or training.

> *It's quite straightforward and quite well explained so it didn't need anything extra particularly.* [GP, female, month 1]

Installation

The installation of the software was completed in the month prior to study initiation, with practices having access to a "practice" module on diabetes in the 2 weeks prior to study initiation so any technical issues could be addressed. The installation, which was done remotely and without much interruption to the practice, was reported to be a smooth process for most. For those who required additional assistance, the use of a study coordinator and technical support ensured PMs felt well-supported during this process.

> *I think what really has gone well is how it seamlessly was implemented. There was no - there's no interruption.* [PM, female, month 1]

Due to the pragmatic approach of the trial, practices determined how many workstations in their practice would have FHT installed at the start of the trial. A total of 14 practices had FHT installed on all clinical computers. Five practices had FHT installed on only one computer at trial initiation, and of these, 4 made the decision to add FHT to additional computers later in the trial. Implementation logs and technical reports indicate that 3 practices were offline for a short period of time (range: 2 - 6 wk), although this does not appear to have had a significant impact on the use of the system.

General Practice Characteristics

There was a large variation in the number of patients identified for follow-up across practices. Three inner-city practices, which had a younger and transient patient population, reported that the cancer module may not be useful in their clinic, given the low number of patients flagged by FHT. For example, in one practice, only 14 patients were flagged for follow-up during the entire 12-month trial period. While these practices acknowledged that the FHT cancer module was less useful for them, it did not deter them from continuing to use the tool after the trial, where they would have access to additional FHT modules (see Software Usability section).

> *Actually, it is cancer topic I don't think that it is very suitable for our clinic because our clinic – the majority of our patients are international students, and they are very young.* [PM, female, month 12]

Context

In exploring context, there were 2 prominent themes: the COVID-19 pandemic and staff turnover. Both themes were underpinned by engagement logs, implementation diaries, and qualitative interviews.

COVID-19

The FHT trial was conducted during the COVID-19 pandemic. In Victoria, restrictions were placed on how and when people could leave their homes, with Melbourne experiencing lockdowns for 262 days during the pandemic. There was a major shift in usual care, and many consultations were conducted via telehealth. During 2020, there was an 8% reduction in cancer-related diagnostic tests nationally, with greater reductions seen in Victoria [44]. The trial continued during a nationwide COVID-19 immunization rollout in primary care, and the burden on general practice was high. There were reports throughout the trial that practices could not devote as much time as they would have liked to FHT or to attend the ECHO sessions due to competing webinars related to COVID-19.

> *It's been a time of change, a lot of updates, a lot of new technology with telehealth. Yeah, there's been a lot going on because of COVID.* [PM, male, month 12]

Staff Turnover

Consequently, staff turnover was a common theme throughout the trial, and the resultant loss of information and increased resource pressure featured heavily in the month 12 interviews. A total of 9 practice champions left their practice during the trial, with 2 practices ending the trial with no replacement. Many interviewees talked about the magnitude of staff turnover during the pandemic and how it was a barrier to use and to keep up momentum in the study.

> *We lost two staff, and two doctors at the end of last year. Now we've got two doctors that we're training again. We started off from scratch again.* [GPN, female, month 12]

Mechanisms of Impact

We found 4 mechanisms associated with the delivery of the intervention: adoption and integration, training and support, software usability, and clinical recommendations. The sources of data varied within each theme. Technical reports, usability surveys, and interviews supported adoption and integration. Training and support were underpinned by engagement logs, education session surveys, and interviews. Software usability was supported by the usability survey, interviews, and engagement logs. The final theme of clinical recommendations was elucidated from technical reports (in particular, recommendation queries), which were further explored in the educational sessions and qualitative interviews.

Adoption and Integration

The majority of practices reported that they did not use the QI and audit and recall components of the tool, only the CDS, which was delivered at the point of care. The CDS was considered easy to use and quick to learn and was therefore easily integrated into the clinical workflow by matching the resources available in a busy general practice. However, the audit, recall, and QI components of the tool encountered a number of barriers. First, in comparison to the CDS tool, where recommendations are actively delivered to the GP, the audit and recall tool requires the user to visit a web page and log on to access this part of the tool. Second, there were additional layers of complexity and multiple steps involved in order to identify, review, and recall patients identified in the audit tool.

Training and Support

The level of engagement between the study coordinator and most participating practices was high, and the support provided by the research and technical team facilitated the continued involvement of practices in the study. No practices in the intervention arm withdrew during the study period.

> *The co-operation between the teams and myself was amazing. There were no issues whatsoever and they were always there to help … it was really good.* [PM, female, month 12]

Practice staff who attended training sessions or used the web-based resources found the training adequate enough to use the tool, and practice champions reported that they would be comfortable training other members of the practice who could not attend. However, in most interviews, especially with the GPs who did not attend the training sessions, it became evident that components of training on how to use FHT did not reach the entire practice. For example, many GPs were unaware of the patient deferral button (which allows GPs to pause recommendations for a patient for a specified period of time) or that there are patient resources available. The post-ECHO session surveys highlighted that the education and case discussion components of the ECHO sessions were useful to GPs and GPNs in managing more complex patient scenarios, but did not influence the way in which the tool was used.

Software Usability

Of the 12 usability survey responses, 11 (92%) would recommend FHT to others. As part of the usability survey, respondents filled in a SUS [37]. The results of the survey align with the separate qualitative results from the clinical interviews in that FHT is reported to be easy to use, simple, and intuitive [35]. The average SUS score from the respondents was 74 (out of 100), consistent with an above-average score (average score=68; score >70 is considered good).

Acceptance and perceived usefulness of the FHT software were indicated by the number of practices agreeing to continue using the FHT software posttrial. A total of 18 of the 21 practices opted to continue using the software after the trial ended (practices were offered a 3 mo extension), and 17 practices opted to continue using the tool into 2023‐24.

Clinical Recommendations

The software included a menu option to "report recommendation query" if the GP or GPN thought the recommendation was appearing in error or wanted further information. Five queries about the clinical recommendations in FHT, from 3 practices, were received during the trial. The most frequent recommendation query centered around the clinical recommendations for raised platelets. The risk of undiagnosed cancer increases at a platelet count threshold of 400×10^9/L, but different laboratories report an upper limit of either 400 or 450 $\times 10^9$/L; this caused some confusion among GPs if a patient was flagged with a count in the range of 400‐450x 10^9/L. This issue was addressed in training sessions and regular communications (monthly emails, newsletters), but the perceived error may have impacted some GPs' willingness to use the tool and their trust in the recommendations. Interestingly, there were no queries about the recommendations for raised PSA (the FHT recommendations were based on current Australian guidelines for PSA follow-up with a lower limit of 3ng/mL in men over 50, which contrasts with some laboratories that report a lower limit of the normal range of 4ng/mL). Established referral pathways and familiarity with the abnormal test as a cancer marker (raised platelet is a relatively new marker of cancer) may have been a contributing factor to this difference in response.

Discussion

Overview

In this study, we describe a comprehensive process evaluation exploring the delivery of a complex intervention as part of a pragmatic, randomized trial, where a module to support cancer diagnosis was implemented in general practice. The process evaluation describes implementation gaps and the mechanisms that drive implementation successes and failures in order to provide context to the outcomes from the trial [22].

Principal Findings

The FHT cancer module intervention did not demonstrate a significant improvement in the follow-up of abnormal test results in the patients flagged by the tool. While we hypothesize that the high-performing practices across both arms may have led

to a ceiling effect (ie, there was limited room for improvement given the high rates of follow-up in both arms), an absence of any intervention effect may in part be due to implementation barriers, primarily relating to practice characteristics and contextual factors. There was limited ability for some specific practices to engage with the tool when their patient population was not suited to the FHT module that was implemented. Given this variation in the relevance and usefulness between practices, the use of the FHT cancer module may be better targeted to certain practices based on size, location, and patient demographics.

Comparison to Prior Work

In comparison to interventions with only one component, complex interventions require more time and resources, and are, unsurprisingly, more difficult to implement [31,45]. We found that the uptake of the supportive components of the intervention was low, aside from some initial training on the software. It was also indicated in the interviews that the supporting components were not considered necessary to use the CDS. While the implementation of new software in general practice requires some training and support, the results of this process evaluation indicate that a scaled-back approach to implementation, one which aligns with the time and resources available to general practice, may have been sufficient for the CDS component of the tool [46]. However, given the null outcomes of the trial, the low uptake of the audit tool, and significant contextual factors (COVID-19 pandemic), more work is needed to determine the usefulness of each component, or combination of components, in supporting this type of change in practice.

Implementing new technologies in general practice is a complex and dynamic process, and despite the potential to improve patient outcomes, many tools have low uptake after implementation [47,48]. The trial consisted of a number of implementation strategies that aimed to optimize the uptake of FHT in routine care, and these methods were applied primarily at the professional level (eg, education or training strategies targeting health care professionals and identification of practice champions) [49]. We found that the use of a practice coordinator facilitated the continued involvement and engagement of practices throughout the trial, similar to previously reported successful implementation strategies used in complex evaluations delivered in general practice. One overview of reviews concluded that practice facilitators, who work with practices in areas such as QI, problem-solving, and education, are almost 3 times as likely to adopt evidence-based guidelines, and practice facilitation improved the adoption of guidelines associated with many chronic diseases [32]. But given the large amount of staff turnover, driven by the COVID-19 pandemic, identifying, maintaining, and replacing practice champions was difficult and resulted in a loss of information and a barrier to engagement for some practices.

Strengths and Limitations

This process evaluation was extensive, with a multi-modal approach to collecting process data, including interviews, surveys, technical and software data, engagement logs, and implementation diaries. Interviews and usability surveys were carried out at 2 time points during the trial, to address the dynamic nature of implementation barriers and facilitators and how perceptions of the tool can change over time. This substantive evaluation provides context to a complex intervention and the environment in which it was implemented.

There were, however, some limitations. While all practices were invited to take part or contribute to each component of the process evaluation, there were 3 practices who did not participate in an interview at any timepoint or complete any surveys. The opt-in method for the interviews and surveys meant that we may not have sufficiently captured the views of practices who were less engaged with the intervention. These 3 practices did contribute some data to the process evaluation, through software data, technical information, and engagement logs, which were captured from all practices involved in the trial.

The burden of the COVID-19 pandemic in general practice and the resultant impact on staffing was a core theme throughout the process evaluation and provided context when interpreting the trial results. A second limitation was that the pandemic also likely impacted the time, availability, and resources for general practice staff to participate in the interviews and contributed to the low response rate for the usability survey. To mitigate this, we provided numerous opportunities for users to engage in interviews and respond to surveys throughout the trial and promoted such activities through the continued engagement with each practice champion.

Finally, we had originally planned on including some additional software use statistics to complement the qualitative components of the intervention; however, incomplete data prohibited our ability to do so. Software use data would have allowed us to triangulate users' responses via interviews and surveys with their time using the software, including what parts of the tool they used and when. Future studies would benefit from including software statistics to cross-check the qualitative results.

Implications and Future Research

There are implications for both research and practice. While the FHT cancer module did not increase the proportion of patients followed up according to guidelines, the process evaluation highlighted factors around usability, which facilitated the adoption and integration of the CDS component of the tool. This, coupled with the acceptability findings from separate clinical interviews [35], and the willingness of the majority of practices to continue using the tool after the trial finished, indicates that different modules developed for use in FHT should be explored, as well as CDS tools for cancer diagnosis more broadly. There are also considerations for designing complex interventions that involve the use of a new technology. Given the low uptake of the supporting components of the tool, but indications of use and acceptability of the CDS component of the software, it is unclear whether a multifaceted implementation strategy is useful when implementing new CDS tools, especially if it has been carefully co-designed to meet the needs of users. Future work should be undertaken to determine if a scaled-back approach, which meets the time and resource availability of general practice, could be as effective in supporting the delivery of novel CDS tools.

Conclusions

This process evaluation highlights the implementation and process-related gaps that could be addressed in future studies that aim to implement diagnostic support tools for cancer in general practice. While some of the factors were context-specific (eg, driven by the COVID-19 pandemic), barriers such as time, resources, and practice variations, alongside considerations of design elements, could be built upon to optimize future CDS and QI programs.

Acknowledgments

We would like to thank the general practitioners, health care professionals, and consumers who provided input to the development of Future Health Today (FHT), piloted the tool in their practices, and participated in this trial. We are grateful to the consumer and general practice advisory groups who provided important insights into this trial. We would like to acknowledge the Primary Care Collaborative Cancer Clinical Trials Group (PC4) for their support on this project. Deidentified patient data from the Patron primary care data repository (extracted from consenting general practices), which has been created and is operated by the Department of General Practice and Primary Care, the University of Melbourne, were used to underpin trial feasibility, sample size calculations, and to evaluate the outcomes of the trial. The Paul Ramsay Foundation provided funding for staff costs related to the technical development of FHT and the Implementation and Evaluation team members. They have also provided funding for professional staff support and general practice and consumer advisory groups. The development of the cancer module of FHT was supported by the CanTest Collaborative (funded by Cancer Research UK C8640/A23385) of which JE is an Associate Director. JE is supported by an NHMRC Investigator grant (APP1195320). JMG is supported by a Victorian Cancer Agency Mid-Career Fellowship (MCRF21025).

Data Availability

Deidentified datasets analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Despite its potential to predict and detect early cancer risks, genetic testing remains underused by the public. This study, guided by the health belief model (HBM), examined key factors influencing an individual's willingness to undergo genetic testing for cancer, with a particular focus on gender, caregiver status, and participation in online social support groups.

Objective: This study aimed to explore the factors that can influence the individual's decision to undergo preventative genetic testing for cancer so that more informed action can be taken to encourage the individuals to engage in preventative health behavior.

Methods: This study uses data collected from the 2020 Health Information National Trends Survey (HINTS 5 Cycle 4), which included 2947 respondents representing 199,510,996 US adults aged 18 years and older. Multivariable logistic regression and survey-weighted generalized linear models were applied to examine the relationship between cancer genetic testing and caregiver status, participation in online support groups, gender, and constructs associated with the HBM, while controlling for sociodemographic and health-related characteristics.

Results: Our findings show that women are more likely to undergo cancer genetic testing, with gender moderating the influence of perceived susceptibility (β=2.54, *P*=.03) and severity (β=0.94, *P*<.050) on testing decisions. In line with the HBM, perceived benefits (β=0.19, *P*=.03) and cues to action (β=2.86, *P*<.001) increase the likelihood of testing. Results also show that caregivers of patients with cancer (β=1.25, *P*=.04) and those actively participating in online health support groups (β=0.47, *P*=.04) are also more likely to engage in cancer genetic testing.

Conclusions: Cancer remains a significant health challenge in the United States, with 1.8 million new cases and 606,520 deaths annually. Early detection is vital for treatment success. This study investigates factors influencing the decision to undergo genetic testing for cancer. The examination of caregiver status and online support groups as influencing factors, along with the HBM, provided a significant theoretical contribution to the health care research domain. Results indicated that caregivers and men should be directly targeted with messaging on genetic cancer screening as a proactive health behavior. Additionally, online support groups can promote early detection and encourage participation in genetic testing. Future research should further explore implementing proactive outreach strategies to encourage wider adoption of genetic testing for cancer.

KEYWORDS

genetic testing; cancer; health belief model; caregiver status; online social support; gender differences

Introduction

Overview

Cancer remains one of the most urgent health challenges in the United States, with approximately 2 million new cases and 611,000 deaths projected to occur in the United States in 2024 [1]. These figures highlight the importance of early detection and timely intervention, which are critical for improving treatment outcomes and reducing cancer-related mortality [2]. Early detection, particularly through predictive methods, enables health care providers to identify cancers at earlier stages, where treatment options can significantly improve the chances of successful outcomes. Consequently, the development and widespread adoption of effective screening strategies have become paramount in the fight against cancer.

Among these strategies, genetic testing has emerged as a pivotal tool in cancer prevention and early detection [3]. By analyzing an individual's DNA, genetic testing can identify mutations that may predispose individuals to various forms of cancer [4]. This predictive capability empowers individuals with knowledge that allows them to take preventive actions or pursue early treatments. As medical science and technology continue to advance, the scope of genetic testing has expanded to detect a wide range of inherited disorders, making it an indispensable approach for reducing cancer risk [5,6].

The health belief model (HBM) offers a valuable framework to understand why individuals engage in preventive behaviors like genetic testing. The HBM suggests that individuals' health behaviors are shaped by their perceptions of susceptibility, severity, and the benefits of action [7]. This model has been widely applied to the study of various preventive health actions, including vaccinations for H1N1 [8] and COVID-19 [9], as well as screening for conditions like diabetes [10] and several types of cancer [11-14]. Alongside the HBM, three key factors—caregiver status, participation in online social support groups, and gender—are likely to influence preventive behaviors related to genetic testing.

Caregivers, who are often family members, gain a deeply personal and intimate understanding of cancer's devastating impact. Due to shared genetic ties and family history, these caregivers frequently face a higher risk of developing cancer themselves [15,16]. Their close connection to the disease makes them a critical demographic for studying behaviors related to genetic testing. Given their heightened risk and firsthand exposure to cancer, caregivers may be particularly motivated to pursue genetic testing as a preventive measure.

In addition to caregiver status, online social support groups have been shown to play a crucial role in promoting preventive behaviors. Hwang et al [17] demonstrated that participation in online peer support groups significantly increased motivation for colorectal cancer screening, reinforcing participants' belief in the effectiveness of early detection. Lastly, gender has a profound influence on preventive health actions. Research indicates that women tend to be more proactive in engaging in preventive health behaviors [18-20]. For instance, women with low social support are less likely to participate in breast cancer screening, further illustrating the interplay between social support and gender in health decision-making behaviors [21].

The remainder of this paper is organized as follows. First, we provide an overview of the literature on genetic testing and the HBM. Next, we develop hypotheses and propose our research model. We then outline the research methodology and present the results. Following this, we discuss the findings, exploring both theoretical and practical implications. Finally, we conclude with a summary of the key insights gained from this research and address its limitations.

Background

Advancements in identifying gene mutations have made genetic testing a crucial tool in reducing illness and death by enabling early detection and preventive measures [5]. Predictive genetic testing, which assesses an individual's risk of developing diseases like cancer, focuses on identifying genetic mutations linked to disease susceptibility [22]. However, challenges persist in diagnosing hereditary breast and ovarian cancers, particularly in terms of genetic literacy and interpreting test results [23]. Nelson et al [24] emphasize the critical role of genetic counseling in BRCA-related cancer testing, highlighting the importance of providing informed decision-making support to patients.

Prior research also suggests that people with a family history of cancer often overestimate their risk. Their decisions about genetic testing are often influenced more by their subjective perceptions of vulnerability than by objective data [25]. This cognitive bias can lead to increased anxiety. It may cause individuals to rush into testing without enough information or avoid testing out of fear of the results. Despite these misperceptions, genetic testing consistently offers significant benefits, regardless of the outcome. Whether the results confirm a genetic predisposition or provide reassurance, testing allows individuals to make informed health decisions, take preventive measures, and access appropriate counseling and support services [26]. This highlights the importance of education and counseling in helping individuals to more accurately interpret genetic risks and use the information to make effective health care choices.

Caregivers of patients with cancer often play a pivotal role in health care decision-making, including decisions about genetic testing [27]. As primary support figures, caregivers are frequently involved in gathering health-related information, navigating complex medical choices, and encouraging preventative behaviors. Social support groups, both in-person and online, have been shown to provide critical informational and emotional support during these processes [28]. With the rise of online communities, individuals considering genetic testing now have greater access to peer support and shared experiences. Silence [29] demonstrated that online cancer communities facilitate advice-seeking and information-sharing, creating a valuable space for individuals to navigate genetic testing options. Similarly, Ruco et al [30] found that online social interactions significantly increase participation in cancer screening, highlighting the potential of these platforms to influence health-related behaviors. Given their influence in health decisions and the growing prevalence of online support networks, understanding the combined impact of caregiver status and participation in online social support groups is essential for accurately capturing the social and behavioral drivers behind genetic testing decisions.

The HBM is frequently used to examine health behaviors by considering factors such as perceived susceptibility, severity, cues to action, benefits, barriers, and demographic variables [7]. Bunn et al [31] and Hartman [32] successfully applied the HBM to predict decisions about preventive screenings, like colon cancer screening and mammography. The HBM provides a robust framework for understanding and influencing health-related decision-making, particularly in the context of preventive interventions such as genetic testing.

Theoretical Model

Health Belief Model—Perceived Susceptibility

Perceived susceptibility is an individual's belief about their likelihood of experiencing a health condition and is a key driver of health-related behavior according to the HBM [33,34]. Research consistently demonstrates that higher perceived susceptibility significantly influences medical decisions. For instance, Champion and Skinner [35] found that women with greater perceived susceptibility to breast cancer were more likely to undergo mammography. Similarly, Irigoyen-Camacho et al [36] observed that older adults with heightened perceived susceptibility to COVID-19 engaged more in preventive behaviors. Meta-analyses further confirm the strong correlation between perceived susceptibility and health behavior change [37,38]. Thus, we hypothesize the following:

Hypothesis H1a: Perceived susceptibility positively influences an individual's decision to undergo genetic testing for cancer.

Further, the impact of perceived susceptibility varies by gender. Studies suggest that women generally perceive greater health risks and, therefore, are more likely to adopt health-promoting behaviors, such as regular screenings and healthier lifestyles [39]. For example, Lisha et al [40] found that women with similar levels of physical activity as men had lower alcohol consumption. Based on this, we hypothesize the following:

Hypothesis H1b: Gender moderates the relationship between perceived susceptibility and an individual's decision to undergo genetic testing for cancer.

Health Belief Model—Perceived Severity

Perceived severity refers to an individual's belief about the seriousness of contracting an illness [34]. According to the HBM, higher perceived severity increases motivation to engage in health-promoting behaviors [35]. Studies by Witte and Allen [41] and Brewer et al [37] show that individuals who perceive health threats as severe are more likely to adopt preventive measures, such as vaccination. Similarly, Irigoyen-Camacho et al [36] found that the perceived severity of COVID-19 significantly influenced compliance with stay-at-home guidelines. He et al [42] also reported that individuals with high perceived severity of colorectal cancer were more likely to undergo colonoscopy. These findings highlight the pivotal role of perceived severity in driving medical action. Thus, we hypothesize the following:

Hypothesis H2a: Perceived severity positively influences an individual's decision to undergo genetic testing for cancer.

Further, extant research found that women perceive risks higher and engage in more preventive health behaviors [43]. Women generally report higher levels of perceived severity regarding health issues compared to men, and this heightened perception is linked to greater engagement in preventive health behaviors [39]. Sattler et al [44] also demonstrated that women were more likely than men to perceive the severity of health threats such as COVID-19, which translated into a higher likelihood of adopting recommended health behaviors. Thus, we extend this notion and hypothesize the following:

Hypothesis H2b: Gender moderates the relationship between perceived severity and an individual's decision to undergo genetic testing for cancer.

Health Belief Model—Perceived Benefit

Perceived benefits refer to an individual's belief in the positive outcomes of a health action, and they play a crucial role in motivating behavior change [35]. For instance, individuals are more likely to engage in physical activity if they believe it will lead to significant health improvements [45]. Similarly, Chen et al [46] found that perceived benefits significantly impact decisions to get vaccinated. Chen et al [47] further confirmed the association between perceived benefits and preventive behaviors. Bosompra et al [48] found that perceived benefits significantly impacted decisions to undergo genetic testing for cancer susceptibility. Based on this, we hypothesize the following:

Hypothesis H3: Perceived benefits positively influence an individual's decision to undergo genetic testing for cancer.

Health Belief Model—Perceived Barrier

Perceived barriers refer to an individual's assessment of obstacles that hinder the adoption of health-related behaviors [34]. Research consistently shows that these barriers negatively impact medical decision-making. According to the HBM, barriers may include factors such as cost, time, inconvenience, and fear of adverse outcomes [35]. A systematic review by Al-Noumani et al [49] identifies perceived barriers as a key predictor of poor adherence to health behavior changes in chronic conditions. Similarly, studies demonstrate that perceived barriers influence compliance with COVID-19 preventive measures over time [50,51]. Building upon these findings, we hypothesize the following:

Hypothesis H4: Perceived barriers negatively influence an individual's decision to undergo genetic testing for cancer.

Health Belief Model—Cues to Action

Cues to action are stimuli that prompt individuals to engage in health-promoting behaviors and are crucial for motivating medical action [35]. In the HBM, cues can be internal, such as experiencing symptoms, or external, like advice from others or health campaigns. Carpenter [52] found that both internal cues, like symptoms, and external cues, such as media messages, significantly increase the likelihood of seeking medical care. Similarly, Glanz et al [53] showed that health communication campaigns effectively acted as external cues, leading to higher vaccination and screening rates. Based on this, we hypothesize the following:

Hypothesis H5: Cues to action positively influence an individual's decision to undergo genetic testing for cancer.

Caregiving

A caregiver provides care and support to someone with health-related needs due to chronic illness, disability, or aging [54]. When a family member is diagnosed with cancer, caregivers are deeply involved in diagnosis, treatment, and survivorship care [55]. During this time, they interact closely with health care providers, gather medical information, and

witness their loved one's experiences. The Center for Disease Control encourages caregivers to practice self-care and engage in preventive health care [56]. Research shows that spousal caregivers are more likely to undergo cancer screenings [57,58], with evidence of increased screening for stomach, breast, and cervical cancer among caregivers [59]. Additionally, caregivers are more likely to adopt health-promoting behaviors [60]. Extending this idea to genetic testing, we hypothesize the following:

Hypothesis H6: Caregiving positively influences an individual's decision to undergo genetic testing for cancer.

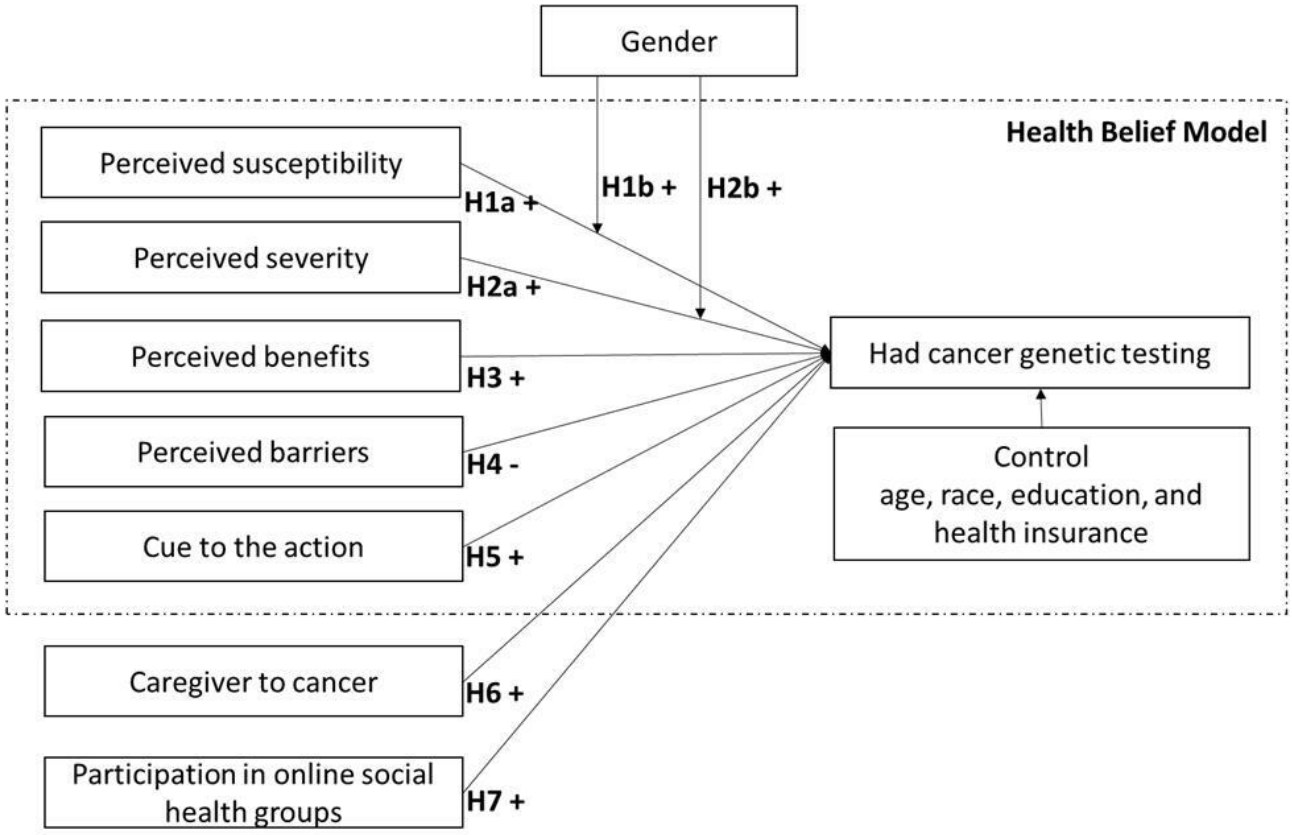
Online Social Support

Online social support groups provide a platform for individuals to share experiences and receive encouragement from others facing similar health challenges. This support fosters motivation and adherence to health goals. Participants often feel more committed to their health plans when they receive positive feedback and peer encouragement [61]. These groups also offer emotional support, reducing stress and anxiety, leading to better adherence to health-promoting behaviors and overall well-being [62]. Additionally, personalized advice from peers who have faced similar issues can be more practical and relevant than generic information, resulting in more effective health behavior changes [63]. A systematic review further supports the effectiveness of social media tools in delivering interventions for cancer prevention and management [64,65]. Based on these insights, we hypothesize the following:

Hypothesis H7: Participation in online health communities positively influences an individual's decision to undergo genetic testing for cancer.

Based on these hypotheses, our proposed research model is presented in Figure 1.

Figure 1. Research model.



Methods

Data

We used data from the 2020 National Cancer Institute Health Information National Trends Survey (HINTS 5 Cycle 4) survey, which is publicly available on the HINTS website [66]. Table 1 presents the correlations between the principal variables with survey weights. High correlations can indicate multicollinearity, but all correlations fall below the threshold of 0.5 [67], so multicollinearity was not an issue. The table also includes the means and SDs for the key variables.

Table . Correlation matrix.

	Mean	SD	PSUS[a]	PSEV[b]	PBEN[c]	CUES[d]	CC[e]	OSS[f]
PSUS	0.732	0.665	1.000					
PSEV	2.509	0.951	0.010	1.000				
PBEN	9.873	1.585	0.060	0.010	1.000			
CUES	0.438	0.704	0.160	−0.120	0.100	1.000		
CC	0.019	0.369	0.030	0.030	−0.090	0.020	1.000	
OSS	0.266	0.746	−0.020	0.040	0.060	0.040	0.010	1.000

[a]PSUS: Perceived susceptibility.

[b]PSEV: Perceived severity.

[c]PBEN: Perceived benefit.

[d]CUES: Cues to action.

[e]CC: Caregiving cancer.

[f]OSS: Online social support.

Measurements

The complete set of questionnaires for the dependent, independent, and control variables can be found in Multimedia Appendix 1. Although many variables are measured using multi-item scales, some are captured through single-item measures. The use of single-item measures is deemed appropriate when the question is straightforward and unambiguous, minimizing the risk of varied interpretation [68]. Moreover, single-item measures are widely recognized and commonly used within the health care domain [60,69,70], further supporting their validity in this study.

Outcome Variable: Cancer Genetic Testing

The main outcome variable "Had cancer genetic test" is a dichotomous variable and coded "1" for an individual who had a genetic test for cancer, otherwise "0." In our data, 142 respondents said they had cancer genetic testing; this represents 8,368,022 in the population when using survey weights. In total, 2805 respondents said they never had cancer genetic testing, which represents 191,142,974 in the population when using survey weights.

We effectively mitigated the potential concern of skewed outcome variables through the application of survey weights. Survey weights are designed to adjust for the complex survey design, including oversampling and nonresponse, ensuring that the results are representative of the target population. Studies have shown that when survey weights are appropriately applied, they can correct for biases introduced by skewed distributions in outcome variables, leading to more accurate and generalizable results [71].

Primary Independent Variables: Cancer Caregiver and Online Social Support

Caregiver cancer is coded as '1' if the individual is caring for or making medical decisions for someone with cancer, and '0' otherwise. Online social support is coded as '2' for individuals who both share health information on social networking sites and participate in an online forum or support group related to similar health or medical issues. If they engage in only one of these activities, it is coded as '1,' and if neither activity is present, it is coded as '0.'

Support Independent Variables: Health Belief Model

Perceived susceptibility is coded as "1" if first- or second-degree biological relatives had cancer, otherwise "0." Perceived severity ranges from "1" to "5" for respondents' general health, varying from "Excellent" to "Poor." Cues to action are coded as "1" if respondents have heard of cancer genetic testing, otherwise "0."

The perceived benefit was obtained by summing respondents' answers to 3 survey questions: How important is knowing a person's genetic information for preventing cancer? How important is knowing a person's genetic information for detecting cancer? and How important is knowing a person's genetic information for treating cancer. These questions have 4 options from "Not at all" to "Very." Several papers have pointed to income as a potential barrier to preventative health care [72,73]. Hence, we consider income as a proxy for perceived barrier, and it has 5 categories "1" to "5." Less than US $20,000 is coded as "1" while US $75,000 or more is coded as "5."

Moderating Variable: Gender

Females were coded as "1" and male as "0."

Control Variables

Race, education, marital status, insurance, and age were used as controls in the model. Whites were coded as "1" and non-Whites were coded as "0." Education of more than high school was coded "1" for individuals, otherwise "0." For married individuals, married was coded as "1", or else "0." Insured individuals were coded as "1" or else "0." We used the natural log of "Age" in our model as "Age" varies from 18 to 102 years.

Statistical Analysis

This study uses survey weights to report national estimates. We used survey-weighted generalized linear models to test the hypotheses in R using the "survey" package. We used HINTS-supplied survey weights using jackknife variance estimation techniques to account for the complex HINTS sampling design and to calculate nationally representative

estimates [74]. Since we used publicly available deidentified data, the Institutional Review Board review was exempted.

Common Method Variance

Data collected with a self-reported single survey may suffer from common method variance (CMV), which hampers the relationship between the variables [75]. To check if our data are suffering from CMV, we used the marker variable technique [76]. A marker variable is a variable that is theoretically unrelated to one or more of the principal variables measured in the study and typically should have a low correlation with the variables of interest.

The theoretically unrelated construct "UnderstandOnlineMedRec" (UOM) was used as a marker variable. The correlation between the marker variable UOM and other principal variables is very low, indicating that CMV is not a problem. The UOM for perceived susceptiblity was 0.03, that for perceived severity was 0.18, that for perceived benefit was −0.03, that for cues to action was −0.21, that for caregiving cancer was 0.02, and that for online social support was 0.02.

Ethical Considerations

The HINTS 5 survey, conducted with the general population, underwent expedited review and received approval from the Westat Institutional Review Board on March 28, 2016 (project no. 6048.14). In addition, on April 25, 2016, the National Institutes of Health Office of Human Subjects Research determined that the survey did not involve human subjects research, providing an exemption (exempt no. 13204) [77]. This analysis used deidentified, publicly available data from the HINTS, which did not constitute human subjects research as defined by 45 CFR 46.102 and, therefore, did not require IRB review. The original consent and IRB approval cover secondary analysis without the need for additional consent. No compensation was provided for participation.

Results

Study Population Characteristics

The data include 3865 civilian, noninstitutionalized US adults aged 18 or older. After filtering for valid responses to the question about genetic testing for high-risk cancer, our final sample consisted of 2947 respondents, representing 199,510,996 US adults. Descriptive statistics of the survey respondents are shown in Table 2 with survey weights applied.

Table . Descriptive statistics.

Demographic characteristics	Sample size, n (%)	With survey weights
	2947 (100)	199,510,996

Insurance	2.18795	1.21807	1.796	0.0822	No

The analysis did not identify a significant direct relationship between perceived susceptibility and the decision to undergo genetic testing (β=−0.70805, *P*=.36), leading to the rejection of hypothesis H1a. However, gender was found to be a significant moderator in this relationship. Specifically, women who perceive themselves as susceptible to cancer are significantly more likely to pursue genetic testing (β=2.53956, *P*=.03), providing support for hypothesis H1b.

Similarly, no significant direct association was observed between perceived severity and the decision to undergo genetic testing (β=−.58773, *P*=.13), leading to the rejection of hypothesis H2a. However, gender again played a moderating role in this relationship. Women were more likely than men to opt for genetic testing when they perceived cancer as a severe threat (β=.94366, *P*=.03), supporting hypothesis H2b.

Beyond gender effects, the findings indicate that individuals who perceive greater benefits from genetic testing are more inclined to undergo testing (β=.18903, *P*=.03), confirming hypothesis H3. The expected relationship between perceived barriers—represented by income in this study—and genetic testing decisions (hypothesis H4) was not supported (β=−1.11782,−0.17123, 0.44008, 0.05962, *P*>.05).

Cues to action emerged as a significant predictor of genetic testing decisions, with greater exposure to such cues being strongly associated with an increased likelihood of pursuing genetic testing (β=2.85722, *P*<.001), supporting hypothesis H5. Additionally, individuals who serve as caregivers for patients

with cancer were found to be significantly more likely to engage in genetic testing themselves (β=1.25257, *P*=.04), confirming hypothesis H6. Lastly, participation in online social health groups was positively associated with the likelihood of undergoing genetic testing (β=.47306, *P*=.04), supporting hypothesis H7.

Discussion

Summary of Findings

In line with previous research [78,79], our findings indicate that perceived susceptibility alone may not be enough to motivate individuals to undergo genetic testing. This suggests that additional cues to action or contextual influences may play a crucial role in shaping decision-making.

Moreover, the results show that perceived susceptibility has a stronger effect on genetic testing behavior among women compared to men. One possible explanation is that women may be more sensitive to health risks, particularly hereditary cancers such as breast and ovarian cancer, making them more likely to act on their perceived vulnerability.

This finding is consistent with existing literature [80,81], which suggests that while perceived severity is an important factor, it may not be a sufficient motivator for health-related behaviors without the presence of additional reinforcing elements.

The results also emphasize the importance of accounting for gender differences in health risk perceptions and decision-making. Women's stronger response to perceived severity may be attributed to their heightened awareness of specific cancer risks and a greater tendency to engage in proactive health behaviors.

Additionally, our findings reinforce a core principle of the HBM, which asserts that perceived benefits are a key driver of health-related actions.

Results further suggest that traditional barriers, such as cost, are being alleviated through evolving health care policies and financial assistance programs [82,83]. Measures such as subsidized testing, reduced out-of-pocket expenses, and insurance coverage for preventive screenings have helped minimize these obstacles [84].

Cues to action emerged as a significant predictor of genetic testing decisions. One explanation for this finding is the changing health care landscape, particularly in preventative care and personalized medicine. Many providers now recognize the value of genetic testing for early risk identification, prompting efforts to reduce financial and logistical barriers [85]. Major insurers increasingly cover preventative genetic testing, reducing costs for individuals [86]. Additionally, online support groups play a role by informing individuals about available financial assistance and providing emotional support, reducing psychological barriers like fear or anxiety about test results [87]. These developments suggest that the traditional "perceived barriers" construct in the HBM may not be relevant in the context of genetic cancer testing.

Another important result from the study is the role of caregiving in influencing decisions to undergo genetic testing. This finding underscores the role of online communities in promoting health-related behaviors by providing access to information, emotional support, and shared experiences. These groups act as cues to action by reducing uncertainty and raising awareness about the benefits of genetic testing, empowering individuals to make more informed health care decisions, especially in preventative care contexts.

Theoretical Contributions

Our study extends the prior body of research on HBM by examining factors that influence an individual's decision to undergo cancer genetic testing and incorporating variables that have not been widely explored in prior research. One of the key theoretical advancements of this study is the evidence supporting the moderating role of gender in the relationship between perceived susceptibility, perceived severity, and health behavior change. Our results demonstrate that women are significantly more likely to undergo genetic testing when they perceive higher susceptibility or severity of cancer, thus supporting the hypotheses related to gender moderation. Gender disparity in health decision-making behavior is rooted in cultural, psychological, or social factors that make women more responsive to health risks, particularly those related to cancer, such as breast and ovarian cancer. These findings align with prior research indicating that women are generally more responsive to health risks, particularly in the context of cancer (eg, breast and ovarian cancers), where early detection and preventive measures are critical [35,88]. This gender-specific behavior underscores the need for health interventions that are tailored to reflect differences in health perceptions and behaviors between men and women.

This study extends the HBM by incorporating caregiving as a variable that influences health behaviors. Our results indicate that individuals who are caregivers to patients with cancer are significantly more likely to engage in cancer genetic testing. Caregivers, who are often emotionally and practically involved in managing the health of others, are more attuned to genetic risks and motivated to take preventive action for their own health [89]. This finding suggests that future interventions could target caregivers specifically, providing them with information about the benefits of genetic testing and encouraging preventive health behaviors.

Furthermore, the study highlights the growing importance of digital communities, such as online social health groups, in shaping health behaviors. Our analysis shows that participation in these groups is positively associated with the likelihood of undergoing genetic testing. This finding is consistent with existing literature that points to the influence of social networks on health behavior change [90,91] and the growing importance of digital communities in shaping health behaviors. Online platforms can serve as a source of information, support, and motivation for individuals contemplating health-related decisions. In online platforms, individuals can share experiences, advice, and support, building virtual environments that encourage proactive health actions like genetic testing. As such, health practitioners and policy makers could leverage the power

of these digital communities to enhance awareness and promote the benefits of genetic testing and other preventive health measures.

Practical Implications

This study's findings have several practical implications for health care providers and public health campaigns. Our results support the importance of perceived benefits in the decision to get genetic testing. Efforts to promote cancer genetic testing should focus on clearly communicating the benefits of early detection, such as the ability to develop personalized cancer treatment plans using information from genetic testing. Early diagnosis significantly improves cancer outcomes, particularly when care is provided at the earliest possible stage [92]. Especially with cancer genetic tests, there is immense potential to facilitate early detection and personalized treatment strategies [93]. Our results also support the importance of cues to action in the decision to get genetic testing. Timely and effective communication can motivate individuals to take proactive steps in their health care journey. However, the success of these interventions depends on individuals' willingness to engage in preventive health behaviors. Public health officials can pursue changes to health care policy that will incentivize individuals to be proactive about their health and get genetic cancer screenings. Financial incentives have proven to be effective in encouraging individuals to get screenings [94]. Employers already reduce individual monthly insurance premiums by requiring employees to get regular health screenings [95]. Insurance providers can simply add free or reduced-cost genetic cancer screening in the included health care screenings, thus implicitly encouraging and supporting individuals to get screened.

The moderating role of gender highlights the need for improved public health campaigns directed towards men. The Center for Disease Control highlights that "men have higher rates of getting and dying from cancer than women" [96]. There is a lack of online social discourse on genetic testing, which may be the reason for lower male engagement with genetic testing [97]. To address this concern, there has been a notable increase in the number of public health campaigns encouraging men to get screening tests. Recent research has examined how to leverage social media to bring public awareness to the value of genetic testing for prostate cancer [98]. Further efforts in this area could focus on developing messaging on the benefits of early detection using gender-coded language to specifically target men. To improve online social discourse on cancer genetic testing [97], public health organizations can post informative messages on X (formerly Twitter) to encourage discussion of genetic testing, create and participate in regional Facebook groups and pages to develop a community of men interested in genetic testing, and share Facebook and YouTube videos to dispel concerns and address any misconceptions regarding genetic testing. Additionally, our research found the role of caregivers is particularly noteworthy. Our results indicate that caregivers are more likely to seek genetic testing, potentially due to their heightened awareness of cancer risk factors through their caregiving experience [98]. Health care providers should recognize caregivers as a key demographic for targeted interventions. By educating caregivers on the benefits of genetic testing, both for themselves and their families, health care professionals can increase the uptake of this preventive measure. Caregivers, often deeply involved in health care decisions, could also serve as advocates for genetic testing within their broader social networks, further amplifying the reach of these interventions.

In addition, the positive association between online social health group participation and genetic testing uptake suggests that digital platforms can be effective tools for health promotion. These platforms, where individuals can share experiences and seek advice, provide a valuable avenue for disseminating information about the benefits of genetic testing. Public health campaigns that leverage social media and online communities could encourage greater awareness and engagement with preventive health behaviors [99]. Engaging individuals in these groups may also help to reduce the stigma or fear surrounding genetic testing, ultimately facilitating behavior change.

Limitations and Future Research

Despite its contributions, this study is not without limitations. First, the research relied on secondary data, which constrained the analysis to available variables. The use of secondary data limits the flexibility to explore unmeasured constructs that may further elucidate the decision-making process surrounding genetic testing. Furthermore, we used the HINTS data that were collected in 2020, and hence, it may not fully capture the most recent trends and developments. Future research could consider incorporating primary data collection methods to include more contemporary variables and insights reflective of the current landscape.

Though our study examines the role of caregiving and participation in online support groups in influencing the genetic testing decision, it is important to acknowledge certain limitations that may reduce the potential positive impact of these factors. For instance, barriers such as limited digital literacy, unequal access to the Internet, and socioeconomic disparities can hinder individuals from fully benefiting from online health resources and support networks. These barriers may be particularly pronounced in underserved or marginalized populations, where individuals may lack the necessary tools or knowledge to engage in digital health activities effectively. Future research could address these limitations by exploring how cultural contexts, including beliefs, norms, and values, shape the genetic testing decision. Examining how different communities perceive genetic testing and their access to digital resources can provide more nuanced insights into reducing disparities and improving health outcomes across diverse populations.

Conclusions

This study explores the factors influencing the decisions to undergo cancer genetic testing in the US population. Our findings emphasize the significant roles of perceived benefits, cues to action, caregiving for patients with cancer, and participation in social health groups in motivating genetic testing. Additionally, gender moderates the relationship between genetic testing and both perceived susceptibility and severity of cancer risk. Given the hereditary nature of cancer, increasing

awareness of genetic testing benefits is essential for promoting preventive health behaviors.

The study contributes to both theory and practice. Theoretically, it extends the HBM by incorporating cancer-specific constructs and highlighting the role of information systems in health decision-making. Practically, it offers actionable insights on how tailored education and social support can foster proactive health behaviors, particularly among caregivers and social health communities. Targeted campaigns, especially within online support groups or aimed at men, can further promote early detection. Future research can explore these strategies to increase the adoption of genetic testing for cancer.

Abstract

Background: Skin cancers, including melanoma and keratinocyte cancers, are among the most common cancers worldwide, and their incidence is rising in most populations. Earlier detection of skin cancer leads to better outcomes for patients. Artificial intelligence (AI) technologies have been applied to skin cancer diagnosis, but many technologies lack clinical evidence and/or the appropriate regulatory approvals. There are few qualitative studies examining the views of relevant stakeholders or evidence about the implementation and positioning of AI technologies in the skin cancer diagnostic pathway.

Objective: This study aimed to understand the views of several stakeholder groups on the use of AI technologies to facilitate the early diagnosis of skin cancer, including patients, members of the public, general practitioners, primary care nurse practitioners, dermatologists, and AI researchers.

Methods: This was a qualitative, semistructured interview study with 29 stakeholders. Participants were purposively sampled based on age, sex, and geographical location. We conducted the interviews via Zoom between September 2022 and May 2023. Transcribed recordings were analyzed using thematic framework analysis. The framework for the Nonadoption, Abandonment, and Challenges to Scale-Up, Spread, and Sustainability was used to guide the analysis to help understand the complexity of implementing diagnostic technologies in clinical settings.

Results: Major themes were “the position of AI in the skin cancer diagnostic pathway” and “the aim of the AI technology”; cross-cutting themes included trust, usability and acceptability, generalizability, evaluation and regulation, implementation, and long-term use. There was no clear consensus on where AI should be placed along the skin cancer diagnostic pathway, but most participants saw the technology in the hands of either patients or primary care practitioners. Participants were concerned about the quality of the data used to develop and test AI technologies and the impact this could have on their accuracy in clinical use with patients from a range of demographics and the risk of missing skin cancers. Ease of use and not increasing the workload of already strained health care services were important considerations for participants. Health care professionals and AI researchers reported a lack of established methods of evaluating and regulating AI technologies.

Conclusions: This study is one of the first to examine the views of a wide range of stakeholders on the use of AI technologies to facilitate early diagnosis of skin cancer. The optimal approach and position in the diagnostic pathway for these technologies

have not yet been determined. AI technologies need to be developed and implemented carefully and thoughtfully, with attention paid to the quality and representativeness of the data used for development, to achieve their potential.

Introduction

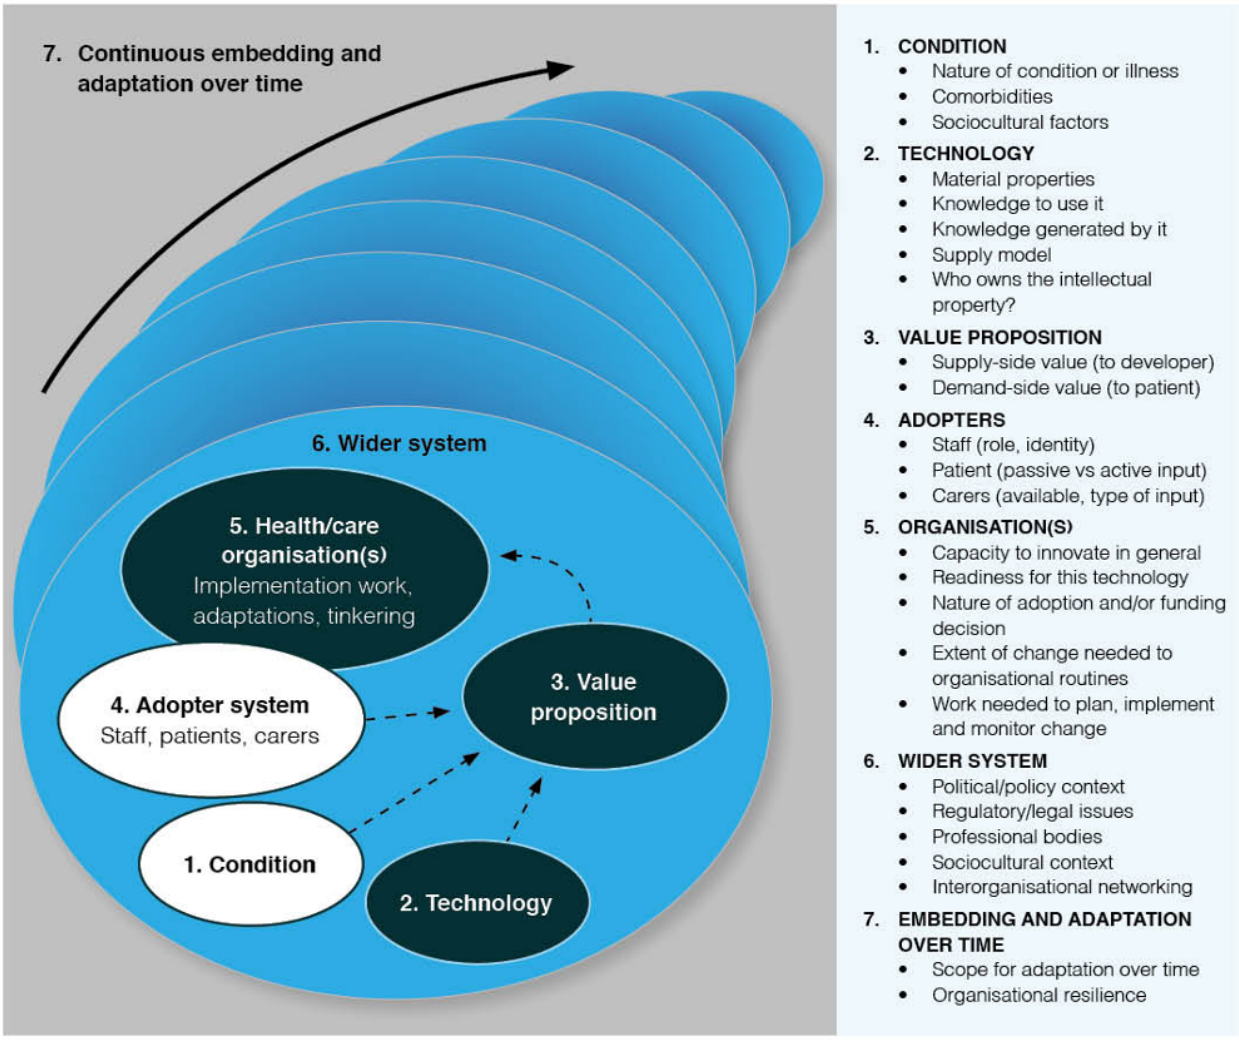
Background

Skin cancers are among the most common cancers worldwide, with increasing incidence in most populations [1,2]. Melanoma is the most lethal skin cancer, but keratinocyte cancers (KCs), which include squamous cell carcinomas and basal cell carcinomas, comprise most skin cancers [1-3]. There were >200,000 skin cancer diagnoses in England in 2021, comprising 193,000 nonmelanoma skin cancers (which include KCs) and nearly 16,000 melanomas [4]. The World Health Organization estimates that 2 to 3 million nonmelanoma skin cancers and 132,000 melanomas occur globally each year [5]. Earlier diagnosis of skin cancers is associated with statistically significantly better outcomes [3]. In the United States, early detection of melanoma is associated with >99% five-year survival but falls to 74% when it has spread to lymph nodes and 35% when spread to distant organs [6].

There has been a substantial interest in applying artificial intelligence (AI) to the diagnosis of skin cancer through visual analysis of skin lesions, either through a smartphone app or uploading images of skin lesions. Many AI technologies have been designed for use by patients and a handful for use by clinicians as clinical decision aids [7,8]. Most of these technologies do not have the appropriate regulatory approvals in place to support their safety and efficacy when used in these settings [9], with limited evidence on their efficacy and accuracy from clinical trials or real-life clinical settings [7,8], although some evidence is emerging [10,11]. There is limited evidence on how users in clinical settings interact with AI technologies and how this might affect patient safety [12], and a lack of qualitative studies reporting public perspectives [13].

Implementation of a diagnostic technology in clinical settings is a complex process and prone to failure—a technology must pass through several stages of development before implementation is likely to be successful [14]. Several frameworks analyze factors around the implementation of new technologies. In this study we chose to use the Nonadoption, Abandonment, and Challenges to Scale-Up, Spread, and Sustainability (NASSS) framework [15] to help understand and interpret the data. This framework incorporates complexity principles and allows researchers to identify and explain the manifestations of complexity in technology-supported change projects (Figure 1) [15]. We believe that these attributes made it best suited to this study compared with other conceptual frameworks for implementation research.

Figure 1. The Nonadoption, Abandonment, and Challenges to Scale-Up, Spread, and Sustainability (NASSS) framework [15].



Objectives

The aim of this study was to consult several stakeholder groups (ie, groups that may have views or concerns about the use of AI to help diagnose skin cancer in primary care) to provide in-depth understanding of barriers and facilitators to the implementation of AI technologies for the early diagnosis of skin cancers in primary care settings. Depending on how AI is implemented in the skin cancer diagnostic pathway, users of the technology could include members of the public, patients, general practitioners (GPs), primary care nurse practitioners (NPs), and dermatologists. Dermatologists also receive most referrals from primary care for suspected skin cancers. AI researchers working in both academic and commercial settings are the primary developers of AI technologies. The views of all these groups were important to understand.

Methods

Design

This was a qualitative study that was performed using semistructured interviews of stakeholders.

Recruitment and Sampling

Four groups were selected for the study: (1) members of the public, (2) patients previously diagnosed with skin cancer, (3) health care professionals (HCPs; including GPs, primary care NPs, and dermatologists), and (4) AI researchers from academic and commercial settings. Members of the public were approached via the Cambridge Biomedical Research Centre Patient and Public Involvement (PPI) group and “snowballing” invitations to their colleagues. Members of the public with a history of skin cancer were included in the patient group, with additional patients approached via Melanoma Focus (a UK melanoma charity that provides information, guidance, and support for patients, carers, and HCPs) [16]. GPs and primary care NPs were identified through the Primary Care Dermatology Society [17], with additional GPs approached via Sermo (medical market-research organization) [18]. Dermatologists were identified from the British Association of Dermatologists (BAD) [19] and through snowballing. AI researchers from academic settings were identified through contacts within academic institutions, and AI researchers from commercial settings were recruited via email from companies identified in 2 reviews [7,8]. In this paper, we use primary care practitioner (PCP) to denote any medical practitioner that works in a primary

care setting and might consult with a patient about a suspicious skin lesion, including GPs, family doctors, NPs, physician assistants, and paramedic practitioners. HCP is used when we refer to the views of wider HCPs, including secondary care HCPs. Staff who work in primary and community care and do not have clinical training and experience in the diagnosis of skin cancer but could potentially use an AI technology with patients with suspicious skin lesions are referred to as allied HCPs; a wide variety of professions could be included in this group, but it certainly includes practice nurses, health care assistants, clinical navigators, pharmacists, and podiatrists.

Participants were sampled to achieve a spread of age, sex, and geographical location within each participant group. Patients and the public were recruited to achieve a spread of ages >60 years and <60 years, reflecting the average age of skin cancer diagnosis. HCPs and AI researchers were recruited to achieve a spread of ages >45 years and <45 years, reflecting the midcareer point of these professions. Patients were sampled to include a range of prior history of skin cancer types. GPs were sampled to include a spread of roles (GP partner, salaried GP, locum GP, GP with extended role in dermatology). Participants were asked how supportive they were of using AI technologies to help diagnose skin cancer in primary care (using a Likert scale of strongly disapprove, disapprove, neutral, approve, and strongly approve). We aimed to recruit at least 1 participant in each group who disapproved and at least 1 who approved of the use of AI in this setting to obtain a range of perspectives.

Ethical Considerations

Ethics approval for this study was granted by the Cambridge Psychology Research Ethics Committee (PRE.2021.098). Participants gave informed written and verbal consent to take part in the interviews. Patient and public participants were invited to bring a friend or family member with them to take part in the study if they wished. All interviews were digitally recorded and transcribed verbatim by a professional transcription company. Transcripts were checked and anonymized before analysis. To facilitate recruitment, a £20 (US $25.24) Apple iTunes or Google Play voucher was offered to all participants.

Data Collection

An interview topic guide was developed with input from our PPI group to explore views on facilitators and barriers to the use of AI technologies to help diagnose skin cancer in primary care. All interviews were conducted by OTJ, who has a clinical background, with guidance from NC, a health services researcher with expertise in qualitative research. Interviews took place on the web using Zoom (Zoom Video Communications) at a time of the participants choosing between September 9, 2022, and May 25, 2023. Interview schedules for patients and members of the public and HCPs and AI researchers are available in Multimedia Appendix 2. Details on the interviews are reported in the COREQ (Consolidated Criteria for Reporting Qualitative Research; Multimedia Appendix 3) checklist. Interviews continued until we had a rich, multifaceted dataset. A reflexivity journal with field notes was kept and was discussed at regular meetings during the study.

Analysis

Interviews were analyzed inductively and deductively using thematic framework analysis [20]. Two researchers (OTJ and NC) repeatedly read the first 5 transcripts to become familiar with the data and generate initial codes. These initial codes were compared with the NASSS framework (Figure 1) [15] to generate a comprehensive list of codes. The remaining transcripts were then read and indexed using NVivo (version 14; Lumivero) [21], with codes modified or created as required where the data did not fit comfortably into the NASSS framework. Coding was completed by OTJ with a sample of transcripts (7/29, 24%) checked by NC. Codes were defined and discussed regularly in team meetings (OTJ, NC, and FMW), and coding files were saved throughout the process to maintain an audit trail of changes to the code tree. Data were charted into Microsoft Excel [22], and the characteristics, similarities, and differences between data were identified. Relationships and connections between categories were then mapped to generate the themes presented in the results. Themes were further refined with guidance from senior team members (FMW and SS [health psychologist]). Together this broad authorship group of clinical academics and behavioral scientists added rigor to data analysis and interpretation.

Results

Participants

A total of 29 interviews were conducted with members of the public (n=6, 21%), patients (n=5, 17%), HCPs (n=13, 45%), and AI researchers (n=5, 17%; Table 1). Participants were recruited via mailing lists and social media; therefore, the denominator is unknown.

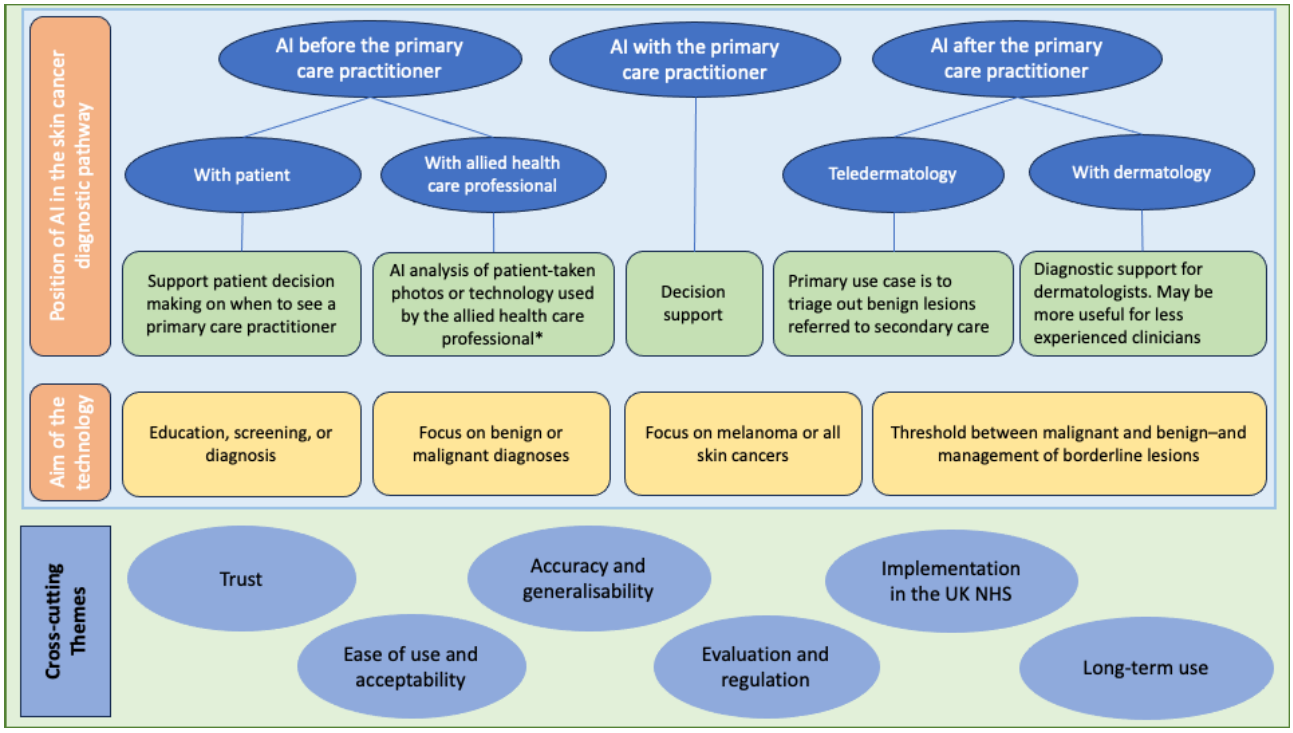
[g]Including the Netherlands and North America.

[h]Educational qualification categories were taken from the UK National Census 2021. Definitions are available on the internet [23].

[i]Basal cell carcinoma (n=3), melanoma (n=1), and Merkel cell carcinoma (n=1).

The *Results* section is structured around the major themes and subthemes generated from the data. Major themes included the "position of AI in the skin cancer diagnostic pathway" and the "aim of the AI technology." There were several cross-cutting themes, including trust, acceptability, generalizability, evaluation, regulation, implementation, and long-term use (Figure 2). Participant quotations are identified by participant group, sex, and age.

Figure 2. Issues around the design and intended positioning of artificial intelligence (AI) technologies for the diagnosis of skin cancer that were identified from the data, and further cross-cutting themes identified. *Allied health care professionals that could use the technology include pharmacists, health care assistants, practice nurses, podiatrists, hairdressers, and potentially many more. UK NHS: UK National Health Service.



Position of AI in the Skin Cancer Diagnostic Pathway

AI Before the PCP

Patients and members of the public felt that giving patients access to AI technology would be more accurate than "random googling" and could help them to decide when to see a physician. However, they expressed concerns about using the AI technology without clinical input. The loss of the human touch in consultations worried them, including how the diagnosis would be communicated and whether patients would be able to get a PCP follow-up appointment to discuss the diagnosis and ask questions. Another concern was whether all patients would be able to effectively use the technology and the potential for it to exclude some groups of patients, including older people. Patients and the public discussed the risk of overuse of the technology by patients; they felt that implementing it in a practice nurse and allied HCP-led clinic would reduce the risk of overuse while also making it easier for patients to access skin lesion assessments.

All HCPs could envision AI technology being used by patients and thought there would be a high demand for this service. Some dermatologists felt this could be a useful approach, particularly for patients at high risk of skin cancer between dermatology clinic appointments; however, they were concerned about the potential for overuse and subsequent workload due to false positives that would inevitably occur. They thought patients might struggle to understand the risks, benefits, and the output of the AI technology and would find it difficult to take high-quality images needed for the AI to analyze. Some HCPs commented on the potential psychological benefits of AI technology, in particular reducing patient anxiety if the technology reduced the number of urgent suspected cancer referrals, although some HCPs felt that it could increase patient anxiety through increasing access to skin lesion checks. Dermatologists and NPs commented on how accurate AI technology could enable a wide variety of allied HCPs to use the technology to triage patients presenting with suspicious skin lesions, which may improve access and enable earlier detection of skin cancer. GPs reported both positive and negative views on the potential of positioning AI technologies in the role of triaging patient-submitted photographs before an appointment with a PCP.

AI researchers from academic backgrounds were broadly skeptical of patients having access to AI technology themselves, highlighting concerns about the diagnostic accuracy of the technology, the risk of false reassurance, and that patients would not necessarily understand the context of when it was safe to use. However, AI researchers from commercial backgrounds felt that, if the AI technology was accurate enough, positioning AI technologies with patients had the greatest potential for

impact. They highlighted various potential positive effects, including reducing the barriers to getting a skin lesion assessed, helping patients make better decisions about when they needed to see an HCP, and educating patients about skin cancer.

AI With the PCP

Patients commented that GP surgeries are accessible for most patients and so are an ideal place to locate the technology. They felt that if they were consulting about a potentially serious skin cancer (ie, melanoma), they would like to be able to speak to a PCP. Combining the clinical judgment of the PCP with the AI technology was generally viewed as being more powerful than the PCP alone and could be more beneficial for PCPs with less experience in skin cancer and reduce the variability in skin cancer triage in primary care. The public discussed whether PCPs would become reliant on the AI technology and lose their clinical judgment and even whether this was an issue if the AI diagnostic accuracy were better than the PCP's.

GPs largely wanted PCPs to have access to the AI technology and were concerned that the implementation of AI technology at other points in the diagnostic pathway could undermine their gatekeeping role. They believed that PCPs are well positioned to triage and monitor skin lesions over time and provide continuity of care and that it would be more efficient for the technology to be used to triage a lesion in a single consultation instead of needing a separate appointment to capture the image. NPs agreed that AI technology would be best placed with a PCP. One GP emphasized that the positioning of the technology in the diagnostic pathway is probably the most important factor in how impactful it will be.

Dermatologists expressed the opinion that something was needed to improve the accuracy of referrals to secondary care but were not sure implementing AI technology in primary care was the best approach. A broad educational program for PCPs was suggested as a better alternative. Whether AI technology is currently accurate enough to be used by PCPs was a concern, as well as the risk of deskilling PCPs in skin lesion recognition. Dermatologists did see benefits in situating AI technology with PCPs to help with rarer skin cancer recognition, to break bad news, and answer patient questions, and to give PCPs more confidence in diagnosing a lesion as benign and not referring on to secondary care.

Most AI researchers expressed strongly that a "human-in-the-loop" approach (ie, where a human clinician is always involved in decision-making alongside the AI) is needed. Potential benefits of this approach included increased safety, allowing for patient interactions, allowing the PCP to focus more on the patient, and increasing knowledge of PCPs. AI researchers also discussed that the decision to biopsy or refer a skin lesion involves many biopsychosocial and clinical factors outside of the appearance of the lesion, which cannot be measured or considered by the AI and thus needs input from a PCP.

AI After the PCP

Use of AI technology to triage referrals from primary care to secondary care in a teledermatology setting was only mentioned by 1 GP and 2 dermatologists. The dermatologists suggested AI technology could help triage obviously benign skin lesions, preventing them from being referred to a dermatology clinic.

Few participants commented on positioning an AI technology with dermatologists. Dermatologists believed that it could be a useful training tool, and in the future, if it were proven to be more accurate than dermatologists, then it could be implemented in dermatology clinics. One AI researcher agreed and discussed how AI technology could help improve dermatologists' consistency in diagnosis (Textbox 1).

Textbox 1. Positioning of artificial intelligence (AI) in the skin cancer diagnostic pathway.

AI before the primary care clinician

- So I think people first self-diagnose via Google a lot anyway so having something that's a little bit more accurate than self-diagnosis is probably helpful. [Patient 4; female, aged <60 years]
- I don't think it would be effective giving it directly to patients, least of all because they won't have the training and the right level of professional knowledge in being able to interact with digital innovations effectively. [Patient 1; male, aged <60 years]
- I would be a little bit concerned about it just being open-ended, because...the potential for over-use by some people and under-use by others would be quite large, I think. So, I think...a nurse-led clinic or something like that might be better. Or give people the option. [Member of the public 3; female, aged >60 years]
- I know from doing online and video consultations during COVID, what was quite evident is that patients have got varying skills in terms of how they use their mobile devices to show you their skin remotely and taking images, and the quality of those images. So I think you'd have to think very carefully about who is taking the image, what they understand about what the clarity of that image needs to be, and what devices they're being used on. Because that's going to affect your interpretation. So I would be hesitant to say as a matter of routine for it to be patient led. [NP1 (nurse practitioner 1); female, aged >45 years]
- And seeing this opportunity, for example, hairdressers, podiatrist, pharmacist, they get asked a lot about these things, about lesions. And from time to time you get referrals because they went to the hairdresser and they spotted a mole... it would be a good thing to implement in these areas, expand beyond the GPs. [Dermatologist 3; female, aged <45 years]
- I would really like to then streamline the process. So we have an ability within our practice that the patient doesn't need an appointment for asking about a mole of concern and they can send a photo. That photo would be reviewed by a clinician. It would be absolutely fantastic if that photo was also able to be reviewed by an AI process and advise whether there were concerning features on it or not. It would be useful if that photo could then be reviewed again six weeks later against a new photo to assess for changes. [GP5 (general practitioner 5); male, aged <45 years]
- Yeah, it (using the app) has especially low barrier to use it so it's way lower than going to a doctor or going to a dermatologist. It is really a first step into being more interested or more concerned about skin cancer. And I think it can help to raise awareness (of skin cancer) and inform people better. [AIR4 (AI researcher 4); male, aged >45 years]

AI with the primary care clinician

- I don't want to think that a doctor would see results on an app and still not think about it at all...But I think with time they might lose their skills. [Member of the public 6; female, aged <60 years]
- I'd love it in my hands. Anything that saves primary care queuing people up in dermatology...I think skin is difficult. And so my feeling is that human error will always exist and I guess if you've got something to support you in making the correct diagnosis in serious skin lesions, then it seems to me like a win-win and a sensible option. [GP2; male, aged >45 years]
- Most patients with a lesion will go straight to their GP. So I think definitely that's where it's going to be best placed and whether that's a specialist nurse within a GP setting or a GP, certainly within that primary care set up I think is most relevant. [NP1 (nurse practitioner 1); female, aged >45 years]
- I think selfishly, I'd be disappointed if I was told you don't need your dermatoscope anymore, because it's an area I'm really interested in and I'm really enjoying...because if it's automated and, therefore, you lose the skill set and you lose motivation around the topic. [NP3; male, aged <45 years]
- I would be worried about de-skilling our GPs by giving them a tool that tells them what to do. [Dermatologist 3; female, aged <45 years]
- The great thing would be if they were able to pick up those skin cancers that they haven't thought about, for example, amelanotic melanomas, or nodular melanomas, that they don't follow the typical a, b, c, d criteria. [Dermatologist 3; female, aged <45 years]
- If AI had a really, really good dataset of benign lesions, that would give a GP confidence to say 'no, that's benign, that doesn't need to be referred in' [Dermatologist 4; female, aged >45 years]
- They (dermatologists) are very experienced and they don't need a tool. But some of those tools might be needed for the people who refer patients, not to make any mistake at that stage for the early detection...So I can think of those two aspects, like speed and a better decision for the practitioner. I see really big opportunities in those kinds of things. [AIR2; male, aged <45 years]

AI after the primary care clinician

- So,...either a patient-generated image, but preferably taken in primary care on a high-quality camera and sent securely to dermatology for triage, then the AI helping with that triage process. [GP3; male, aged <45 years]
- In secondary care it would be really helpful, I think particularly for juniors starting out, to have a list of the differential, including the rarer things that could possibly be consistent with the appearances that the algorithm has identified. But giving you ranking of likelihood. [Dermatologist 2; female, aged >45 years]

Aim of the Technology

Education, Screening, or Diagnosis

Participants mainly discussed AI technology as a diagnostic tool; however, participants from all groups raised alternative uses. Patients discussed skin self-monitoring, including sequential monitoring of skin lesions over time, and patient education about the "red flags" of skin cancer. All groups discussed the potential to raise awareness and educate patients about skin cancer, including skin cancer prevention and how to perform skin self-monitoring.

GPs and NPs discussed the potential for AI technologies to educate PCPs and improve diagnostic skills. They suggested that a potent educational attribute would be if the AI technology could highlight visual features of skin cancer in images of skin lesions; AI researchers commented that these types of features have been developed. Dermatologists discussed the potential use of a patient-facing AI technology as a screening tool for high-risk populations.

Focus on Benign or Malignant Diagnoses

Patients and members of the public stated that the primary aim of the AI technology should be a very high accuracy to avoid missing skin cancers and giving false reassurance; to achieve this, the technology would need to have a high sensitivity. All HCP groups commented that aiming to diagnose benign skin lesions might be a safer approach with less risk of missing skin cancers. They proposed that focusing on diagnosing specific common benign skin lesions, such as seborrheic keratoses and dermatofibromas might reduce unnecessary referrals to secondary care.

Focus on Melanoma or All Skin Cancers

Patients were primarily concerned that any AI technology was accurate for melanoma. Some members of the public had experience of KCs in family or friends and felt AI technologies should also address KCs. GPs were primarily concerned about melanoma because it often affects younger patients and has higher mortality—they felt that AI technologies could be applied to other skin cancers in the longer term. Dermatologists and a NP commented that diagnosing all types of skin lesions, including all skin cancers, was important, especially for technologies that are designed to be used by patients or HCPs with less experience in diagnosing skin cancer. However, some dermatologists thought it could be difficult to train AI to diagnose KCs accurately, because patient history often has greater importance than for melanoma, and AI currently does not always incorporate this.

Threshold Between Malignant and Benign and Management of Borderline Lesions

All groups discussed the difficulty in setting a threshold between benign and malignant lesions for the AI technology, in essence how to translate the continuous risk score generated by the AI into a binary clinical decision of whether to refer a patient or biopsy a skin lesion. A 3-layer management strategy was suggested by several participants with further assessment of lesions that are close to the threshold, either through follow-up assessment in primary or secondary care or through sequential monitoring over time (similar to short-term sequential digital dermoscopy imaging models that already exist [24]). NPs and dermatologists reflected on how this issue demonstrates the complexity of clinical practice and that clear guidelines will be needed about what to do at each risk level (Textbox 2).

Textbox 2. Aim of the artificial intelligence (AI) technology.

Education, screening, or diagnosis

- I guess you always take a picture at a point in time and...say you noticed it change in a couple of months could you go back and say, it's changed from this to this, and almost keeping a progression record...I think that would be a really helpful feature. [Patient 4; female, aged <60 years]
- Give people recommendations of you should not go out unless you're wearing 50 SPF, we think you should not sunbathe between 12 and four, just because it's cloudy does not mean you're not going to burn...put a kid in a sun hat so they don't have sunstroke. [Member of the public 3; female, aged >60 years]
- I say to them (patients) there are mole apps that you can monitor, and that maybe it's not great in terms of getting a diagnosis, but they're more aware and they're keeping attention more to a particular lesion. And definitely it helps to diagnose cancer in the early state than what we saw years ago. [GP1 (general practitioner 1); female, aged <45 years]
- But the way I used AI was to try to train on some features in the image rather than giving me a diagnosis. For instance, to teach a deep learning algorithm to tell me whether that the borders are regular or irregular, 'cause that's something subjective sometimes between readers...So I used AI to reveal the features rather than giving the full diagnosis. [AIR2 (AI researcher 2); male, aged <45 years]
- So if you could develop one that was validated it might be useful for selected patients, maybe not the entire population but particularly high risk patients, maybe patients with lots of moles. [Dermatologist 2; female, aged >45 years]

Focus on benign or malignant diagnoses

- The first aim of the app needs to be to go and get it checked or not, or to go and get it biopsied or not. [Patient 4; female, aged <60 years]
- Just screening out the seborrheic keratosis, the pigmented dermatofibromas, the benign...if it could screen all of those out, which are the vast majority of the two-week-wait referrals that we see, that would be incredibly important for providing a better, more targeted service...plus potentially triaging things that are so unlikely to be a cancer that they don't need to be referred. So it kind of works both ways, early detection and reducing the massive numbers of 2-week-wait referrals that we get. [Dermatologist 2; female, aged >45 years]

Focus on melanoma or all skin cancers

- I think melanoma is the most important because I'd like to think that because your differential features for a squamous cell are quite obvious, that would be referred on anyway. I think it's melanoma and other pigmented lesion differentiation that's really tricky. So my thought would be more melanoma, and certainly that's what I've used it for. [NP1 (nurse practitioner 1); female, aged >45 years]
- People just think it's about diagnosing melanoma, where actually it's not. It's about recognising all skin lesions. You've got to diagnose benign lesions, and you've to diagnose malignant lesions, and it's not just melanomas, you've got BCCs, you've got SCCs, you've got AKs, and then you've got all the benign lesions. [Dermatologist 1; female, aged >45 years]

Threshold between malignant and benign—and management of borderline lesions

- I guess one approach you could take with marginal cases, you could say that we suggest you get re-tested in six months' time or something like that. So, you have a three-layer band. One you definitely need action, one you definitely don't, and then a middle level where you come back for a test after a bit. [Member of the public 3; female, aged >60 years]
- What I suggest would be good...if you're less than 70 per cent sure, it's an arbitrary...whatever number sure, then there is clinician involvement. So take a deeper dive into the history and that person then comes in and is looked at. [NP3; male, aged <45 years]
- So I think it would be really interesting, if when I looked at a lesion I gave the patient a percentage of how right I thought I was or even any diagnosis. I mean, I'd love that, that would be really cool to have that honesty. 'I think you've got a viral chest infection, I'm about 50-50, I'm going to hold off on the antibiotics, but here's some strict safety netting.' Yeah, I don't know whether I'd want to give the patient that information. [NP3 male, aged <45 years]
- So it would come back with a comment like 'this is 80% likely to be a melanoma, this is 20% likely to be a melanoma' and there would have to be some sort of understanding, some sort of cut off, what is the point at which a referral is merited...And I suppose that one of the dangers...where do you cast the net in terms of risk? [Dermatologist 4; female, aged >45 years]

Cross-Cutting Themes

Trust

Patients and members of the public often raised the issue of trust. The newness of the technology, the involvement of private companies and concerns about data privacy, and the diagnostic accuracy being <100% were all felt to be reasons for a lack of trust. However, there were also participants who thought patients would trust a consultation with a PCP more if it involved AI technology, even if it had made no difference to the assessment. GPs worried that patients could demand the AI technology be used in consultations and were concerned about the risk of false reassurance. NPs felt that patients fundamentally trust people more than machines. Dermatologists stated that there is not enough evidence that existing AI technologies are safe and accurate enough to be used in clinical practice and that it is difficult for patients to determine which patient-facing AI technologies they can trust.

AI researchers discussed that the "black box" nature of AI technologies should not be a barrier to trust, as we similarly do not understand the mechanism of action of many medications.

They felt that if clinicians recommended or adopted an AI technology, then patients would be more likely to trust it.

Ease of Use and Acceptability

Ease of use was a major concern for patients and members of the public; participants discussed that a technology that is easy to use enables patients to take high-quality images that are better suited for AI analysis and reduces the risk that patients will be unable to use the technology or use it incorrectly. Several members of the public raised the importance of enabling patients to choose how to consult, rather than mandating a consultation type that is inappropriate for them. GPs and NPs' primary concern was that it should be easy to integrate the AI technology with their current computer and Wi-Fi systems. Dermatologists and patients were concerned about whether the technology would facilitate taking high-quality images for the AI to analyze. AI researchers commented on how practical limitations of a technology can prevent it being used, even if it is potentially very beneficial; therefore, "real-world factors," such as cost, ease of use, and how well it fits into clinical workflows, need to be considered.

Accuracy and Generalizability

Accuracy was raised frequently by all groups and is linked to many of the subthemes. The primary concerns were the false negative rate and the risk of false reassurance and whether the diagnostic accuracy is generalizable to other clinical settings, using different camera technologies, and with other populations and demographics. AI researchers commented that currently AI technologies are often developed on small datasets, which are not representative of the general population and may contain errors and biases and hence, do not generalize well to be accurate in all sections of the population. Members of the public and HCPs were concerned this might mean AI technologies would be less accurate in melanin-rich skin or for rarer skin cancers.

AI researchers discussed how this situation might be improved with close collaboration between clinical and AI researchers and a focus on data quality in a "data-centric" approach. An AI researcher from a commercial background commented on the challenges in collecting a representative dataset for AI development and testing. There are fewer publicly available images of skin lesions in melanin-rich skin, and their app had significantly lower uptake among patients with melanin-rich skin.

Evaluation and Regulation

Patients felt that AI technologies should be evaluated by a mix of professionals before they can be adopted, including independent confirmation of diagnostic accuracy. Patients were concerned that AI technology would be adopted based on novelty and hype or because it is cheaper than clinicians' time when it may not be in the best interests of patients and their clinical care. HCPs felt that significant data from clinical trials would be needed to evaluate AI technologies but recognized that this might take time. AI researchers were concerned that we currently lack good measures to evaluate AI algorithms for use in clinical settings. They stated that the current practice of using simple diagnostic accuracy measures (eg, sensitivity and specificity) is not comprehensive enough to demonstrate the accuracy, benefits, and risks of AI technologies. AI researchers added that, while clinical studies, due diligence, and understanding biases and flaws in an AI system are all important aspects of evaluation, there are other factors, including business sustainability, that need to be considered before a decision on adoption can be made. Many groups commented on the need for health-economic evaluation as part of any evaluation program.

Patients and members of the public often disclosed that they did not understand regulatory processes. Some felt it was important that AI technologies had a Conformité Européene marking and were evaluated by a national body. HCPs were concerned about regulatory processes for AI technologies not being as robust as for medicines and treatments. GPs raised concerns about where the medicolegal responsibility for errors related to the use of AI technologies would lie. Dermatologists wanted the use case for AI technologies to be made clear and for the regulator to assess the technology based on this but acknowledged that regulating AI technologies is challenging. An AI researcher commented that regulatory processes for AI technologies are becoming more complex.

Implementation in the UK National Health Service

Members of the public and GPs discussed variation in National Health Service infrastructure in different regions of the United Kingdom, including wireless connectivity, and how this could make implementation difficult.

Most participant groups commented on the capacity of the health care system to implement a new technology where resources are strained. Current pressures may mean that PCPs have insufficient time to understand and implement a new technology. Some HCP participants highlighted that an AI technology with a low specificity might lead to a significant increase in referrals and worsen workload pressures. Conversely, some NPs and dermatologists commented that use of AI technology could help to reduce the number of referrals to secondary care. AI researchers hoped AI technologies could be used alongside PCPs and dermatologists to ease workload pressures.

All groups commented on the importance of professional bodies in the implementation of new technologies. Patients and HCPs felt that implementation would be greatly helped if professional bodies, such as the National Institute for Health and Care Excellence, National Health Service England, Integrated Care Boards, the BAD, or the Medicines and Health products Regulatory Agency, had recommended or evaluated it. GPs and NPs believed any decision to adopt and fund AI technology would need to come from a higher body rather than individual GP practices. AI researchers commented on the importance of the views of professional bodies for the adoption of AI technologies but also on the associated commercial challenges as these bodies vary internationally.

NPs and dermatologists highlighted the need for adequate training in how to use an AI technology as part of the implementation process and clear guidelines on how the AI technology should be used and interpreted.

Long-Term Use

The unique potential for AI technologies to continue learning after implementation and for diagnostic performance to improve over time was raised by different participant groups. GPs and patients assumed that this feature would be standard practice and that regular updates would sequentially improve the AI technologies performance as it learned from new data. Few participants commented on how this process could be regulated in practice.

A major concern of all groups was how to check that the AI technology was performing accurately. AI researchers were particularly worried about the potential for the performance of the AI technology to deteriorate over time, referred to as "drift in performance." They commented that this could occur because of a change in the way the AI technology is used, a change in the population (for example, using the technology in a population with lower skin cancer prevalence or different demographics compared to the development and testing datasets), a change in the hardware, or a change in the accuracy of the technology over time. All groups suggested "sanity checks" that could be used regularly to detect if an AI technology was not performing accurately. These "sanity checks" included expert systems monitoring image metrics over time, comparing the prediction of the new AI technology to the previous AI gold standard; a clinician reviewing all cases that the AI diagnoses as "likely skin cancer" or where AI has low confidence in the diagnosis; or limiting the use of AI technologies with a "human-in-the-loop" approach. AI researchers added that there needs to be an incentive for the makers of the AI technology to maintain and provide ongoing support long-term (Textbox 3).

Textbox 3. Cross-cutting themes.

Trust

- The fact that it hasn't been the norm within the health care setting, I think will make quite a lot of people feel uncomfortable. So the fact that it's just so up and coming and new will naturally spark a bit of anxiety in terms of people and they think about if it's safe, if it's got the same principles and standards in place in terms of care, safety, confidentiality et cetera. [Patient 1; male, aged <60 years]
- I think there is also a section of the population who are very suspicious of data not being used correctly. So, you would need to have some sort of reassurance about correct data use as well. [Member of the public 4; female, aged >60 years]
- I think people fundamentally put trust in people and we're still wary about putting trust in machines, or computers, because we've been fed sci fi for years that makes us worry, and also I do think that we still think we know best, even though the algorithms that will be in the computer will be absolute gold standard, and they won't be tired, hung over, jaded, they'll be right every time. [NP3 (nurse practitioner 3); male, aged <45 years]
- I think the concern at the moment is that there isn't enough evidence that any of these machines, or machine learning is up to speed to be able to make diagnoses without missing any skin cancer, and that includes rare skin cancers, skin cancers with rare presentations, or in different ethnicities. [Dermatologist 3; female, aged <45 years]
- Yeah. I'm just really unsure in how far, to be honest, machine learning can or will take over a medical setting, or should. The more I see and read, the more I'm getting also suspicious. [AIR3 (AI researcher 3); female, aged <45 years]
- I would question the premise that being a black box is actually a terrible thing or even a novel thing, because clinicians are black boxes. As far as I understand for most medicines we have no idea why they work, and we still use them because statistically it works. And as long as we regularly check that our models work statistically then who cares whether that's a chemical or a computational black box. Obviously, it's nicer if you can also present the clinician with some data that the clinician then can use to make further judgment calls. [AIR1; male, aged <45 years]
- As a field we're only beginning to scratch the surface of what that means, to trust technology. If say my physician tells me, this is a good way to understand more about your skin conditions, there's some element where I trust he or she as a professional and the information relayed is therefore accurate, and therefore that trust extends to the thing they had suggested. [AIR5; male, aged <45 years]

Ease of use and acceptability

- So, being accurate, being honest, easy to use, easy to understand. And easy for the GPs to use as well, the other health care professionals who've got to get the information through that as well, easy for them. Because they're going to have to look at whatever it's come up with and try and make some sense of that before they actually sit down in front of us. [Member of the public 1; female, aged >60 years]
- For me patient choice is so important—so both have a machine in the GP surgery for those who would prefer to do that and have an app for the people who are quite comfortable using those. [Member of the public 1; female, aged >60 years]
- I suppose if it was a lengthy process. So if there was dodgy Wi-Fi or it's hard to get your image or it's taking time to upload...I suppose it's just the practicalities and the ease of the software and hardware that you're using, those will be barriers, if it didn't work. [NP1; female, aged >45 years]
- How easy is it to take the photograph? I think that's really important. Because I get loads of referrals with photographs, but the photographs are completely useless, they're blurred and a complete waste of time. Somebody's ticked the box and said, sent a photograph, but they might as well not be there. [Dermatologist 1; female, aged >45 years]
- If you have a technology that's extremely beneficial for a certain disease but it's really expensive, it takes a really long time, and it's hard to use then no one will ever use it. So there's real world factors there. [AIR5; male, aged <45 years]

Accuracy and generalizability

- I think the key issue is generalisability, because algorithms are developed on a very small set which have very specific properties and there is biases. And then of course, they do not work on a wider range of other images from other scanners from other countries...this is a huge issue, the generalisability. You have all these algorithms that achieve higher numbers in one setting but it doesn't mean that they will work well on new data they have not seen. [AIR3; female, aged <45 years]
- They need to make sure that there is a proper diversity of people in there. Because AI is only ever going to be as good as what you use to train it. So I think they need to be particularly careful about diversity of skin color and capturing the wide variety that's needed. [Member of the public 13; female, aged >60 years]
- For us it's a kind of a chicken and egg problem. So, there's not a lot of data for darker skin available, so training on that...and especially proving the accuracy on dark skin it's almost impossible...We don't have the users, we don't get the data, we don't get the proof of how good we are on darker skin—so that definitely is a loop that we need to break at some point. [AIR4; male, aged >45 years]

Evaluation and regulation

- I have come across many issues because algorithms have been evaluated with measures that are actually not measuring what you would want or need in a clinical setting...So I actually think the most important thing right now would be to set up proper evaluation schemes and to think about how deep learning models should be or can be properly evaluated...The real question is, how do we evaluate them to make sure they will work in a medical clinical setting. [AIR3; female, aged <45 years]
-

So this is definitely a concern, not to send too many users into healthcare. The first concern's accuracy, we don't want to miss too many skin cancers, for sure, but the second concern is definitely also the health economic case. So, we can of course send a huge amount of people into healthcare. We find more skin cancer, we reach our goals of finding more skin cancer, that's fine. But we don't solve a real problem, we make it worse for the healthcare system as well. [AIR4; male, aged >45 years]

- I worry a little bit that if it's something that is a manageable cost it might be overused. It's a way to shift a number of patients who you might otherwise see...They're always on an efficiency drive, they're always under pressure to save money...I don't know whether, if the technology was affordable for GP surgeries, they would just think, oh great...we're short of doctors we can just process people through the hands-off routine...you stop thinking about it in clinical terms and you start thinking about it in financial terms. [Patient 2; female, aged <60 years]
- I think that's really important that it has CE marking; because I see a lot of apps and crap in the digital space that a lot of people are buying and spending money on and they're not evidence-based medicine. [Member of the public 2; female, aged <60 years]
- I know it (regulation) is fairly patchwork. Obviously, when it comes to medication and prescribing, there's fairly robust regulatory systems... When it comes to certain equipment, some patient devices it's a bit piecemeal. But I would be fairly reassured if the MHRA covered this equipment. [GP3; male, aged <45 years]
- I've been indoctrinated by the British Association of Dermatologists. And what they explained. They gave a position statement, I think it was a year or two ago, and we were've told these are medical devices and therefore they need to go through these medical regulatory agencies. I think before Brexit it obviously would have been Europe as well and now I think it's MHRA should be responsible for this. Which makes sense because obviously it's a very important thing for patients and for doctors, medicolegally as well. So it needs to work for its purpose, for what they say it's going to be doing. [Dermatologist 3; female, aged <45 years]
- And also where does it stand legally? If you come to me and you show me a mole and I do my AI thing and I say to you computer says no, and off you go and you keep doing the things that you do, and then two years later you come back to me with a large black blobule, sentinal lymph node biopsy positive...is that my fault? Is that the AI's fault? And if it's the AI's fault, who are you suing? [GP6; female, aged >45 years]

Implementation in the UK National Health Service (NHS)

- I think when you're an external looking in at the NHS it's just a monster beast to try and understand different parts of it...Overall I think integration of digitals is great, but it's not uniform, and also there are massive connectivity issues still in some areas...Some parts of the country are doing amazing things, and other parts are so backward. [Member of the public 2; female, aged <60 years]
- I'm just very much aware that the basics of general practice is under so much pressure that adding a new technology and complication is not everybody's first priority...I appreciate a lot of these new technologies can save time and resources in the long term, but certainly, if I'm thinking now of the start of a difficult winter, it's going to be a tough sell right now. [GP3; male, aged <45 years]
- One of the things I came across is that there was a shortage of dermatologists in general. This means that the practitioner is expected to see a lot of patients in the same day...the practitioner is a human, maybe some stress, or he had a bad day, he might not spot some feature in that image. So those (AI) tools can be something that fixes this gap if in that day he had a bad day and didn't notice some features. [AIR2; male, aged <45 years]
- So it's going to cost something to have this kind of level of equipment, but there's not an infinite amount of money in GP land, if they're spending on that then it's coming out of somewhere else, which might mean we won't have the money or equipment for something that may benefit patients. [NP2; female, aged <45 years]
- It's got to come with the support and the training along with it, it's not just about getting a new piece of kit...I think the important thing is that that cost incorporates training and a clear understanding of the device and what it's used for, and why, and how to use it. It's silly to give a piece of kit and then not have the support to know how to use it best. [NP1; female, aged >45 years]

Long-term use

- In some ways the accuracy would build as the technology was used. So the longer it's been in play the more you can depend on it probably...I assume that you don't just test the heck out of it and say it's fine now and then stop refining it. [Patient 2; female, aged <60 years]
- Let's say the model was trained in a way it works really well when you are taking dermatoscope photos, and it gives you a really good sense of the malignancy potential there and the studies support this. Then a patient sends you a photo...and this photo was taken using a smart phone with different kinds of lighting conditions, in a setting where it was actually never designed for use but that fact is not obvious to anyone who hasn't been thinking about this for a really long time. So with the best of intentions, I think you could still have a situation where the performance starts drifting away from how it was designed for use. [AIR5; male, aged <45 years]
- Maybe scanners will change...It is not clear that if an algorithm works well on the scanner of the last generation, even from the same company, (if) you get a new one that it would work on that as well...They (scanners) will not stay the same, but then we really should think about how do we integrate new modalities into the machine learning models, because it's not sustainable to develop something on a fixed dataset. [AIR3; female, aged <45 years]
- It should be tested before it gets to the GP surgery, and then it should be checked...at regular intervals, to make sure it's still working correctly. Because if you start falsely diagnosing people, that could be a complete waste of time. [Patient 3; female, aged >60 years]
- If we look at a top-level view across all AI it's really hard to summarise in a single sentence whether this will help or hurt. But if developed well, if used well I still do believe there's lots of great potential here. [AIR5; male, aged <45 years]

Discussion

Principal Findings

In this study, many of the discussions centered on 2 simple questions: who is going to use the AI technology, and what is it going to do? Most participants commented on positioning AI technology with patients or allied HCPs (before the PCP) or with the PCP as a decision support tool. Few participants proposed positioning the technology to triage referrals to secondary care or as a decision aid for dermatologists. Participants highlighted several overarching topics as important to them, including trust, acceptability, generalizability, evaluation, regulation, implementation, and long-term use.

The risk of false negatives resulting from an AI technology with poor sensitivity and missing skin cancers was a major concern for all participant groups. Missed skin cancers, especially melanoma, are likely to lead to late diagnosis and worse outcomes for patients [3,6]. One potential benefit of AI technology mentioned by all groups was the reduction in the workload of health care services, primarily through effective triage of patients that need to see PCPs or specialist clinicians. This could be the case if the AI technology has a good specificity with few false positive results. False positives are inevitable, but an AI technology with a low specificity could significantly increase the workload of health care services. This was a concern raised by HCPs, but few other participant groups commented on this risk. It has been suggested that overdiagnosis of melanoma is rising due to increased rates of skin examination, decreased thresholds for biopsying skin lesions, and for labeling morphological changes on histopathological examination as malignant [25]. Implementation of an AI technology with low specificity could increase both rates of skin examination and biopsy rates, both potentially contributing to overdiagnosis.

AI researchers were the most pragmatic, expressing concerns about the generalizability of many AI technologies and the relevance of current testing approaches in preparation for clinical implementation. They were concerned about the robustness of the datasets underlying AI technologies, including the representativeness of skin cancer prevalence and patient demographics in the datasets. They felt that, at the current time, these technologies need to be implemented with a human in the loop. Many HCPs were aware of the lack of evidence and potential risk to patients that has been publicly commented on by the BAD [9]. Patients and the public were aware of potential improvements in patient access, diagnostic accuracy, and reduced workload AI technologies could offer but were concerned about the risk of missing cancers and losing the opportunity for human interaction and to ask questions.

Complexity underpins most of the generated themes. Developing, evaluating, implementing, regulating, and maintaining AI technology in health care settings are all multifaceted, complex processes containing many opportunities for error, as laid out in the CanTest framework [14]. Therefore, it is unsurprising that so many diagnostic technologies fail at the implementation stage [26]. Several studies have discussed the complexity of implementing digital, AI, and machine learning (ML) interventions into health care settings; they recommended a whole-of-system approach with particular focus on how users interact with devices and user training [12,27].

Comparison With Existing Literature

The NASSS framework [15] was chosen to guide this study because it includes a wide range of domains that help capture the complexity of implementing health care interventions [28]. Most of the cross-cutting themes link closely to NASSS domains, specifically “knowledge to use the technology,” “demand-side value (to patient),” “adopters,” and “organizations.” There were several themes raised that did not fit into the NASSS framework (such as the potential for continued learning with AI technologies), as well as themes (such as trust and acceptability) that seemed to lose some of their breadth and nuance by being contained within the NASSS domains. We chose to code both inductively and deductively, which allowed us to better capture participants’ views and build knowledge about applying the NASSS framework to novel AI technologies.

A recent Swedish study used an AI-based melanoma decision support aid for clinicians as an example technology to generate discussions with participants about the implementation of decision aids. In keeping with their findings, many participants in our study discussed the issues of accuracy, safety, data security, liability, ease of use, and integration [29]. Our findings support those of a recent systematic review on the use of ML-based risk prediction models in health care settings [13] in which participants demonstrated largely positive views of AI technologies but identified many barriers. Echoing findings from several recent studies [30-33] we identified concerns about diagnostic accuracy, risk of patient harm, ease and speed of use, HCP overreliance on the technology, legal liability, data protections, data quality, impersonality, and positioning in the diagnostic pathway. In particular, we identified aspects of the consultation participants felt that AI technologies could not replicate, that is, the need for human interaction and clinical experience and judgment. Participants commented on the risk that AI technologies will not be effective in minority populations who are inadequately represented in training and testing datasets and may exclude populations with lower technological literacy, such as older people.

The wide variety in positioning and approach of existing AI technologies [7,8] indicates that the optimal position and approach have yet to be determined. Several participant groups highlighted that they wanted more evidence of the accuracy of technologies in real-life clinical use. This fits with recent reviews of AI technologies aimed at detecting skin cancer [7,8,33], although increasing evidence from clinical trials is emerging [10]. PCPs were keen to have an AI technology to support their diagnostic decision-making, in keeping with findings from a previous study [34]. AI researchers highlighted a growing body of research in AI technology development for health care settings, including the “human-in-the-loop” approach and the “data-centric AI movement” [12,35,36].

Regulation was a topic raised by several participant groups. The fast-moving pace of AI development makes regulation of AI technologies challenging: underregulation risks patient safety while overly zealous regulatory approaches could hinder AI

development pipelines and implementation [37,38]. AI has the unique potential to continue developing over time as it is exposed to more data. Regulatory bodies around the world are attempting to keep up with the rapid developments in AI technologies. In the United States, the Food and Drug Administration has proposed the 510k pathway, which facilitates the approval of software as a medical device if it is substantially based on a previously approved technology [39], and is developing an approach to an AI-ML workflow that would enable continued learning after implementation [40]. There are emerging national and international regulatory policies, including the European AI Act, the United States AI Bill of Rights, and the United Kingdom policy on AI [41-43].

Strengths and Limitations

To the authors' knowledge, this is the first study to report the views of a broad range of stakeholders about the use of AI technologies to facilitate the earlier diagnosis of skin cancer in primary care settings. We had good variation among interviewees in terms of background, age, sex, and geographical location. The study benefited from PPI at every stage, and a strong conceptual framework was used to develop the framing of the interview schedule and data coding.

Aiming to recruit a wide range of stakeholders was a conscious choice, as we felt this was important to achieve a breadth of opinions; the trade-off was that time and resources meant we were only able to include limited numbers in each participant group. The aim was to achieve breadth of opinion without necessarily achieving saturation. AI and clinical implementation are complex subjects, which meant that we were more likely to recruit participants with higher educational attainment and who are engaged with health care research or AI; both these aspects may have affected the balance of views we obtained. We only recruited 1 participant who reported that they disapproved of using AI technologies to help diagnose skin cancer. Skin cancer is more common in melanin-poor skin; however, a key limitation of current AI technologies is their lack of training and testing in populations with melanin-rich skin. We recruited limited numbers of participants with melanin-rich skin in this study, so participant views on this issue may be incomplete. In contrast to other participants, AI researchers were largely based outside the United Kingdom, reflecting the location of the majority of commercial companies developing these technologies. However, it meant their knowledge of United Kingdom clinical practice and diagnostic pathways was sometimes limited.

Implications for Clinical Practice, Research, Adoption, and Policy

Health care services are working under extreme pressures in primary and secondary care [44]. AI technologies aimed at diagnosis or triage of skin lesions could facilitate early diagnosis of skin cancer to improve outcomes for patients and potentially ease some of these pressures. However, before this can happen, research is required to prove their efficacy with real-world clinical populations and to address the questions that remain about the most effective positioning of the technologies in the diagnostic pathway and the optimal approach for their use. Diagnostic technologies that are used in populations that are different from those they were developed and tested in are prone to spectrum bias [45]. Better measures of clinical performance are required to inform these studies, which consider not only diagnostic accuracy but also provide a measure of generalizability and dataset quality [46].

Some of our findings can be used to further develop the NASSS framework, for example, to consider in more depth how users interact with an AI technology and the potential for continued development after implementation. When developing an AI technology aimed at the diagnosis or triage of skin cancer, developers need to consider carefully and be specific about the intended use, including where it will fit into the diagnostic pathway for skin cancer and the approach that it is going to take. Developers must also consider the quality and representativeness of the data they use to develop the AI.

The decision to adopt an AI technology is complex and multifaceted. Clear regulatory processes that consider unique features of AI technologies need to be established, including continued learning, to ensure AI technologies are safe and effective when used in clinical settings. Adopters should also consider what safety nets are in place to identify poor performance and reduce false negative results, such as expert systems and regular "sense checks."

Conclusions

AI technologies are being designed with a wide variety of approaches, and the optimal approach and position in the skin cancer diagnostic pathway for these technologies have not yet been determined. AI technologies have the potential to help detect and diagnose skin cancer, to improve patient experience and outcomes, and to reduce the workload of overstretched health care systems. However, we have identified important concerns surrounding trust, acceptability, usability, generalizability, evaluation, regulation, implementation, and long-term use. These technologies need to be developed carefully and thoughtfully to achieve their potential, guided by evidence-based approaches and appropriate implementation, taking into consideration long-term sustainability and safety.

Acknowledgments

The authors would like to thank our patient and public involvement and engagement group—Margaret Johnson, Jenny Hunt, Sylvia Bailey, and John Lancaster—who contributed to study development, recruitment strategies, study materials, and the interview schedule. The authors would also like to thank Professor Steve Morris, who contributed to the development of the study.

The research was supported by a Cancer Research UK Cambridge Centre Clinical Research Fellowship for OTJ. JE is supported by an NHMRC Investigator Award (grant APP1195302). SES is supported by Barts Charity (grants G-001520 and MRC&U0036). RNM is Chair of the AI Working Party Group at the British Association of Dermatologists. The funding sources had no role in the study design, data collection, data analysis, data interpretation, writing of the report, or in the decision to submit for publication.

Abstract

Background: Decision aids improve patient and clinician decision-making but are underused and often restricted to clinical settings.

Objective: Given limited studies analyzing the feasibility of disseminating decision aids through social media, this study aimed to evaluate the acceptability, trust, and engagement of women with social media as a tool to deliver online decision aids for cancer treatment.

Methods: To prepare for potential dissemination of a breast cancer decision aid via social media, a cross-sectional survey in February 2023 was conducted via Prime Panels, an online market research platform, of women aged 35-75 years in the United States. Demographics, health, cancer information-seeking behaviors, social media use, trust in social media for health information, as well as the likelihood of viewing cancer-related health information and clicking on decision aids through social media, were assessed. Statistical analyses included descriptive statistics, correlations, and multivariable ordinal regression.

Results: Of 607 respondents, 397 (65.4%) had searched for cancer information, with 185 (46.6%) using the internet as their primary source. Facebook (Meta) was the most popular platform (511/607, 84.2%). Trust in social media for health information was higher among Black (14/72, 19.4%) and Asian respondents (7/27, 25.9%) than among White respondents (49/480, 10.2%; *P*=.003). Younger respondents aged 35-39 years (17/82, 20.7%) showed higher trust than those aged 70-79 years (12/70, 17.1%; *P*<.001). Trust in social media for health information was linked to a higher likelihood of viewing cancer information and accessing a decision aid online (*P*<.001). Participants who rated social media as “Trustworthy” (n=73) were more likely to view cancer information (61/73, 83.6%) and click on decision aids (61/73, 83.6%) than those who found it “Untrustworthy” (n=277; view: 133/277, 48.0%; click: 125/277, 45.1%). Engagement with social media positively correlated with viewing online cancer information (Spearman ρ=0.20, *P*<.001) and willingness to use decision aids (ρ=0.21, *P*<.*001*). Multivariable ordinal regression analyses confirmed that perception of social media’s trustworthiness is a significant predictor of engagement with decision aids (untrustworthy vs trustworthy β=–1.826, *P*<.001; neutral vs trustworthy β=–0.926, *P*=.007) and of viewing cancer information (untrustworthy vs trustworthy β=–1.680, *P*<.001, neutral vs trustworthy β=–0.581, *P*=.098), while age and employment status were not significant predictors.

Conclusions: This exploratory study suggests that social media platforms may increase access to health information and decision aids. No significant differences were observed between demographic variables and the use or trust in social media for health information. However, trust in social media emerged as a mediating factor between demographics and engagement with cancer information online. Before disseminating decision aids on social media, groups should identify existing trust and engagement patterns with different platforms within their target demographic.

KEYWORDS

shared decision-making; SDM; decision aids; cancer treatment; breast cancer; digital health; social media; health communication; online decision aids; health information-seeking behavior; trust in health information; healthcare accessibility; mhealth

Introduction

An estimated 2,001,140 new cancer cases are expected in 2024 [1]. Shared decision-making (SDM) describes a process between the clinician and patient to facilitate preference-sensitive choices [2]. Decision aids, which can support the SDM process, are evidence-based tools designed to provide patients with information, clarify their preferences, and prepare them to make a choice [3,4]. In this study, we explore the potential of social media as an avenue for engagement with decision-making tools.

SDM has been shown to be important for cancer decision-making, with multiple randomized controlled trials demonstrating that decision aids improve patient knowledge and the quality of decisions [3-11]. Unfortunately, decision aid use has been limited, and their dissemination has been largely confined to clinical settings. A 2010 study revealed that only 24% of clinicians working with patients with cancer used decision aids [12-18]. The focus on clinical settings as the singular forum for decision aid deployment is predicated on clinician buy-in and may restrict the use of decision aids to a select cohort of the population [12-19].

Social media offers a promising means for disseminating decision aids without relying on health care access. It may also provide a more extended and personalized modality for disseminating information [20]. With 81% of Americans using social media, a number that continues to grow, social media platforms present an underused opportunity to disseminate highly accessible decision-making tools [21]. Social media can help to overcome challenges associated with traditional clinical encounters (ie, time, workflow, etc) and can enhance the patient-clinician relationship by promoting empowerment, reducing communication barriers, and increasing knowledge about conditions and treatment options [14,22].

Numerous studies have highlighted the positive impact of web-based decision aids for women, particularly in the context of breast cancer, the leading cause of cancer among females [23]. Despite the potential benefits of social media for decision aid dissemination, it remains uncertain whether females will use cancer-related decision aids available through social media or other online channels. To address this gap, we examined factors influencing engagement with decision aids on social media and explored health information-seeking behaviors across various platforms. This study aimed to evaluate the feasibility, acceptability, trust, and engagement with social media as a tool to deliver online decision aids to women for cancer treatment. By focusing specifically on women, we aimed to address the unique health and decision-making needs of this population and provide insight for future research on breast cancer-related decision aids.

Methods

Survey Design

A cross-sectional survey was designed to assess the use and preferences for social media–advertised decision-making tools for cancer care. The survey involved several key areas of inquiry (Multimedia Appendix 1). Briefly, these areas included “Health-Related Information Behaviors” (5 questions) to assess participants’ behaviors in seeking and using health information; “Sources of Health Information” (3 questions), exploring individuals’ preferences and trust levels in various health information sources; “Social Media Use” (18 questions), examining patterns and motivations behind social media interactions, particularly concerning health information; and “Demographic Data” (10 questions), covering a wide range of personal and socioeconomic factors. Within the “Social Media Use” section, two items related to the main outcomes of the study were embedded, created by the study team, which asked participants to imagine themselves or a loved one deciding about cancer treatment and then assessing their likelihood of viewing cancer treatment information or clicking on a decision aid posted on social media. Other survey questions were adapted from items from the Health Information National Trends Survey [24]. Items assessing reasons to use social media included categories identified in the literature through the uses and gratifications theory and the social media engagement model [25-27].

The response formats varied according to the specific inquiry, including multiple-choice options, checkboxes for applicable answers, and Likert scales for assessing attitudes and opinions. Although all 39 questions could be answered, branching logic was used to tailor the survey based on participants’ responses (eg, only those reporting the use of specific social media platforms were asked follow-up questions about their motivations for use). The survey was designed to be completed within 5 to 10 minutes and included 2 attention-check questions. One single question, with the associated branching logic, was shown on the screen at a time. Participants were unable to skip questions (except for the questions asking the frequency of use and reason for use of social media platforms) and were notified, “Please answer this question” if attempted to skip. Participants were able to go back and change their answers if desired. The order of survey items, and answers, was fixed and not

randomized, as the survey design prioritized logical flow and ease of navigation for participants. This study is reported in a manner that is consistent with the specified Checklist for Reporting Results of Internet E-Surveys (CHERRIES) guidelines (Multimedia Appendix 2) [28].

Population Targeting and Survey Distribution

The survey was designed and hosted on the Qualtrics platform (Qualtrics, Provo) and distributed in February 2023 via Prime Panels, a component of Cloud Research [29]. Prime Panels uses a novel data collection method by aggregation of diverse opt-in market research panels into a comprehensive sampling platform, facilitating the recruitment of participants from existing commercial panel pools. This method supports demographic quotas and specific eligibility criteria, enhancing data representativeness, especially among hard-to-reach populations. Eligible participants were invited to participate through targeted email and dashboard invitations sent by the market research panels within the Prime Panels network, based on the demographic criteria specified for the study [30]. Participants were required to complete the survey in a single sitting, and no reminders were sent to those who did not finish it during that session. Due to the wide distribution on several platforms, response rates and the total number of invitations sent were not calculated by Prime Panels.

We aimed to gather a representative sample of United States females aged 35-75 years for this study, as this age range represents the peak period for breast cancer diagnosis. The study exclusively enrolled female participants to direct focus toward future research efforts related to breast cancer in women. Using 2022 US Census data, the population of females aged 35-75 years were inputted into the Qualtrics sample size calculator with a 99% CI and a 5% margin of error to determine the required sample size [31]. Based on these calculations, the survey targeted approximately 660 female participants, with an additional 15% included to account for potential exclusions due to poor response quality, bringing the total recruitment goal to 750 participants. Study specific eligibility criteria incorporated into the Prime Panels query included female participants aged 35 years or older with US IP addresses. Demographic quotas based on United States Census Bureau parameters were set as: 16% Hispanic, Latino, or Spanish origin; 78% White; 13% Black; 5% Asian; 2% American Indian or Alaskan Native; and 2% other races. Age quotas aimed for an equal distribution between the 35-55 years and 56-75 years age ranges to reflect the demographics of breast cancer survivors. To ensure survey security, Qualtrics options for “Bot Detection,” “RelevantID,” and “Prevent Indexing” were enabled.

Statistical Analyses

Data analysis was performed using Microsoft Excel and SPSS Statistics (version 28.0; IBM Corp). Graphs were constructed via R Statistical Software (version 4.1.2; R Core Team 2021). Descriptive statistics characterized the demographic characteristics, health-seeking behaviors, and social media engagement of the study population. Social media engagement was determined based on respondents’ selections of platforms they actively used, followed by survey questions that assessed the frequency of engagement with each platform. These questions categorized usage frequency into 4 levels: multiple times a day, once a day, at least 3 times a week, or less than 3 times a week. Numerical values ranging from 1 to 4 were assigned to these categories, with 1 indicating the least frequent usage and 4 the most frequent. An “Overall Social Media Engagement Score” was computed by aggregating these values across all platforms used by a respondent. Participants were classified into 4 groups based on their “Overall Social Media Engagement Score” to approximate quartiles for analysis. These groups were defined as follows: “Low Engagement” (scores of >0 and ≤3), “Moderate Engagement” (scores of >3 and ≤4), “Moderate-High Engagement” (scores of >4 and ≤8), and “High Engagement” (scores of >8 and ≤23).

To ensure data integrity, surveys were excluded based on the following criteria: completion times shorter than 3 minutes or longer than 20 minutes, flags from Qualtrics indicating duplicate responses, an Amazon Mechanical Turk fraud score above 50, or incorrect responses to two embedded control multiple-choice questions.

Analysis of Trustworthiness of Social Media

To evaluate associations between demographic factors and the perceived trustworthiness of social media as a reliable source of health information, chi-square, and Fisher’s exact tests were performed. To ensure that there were enough observations in each category for the statistical analysis to be reliable, the response categories “Trustworthy” and “Very Trustworthy” were merged into a single “Trustworthy” category, while “Untrustworthy” and “Very Untrustworthy” were combined into “Untrustworthy.”

Analysis of Social Media Engagement

In terms of the two questions assessing the likelihood of engaging with cancer treatment-related information seen on social media, responses were condensed from a 7-tier scale to 3 categories: “Unlikely” (1-3), “Neutral” (4), and “Likely” (5-7) to ensure a more balanced distribution of responses, as some of the original categories had very few observations. Spearman rank correlation coefficients were calculated to quantify the strength and direction of the association between the “Overall Social Media Engagement Score” and the tiered scores representing the likelihood of interacting with cancer-related information. For visual interpretation, the mean likelihood of respondents interacting with cancer-related information was calculated for each unique “Overall Social Media Engagement Score.” For all analyses, statistical significance was set at a P value of less than .05, using 2-tailed testing.

Analysis of Likelihood to View Cancer-Related Health Information or Click on Decision Aid

Nonparametric tests, specifically the Kruskal-Wallis and Mann-Whitney U tests, were used to evaluate the relationships between demographic characteristics, trust in social media, and the propensity to use decision aids or view cancer-related health information on these platforms. Variables that were found to be significantly related to the use of decision aids or viewing health information at $P \leq .10$ were then checked for multicollinearity via variance inflation factor (VIF) values <5 before inclusion in an ordinal regression model.

Ethical Considerations

This study was reviewed and received approval from the institutional review board at Ohio State University as exempt (protocol 2022E0836). Informed consent was obtained from all participants involved in the study. Participant data were collected anonymously, with no identifying information retained in the dataset. The original informed consent included provisions for the use of deidentified data for research purposes, as reviewed and approved by the institutional review board. Data were stored in a secure, password-protected database accessible only to study investigators. All participants were compensated by Prime Panels in the amount agreed to by the platform through which they entered the survey, which is unknown to study personnel.

Results

A total of 757 responses were initially recorded at the completion of distribution. Of these, 607 met inclusion criteria with a Qualtrics "Response Quality" of 99.0%. Participants completed the survey in a mean SD time of 5.5 (SD 2.6) minutes.

Respondent Demographics

All participants were female, aged 35-75 years (Table 1). Of the 607 respondents, most were non-Hispanic (556/607, 91.6%) and White (480/607, 79.1%). The most common education level was some college or an associate degree (201/607, 33.1%). The most common income range was US $20,000 to US $35,000 (119/607, 18.9%), with over half (327/607, 53.9%) earning less than US $50,000 annually.

Health-Seeking Behavior

In total, 551 out of 607 participants (90.8%) had sought health or medical information from various sources at some point (Table 2). Out of 551 respondents, the internet was the most common first source of health information (n=441/551, 80.0%), while 75 or 13.6% consulted a doctor or health care provider.

Table 2. Characteristics of health-seeking behaviors.

Question	Respondents (N=607), n (%)
Have you ever looked for information about health or medical topics from any source?	551 (90.8)
The most recent time you looked for information about health or medical topics, where did you go first?	551 (100)
Doctor or health care provider	75 (13.6)
Internet	441 (80)
Brochure or pamphlet, etc.	10 (1.8)
Friend or coworker	3 (0.5)
Family	11 (2)
Cancer organization	2 (0.4)
Newspapers	1 (0.2)
Books	5 (0.9)
Library	2 (0.4)
Telephone information number	1 (0.2)
The most recent time you looked for information about health or medical topics, who was it for?	551 (100)
Self	408 (74)
Someone else	72 (13.1)
Both oneself and someone else	71 (12.9)
Which of the following sources have you used in the last month as a source of news or information about health topics?[a]	592 (100)
Blogs or personal websites	72 (12.2)
Center for disease control and prevention	133 (22.5)
World Health Organization	63 (10.6)
Government	46 (7.8)
Community or faith leaders	19 (3.2)
Online news	256 (43.2)
Email	48 (8.1)
Family and friends	204 (34.5)
Health professionals	282 (47.6)
Radio	22 (3.7)
Podcasts	27 (4.6)
TV	69 (11.7)
Social media	119 (20.1)
Print media	46 (7.8)
Video sharing sites	53 (9)
Have you ever looked for information about cancer from any source?	607 (100)
Yes	397 (65.4)
No	210 (34.6)
In the past 12 months, have you used the internet to look for cancer information for yourself?	397 (100)
Yes	185 (46.6)
No	212 (53.4)
Where do you access your social media accounts?[a]	603 (100)
Computer or laptop	258 (42.8)
iPad or tablet	159 (26.4)

Question	Respondents (N=607), n (%)
Smartphone	497 (82.4)

[a]Participants were able to check all that apply.

Social Media Use and Engagement

In total, 80 out of 607 or 95.6% of respondents used social media. Of these, Facebook was the most popular platform, used by 511 or 84.2%, and was used primarily for social interactions by 338 out of 487 respondents (69.4%). YouTube (Alphabet Inc) and Instagram (Meta) were primarily used for entertainment (189 out of 251 or 75.3% and 110 out of 193 or 57.0%, respectively). 18.5%, or 112 out of 607 respondents, demonstrated a “Low Engagement” pattern regarding social media use.

Trustworthiness of Social Media

The majority of the 607 respondents found social media trustworthy (73/607, 12.0%) or neutral (257/607, 42.3%) for health information. Black or Asian race, younger age, and longer duration of US residency were associated with greater trust in social media. Among Black respondents, 14 out of 72 (19.4%) considered social media trustworthy, compared to 49 out of 480 (10.2%) of White respondents (P=.003). Asian respondents showed even higher trust levels, with 7 out of 27 (25.9%) rating social media as trustworthy. Younger individuals also reported greater trust, with 17 out of 82 (20.7%) of those aged 35-39 years trusting social media compared with 12 out of 70 (17.1%) among those aged 70-79 years (P<.001). In addition, respondents with longer US residency (more than 15 years) showed greater trust, with 272 out of 587 (46.3%) indicating trustworthiness in social media, compared with only 5 out of 20 (25.0%) of those with less than 15 years of residency (P=.004). In total, 277 respondents (45.6%) noted social media to be untrustworthy (Table 3).

Table 3. Factors associated with perceived trustworthiness of social media as a source for health information.

[b]$P<.05$.

[c]GED: graduate educational diploma.

Among social media platforms, the highest proportion of trustworthy users was noted among the 80 WhatsApp users (n=17, 21.3%), followed by 23 out of the 136 (16.9%) Twitter users. Amongst the 511 respondents who used Facebook, the most frequently used platform, 65 or 12.7% reported trust in social media for health information.

Use of Cancer Information or Decision Aids Through Social Media

Participants who considered social media "Trustworthy" (n=73) were more likely to view cancer information (n=61, 83.6%) or click on a decision aid through social media (n=61, 83.6%) than the 277 respondents who viewed social media as "Untrustworthy" (view: n=133, 48.0%; click: n=125, 45.1%) (Tables 4 and 5). Younger participants, particularly those aged 35-39 years were more likely to view cancer-related information through social media. Only 10 out of 57 (12.2%) in the 35-39 years age group rated their likelihood as "unlikely," compared with 54 out of 89 (32.7%) aged 60-69 years. Among respondents aged 35-39 years, 54 out of 82 (65.9%) were likely to click on the decision aid, while in the 60-69 years age group, 87 out of 165 (52.7%) indicated they were likely to click.

[b]*P*<.05.

[c]GED: graduate educational diploma.

The “Overall Social Media Engagement Score” was associated with increased likelihood of viewing cancer treatment-related information (Spearman ρ=0.210, *P*<.001; Figure 1). For instance, among those with an engagement score of 1, only 10 out of 25 (40%) were likely to view cancer information, whereas among those with an engagement score of 8, 28 out of 44 (63.6%) were likely. In addition, the engagement score was also associated with accessing a decision aid on social media (Spearman ρ=0.203, *P*<.001; Figure 2). Among respondents with an engagement score of 1, only 8 out of 25 (32%) were likely to click on the decision aid, whereas for those with a score of 8, 25 out of 44 (56.8%) indicated they were likely.

Figure 1. Mean likelihood of viewing cancer-related health information seen on social media by "Overall Social Media Engagement Score.".

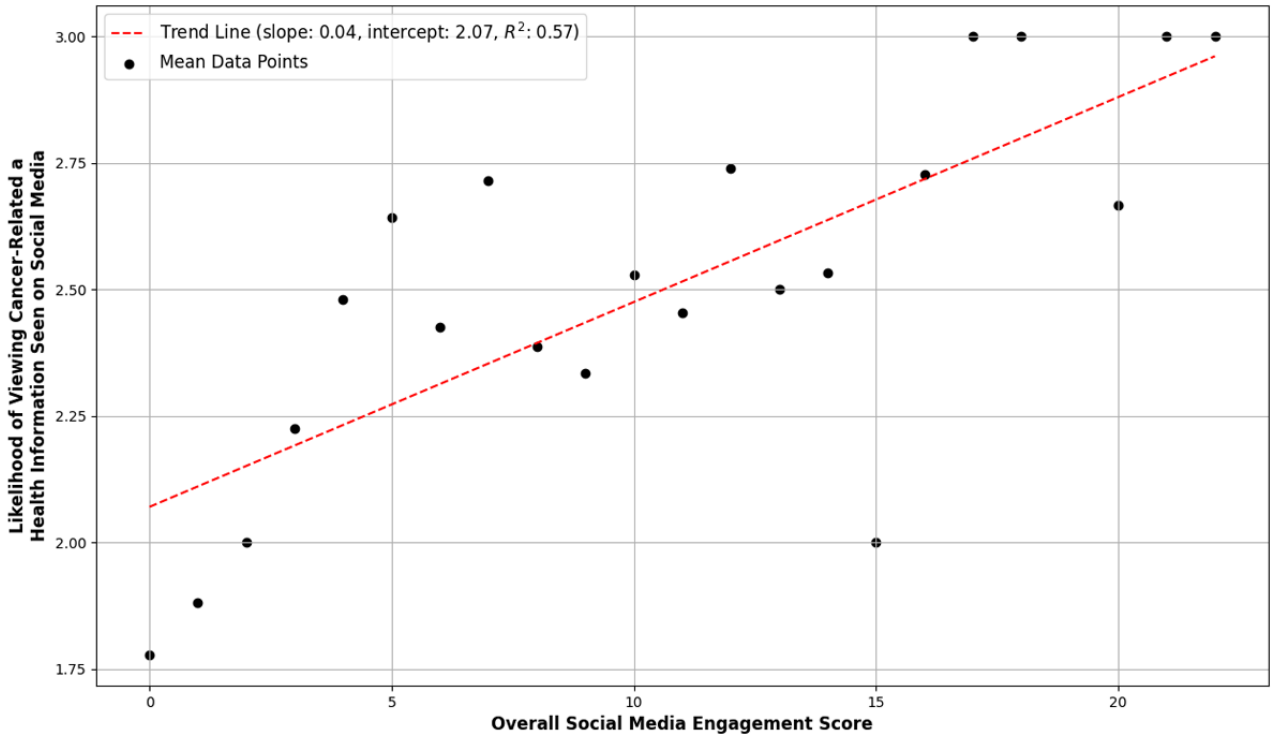

Figure 2. Mean likelihood of clicking on a decision aid seen on social media by "Overall Social Media Engagement Score.".

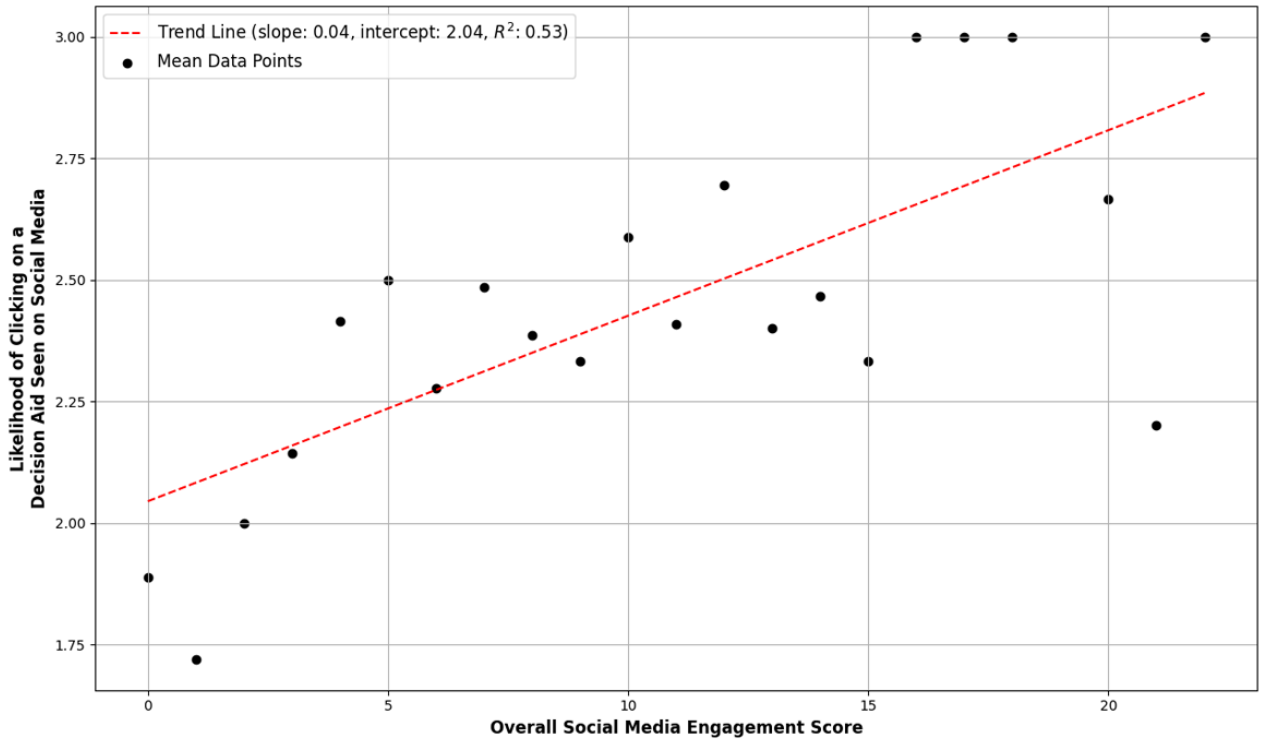

Age, employment, and perceptions of trustworthiness of social media were included as covariates in the ordinal regression models after significant multicollinearity was ruled out variance inflation factor (VIF≤1.2). The model fit for estimating the likelihood of clicking on decision aids was significant (χ^2_9=60.7, *P*<.001, Nagelkerke R^2=0.113). Respondent perception of the trustworthiness of social media for health information was a significant predictor. Compared with those who found social media trustworthy, respondents who considered social media "untrustworthy" (β=–1.826, Wald χ^2=29.14, *P*<.001) or "neutral" (β=–0.926, Wald χ^2=7.22, *P*<.007) were less likely to click. Age category (*P*=.59) and employment status (*P*=.29) were not significant predictors.

The model for viewing cancer-related health information was also significant (χ^2_9==70.4, P<.001, Nagelkerke R^2=0.133). Relative to those rating social media as trustworthy, those rating it as "untrustworthy" had significantly reduced odds of viewing cancer-related health information (β=–1.680, Wald χ^2=24.31, P<.001) while the reduction in likelihood of those rating it "neutral" did not reach statistical significance (β=–0.581, Wald χ^2=2.74, P=.10). Once again, age (P=.35) and employment status (P=.22) were not significant predictors.

Discussion

Principal Findings

The expanding role of social media in health information dissemination underscores a shift in public health communication. The internet is the most frequently reported source of information for individuals with cancer, especially among women, aligning with our findings [32]. To our knowledge, this is the first study to examine factors influencing engagement with decision aids and cancer-related information amongst women using social media platforms.

These study findings suggest that social media holds potential as a platform for the effective dissemination of cancer decision aids to women. Overall social media usage was high, with almost half of the respondents reporting moderate-high to high engagement. We found that about two-thirds of participants searched for cancer-related information, and nearly half of those used the internet to seek such information for themselves in the past year. Usage patterns varied across platforms: while Facebook emerged as the most used platform, WhatsApp was perceived as the most trustworthy source for health information among our respondents.

Most respondents expressed interest in engaging with cancer treatment information or clicking on a decision aid via social media. Higher frequency of social media use correlated with a higher likelihood of interacting with cancer-related content and decision aids online. In addition, trust in social media appears to be a mediating factor in the relationship between demographics and engagement with cancer information on social media. While younger participants and those who worked full time were more likely to view cancer-related information and click on a decision aid, this effect may be a function of their higher likelihood of trusting social media.

Comparison to Previous Work

Integrating two primary concepts of this study, trust in social media and the likelihood of engaging with health-related content, our findings suggest that individuals who perceive social media as a trustworthy source of health information are more likely to interact with cancer-related treatment information, regardless of their demographic. Numerous consumer studies have highlighted the importance of source credibility in engagement [33-35]. We recognize that trust is a multifaceted construct that is objectively hard to evaluate because it is influenced by factors including demographics, past experiences, and societal and cultural norms [36]. Future studies should focus efforts on better understanding their impact on health information engagement.

Recently, a study by Fridman et al [37] analyzed social media usage and trust in health information among patients with cancer and caregivers, focusing on demographic factors linked to social media use for medical decisions. They also found that a substantial proportion of patients with cancer and caregivers trust social media for health information. Factors associated with higher trust and engagement with social media tools included young age, Black race, and lower education levels. This is consistent with our findings that support trust as a motivating factor for engagement with social media in a medical decision-making context.

Our study was designed to identify trends and general usage patterns across several social media platforms. Facebook (Meta) was the most popular platform among our survey respondents, with 84.2% reporting usage, aligning with 2023 national data indicating that 69% of consumers use Facebook, making it the most used social media site [38]. This is consistent with findings from a recent study which found that Facebook was the most frequently used social media platform for health behavior interventions [39]. However, Facebook is not perceived as being as trustworthy as some of the other platforms. Given the relationship between perceptions of trustworthiness and the likelihood of a respondent using health decision aids on social media, popularity should not be the only factor guiding dissemination. The demographic profile of users also continues to evolve. For example, although less widely used overall, WhatsApp (Meta) is increasingly popular among Latino or Hispanic populations in the United States [40]. These trends highlight the importance of understanding variations in platform use amongst different cohorts when considering platform selection.

In addition, consideration of platforms that can deliver information in diverse formats (eg, text, video, photos, and polls) is important, as each platform's design and interaction style may be better suited for specific sub-audiences. Future research should focus on exploring platform-specific strategies for health information delivery, especially as new platforms emerge (eg, Bluesky [Bluesky PBLLC] and Threads [Meta]) and others become less frequent.

Moreover, the frequency of social media use has a significant impact on the likelihood of engaging with decision aids or accessing cancer-related health information. Frequent social media users may be more likely to perceive others on these platforms as having integrity and competence. They may also report stronger connections with and greater concern for other network users [41]. Frequency of social media use can significantly influence user interactions, such as clicking behavior [42]. However, our Spearman correlation analysis, which focused solely on frequency, accounted for only about 4% of the variance in viewing and clicking behaviors. This suggests that trust, along with other unmeasured factors, likely plays a critical role in these engagement dynamics.

Strengths and Limitations

This exploratory study provides insight into the use of decision aids for health information on social media and highlights the key role of trust. It is an important stepping stone for future research assessing online health behavior among female patients

in cancer. A key strength of our study is the large sample size (N=607) and the inclusion of a cohort that is fairly representative of United States female population demographics based on census data, enhancing the generalizability of our findings. In addition, by recruiting a female-only cohort, our study offers a more nuanced understanding of preferences and engagement patterns among women, which can inform the development of female-specific cancer decision aids tailored for social media.

As a cross-sectional survey-based study, this study was not designed to explore the many complex, nuanced factors associated with online use behavior. First, the survey, although informed by widely used and nationally developed surveys, was not pretested or pilot-tested for face validity. This lack of initial testing may have been associated with increased confusion among participants and could have influenced responses and overall participation in the survey. Relatedly, we were close but unable to meet the overall target population size of over 660 after the application of exclusion criteria. Second, as an internet-based survey, it was subject to selection bias. Participation required English proficiency, internet access, and the ability to navigate an online survey. While incorporating multilanguage options can be considered, facility and comfort with the internet would still be required. Third, we were unable to recruit a racially diverse population that would be matched with corresponding US census data. For instance, the proportion of Hispanic respondents was nearly half of the intended goal (7.9% vs 16%). However, there was more variation in age, education, and income distribution of respondents. Future efforts in larger populations should focus on targeting underrepresented demographics via other survey distribution platforms and recruitment strategies.

Fourth, regarding statistical analysis, although a multivariable regression was performed, our regression models only accounted for roughly 10%-15% of the likelihood of viewing health information or clicking on a decision aid seen on social media. Moreover, potential influences from unmeasured factors, such as medical conditions or personality traits, further complicated attempts to understand these complex dynamics [43,44].

Future Directions

This study offers an initial insight into factors influencing online health information and highlights the role of trust. Future research should explore the potential of social media for the delivery of online decision aids specifically designed for patients seeking cancer information. Our study points to the need for pilot testing health decision tools within the target demographic to help with tool optimization and reliability of findings. Trust is a nuanced concept, and efforts should focus on ways to better quantify and distinguish between trust in both social media platforms and online materials.

Once decision aids have been refined for their target population, continued efforts should consider strategies to promote adoption and optimize engagement. Partnering with reputable health organizations, featuring endorsements from trusted medical professionals, and using verified accounts for content delivery can all be considered. Examining platform-specific formats, such as interactive content on Facebook or visual aids on Instagram, could help increase diffusion. Presenting clear, evidence-based information in user-friendly, visually engaging formats (eg, infographics or explainer videos) may further increase credibility. Incorporating interactive features that allow users to connect with health care providers or support groups on social media could also render greater trust and engagement. Research on these trust-building strategies would offer valuable insight into optimizing social media as a reliable and accessible channel for health information dissemination.

Authors' Contributions

All authors read and approved the final manuscript. ARJ, GAL, GBS, CNL, and TMM conducted formal analysis. ARJ, GAL, and GBS handled visualization. ARJ, GAL, GBS, and MCP, TMM, CNL contributed writing- original draft. ARJ, GAL, GAS, MCP, and YR performed review and editing. YR, MCP, CNL, TMM, and BO handled methodology. MCP, CNL, TMM, and BO conducted to conceptualization. TMM, CNL and BO managed data curation.

Conflicts of Interest

Author MCP was a consultant for Epi-Q, Inc in 2023 and UCB Biopharma in 2024, on topics unrelated to this manuscript. All other authors reported no conflicts of interest.

Abstract

Background: Commonly used digital health technologies, such as electronic health record systems and patient portals as well as custom-built digital decision aids, have the potential to enhance person-centered shared decision-making (SDM) in cancer care. SDM is a 2-way exchange of information between at least a clinician and the patient and a shared commitment to make informed decisions. However, there is little evidence in the literature on how technologies are used for SDM or how best they can be designed and integrated into workflows and practice. This may be due to the nature of SDM, which is fundamentally human interactions and conversations that produce desired human outcomes. Therefore, technology must be nonintrusive while supporting the human decision-making process.

Objective: This study examined how digital technologies can help cancer care professionals improve SDM in oncology consultations.

Methods: Health care professionals who treat patients with cancer were invited to participate in online co-design focus group meetings. During these sessions, they shared their experiences using digital technologies for SDM and provided suggestions to improve their use of digital technologies. The session recordings were transcribed and then analyzed using qualitative thematic analysis. The 3-talk SDM model, which consists of 3 steps—team talk, option talk, and decision talk—was used as the guiding framework. This approach was chosen because the 3-talk SDM model has been adopted in Australia. The researchers walked the participants through the SDM model and discussed their routine clinical workflows.

Results: In total, 9 health care professionals with experience treating patients with cancer and using technologies participated in the study. Two focus groups and 2 interviews were conducted in 2024. Three themes and 7 subthemes were generated from the thematic analysis. The findings indicated that various digital technologies, such as electronic health record systems, mobile devices, and patient portals, are used by cancer care professionals to help improve patients' understanding of their disease and available care options. Digital technologies can both improve and undermine SDM. Current systems are generally not designed to support SDM. Key issues such as data integration and interoperability between systems negatively impact the ability of digital technologies to support SDM. Emerging technologies such as generative artificial intelligence were discussed as potential facilitators of SDM by automating information gathering and sharing with patients and between health professionals.

Conclusions: This research indicates that digital technologies have the potential to impact SDM in oncology consultations. However, this potential has not yet been fully realized, and significant modifications are required to optimize their usefulness in person-centered SDM. Although technology can facilitate information sharing and improve the efficiency of consultation workflows, it is only part of a complex human communication process that needs support from multiple sources, including the broader multidisciplinary cancer team.

Introduction

Background

Shared decision-making (SDM) is defined as a collaborative approach in which patients and health care providers work together to make medical decisions [1]. SDM emphasizes a cooperative relationship between the patient and the physician, characterized by a 2-way exchange of information and a shared commitment to making informed medical decisions [2]. During the SDM conversation, patients and clinicians share information, express preferences, participate in discussions to gain insights, negotiate conflicts, solve problems, and ultimately make decisions [3]. Through this approach, patients can play an active role in their care [4], while physicians gain a better understanding of the unique needs of each patient. Physicians can then make informed and collaborative recommendations that aim to improve patient health outcomes [5]. The use of SDM is particularly crucial in oncology consultations, as the results of treatments are often uncertain. This uncertainty makes treatment decisions complex for patients who often have to choose between aggressive disease management and maintaining their quality of life [6]. Therefore, SDM has been implemented in oncology consultations in several hospitals around the world, and perceptions of its use by cancer care specialists in hospitals have been studied [7-9]. Despite the integration of SDM into health policies and practice standards [10,11], the benefits of SDM are slow to materialize at the operational level [12], and a fragmented health care system can complicate the implementation of SDM.

Efforts have been made to integrate decision aids into electronic health record (EHR) systems used by oncologists [13]. Current EHRs used in oncology practices in hospitals may include functions to facilitate the scheduling of patient consultations and follow-ups, history taking, review of examination results, electronic medication management systems, and care planning [14,15]. However, existing EHRs often do not provide complete details about patients' health values and preferences [16]. This lack of patient details can cause clinicians to misunderstand patient preferences when patients experience cognitive difficulties or when their health conditions worsen too quickly to participate in SDM, which can have significant adverse consequences [16]. The introduction and integration of additional digital tools, such as cancer care dashboards, into EHRs that display patient treatment outcomes and other clinical measurements to monitor patient health status have been developed to increase the ability of both clinicians and patients to visualize results and aid decision-making [17] and to aid the stakeholders during SDM to improve cancer care delivery [18].

Research is ongoing to understand how digital health tools and EHRs can be combined in innovative ways to improve the SDM process [19]. In particular, we need to collect more detailed information to pinpoint where additional digital technology could be developed and used to help the SDM process in the delivery of cancer care. This paper examines how EHRs and other digital tools are used in practice to inform possible future improvements in applied digital technology to facilitate SDM in oncology consultations.

Objectives

Hence, the objective of this study was to explore how health care professionals use digital technology to support SDM in oncology consultations, understand the barriers to technology that support SDM in oncology consultations, and understand the opportunities for future technology to improve SDM in oncology consultations.

Methods

Study Design

This study design was informed by the 3-talk SDM model and the approach of previous studies to develop digital tools to support SDM [20]. The 3-talk model incorporates the principles of team-based collaboration throughout a multistage consultation process and is highly recognized in the health care sector. This model has 3 main components: team talk, option talk, and decision talk [21].

Therefore, to investigate the role of digital technology in SDM in oncology consultations and to achieve the study objectives, we applied the design thinking framework [22]. Design thinking is a creative approach that has been used effectively to address problems in the health care sector [23,24]. It helps to collect user insights to develop efficient products, services, and experiences [23]. Ideas are quickly prototyped and improved through continuous iterations [25]. This study design was chosen because it emphasizes collaboration with end users throughout the problem-solving process. We developed low-fidelity wireframe prototypes of EHRs. This technique was chosen to investigate the potential of EHRs to help oncologists and patients with cancer collaborate on decisions because it has been suggested to be effective in health care management and innovation [26]. Low-fidelity prototypes (Multimedia Appendix 1) were quickly created using affordable graphic software, allowing feedback to be gathered without consuming significant time and resources. We applied co-design and low-fidelity prototyping methods with study participants in focus groups and one-on-one interviews.

Participants and Settings

Health care professionals with opinions on the role of digital technologies in oncology consultations were invited to participate in this study. Specialists in medical and radiation oncology, as well as physicians in training programs, were included. Through existing university connections and local cancer networks, participants were purposefully recruited from 5 cancer care centers in Sydney, Australia. A researcher (TS)

initially contacted key potential participants who collaborated on previous research projects in oncology via email and introduced them to AY. AY then followed up on the communication by providing an information package about the research project and suggesting focus group schedules. The focus groups and interviews were scheduled on Microsoft Teams for remote videoconferencing, and the participants' attendance was recorded.

Data Collection

Guided by the core components of the SDM 3-talk model—team talk, option talk, and decision talk—a focus group and interview topic question guide were developed in advance to shape study inquiries in alignment with the SDM model. The researchers (AY, JK, AJ, and TS) iteratively developed the topic question guide. The topic guide was pretested by running pilot focus group sessions with researchers working on other health care projects within the department. Their feedback helped to refine the topic questions and focus group process. The final version of the topic question guide is shown in Multimedia Appendix 1. The topic questions were used to ask participants about their experience with how technology is used to support SDM within each component of the 3-talk SDM model, particularly if they used the 3 SDM core components in their usual medical practice. The focus groups and interviews were semistructured and guided by the topic questions. The low-fidelity prototypes were presented to participants after discussing the application of technology in their practice, and feedback was sought on the usefulness of the concepts included in the prototype design. The prototypes also served as a trigger for further discussion.

Each focus group and interview concluded by summarizing and reflecting on the discussion and confirming the accuracy of the researcher's understanding of the information provided by the participants while they were still present. This final concluding step was necessary because scheduling busy, working health care professionals providing cancer care to patients for study reviews is difficult.

All interviews and focus groups were recorded in video and audio formats. They took place online between April and May 2024. Author AY led all the focus groups and interviews.

Data Analysis

Three researchers (AY, AJ, and TS) analyzed the qualitative data collected using the reflexive thematic analysis as a framework by Braun and Clarke [27-30]. This method guided the initial coding process applied to the focus group meetings and interview recording transcripts, which were deidentified and anonymized. The researchers first read through the transcripts to fully understand the data. They then proceeded with line-by-line coding, collaboratively compiling and discussing the codes. After completing the coding, the codes were inductively arranged into themes and subthemes. Researcher AY created a codebook, and the researchers engaged in multiple discussions to agree on the identified themes and subthemes. The codebook was tested on 1 transcript. Iterative discussions and consensus resulted in a refinement of the codebook. The final codebook was then used to code the remaining focus groups and interview transcripts. Then, AY used the codebook to code the content of each remaining transcript. Columns in an Excel (Microsoft Corporation) sheet were created to represent different themes and subthemes. AY analyzed the content of each transcript line by line and coded the text. The coded chunks of text were extracted and added to the Excel table according to their alignment with the themes. As new knowledge was found, the codes were refined accordingly. Afterward, AJ reviewed, modified, and confirmed the recategorization of the codes. Eventually, AY finalized the recorded data in the Excel sheet.

Ethical Considerations

The Human Research Ethics Committee of the University of Sydney approved this study (project number: 2023/790). All participants provided written informed consent. Data collected were anonymized and deidentified, and the research data were stored in the university's secure computer systems. All the participants provided their time and information freely without receiving financial compensation.

Positionality of the Research Team

Our research team (TS, JK, and AJ) has extensive experience conducting research on the implementation of digital technologies in health care organizations in Australia from an academic point of view. On the other hand, author AY is a practicing professional with experience in developing and implementing computer software in hospital settings for clinicians. We believe that digital technologies can improve health care. Thus, we are driven to implement the latest innovations in health care.

Results

Participants

The study involved 9 participants who participated in different co-design focus groups and interview sessions. One focus group was attended by 5 (56%) participants; another focus group was attended by 2 (22%) participants. Two interviews were conducted one-on-one. Each session lasted between 30 and 60 minutes. The participant demographics are presented in Table 1.

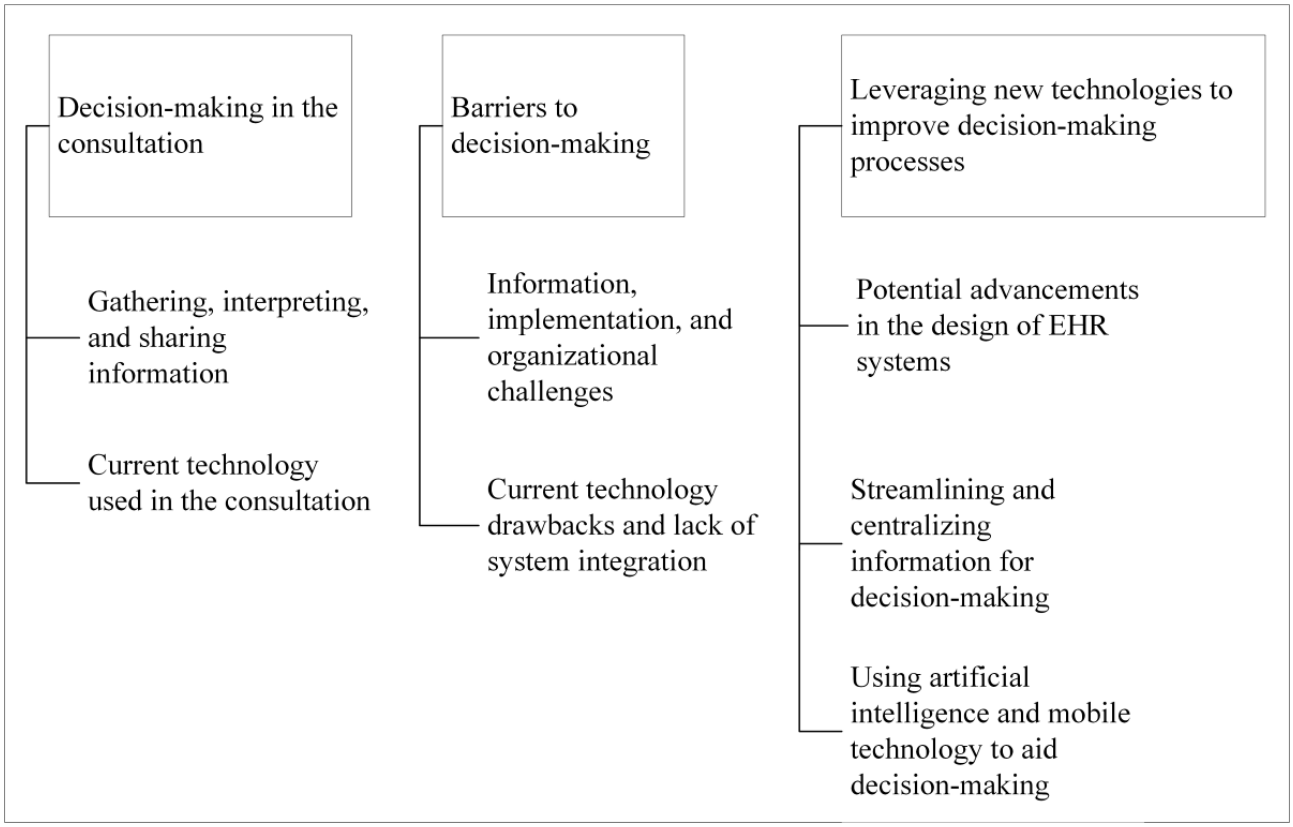
Table 1. Individual participant characteristics.

Participant ID	Session ID	Cancer Care Center ID	Sex	Cancer care stream	Level of experience
P1	A	C1	Female	Breast and lung	Radiation oncologist (consultant)
P2	B	C1	Male	Breast and lung	Radiation oncologist (consultant)
P3	B	C1	Male	Breast and lung	Radiation oncology registrar (in training program)
P4	B	C2	Male	Prostate	Radiation oncology registrar (in training program)
P5	B	C2	Female	Prostate	Radiation oncologist (consultant)
P6	B	C2	Female	Prostate	Radiation oncology registrar (in training program)
P7	C	C3	Male	Lung and head and neck	Medical oncologist (senior consultant and hospital executive)
P8	C	C4	Male	Perioperative	Anesthetic registrar (in training program)
P9	D	C5	Female	Lung	Respiratory specialist (consultant)

Overview of Themes and Subthemes

Three themes and 7 subthemes were generated from the thematic analysis. The three themes are (1) decision-making in the consultation, (2) barriers to decision-making, and (3) leveraging new technologies to improve decision-making processes (Figure 1).

Figure 1. Overview of themes and subthemes. EHR: electronic health record.



Theme 1: Decision-Making in the Consultation

Overview

Participants discussed their decision-making process during consultations and how they felt their clinical workflow aligned with the 3-talk SDM model while being prompted by the wireframe prototypes. The participants appreciated the 3-talk SDM model for breaking the clinical decision-making process into 3 core components:

> *...in general,...this is quite similar to what my approach is in the clinic.* [Participant P4 B C2]
>
> *...it's interesting, and I appreciate this model...breaks it into three pieces.* [Participant P7 C C3]
>
> *...I like team, option, and decision...I hadn't heard of it, but it's exactly how I structure my consultation.* [Participant P9 D C5]

On the basis of their experience, participants highlighted that they did not differentiate between the option talk and the decision talk components:

> *I...in the real world, don't differentiate between option talk and decision talk. So, option talk and decision talk, for me, is the same process. So, as I'm discussing options...I don't sit there and say here are all the options. Now, let's stop and have a discussion about the decision. I blend those two conversations together.* [Participant P7 C C3]

Participants described how they collect information by talking to their patients directly rather than having them fill out responses to a list of questions in advance:

> *I'm actively, kind of, discussing what would be involved in making a decision to go down this pathway. What further information would be needed? So, the implication for digital technology is that it's the same technology I use while discussing options. I don't sort of stop and say now, here's another one I prepared earlier. And let's talk about it this way.* [Participant P7 C C3]

Some participants were concerned about patient privacy:

> *...in the waiting room, I'm not sure...I don't know that I can see an easy way to get personalized digital information in the waiting room, in a safe way. I think that...needs some human and clinical inputs...it could be like a nurse coordinator, someone like that could meet with the patient before going to the consultation. So, there's all those sorts of very personalized differences.* [Participant P9 D C5]

Another important step, in their view, is that the participants noted that they plan activities before patients visit for their consultations:

> *So firstly,...these patients would have been discussed by the multidisciplinary team before they saw me with the surgeons and medical oncologists,...and we would have a plan of action from the MDT.* [Participant P1 A C1]

After the multidisciplinary team planning discussions, the participants described how they would discuss the situation with the patient and involve other professionals in the patient model of care:

> *So, we've looked at performance status, frailty, and pulmonary function. We identified things that are needed. We discussed that at the consultation and asked the care coordinator to link up.* [Participant P1 A C1]

The subthemes of decision-making in consultation include gathering, interpreting, and sharing information through digital and analogue communications.

Subtheme 1.1: Gathering, Interpreting, and Sharing Information

Participants said that decision-making often occurred in multidisciplinary team meetings without input from the patient:

> *...some of our decisions or, you know, consensus, optimal decisions are also influenced by our MDT meetings...in most MDT meetings, the patient is not there....we think we are arriving at a decision that can be communicated to patients, but often, it actually doesn't align with their preferences.* [Participant P5 B C2]

When reflecting on the decision-making component of consultations, participants noted that patient wants and expectations at the point of care they were at were shaped by their previous experiences along the way. Participants remarked that some patients may be ready to decide after meeting with the physician, while others may be hearing about their condition for the first time and feel overwhelmed. The participants know that this approach takes longer. Yet, they prefer having the ability to understand the patient's wishes better:

> *...there's a huge variation in what patients want at this point and what they expect, and it also probably is not independent of what specialty you're in and how they've gotten to you. So, you know, for me, by the time a patient's gotten to me, they may well have been through two or three specialists already. They've got...cancer and, so sometimes, they're already primed. They're ready to make a decision. Other times, it's the exact opposite, and this is the first time they've heard they might have cancer.* [Participant P7 C C3]

> *I use the time when I'm talking to patients, collecting...information to kind of just get to know the person...it takes longer than if they fill in a list of questions in advance and I'm just looking down the list...I'm building a relationship. If I look at a screen...that's not the same as asking those questions and, kind of, building a rapport with a patient.* [Participant P7 C C3]

Different approaches were described for different patient situations and desires for information. Participants said that some patients want to know their treatment plan, while others seek detailed explanations of the decision-making process. The preference for the type of clinical workflow in consultations can also depend on the physician's training, work style, and personality:

> *They've got no idea what's going on....it's the opposite conversation, where they absolutely need to go away and think about it....and I think the things you do to help them in those situations are somewhat different. The first one, those people often already have the information they need. The second one, they absolutely don't.* [Participant P7 C C3]

Several important points related to patient care were covered in the participants' discussions. Participants highlighted the challenges of bringing bad news to patients, the need for better participation of patients in decision-making, and the importance of documentation following decisions:

> *I see them at the start...usually, the person who sees them earlier then has to break the bad news, and then...all the referrals afterward...that's where things*

> *fall apart a little bit...they'll get discussed in MDT...but sometimes that's a little bit delayed. Sometimes, the patient doesn't always get the right information. The right time is the other problem.* [Participant P8 C C4]

The reliability of clinical information sources was raised. It is crucial to always refer to a trusted source of information:

> *...and look, the very important thing in clinical medicine is you go to the primary source for the information; you never make, you should never make a significant clinical decision based on anything but firsthand information.* [Participant P9 D C5]

The value of having care coordinators share the patient care to address patient needs and support them throughout their treatment journey was emphasized:

> *...the need for a care coordinator to triage the patient's care needs, ...it's helpful to have the prostate care nurse who can talk to patients about the radiation therapy and the surgery...they [the patients] get time to make the decision about what they want. We refer them to the men's health physiotherapist as well.* [Participant P6 B C2]

Understanding the specific concerns of the patient is key. It is important to begin the decision-making process with the patient's desired outcome and then work out the appropriate care pathway:

> *...you need to work out the patient's goals first...then work backward from that... "Well, I think it isn't that…" "I definitely don't want radiotherapy" or "I definitely do want radiotherapy because my sister had it. It was good."…you might not get the decision if the patient is still sort of weighing things up...the decision is going to be informed by the goals. It's coming back to the quality of life versus the quantity of life.* [Participant P1 A C1]

The information gathering step is followed by reviewing the patient's results and interpreting the situation before the patient arrives for their visit. One participant described this step as follows:

> *...what I'm talking about is more around interpreting patient results...like the pre-three-talk process...is having the information available...when I prepare for the clinic, I like to have an opportunity to read everything in the pile, and everything is there...that I'm not chasing stuff. So, I'll usually look at my clinic two days ahead of time and make...notes in chronological order to try and figure out firstly whether there is any missing information. Umm…then ensuring that it's adequately documented in a way that is more meaningful to me.* [Participant P2 B C1]

After interpreting the available information step, the participants discussed how they communicated the medical information to patients. They like the way visual aids, as suggested in the wireframe prototypes, help them to clarify and make information more understandable, improving patient understanding and facilitating informed decision-making through effective communication:

> *I find, you know, drawing diagrams and having pictorial, sort of, explanations of things help...I think it breaks through language barriers and understanding of things. Anyway, I'm scrolling through the images and going through the results with the patient, pointing things out, simplifying things, maybe drawing...handwritten...document...to help explain things.* [Participant P4 B C2]

Information and knowledge sharing was discussed in addition to visual aids. Participants mentioned that they often explained results using prognostic calculators that can assess life expectancy, especially in older patients. One participant explained how they discuss different options with patients to help them make treatment decisions:

> *...in some lung cancer patients where there are some poor prognostic factors, and even though they've got technically localized disease that could be curable, you might be a bit worried whether this patient can get through six weeks of umm daily treatment. So, sometimes, we do discuss more palliative options...You give the options; you discuss the harms and benefits of options...but I don't...use the EMR [electronic medical record] apart from the imaging information....I do use...e-prognosis calculators to calculate life expectancy, particularly in older persons.* [Participant P1 A C1]

The participants also discussed the idea of summarizing the consultation decisions:

> *...you know, I appreciate that we don't do it today, but you could imagine a summarized transcript of the consultation generated.* [Participant P7 C C3]

Subtheme 1.2: Current Technology Used in the Consultation

Some participants explained that they do not use digital technology extensively in their consultation workflows. Digital technology is only sometimes used to show patients their medical images or to show images of medications. Videos have been used, but the participants found them too slow. They currently do not have interactive digital tools, but the technology would be useful for discussing treatment options:

> *...in terms of the team talk, how do I use digital technology at this point...mostly show people images, ...I show a lot of scans and X-rays. I usually find the videos are a bit slow for the consultation,...the patients get bored.* [Participant P9 D C5]

Decision aids were discussed. Tools to help predict outcomes of cancer treatments are available on the web for physicians to calculate patients' life expectancy and survival rates. Participants described how they use the decision aids in practice:

> *...I use a predictive tool...I will plug the patient numbers in and print them out for the patient. ...we often use it before we see the patient...in medical oncology, there's one for adjuvant systemic therapy...*

> *" ...without adjuvant chemotherapy, this is your 5 or 10-year survival or recurrence, and with...it's..." they'll show the magnitude of benefit. Then, the patient can decide.* [Participant P1 A C1]

Information sharing was emphasized. Participants described how they provide patients with information about advocacy and treatment protocols and search the internet for basic information, such as images, models, or videos. They share the information they find with patients to educate them. These web-based resources are then used to explain treatment procedures and complex equipment operations, saving them time and effort. The patients are then expected to be able to access and review the same web-based information that they have been introduced to and recommended when at home:

> *...radiation therapy is a technology that most people don't know anything about, ...they get confused....the value of images, models, or video to actually just show what a radiation linear accelerator machine is...you don't have to draw a picture of it. You don't have to waste time taking somebody around to look at the machine...trusted website resources.* [Participant P5 B C2]

> *I found myself doing a lot of...very basic Google images search...the information can be so basic...I think we get lost in explaining things.* [Participant P3 B C1]

Theme 2: Barriers to Decision-Making

Two subthemes were identified under the barriers to decision-making theme. The first subtheme, "information, implementation, organizational challenges," focuses on the participants' perceived challenges regarding access to and the quality of information. The second subtheme, "current technology drawbacks and lack of system integration," deals with the participants' difficulties related to the limitations of the EHRs and the lack of information integration.

Subtheme 2.1: Information, Implementation, and Organizational Challenges

Participants pointed out challenges such as experiencing difficulties when communicating with patients from different cultures and non–English-speaking patients in communities. They also mentioned challenges with patients' lack of health literacy:

> *...meeting patients of non-English backgrounds and cultural and health literacy issues; uh, very significant, and that's very hard together in a very quick clinical environment.* [Participant P2 B C1]

The involvement of the family and interpreters was also raised as a challenging area due to the time needed to understand the needs and priorities of the individuals:

> *...family care as support, and...the interpreter as well, ...can be part of the communication process, which can either assist or umm or slow down dramatically the process...It's hard to think of a solution because it takes time to talk to people and find out what's important to them.* [Participant P5 B C2]

Gathering precise patient information during visits, as patients often forget details, was expressed as a difficulty. Participants noted the need to improve communication methods and understand each patient's needs:

> *There are even times when a patient has had a test done, and it's not until they're, literally, sitting in the clinic room before me, and I go, where did you have this done? Sometimes, I have to ask them three questions to clarify...Umm, it's a common assumption of the patients as well. "Don't you have this information?" And the answer is often no, I don't.* [Participant P6 B C2]

Verifying the accuracy of the information patients provide can be time-consuming, as one participant pointed out the following:

> *...patients come in...and say, oh yes, I had a scan. ...you spent 5 minutes searching all the providers...then you Google where they live and what radiology practice is in their town, and then you find out they did have a scan, but it was an MRI of their ankle. It wasn't actually their chest, but they don't remember.* [Participant P9 D C5]

Subtheme 2.2: Current Technology Drawbacks and Lack of System Integration

Manual processing of information and uploading data into the EHRs is problematic for physicians, especially under time pressure:

> *At the moment, when we upload imaging, it's not the actual images themselves,...to, just, get the image in, I take a screenshot and paste it into a document in the EMR, or I am literally, highlighting and copying the text from the report and pasting it in,...when you are time-pressured, that's just how you get it done.* [Participant P6 B C2]

Obtaining and merging data from various sources presents additional challenges to physicians. Especially the lack of integration among older information systems for data sharing was considered a drawback. This situation caused difficulties in accessing different systems for decision-making tasks:

> *...needing multiple passwords in multiple different information systems or not having access to all the patient results. ...unfortunately, most hospitals, including ours, rely so much on a technology called fax.* [Participant P2 B C1]

The participants said the systems could not provide integrated results even when patients had medical tests conducted in public hospitals:

> *There are already difficulties in accessing scans and results...done even in other public hospitals...patients have blood tests done by multiple providers. Imaging from multiple different providers.* [Participant P6 B C2]

Besides the lack of system integration, 1 participant pointed out that their hospital does not have full access to the facilities of EHRs:

> *I sit in a hospital that does not use an EMR or has a partial EMR. So, the medical notes don't go, for the most part into an EMR, it does in the oncology clinics, but that's not where I work anymore. So, we mostly write on paper in the private clinic. I use my own digital interface and I'm always zooming around to different portals, external radiology, different pathology providers, et cetera.* [Participant P9 D C5]

Poor wireless digital communication network connectivity was also mentioned as another drawback:

> *...it's again getting onto another website, potentially getting password...Terrible Wi-Fi in most cancer centers...I think that is a big barrier.* [Participant P5 B C2]

Theme 3: Leveraging New Technologies to Improve Decision-Making Processes

The theme "leveraging new technologies to improve decision-making processes" encompasses the following subthemes: (1) participants' interest in implementing potential improvements to advance the design of EHR systems; (2) making data more accessible and understandable by streamlining, centralizing, and communicating information for collaborative decision-making; and (3) helping to share evidence data and decisions with patients' care team members outside consultations, as well as analyzing patients' data using artificial intelligence (AI) and mobile technologies.

Subtheme 3.1: Potential Advancements in the Design of EHR Systems

Participants expressed their interest in improving the design of the EHRs. They highlighted the need for improved access to laboratory diagnostic test results and recommended automatically providing reliable medical information from different systems:

> *...if there was some magic like a digital resource that could do all of that detection for me and link me to multiple different providers and go to clinical labs...and pull it all in, I would love it...If it was as good as me, it would be transformative. But you'd have to really be sure and be able to trust it...and then...the reliability of information.* [Participant P9 D C5]

There is interest in decision-making tools to help patients make treatment decisions. Participants said they do not need additional electronic devices to replace what they already have. They want decision-making tools to help patients choose their preferred treatments according to their desires and goals, especially when treatment options are risky:

> *...some, sort of decision tool may help in those situations where radiotherapy is high risk or trying to help people decide about quality versus the longevity of life or some sort of tool where you...answer to some questions..."quality of life is more important to me or length of life is more important" ...it would be good to have a tool where you can...help guide the patients to...their priorities...and...help the decision-making...I don't want any extra devices. I'd do it on the computer and then, maybe, print it out for the patient rather than an iPad type stuff.* [Participant P1 A C1]

Subtheme 3.2: Streamlining and Centralizing Information for Decision-Making

Centralizing and systematically organizing medical information to make it more accessible and easier to interpret is important to some participants. These participants were interested and emphasized that providing the right information to the physician at the point of care would help:

> *...one thing I found very helpful is the centralization of information. ...things like scans, test results from clinics or centers outside of the...health system...something that aggregates that information into...something to sort of centralized or funnel information to us...having patient information presented in a way where...making things more centralized, it would be helpful to us.* [Participant P3 B C1]

Other participants stressed the importance of obtaining comprehensive patient information before the consultation:

> *...I guess what I'm talking about is more around interpreting patient results, which is almost...preempted to the whole three-talk process, really...is having the information available.* [Participant P5 B C2]

The introduction of a patient portal for sharing information with patients is seen as a benefit. This would enhance physicians' ability to maintain communication with patients outside of consultations as they consider treatment options:

> *...if there's a patient portal, they can log in and see things, that could be nice. ...if I could say to them... "I've put all these in...I've put in the options...when you go home, you can log into your patient portal..." I could even imagine they could post some questions.* [Participant P9 D C5]

Subtheme 3.3: Using AI and Mobile Technologies to Aid Decision-Making

The potential use of generative AI was discussed to streamline medical documentation and improve patient care. Participants suggested using basic AI to generate patient reports that can be shared with medical colleagues:

> *...information can be more easily extractable...we use very basic artificial intelligence in our practice where we can generate a patient report, for example, where we pull information from different parts of...and combine it with text that we put in the record and that then goes to the general practitioner. So, I can do a treatment summary on a radiotherapy patient in about a minute, and I only have to type a line or two, and yet, a complex report goes back to the general practitioner, and we do that in medical oncology as well.* [Participant P2 B C1]

However, one other participant disliked the idea of using AI for report writing:

> *Wouldn't use it. I write better than generative AI. I think the kind of language that generative AI produces is boring and opaque, and I'm better than that. So, I wouldn't do it yet.* [Participant P9 D C5]

Discussion

Key Findings

This research examined how health care professionals in Sydney use digital technology to support SDM during oncology consultations. It sought to understand the difficulties they encounter when using technology for SDM and explore potential developments of new technologies that could improve the implementation of SDM in clinical oncology settings. First, the findings of this study emphasize the critical need for oncologists to consolidate health information from patients with cancer to facilitate SDM in oncology consultations. The results also highlight a significant misalignment between the current operations of existing EHRs and the clinical practice workflow in oncology clinics to help clinicians follow the SDM process. Second, the study draws attention to the challenges of access to information due to outdated technologies and communication barriers due to language and the lack of knowledge of the patient about health. Nevertheless, the study participants were interested in developing new technologies that could streamline access to health information and automate administrative processes, thus supporting SDM and ultimately improving the delivery of cancer care.

Current Use of Technology to Support SDM in Oncology Consultations

The study participants stressed the importance of consolidating medical information to improve decision-making in oncology consultations. Studies in similar data-driven cancer care management reinforce these findings of the investigation [31]. Similar to other studies on cancer care, participants in this research study have emphasized the critical role that information and data play in driving SDM processes and improving health service outcomes [18]. As digital technologies transform the health care sector, cancer care is also being transformed [32].

Discussions between health care professionals during the study addressed the 3 key components of the SDM model: team talk, option talk, and decision talk [21]. The prototyped EHRs used to investigate the feasibility of supporting SDM with EHRs demonstrated that some components of the SDM model of care, such as option talk, could be implemented to match established oncology consultation practices and workflows where patients and oncologists usually discuss treatment options. However, the phase sequence of the SDM model did not fit fully into the typical consultation procedures or workflow patterns of the study participants. The health care professionals who participated in this study appreciated the SDM model but stated that, in their routine clinical practice, they frequently combined option and decision discussions. This means that EHRs must be flexible to support cancer care workflows to accommodate the iterative nature of the oncology decision-making process.

Study participants highlighted the importance of direct patient communication to foster relationships and ensure complete information collection before choosing treatments or health care options. Previous research in this area has also emphasized the importance of the relationship and communication between oncologists and patients beyond consultation visits in cancer care management [33]. Several study participants have pointed out that a key to the successful implementation of SDM is the integration of digital systems and EHRs, ensuring accessibility to digital information when needed at the correct point of care for the right patient. However, some participants have also stated that they do not use their digital systems or EHRs extensively to support patient discussions. They may use only part of the system to show diagnostic images to share information with the patient. Other participants use EHRs only to look up patient results or document consultations.

Future Use of Technology to Support SDM in Oncology Consultations

Cancer treatment is based on data, involves multiple disciplines, is a lifelong process, and is increasingly dependent on the smooth digital exchange of clinical information [34]. In this study, the participants identified several key obstacles to SDM in their clinical oncology settings related to access to information, implementation, organization, and limitations of current technology, specifically EHRs. In addition, the participants mentioned communication challenges due to language barriers, emotions, comprehension, low health literacy, participation of patients, difficulties in accessing and integrating patient data, lack of information that often leads to poor data quality and inefficient processes, time pressure, and lack of privacy. Similar barriers have been reported by Steenbergen et al [35]. The participants informed the research about the absence of integrated systems and their continued dependence on outdated technologies in their clinical settings, which hinders information exchange between cancer care facilities. Furthermore, during the investigation, some health care professionals who participated in the study described that their hospitals do not have comprehensive EHRs, leading to a greater dependence on paper records and personal digital interfaces. Researchers in Canadian health systems have also reported on clinician experiences with outdated, ineffective, or inefficient technologies that do not fit their clinical workflows [36]. Therefore, the implementation of better information and communication technologies could eliminate some technological barriers and improve the overall efficiency of cancer care provided by oncologists.

During the study, health care professionals said that they use the information from the EHRs to help in their decision-making process to treat cancer. They focused on integrating digital resources to improve efficiency and support patient care. However, integrating quality health data remains challenging due to the lack of guaranteed interoperability, even between EHRs from the same vendor, as reported in a previous study in the United States [37], although the requirement to improve interoperability among digital health systems was legislated in the United States in 2016 [38], and the Fast Healthcare Interoperability Resources specifications were approved by the Health Level 7 International in August 2019 [39]. In June 2024,

the Canadian government introduced Bill C-72, which requires health IT systems to be interoperable [40]. Therefore, the stated goal of the health care professionals, which is to be able to securely access all the health information of their patients in integrated EHRs, is expected to be achieved in Canada in the future [40]. Therefore, future EHRs in the North American health care systems, designed to make health care information more accessible and transparent to patients and the health care team [41], are expected to be available to provide oncologists with critical cancer care data needed to support the SDM process in oncology consultations.

Furthermore, the study participants were interested in the potential benefits of an integrated web-based portal driven by clinical information designed to simplify access to data from private laboratory tests and automate various clinical documentation processes, such as generating interclinician letters and managing patient diagnostic test results. Petrovskaya et al [42] performed an evaluation of web-based patient portals and emphasized the elements that the study participants seek to help improve patient participation in SDM. The researchers stated that the patient portal is connected to the EHRs of health organizations, providing patients with functionalities such as secure and convenient access to medication lists and the ability to arrange and verify appointment availability and communicate with their health care team securely through SMS text messaging, in addition to access to their laboratory test results [42]. However, in a recent patient portal implementation initiative, Grewal et al [43] found that there are technical challenges in enrolling patients to use the patient portal, but involving nurses in the patient education and enrollment process is a promising approach and reinforces the value of multidisciplinary methods in improving patient care.

During the study, the participants explored the concept of a patient web-based portal that can consolidate health information from multidisciplinary treatment journeys. They emphasized the need for sophistication and proper allocation of resources. The participants envision a web-based portal where patients can access information about care options, ask questions, and review details such as their therapeutic plans and preferences. They believe that this would lead to more streamlined communication, better decision-making, and automation that uses AI capabilities. They perceive that AI innovations could help reduce the double handling of information and miscommunication, as well as prevent patients from falling through the cracks in their care. However, trust in AI systems and the data provided emerged as a significant concern among some participants. In an article on digital transformation in cancer care, Papachristou et al [32] emphasized that ensuring the safety, accuracy, and ethical application of data-driven interventions requires building trust among health care professionals, patients, family members, caregivers, and other stakeholders. Nevertheless, integrating AI into the cancer management workflow has been shown to transform individual treatment planning by accurately predicting responses of patients with cancer to different therapies [44].

Efforts to improve EHRs for better cancer care management are ongoing around the world. Two international workshops focused on technology in cancer care management were held in 2019 and 2020 in Europe [31] and one in 2022 in the United States [38]. These workshops addressed SDM processes, data integration and management, analytics, EHRs, and AI-based clinical decision-making [31,38]. While significant progress has been made in implementing EHRs in public hospitals in Sydney for cancer care [15,45], the full potential of EHRs to consistently improve cancer care quality and patient outcomes has not yet been fully realized [38,45]. Similar to the challenges that the participants of this study encounter with poor EHR usability, lack of fitness with clinical workflows, fragmented data sources, and large amounts of data, researchers from other health care jurisdictions have also described similar experiences [31]. The participants suggested that in addition to using technologies, nurses and other health care professionals could also assist in patient engagement. These additional clinical resources have skills, such as patient education and effective communication, crucial to facilitating patient participation in SDM during clinical oncology consultations and can help improve patient outcomes [46]. The effectiveness of SDM is maximized when health care professionals have experience, strong relationships with patients, and sufficient time for treatment discussions [35]. As reported by Steenbergen et al [35], the exchange of knowledge and the efficient flow of health information between clinicians and patients are essential to facilitate SDM in oncology. Consequently, technological opportunities are tailored to support human interactions [31,38].

Barriers to the effective digitalization of information in oncology have been identified. However, continuous innovations and technological improvements have helped minimize the effects of several major barriers. Technological innovations such as Health Level 7 Fast Healthcare Interoperability Resources [47], the Minimal Common Oncology Data Elements [48], and the Systematized Nomenclature of Medicine–Clinical Terms [49] when combined with legislation, such as the Connected Care for Canadians Act in Canada, make better access to health information possible. Therefore, digital health data in oncology can be shared across health care organizations in a more standardized way that all stakeholders can understand.

Conversely, although AI technologies have been introduced in oncology over numerous decades, a persistent distrust exists toward the suggested technology. The level of trust in AI systems influences the acceptance of these technologies. Therefore, frameworks and guidelines have been suggested to tackle the issues related to the reliability of AI-powered health care systems, such as the FUTURE-AI framework, which defines 6 requirements for trustworthy AI [50]. Accepting AI systems in health care depends on ethical principles, trust dynamics, and rigorous evaluation processes [51].

Tools and protocols are available globally to support SDM in oncology consultations. For example, in the United States, tools include Watson for Oncology [52] and the Adjuvant! Platform [53]. In Australia, EVIQ chemotherapy protocols are available nationally [54,55]. In the United Kingdom, the PREDICT tool aids in breast cancer treatment decisions [56]. In Canada, standards for SDM tools have been developed and are often used as a reference by international researchers [57-59]. Despite multiple trials, the integration of these tools and protocols into practice remains nonroutine, and several programs, such as IBM

Watson for Oncology, have failed to meet expectations [60]. These examples illustrate the ongoing challenges.

In summary, various oncology specialists and health care professionals perceive the usefulness of technology in supporting SDM in oncology consultations differently. A senior medical oncologist preferred face-to-face conversations with patients. In contrast, an anesthetic registrar preferred a high level of computerization and welcomed the possibilities of driving health care delivery with data. Other specialists, especially radiation oncologists, did not see the need to use technology extensively when helping patients make treatment decisions, as their oncology specialization typically involves only one treatment modality. However, they do want technology to accurately and promptly share information provided by other health care professionals. However, young health care professionals are ready to adopt more digitalized medical practices. Most health care professionals recognized the value of technology in supporting access to information for consumers, thereby facilitating informed decision-making.

Limitations and Future Research

The first limitation of the study was that only 9 health care professionals were available to participate in the co-design sessions. The second limitation was that no surgeon was identified to potentially participate in the co-design sessions. It is difficult for practicing physicians to allocate time for research projects and to attend co-design sessions when they are already working overtime and long hours providing patient care. Therefore, physicians who participated in the study may not have fully represented the larger oncology practice community. Only their views and practices on SDM were collected. The third limitation was that oncology consultation involves patients, other oncology specialists, and other health care providers. However, they were not invited to participate in this study due to time constraints. Patients and other health care providers may have provided different perspectives on their experience with SDM and the use of digital technology.

A larger group of oncology specialists, including surgeons, would have represented the larger oncology community and provided more generalized views. Furthermore, patients who have had oncological consultations would have provided their views on decision-making processes, particularly SDM. To mitigate the limitations of this study and obtain more generalizable results, our approach should be replicated in future studies with a larger and more diverse group of cancer health care professionals. This diversity would include many specialty dimensions, including surgeons and other health systems specialists. Furthermore, similar future studies should include patients who have experienced oncology consultations.

Conclusions

The findings of this study indicate that digital health technologies can assist in SDM in oncology consultations. This includes providing concise and consolidated information to support decision-making, tools such as multimedia resources to support patient understanding of cancer and treatments, and patient access to information and data outside of the consultation through tools such as patient portals. Emerging technologies, such as generative AI, may assist SDM by consolidating and personalizing information.

Nevertheless, care needs to be taken to ensure that technology does not erode the development of rapport and trust between a clinician and patient. Although EHRs and other systems are continually improving, there are substantial barriers to realizing the potential of technology to improve SDM, including the lack of data integration between systems and integration of new tools and resources into clinical workflows. However, continuous technological innovations and government efforts through new legislations are eliminating some of the digital system integration and data interoperability difficulties.

In conclusion, the study shows that digital technology can facilitate the exchange of information between independent health care organizations and individual health care providers, thus increasing the efficiency of oncology consultation workflows. However, technology is only part of the support needed for the complex human communication process in oncology. Oncology consultation services need support from a multidisciplinary cancer team, which includes other health care professionals and the patient's family. Health care professionals, such as nurses, must educate and prepare patients for consultations. Allied health professionals are often needed to help with language difficulties. Only through an ecosystem that is fully integrated, interoperable, and seamlessly fits in with the human and social interactions of numerous stakeholders involved in the care of a patient with cancer can the goals of the person-centered model of care be achieved through the implementation of SDM in cancer care.

Abstract

Background: Health care system–wide outcomes from routine treatment with erlotinib and gefitinib are incompletely understood.

Objective: The aim of the study is to describe the effectiveness of erlotinib and gefitinib during the first decade of their routine use for treating advanced epidermal growth factor receptor (*EGFR*) mutation-positive nonsquamous non–small cell lung cancer in the entire cohort of patients treated in Aotearoa New Zealand.

Methods: Patients were identified, and data collated from national pharmaceutical dispensing, cancer registration, and mortality registration electronic databases by deterministic data linkage using National Health Index numbers. Time-to-treatment discontinuation and overall survival were measured from the date of first dispensing of erlotinib or gefitinib and analyzed by Kaplan-Meier curves. Associations of treatment outcomes with baseline factors were evaluated using univariable and multivariable Cox regressions.

Results: Overall, 752 patients were included who started treatment with erlotinib (n=418) or gefitinib (n=334) before October 2020. Median time-to-treatment discontinuation was 11.6 (95% CI 10.8 - 12.4) months, and median overall survival was 20.1 (95% CI 18.1 - 21.6) months. Shorter time-to-treatment discontinuation was independently associated with high socioeconomic deprivation (hazard ratio [HR] 1.3, 95% CI 1.1 - 1.5 compared to the New Zealand Index of Deprivation 1 - 4 group), *EGFR* L858R mutations (HR 1.3, 95% CI 1.1 - 1.6 compared to exon 19 deletion), and distant disease at cancer diagnosis (HR 1.4, 95%

CI 1.2 - 1.7 compared to localized or regional disease). The same factors were independently associated with shorter overall survival. Outcome estimates and predictors remained unchanged in sensitivity analyses.

Conclusions: Outcomes from routine treatment with erlotinib and gefitinib in New Zealand patients with advanced *EGFR*-mutant nonsquamous non–small cell lung cancer are comparable with those reported in randomized trials and other health care system–wide retrospective cohort studies. Socioeconomic status, *EGFR* mutation subtype, and disease extent at cancer diagnosis were independent predictors of treatment outcomes in that setting.

KEYWORDS

non–small cell lung cancer; mutations; epidemiology; target therapy; retrospective cohort study

Introduction

Lung cancer is the most common cause of cancer death in the world today [1]. Most clinical presentations of lung cancer are nonsquamous non–small cell lung cancer (NSCLC) [2]. Epidermal growth factor receptor (*EGFR*)–mutant nonsquamous NSCLC was the first type of lung cancer identified with an oncogenic driver that could be directly targeted by drug treatment [3-5].

The treatment of advanced *EGFR*-mutant nonsquamous NSCLC has evolved rapidly following the results of randomized controlled trials demonstrating improved progression-free survival. Initial randomized controlled trials established the superiority of first-generation *EGFR* kinase inhibitors, erlotinib and gefitinib, over platinum-doublet chemotherapy [6-10]. Subsequent randomized controlled trials established the superiority of second- and third-generation *EGFR* kinase inhibitors, including afatinib, dacomitinib, osimertinib, aumolertinib, and lazertinib, over those first-generation inhibitors [11-15]. Other randomized controlled trials compared erlotinib or gefitinib given alone or in combination with bevacizumab, ramucirumab, or chemotherapy [16-20]. In the 15 aforementioned randomized controlled trials, a total of 2257 patients with advanced *EGFR*-mutant nonsquamous NSCLC were allocated erlotinib or gefitinib monotherapy in control or experimental treatment arms. In those erlotinib or gefitinib monotherapy treatment arms, median progression-free survival ranged from 8.0 to 13.3 months. These clinical trial data provide a point of reference against which real-world studies of outcomes from treatment with erlotinib or gefitinib can be compared.

To fully understand outcomes from treatment with erlotinib and gefitinib in the setting of routine care, large-scale observational studies are required in addition to the extensive data already available from randomized controlled trials. Randomized controlled trials may have overestimated the benefits [21], and underestimated the harms [22], associated with the routine use of erlotinib and gefitinib. Compared to participants in randomized controlled trials, patients presenting for routine treatment with erlotinib or gefitinib are older, are of non-Asian ethnicity, have more comorbidities, have poorer performance status, and more often have brain metastasis. Randomized controlled trials have not evaluated many factors potentially impacting treatment outcomes, such as socioeconomic status. To improve their generalizability and avoid bias, observational studies of real-world outcomes from treatment with erlotinib and gefitinib could include all patients treated within a whole health care system or nation rather than being limited to those from 1 or a few institutions. To aid comparisons to clinical trial data, those observational studies could evaluate progression-free survival or proxies of progression-free survival rather than just overall survival, which is strongly influenced by factors other than treatment with erlotinib or gefitinib.

Only since 2019 have large-scale nationwide or health care system–wide studies reported real-world outcomes from routine treatment with erlotinib and gefitinib in patients with advanced *EGFR*-mutant NSCLC from Canada [23], the United States [24], Taiwan [25,26], Poland [27], Finland [28], and the Netherlands [29,30]. Among those aforementioned studies, 5 studies [24-28] reported progression-free survival or proxies of progression-free survival, such as time-to-treatment failure. In those 5 studies, median progression-free survival or its proxy ranged from 9.7 to 13.1 months. These observational data provide a point of reference against which other real-world studies of outcomes from treatment with erlotinib or gefitinib can be compared.

Starting in 2010, erlotinib and gefitinib were introduced into routine use in Aotearoa New Zealand for treating advanced lung cancer. The overall *EGFR* mutation positivity among patients with nonsquamous NSCLC who were tested was 22.5% in New Zealand [31]. To date, the effectiveness of erlotinib and gefitinib in the general population of New Zealand patients with lung cancer has not been described. With this background, this study aimed to describe the effectiveness of erlotinib and gefitinib during the first decade of their routine use for the treatment of advanced *EGFR*-mutant nonsquamous NSCLC in the entire cohort of patients treated in New Zealand. The study also aimed to evaluate associations between baseline factors and the effectiveness of erlotinib and gefitinib in this real-world setting.

Methods

Study Design and Participants

This was a nationwide, population-based, observational, data-linkage, retrospective cohort study that analyzed routinely collected health and administrative electronic data. The study group was a whole-of-population sample comprising a single group of patients. Patients were eligible for inclusion if they (1) were diagnosed with *EGFR*-mutant lung cancer, (2) dispensed erlotinib or gefitinib first before October 1, 2020, and (3) followed thereafter until death or for at least 1 year. Patients were excluded from the study if they had (1) erlotinib dispensed before January 1, 2014, or gefitinib dispensed before August 1, 2012, when positive *EGFR* mutation test results became mandatory for state-subsidized treatment; (2) no notification of a diagnosis of nonsquamous NSCLC in the New Zealand Cancer Registry; or (3) an unactionable or unknown *EGFR* mutation subtype.

Setting

From 2010 to 2020, New Zealand had a resident population ranging from approximately 4.3 to 5.1 million people, comprising predominately New Zealand European (70%), Māori (17%), Asian (15%), and Pacific people (8%) [32] (the total percent is greater than 100 because some people have more than 1 self-reported ethnicity). New Zealand residents were eligible for state-funded health care, including state-subsidized prescription medicines. Starting in 2010, the *EGFR* kinase inhibitor drugs erlotinib and gefitinib were introduced into routine clinical use in New Zealand for lung cancer treatment [33]. From October 1, 2010, to December 31, 2013, erlotinib was state-funded as a second-line treatment for advanced NSCLC, initially without any requirement for *EGFR* mutation testing. From August 1, 2012, gefitinib was state-funded as a first-line treatment for advanced *EGFR*-mutant NSCLC in New Zealand. On May 1, 2013, the National Health Committee of the New Zealand Ministry of Health issued recommendations for *EGFR* mutation testing in New Zealand, including testing of all patients with nonsquamous NSCLC at diagnosis irrespective of stage as part of standard pathology processes. From January 1, 2014, state funding for erlotinib was restricted to treating advanced *EGFR*-mutant NSCLC in New Zealand. During the first decade of routine use of erlotinib and gefitinib for lung cancer treatment in New Zealand, from 2010 to 2020, no other *EGFR* kinase inhibitor drugs were state-funded for use in New Zealand. During the period of study, treatment with erlotinib or gefitinib was provided by 10 public hospitals, and *EGFR* mutation testing was provided by 3 pathology laboratories in New Zealand.

Ethical Considerations

Ethics approval for this study was obtained from the New Zealand Government Ministry of Health Northern B Health and Disability Ethics Committee (reference 13/NTB/165/AM02). As the research retrospectively analyzed routinely collected data and did not involve direct contact with patients, the participants were not able or required to give informed consent by the ethics committee or governance groups who approved the study. The study used the identifiable data, which were password-protected, stored on the secured University of Auckland managed drive, and only accessible to the research team. The study was registered (ACTRN12615000998549). A study protocol and results of a validation substudy have been published [34].

Data Sources

Patients were identified, and data collated from national electronic pharmaceutical dispensing (Pharmaceutical Information Database [PHARMs]), cancer registration (New Zealand Cancer Registry), and mortality registration (National Mortality Collection) databases. Individual-level data on eligible cohort patients were compiled from these national electronic health databases by deterministic data linkage using each patient's unique National Health Index number. Additional data on eligible cohort patients were sourced from regional laboratory test data repositories, databases, and clinical records to determine the *EGFR* mutation status. A validation substudy demonstrated the feasibility and validity of using these national electronic health databases as the main source of data for this study [34].

Outcomes

The primary effectiveness outcome for this analysis was time-to-treatment discontinuation. Prescribing guidelines [35,36] recommend continuing daily treatment with erlotinib or gefitinib until disease progression, as long as treatment is safe and tolerable. In an analysis of randomized clinical trials submitted to the Food and Drug Administration, time-to-treatment discontinuation correlated well (r=0.91) with progression-free survival for patients with advanced *EGFR*-mutant NSCLC treated with *EGFR* kinase inhibitor drugs [37]. Time-to-treatment discontinuation is also less affected by subsequent cancer treatments and other factors that impact overall survival. Time-to-treatment discontinuation thereby reflects the duration of benefit from treatment with erlotinib or gefitinib. Time-to-treatment discontinuation was defined as the duration between the dates of the first dispensing and the last treatment with erlotinib or gefitinib. The date of last treatment with erlotinib or gefitinib was calculated by adding the number of days erlotinib or gefitinib dispensed for at the last dispensing to the date of the last dispensing, except when death occurred before the calculated date of last treatment, in which case the date of last treatment was the date of death. The secondary effectiveness outcome for this analysis was overall survival, defined as the duration between the date of first dispensing of erlotinib or gefitinib and death from any cause. A validation substudy had demonstrated the feasibility and validity of these methodologies for determining the outcomes of this study [34].

Variables

Baseline variables used for patient characterization included age, sex, ethnicity, geographical region of residence, smoking status, performance status, diagnosis year, NSCLC morphology, basis of NSCLC diagnosis, disease extent at cancer diagnosis, socioeconomic deprivation, rurality, comorbidity, choice of erlotinib or gefitinib for initial treatment, and *EGFR* mutation subtype. Socioeconomic deprivation was determined by mapping domicile codes recorded in the New Zealand Cancer Registry

to the 2006 New Zealand Index of Deprivation and was categorized into deciles with 1 being the least deprived and 10 being the most deprived [38]. Rurality was determined using the same domicile codes applied to Statistics New Zealand's Urban/Rural profile [39]. Comorbidity was assessed using a validated pharmacy-based comorbidity index for patients with cancer [40], modified for this study as previously described [34]. Ethnicity was classified into Asian, Māori, New Zealand European, or Pacific, and prioritized ethnicity was used if a registration listed multiple ethnicities (patients with more than 1 recorded ethnicity were allocated to a single ethnic group in order of priority: Māori, Pacific, Asian, and New Zealand European) [41]. *EGFR* mutation variants were classified according to the system of Koopman et al [42] into the following categories: (1) exon 19 deletion, (2) L858R, (3) uncommon actionable variant, (4) exon 20 insertion, and (5) nonactionable or unknown variant. Since *EGFR* mutation variant categories (4) and (5) were unactionable with erlotinib or gefitinib, patients with those variants were excluded from this study. A validation substudy had demonstrated the feasibility and validity of the methodologies used for determining the variables used for this study [34].

Literature Search

For comparing the results from this study to those from randomized controlled trials and other retrospective observational studies, a literature search was undertaken using a combination of the following MeSH terms: "carcinoma, non-small-cell lung," "ErbB receptors," "erlotinib hydrochloride," "gefitinib," "protein kinase inhibitors," and "mutation." Observational studies were included in this comparison if they were nationwide or health care system–wide studies and reported progression-free survival, or a proxy of progression-free survival, measured from the commencement of treatment with erlotinib or gefitinib [24-28]. Institution-based studies [43] and those not reporting progression-free survival or a proxy of progression-free survival [23,29,30] were excluded from these comparisons.

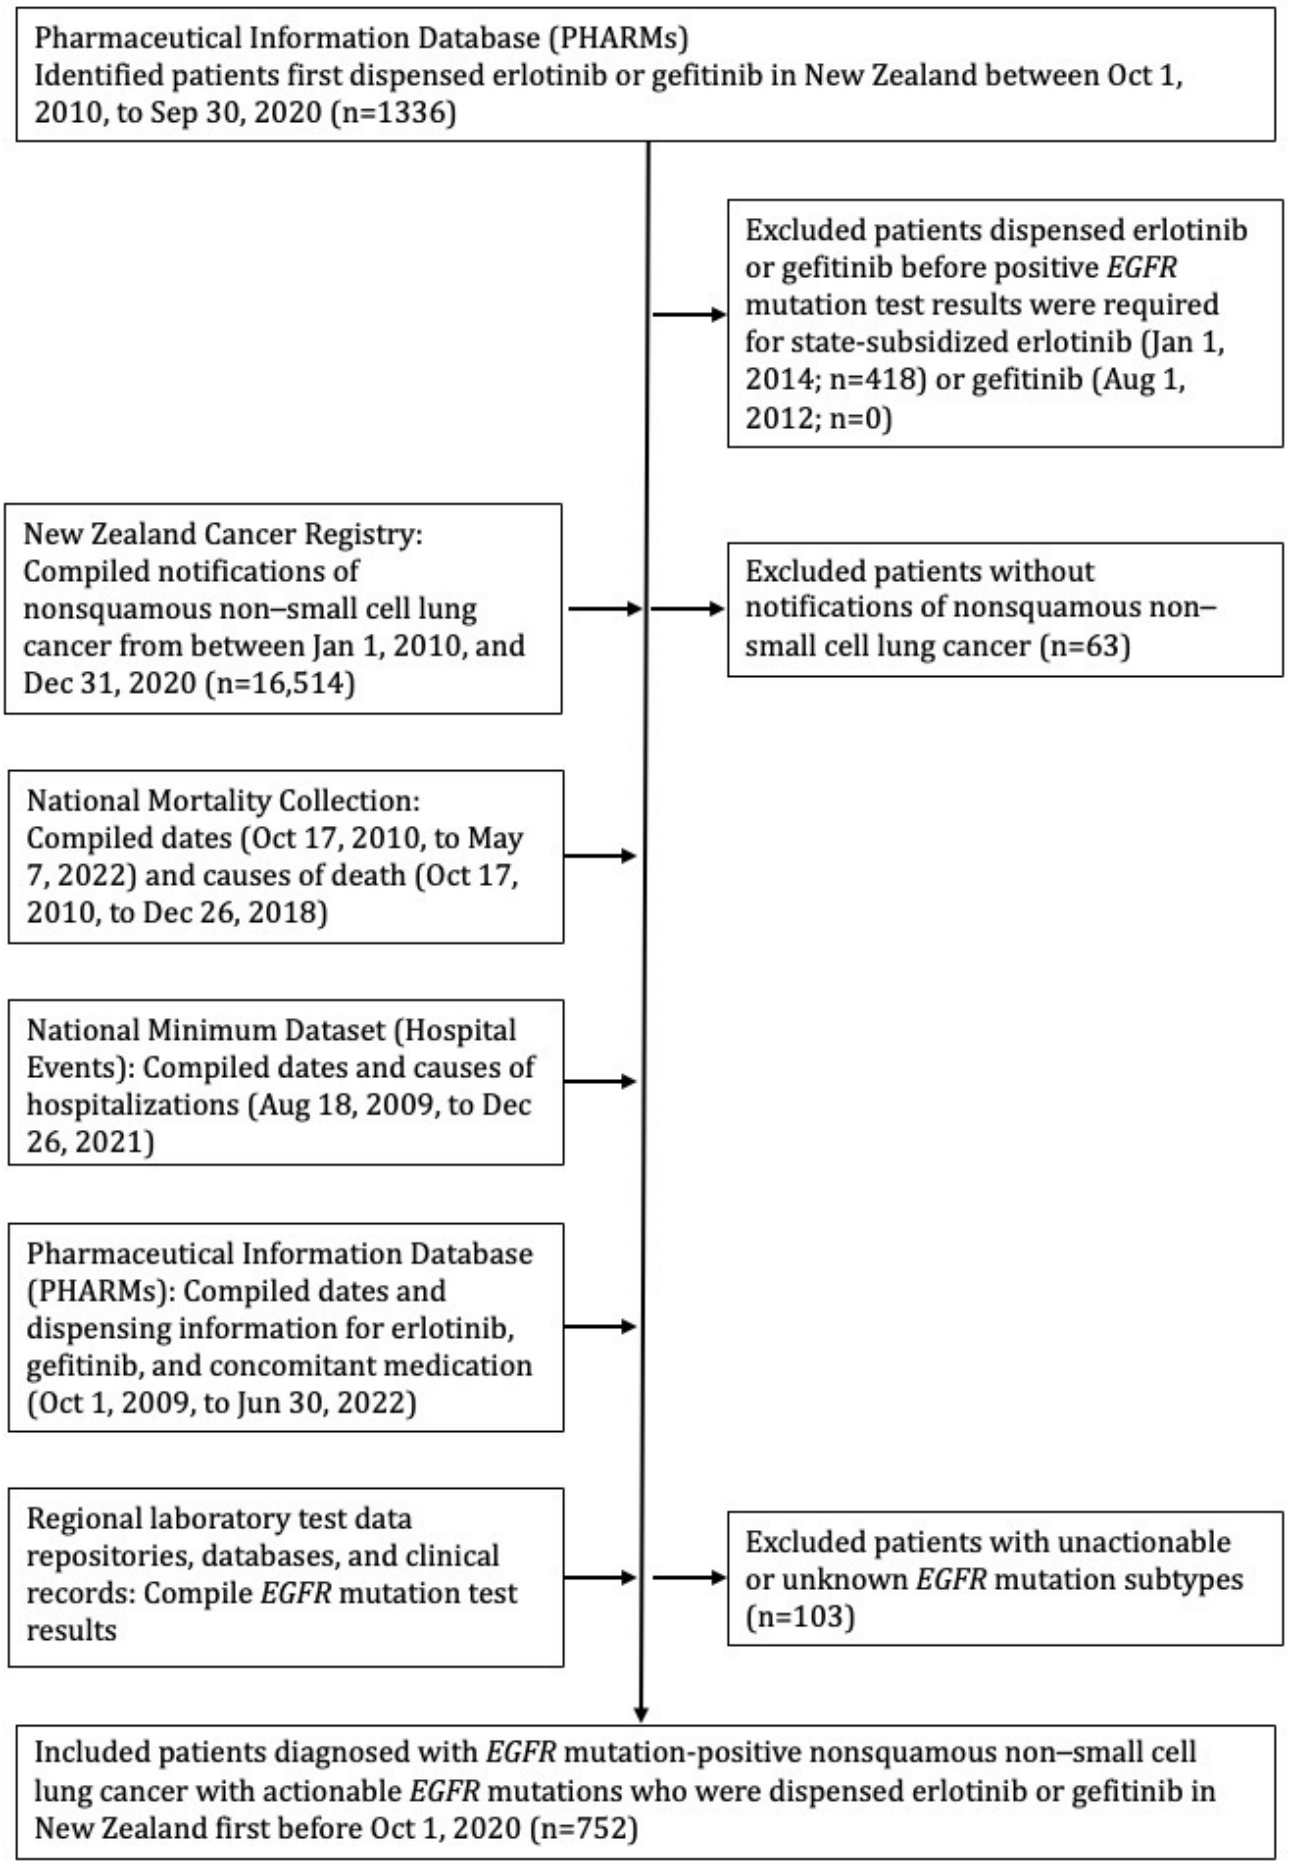
Statistical Analysis

Descriptive statistics were used to analyze the demographic profile and baseline characteristics of the retrospective cohort. Time-to-treatment discontinuation and overall survival were analyzed by Kaplan-Meier curves, and survival differences between subgroups were assessed using log-rank tests. Patients with no known dates of last treatment or death were censored at the date of last follow-up of dispensing (June 30, 2022) or survival (May 7, 2022), respectively. To assess the robustness of estimates of time-to-treatment discontinuation and overall survival, sensitivity analyses were carried out in an expanded study cohort (n=885) that included patients with no registration of nonsquamous NSCLC and those with unknown or nonactionable *EGFR* mutation subtypes, except those with exon 20 insertions. Associations between baseline factors and time-to-treatment discontinuation or overall survival were evaluated by univariable and multivariable Cox regression models to compute hazard ratios and their 95% CIs and *P* values. Baseline factors selected for univariable and multivariable analyses included age, sex, disease morphology, disease extent, *EGFR* mutation subtype, and initial choice of *EGFR* kinase inhibitor drug, which had been identified as independent predictors of outcomes in previous studies [44,45], and ethnicity, comorbidity, socioeconomic deprivation, and residential status (urban vs or rural, and region), which had not been previously evaluated in the New Zealand patient population. There were complete data for all those factors for all 752 cohort patients. Smoking and Eastern Cooperative Oncology Group performance status were excluded from the univariable and multivariable analyses due to high levels of missing data (>50%). Missing extent of disease at cancer diagnosis and ethnicity data were included in univariable and multivariable analyses by adding an unknown category for each of these variables comprising <20% and <1% of patients, respectively. Otherwise, data were complete for all other factors for all 752 patients. Factors were selected for multivariable analyses if they had statistically significant associations with the outcome of interest on univariable analysis. To assess the robustness of the findings of multivariable analyses, sensitivity analyses were carried out using less stringent criteria for factor inclusion. Differences were considered statistically significant when *P* values were less than .05. Data analyses were performed using Stata (version 16; StataCorp LLC).

Results

The assembly of the retrospective cohort and compilation of study data from national electronic health databases was carried out as shown in Figure 1. From the PHARMs, 1336 patients were identified who had been dispensed erlotinib or gefitinib first between October 1, 2010, and September 30, 2020. A total of 418 of those patients were excluded because they were first dispensed erlotinib or gefitinib before positive *EGFR* mutation test results became mandatory for access to state-subsidized erlotinib or gefitinib in New Zealand, leaving 918 potentially eligible patients. From the New Zealand Cancer Registry, 16,516 patients were identified with notifications of nonsquamous NSCLC diagnoses made between January 1, 2010, and December 30, 2020. Of the 918 potentially eligible patients, 63 did not have notifications of diagnoses of nonsquamous NSCLC recorded in the New Zealand Cancer Registry and were excluded, leaving 855 potentially eligible patients. Dates and causes of death and hospitalizations and full dispensing information for erlotinib, gefitinib, and concomitant medications were compiled on those patients from the National Mortality Collection, National Minimum Dataset (Hospital Events), and PHARMs, respectively. *EGFR* mutation test results, smoking status, and Eastern Cooperative Oncology Group performance status were then compiled from regional laboratory test data repositories, databases, and clinical records. Of 855 potentially eligible patients, 103 patients had unactionable or unknown *EGFR* mutation variants, including 33 patients with *EGFR* exon 20 insertions, and were excluded. Finally, 752 patients remained, who had been diagnosed with *EGFR*-mutant nonsquamous NSCLC with actionable *EGFR* mutation variants, and had started treatment with erlotinib or gefitinib prior to October 2020 for inclusion in this study.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of the assembly of the cohort and data collation. *EGFR*: epidermal growth factor receptor.



The baseline characteristics of the retrospective 752 patient cohorts are shown in Table 1. Their mean age was 67 (SD 12) years, and 67% (n=504) were female. About one-quarter were Asian, half New Zealand European, one-quarter Pacific or Māori, and 1.1% (n=8) had other or unknown ethnicity. Most had adenocarcinoma and *EGFR* exon 19 deletions or L858R mutations. The extent of disease at cancer diagnosis was available for only 604 (80.3%) patients, most of whom had distant disease at cancer diagnosis. Smoking status was available for only 301 (40.1%) patients, most of whom were nonsmokers. Performance status was available for only 273 (36.6%) patients, most of whom had limited performance status.

[e]TKI: tyrosine kinase inhibitor.

At the date of the last dispensing follow-up (June 30, 2022), treatment with erlotinib and gefitinib had been discontinued in 724 (96.3%) patients and was continuing in 28 (3.7%) patients. Treatment was discontinued prior to death in 618 patients and at the time of death in 103 patients. Median time-to-treatment discontinuation was 11.6 (95% CI 10.8-12.4) months. The 1-, 2-, and 5-year rates of treatment continuation were 47.3% (95% CI 34.7%-50.9%), 17.4% (95% CI 14%-20.2%), and 3.4% (95% CI 2.2%-5.1%), respectively. Sensitivity analysis in an expanded study cohort (n=885) gave similar results for median time-to-treatment discontinuation (11.1, 95% CI 10.1-11.8 months). Univariable analysis (Table 2) showed that shorter time-to-treatment discontinuation was associated with socioeconomic deprivation, *EGFR* L858R mutations, distant disease at cancer diagnosis, and adenocarcinoma morphology. The initial choice of *EGFR* kinase inhibitor (erlotinib or gefitinib), age, sex, ethnicity, geographical region, year of diagnosis, basis of diagnosis, rurality, and comorbidity were not associated with time-to-treatment discontinuation on univariable analysis. Multivariable analysis showed that shorter time-to-treatment discontinuation was independently associated with socioeconomic deprivation, *EGFR* L858R mutations, and distant disease at cancer diagnosis (Table 2). Sensitivity analyses using less stringent criteria for factor inclusion identified the same independent predictors of time-to-treatment discontinuation (Table S3 in Multimedia Appendix 1).

Table . Univariable and multivariable analysis of time-to-treatment discontinuation.

At the date of last survival follow-up (May 7, 2022), 614 (81.6%) patients had died, and 138 (18.4%) patients were alive. Median overall survival was 20.1 (95% CI 18.1-21.6) months. The 1-, 2-, and 5-year overall survival rates were 69.2% (95% CI 65.8%-72.4%), 43% (95% CI 37.4%-43.5%), and 13.9% (95% CI 11.2%-17%), respectively. Sensitivity analysis in an expanded study cohort (n=885) gave similar results for median overall survival (19.4, 95% CI 17.8-21.2 months). Univariable analysis (Table 3) showed shorter overall survival in association with socioeconomic deprivation, *EGFR* L858R mutations, distant disease at cancer diagnosis, initial choice of *EGFR* kinase inhibitor of gefitinib (vsversus erlotinib), age >65 years, non-Asian ethnicity, residence outside the Northern or Midlands regions, and adenocarcinoma morphology. Sex, diagnosis year, basis of diagnosis, rurality, and comorbidity were not associated with overall survival on univariable analysis. Multivariable analysis showed that shorter overall survival was independently associated with socioeconomic deprivation, *EGFR* L858R mutations, distant disease at cancer diagnosis, and non-Asian or non-Pacific ethnicities (Table 3). Sensitivity analyses using less stringent criteria for factor inclusion identified the same independent predictors of overall survival (Table S4 in Multimedia Appendix 1).

For the purpose of comparison of the results from this study to the existing literature, our literature search identified 15 randomized controlled trials and 5 nationwide or health care system–wide retrospective observational studies. These randomized controlled trials showed that the median progression-free survival for erlotinib and gefitinib monotherapy treatment arms ranged from 8.0 to 13.3 months (Table S1 in Multimedia Appendix 1). The retrospective observational studies showed that the median progression-free survival, or its proxy, ranged from 9.7 to 13.1 months, and the median overall survival ranged from 17.5 to 23.9 months (Table S2 in Multimedia Appendix 1). Our study reports the results following the RECORD (Reporting of Studies Conducted Using Observational Routinely-Collected Health Data) statement checklist (Table S5 in Multimedia Appendix 1).

Discussion

Principal Findings and Comparison to Prior Work

The outcomes from treatment with erlotinib and gefitinib in this study of 752 patients with advanced *EGFR*-mutant nonsquamous NSCLC, treated between 2010 and 2020 in New Zealand, corresponded with those reported in randomized controlled trials and in other large-scale health care system–wide retrospective cohort analyses. The median time-to-treatment discontinuation of 11.6 months found in this study paralleled the median progression-free survival values reported for erlotinib and gefitinib monotherapy treatment arms of 15 randomized controlled trials [6-20], which ranged from 8.0 to 13.3 months (Table S1 in Multimedia Appendix 1). It also paralleled the median progression-free survival values, or its proxy, reported in other nationwide or health care system–wide observational studies of similar patient groups from elsewhere [24-28] (range of median progression-free survival or proxy 9.7 to 13.1 months; Table S2 in Multimedia Appendix 1). The median overall survival of 20.1 months found in this study was also within the range reported in other nationwide or health care system–wide observational studies of similar patient groups [24-28] (range of median overall survival 17.5 to 23.9 months; Table S2 in Multimedia Appendix 1). In this way, this retrospective study has confirmed that the therapeutic benefits expected from erlotinib and gefitinib had been conveyed into the setting of routine care in New Zealand.

EGFR mutation subtype was an independent predictor of outcomes from treatment with erlotinib and gefitinib in this study. Study patients were stratified according to whether their tumors had exon 19 deletions (56%), L858R mutations (34%), or other actionable *EGFR* mutations (10%). Compared to those with exon 19 deletions, study patients with L858R mutations had 30% and 50% increased risks of treatment discontinuation and death, respectively, after commencing treatment with erlotinib or gefitinib. This finding is consistent with those of previous studies exploring outcomes from erlotinib or gefitinib in similar patient groups [45]. *EGFR* mutation subtype may have impacted upon treatment outcomes in this study via the higher pharmacological potency of erlotinib and gefitinib for inhibiting exon 19 deletion *EGFR* oncoproteins compared to those associated with L858R or other *EGFR* mutations [46,47].

Socioeconomic deprivation was an independent predictor of outcomes from treatment with erlotinib and gefitinib in this study. Study patients were stratified into groups with low (41%), intermediate (29%), or high socioeconomic deprivation (30%) based on their residential area. Compared to the study patients from high socioeconomic areas, those from low socioeconomic areas had 30% and 50%, and those from intermediate socioeconomic areas had 20% and 30%, increased risks of treatment discontinuation and death, respectively, after commencing treatment with erlotinib or gefitinib. People from low socioeconomic areas are known to have poorer outcomes from lung cancer due to more limited access to screening and diagnostic services that lead to delayed diagnoses and more advanced disease at presentation [48]. However, few previous studies have evaluated the impacts of socioeconomic deprivation on outcomes from treatment with erlotinib, gefitinib, or other systemic anticancer therapies in patients with *EGFR*-mutant or

other forms of advanced lung cancer. A pooled analysis of SWOG Cancer Research Network clinical trials showed significant associations between socioeconomic deprivation and lower progression-free survival, including in a subgroup of 1307 patients with stage IV NSCLC treated with various platinum-based chemotherapy regimens in randomized clinical trials [49]. Socioeconomic deprivation may have impacted treatment outcomes in this study by limiting access to health care during treatment with erlotinib and gefitinib, directly via other yet to be defined mechanisms or indirectly through correlated predictive factors not accounted for in the multivariable analyses, such as smoking and performance status. Future studies should more closely evaluate the impacts of socioeconomic deprivation on outcomes from the treatment of advanced lung cancer.

Disease extent at cancer diagnosis was an independent predictor of outcomes of treatment with erlotinib and gefitinib in this study. Study patients were stratified according to whether they had localized or regional (18%), distant (62%), or unknown extent of disease (20%) at the time of notification of their diagnosis of nonsquamous NSCLC to the New Zealand Cancer Registry. Compared to those with localized or regional disease extent, study patients with distant disease at diagnosis had 40% and 80% increased risks of treatment discontinuation and death, respectively, after commencing treatment with erlotinib or gefitinib. This finding was consistent with previous studies demonstrating the negative impacts of distant metastasis on outcomes from treatment with erlotinib and gefitinib in similar patient groups [44].

Ethnicity was an independent predictor of overall survival, but not of time-to-treatment discontinuation, in this study. Study patients were categorized as Asian (25%), Māori (10%), New Zealand European (52%), Pacific (12%), or unknown or other ethnicity (1%). Time-to-treatment discontinuation was unchanged among these different ethnic groups when compared to New Zealand European group. However, the risk of death was reduced by 20% and 30%, respectively, in the Pacific and Asian groups but unchanged in the other groups compared to New Zealand European. Overall survival may have been impacted by ethnicity in this study independently of the effectiveness of treatment with erlotinib or gefitinib. Ethnicity may have impacted overall survival indirectly through correlated factors, such as smoking status, that vary between ethnic groups and influence the risk of death [50].

Strengths and Limitations

The strengths of this study include its large population-based sample, internal validity, national generalizability, and unique patient cohort. Only 4 similar analyses [25-28] have included all patients treated in an entire country as far as we are aware. Limitations of the study include those inherent in retrospective study designs or in the use of routinely collected data. The variables available for analysis were limited to those collected routinely during pharmaceutical dispensing and cancer and mortality registration. Some important variables were unavailable or incomplete, such as smoking status, performance status, and clinical stage of disease at the time of commencing treatment with erlotinib and gefitinib, and therefore could not be included in the multivariable analysis. Socioeconomic deprivation was determined by residential area rather than at an individual level, which may have introduced bias. The study did not evaluate the impact of treatments other than erlotinib and gefitinib, which may have influenced overall survival. Safety outcomes were not included in this analysis but will be the subject of subsequent reports.

Conclusions

Outcomes from treatment with erlotinib and gefitinib in this New Zealand cohort of patients with advanced *EGFR*-mutant nonsquamous NSCLC were comparable to those reported in randomized controlled trials and other large-scale health care system–wide retrospective cohort studies. This nationwide study thereby demonstrated that the therapeutic benefits expected from erlotinib and gefitinib had been achieved in the setting of routine care in New Zealand. In that setting, socioeconomic status, *EGFR* mutation subtype, and disease extent at cancer diagnosis were independent predictors of treatment outcomes.

Acknowledgments

The authors thank the patients and their families for contributing to this study. This study has been funded by the Health Research Council of New Zealand project (grant 19-450).

Data Availability

The datasets generated and analyzed during this study are not publicly available due to patient information being identifiable but are available from the corresponding author on reasonable request. For ethics queries, please contact the Health and Disability Ethics Committees at hdecs@health.govt.nz.

Authors' Contributions

PSA, JB, GL, LC, MA, BL, SD, DH, STT, ME, PH, and MJM were involved in conceptualization and funding acquisition. PSA and MJM were involved in validation, writing original draft, and visualization. GL, LC, ME, BL, SD, DH, BM, EB, JW, RL, MA, and MJM were involved in data curation and supervision. JB, GL, and PH were involved in supervision. PSA, STT, and ME were involved in formal analysis and methodology. All authors reviewed and edited the manuscript.

Abstract

Background: Colorectal cancer is now the leading cause of cancer-related deaths among young Americans. Accurate early prediction and a thorough understanding of the risk factors for early-onset colorectal cancer (EOCRC) are vital for effective prevention and treatment, particularly for patients below the recommended screening age.

Objective: Our study aims to predict EOCRC using machine learning (ML) and structured electronic health record data for individuals under the screening age of 45 years, with the aim of exploring potential risk and protective factors that could support early diagnosis.

Methods: We identified a cohort of patients under the age of 45 years from the OneFlorida+ Clinical Research Consortium. Given the distinct pathology of colon cancer (CC) and rectal cancer (RC), we created separate prediction models for each cancer type with various ML algorithms. We assessed multiple prediction time windows (ie, 0, 1, 3, and 5 y) and ensured robustness through propensity score matching to account for confounding variables including sex, race, ethnicity, and birth year. We conducted a comprehensive performance evaluation using metrics including area under the curve (AUC), sensitivity, specificity, positive predictive value, negative predictive value, and F_1-score. Both linear (ie, logistic regression, support vector machine) and nonlinear (ie, Extreme Gradient Boosting and random forest) models were assessed to enable rigorous comparison across different classification strategies. In addition, we used the Shapley Additive Explanations to interpret the models and identify key risk and protective factors associated with EOCRC.

Results: The final cohort included 1358 CC cases with 6790 matched controls, and 560 RC cases with 2800 matched controls. The RC group had a more balanced sex distribution (2:3 male-to-female) compared to the CC group (2:5 male-to-female), and both groups showed diverse racial and ethnic representation. Our predictive models demonstrated reasonable results, with AUC scores for CC prediction of 0.811, 0.748, 0.689, and 0.686 at 0, 1, 3, and 5 years before diagnosis, respectively. For RC prediction, AUC scores were 0.829, 0.771, 0.727, and 0.721 across the same time windows. Key predictive features across both cancer types included immune and digestive system disorders, secondary malignancies, and underweight status. In addition, blood diseases emerged as prominent indicators specifically for CC.

Conclusions: Our findings demonstrate the potential of ML models leveraging electronic health record data to facilitate the early prediction of EOCRC in individuals under 45 years. By uncovering important risk factors and achieving promising predictive performance, this study provides preliminary insights that could inform future efforts toward earlier detection and prevention in younger populations.

Introduction

Colorectal cancer (CRC) is a significant public health challenge, ranking as the third leading cause of cancer-related mortality among both males and females in the United States [1]. It is estimated that in 2023, approximately 153,020 individuals were diagnosed with CRC, and 52,550 succumbed to the disease [1]. While cancer is typically a disease of older age, a concerning trend has emerged—the increasing incidence of early-onset colorectal cancer (EOCRC) in individuals younger than the age of 50 years [1,2]. This increased incidence has led the US Preventive Services Task Force to modify its recommendations, lowering the age to start CRC screening to age 45 [3]. Patients diagnosed with EOCRC tend to present at later stages and face lower disease-specific survival rates, underscoring the need for early detection and treatment initiation [4]. Nevertheless, challenges in addressing EOCRC are compounded by poorly defined risk factors and the role of diagnostic delays. As a result, early prediction and comprehensive understanding of the risk factors of EOCRC are essential for prevention and treatment, particularly for patients who fall below the recommended screening age.

The rapid integration of artificial intelligence and big data analytics has significantly expanded the horizons of medical research and clinical care [5]. Diverse data sources, including imaging and genomic data, have been harnessed for CRC detection through the application of statistical and machine learning (ML) algorithms. Some approaches have included the analysis of tumor DNA and circulating RNA expression profiling data to identify potential pathogenic factors [6,7]. In addition, computer tomography (CT)–based radionics, combined with ML algorithms, have been used to predict the Kirsten rat sarcoma viral oncogene mutation in people with CRC, demonstrating the potential of ML in clinical decision support [8]. Further, a random forest (RF) model trained with standard clinical and pathological prognostic variables, coupled with magnetic resonance imaging (MRI) images, achieved an impressive area under the curve (AUC) score of 0.94 when predicting survival in CRC patients, highlighting the importance of MRI-based texture features in patient survival prediction [9]. However, imaging data produces a small number of unexplainable predictors (around 100), and does not consistently improve diagnostic accuracy and disease prediction, especially when only using imaging data [10]. Furthermore, advanced imaging modalities and genomic data can be costly, with limited accessibility, and lack diversity and representativeness in samples, which could impact timely and accurate diagnosis for all individuals affected by EOCRC or widen already present disparities in patient outcomes.

In contrast to imaging and genomic data, structured data from the electronic health record (EHR) offers a more accessible and cost-effective data source for initial research. Originally designed for administrative and billing purposes, structured EHR data have evolved into valuable tools for health care research, capturing a wealth of patient information, including clinical diagnoses, procedures, medications, and laboratory results, among others [11]. The integration of ML and deep learning with EHR data has demonstrated substantial potential for disease prediction, including Alzheimer disease, gestational diabetes mellitus, and coronary heart disease [12-14]. In the context of CRC, several ML approaches have been used to predict the risk of the disease. For example, Shanbehzadeh et al [15] used structured EHR data and four data mining algorithms to predict CRC risk, identifying critical attributes for the prediction model using the weight statistical χ^2 test. However, the weight statistical χ^2 test assumes independence among variables, which may not hold true in complex datasets where variables are likely correlated. Another study leveraged convolutional neural networks to predict CRC risk based on the structured EHR data from the Taiwan National Health Insurance database [16]. Hussan et al [17] explored multiple ML methods to construct predictive models for CRC among patients aged between 35 and 50 years. However, these studies faced challenges in effectively matching cases and control groups, leading to increased bias and concerns regarding confounding. Furthermore, another limitation across studies is the failure to distinguish between colon cancer (CC) and rectal cancer (RC), despite the differences in clinical presentation, molecular carcinogenesis, pathology, surgical topography and procedures, and multimodal treatment strategies between these 2 cancers [18]. In addition, the lack of model explanations regarding clinical diagnosis of CRC undermined the interpretability and reliability of their strategies. As a result, there is a pressing need for improved methodologies to enhance the reliability and understanding of ML models in EOCRC prediction.

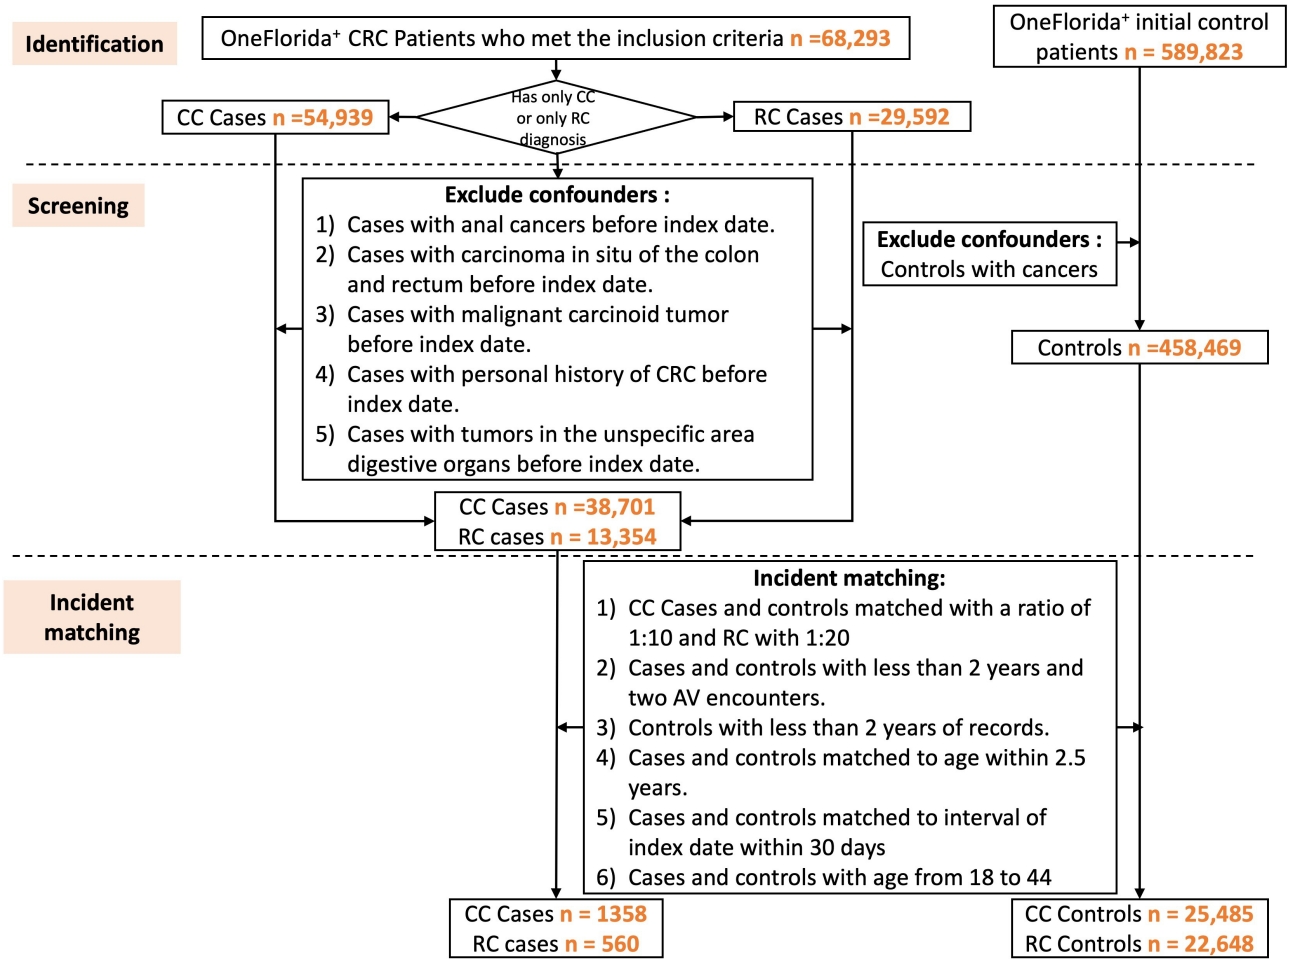
Methods

Data Source and Study Population

This study used deidentified EHR data from the OneFlorida+ Clinical Research Consortium, which operates within the PCORnet Clinical Research Network funded by the Patient-Centered Outcomes Research Institute. PCORnet serves as a national resource dedicated to advancing high-priority health research and improving outcomes through a robust, integrated research infrastructure [19,20]. By combining extensive health data, research expertise, and patient perspectives, it enables network partners to rapidly generate reliable, actionable evidence to support public health and clinical decision-making [19,20]. The OneFlorida+ data encompasses a wide range of patient characteristics from health systems across the southeast, including EHR data collected using the PCORnet Common Data Model [19] regarding demographics, diagnoses, medications, procedures, vital signs, lab tests, and more.

The construction of our study cohort using OneFlorida+ is outlined in Figure 1. OneFlorida+ identified individuals from the OneFlorida+ network, with encounters from January 2012 to January 2023 who met our inclusion criteria as either a case or control. We identified cases of CC using the *International Classification of Diseases, Ninth Revision* (*ICD-9*) code of C18.x or C49A4 or the *International Classification of Diseases, Tenth Revision* (*ICD-10*) code of 153.x, or RC cases with the *ICD-9* code of C19.x, C20.x, C21.0, C21.1, and *ICD-10* code of 154.0 and 154.1. The initial cohort consisted of 68,293 CRC cases (54,939 CC cases and 29,592 RC cases), and 589,823 controls. From those, we excluded patients diagnosed with both CC and RC, other previous cancers, or those who were diagnosed ≥45 years of age. Our final study cohort comprised 1358 CC cases with 25,485 controls and 560 RC cases with 22,648 controls.

Figure 1. Flowchart of patient selection from OneFlorida+. CC: colon cancer; CRC: colorectal cancer; RC: rectal cancer; AV: Ambulatory Visit.

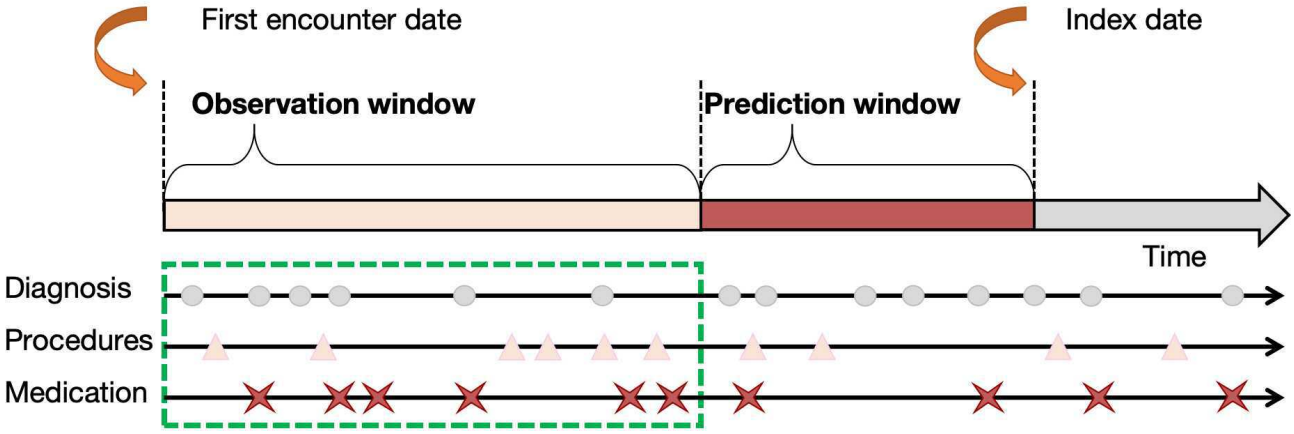


We used an incident matching process to match cases and controls to ensure a fair comparison across these groups. Initially, we retained cases and controls with more than 2 years of records and at least 2 encounters before the first onset date of either CC or RC and ensured that the age gap between matched cases and controls was within 2.5 years. By calculating propensity scores based on race, ethnicity, sex, and birth year (within 2.5 y), we used a narrow caliper of 0.05 with a nearest neighbor approach to achieve a 1:5 case-to-control ratio for each prediction window group [21]. This rigorous methodology ensures a balanced study population for reliable analysis and EOCRC prediction.

Study Setting

We then incorporated a range of different observation periods and prediction windows (Figure 2) to test our prediction algorithms, considering the different use cases. We considered 4 different prediction windows: 0 years, 1 year, 3 years, and 5 years before CRC diagnosis.

Figure 2. Visualization of the observation and prediction windows. For the prediction task. The index date for CRC cases is the date of diagnosis. For the control group, the index date is defined as the closest encounter date to the diagnosis date of the matched case group. The prediction window is the time period before the index date during which CRC cases are predicted. The observation window refers to the specific period during which data is collected or observed for analysis. CRC: colorectal cancer.



Data Preprocessing

The predictors we extracted included data from the demographics, vitals, diagnoses, medications, and procedures tables within the OneFlorida+ Clinical Research Network throughout the observation periods. Age at index date was calculated and categorized into 3 groups (eg, 18 - 29 y, 30 - 39 y, and 40 - 44 y). One-hot encoding [22] was used to represent age groups, race, and sex variables. Statistical analysis shows that the proportion of missing values is approximately 50% (4137/8148 in CC and 1554/3360 in RC). According to [23-25], mean imputation is less sensitive to high proportions of missing data and is more robust compared to other imputation methods, such as median and mode imputations, the indicator method, and regression. Thus, for missing data, we imputed the missing values with the mean of the numerical data derived from the entire sample within each prediction window group. Furthermore, BMI data was categorized into clinically relevant groups, including underweight (≤18.5 y), normal (18.5 - 23 y), overweight (23-30 y), and obese (≥30). Diastolic and systolic measurements were categorized into distinct hypertension stages.

Diagnoses, which were initially represented using *ICD-9* and *ICD-10* codes, were subjected to a data dimensionality reduction process that mapped them into Phecodes [26,27]. Revenue codes and current procedural terminology codes [28] were leveraged to capture billed medical procedures. To integrate these data, we also used the clinical classifications software code [29]. For drug information, National Drug Code [30] and RxNorm codes were used for encoding. National Drug Codes were mapped into RxNorm codes, and further consolidated into anatomical therapeutic chemical classes [31]. To ensure completeness, all features that could not be mapped were retained to prevent any missing information. These steps to transform the data enhanced interpretability and relevance of our predictive models.

Experiments and Validation

We explored several widely used ML models, including linear models such as logistic regression (LR) and the support vector machine (SVM), as well as nonlinear models like XGBoost (Extreme Gradient Boosting) and RF. We adopted two modeling strategies, including (1) prediction without CRC-related features and (2) prediction without cancer-related features, covering the CRC-related features. For the first strategy, features that may be indicative of CRC differential diagnoses (eg, neoplasm of unspecified nature of digestive system) or treatments for CRC (eg, chemotherapy and radiotherapy) were removed from the models and not used as predictors. For the second strategy, we took a more stringent approach by eliminating all diagnoses, drugs, and procedures that could be associated with any cancer from the extracted predictors. This step aimed to identify risk factors while eliminating the influence of other types of cancers, enabling us to focus exclusively on noncancer-related predictors. Regardless of the feature engineering strategy, we maintained a consistent experimental setup. The entire dataset was randomly split into a training dataset and a testing dataset with a ratio of 4:1. Model optimization was conducted on the training set through 5-fold cross-validation, and we fine-tuned hyperparameters using Bayesian optimization. To ensure reproducibility, we fixed the random state seed across all model runs.

To assess the effectiveness of our models comprehensively, we used a battery of evaluation metrics, including AUC, sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and F_1-score. To mitigate the risk of overfitting and to derive robust CIs, we implemented a bootstrapping strategy. This involved conducting 100 experiments by randomly resampling the training and testing datasets. In addition to traditional performance metrics, we delved into the interpretability of the XGBoost models. Specifically, we computed Shapley Additive Explanations (SHAP) values [32] to gain insights into the inner workings of the ML algorithms and to identify the core contribution predictors. This approach aimed to unveil the high-risk factors associated with EOCRC, shedding light on the most influential features in our prediction model. To further assess generalizability, we performed temporal validation on all CC and RC groups, using data before January 1, 2015, for training and data after for testing. We then trained an XGBoost model to evaluate its performance on the test set.

Ethical Considerations

The study was approved and the requirement to obtain any informed consent was waived by the University of Florida

Institutional Review Board (protocol number IRB202201561). The research does not involve greater than minimal risk for participation. Analyses only involve the secondary analysis of data that are either limited datasets or deidentified. Our research team has no direct contact with human participants. All methods were carried out in accordance with relevant guidelines and regulations.

Results

Table 1 provides an overview of the identified study cohorts after propensity score matching for both CC and RC across various prediction windows. Notably, CC cases outnumber RC cases, with approximately twice as many CC cases. Patients in the RC groups were slightly older compared to those in the CC group. Sex distribution in the RC groups was closer to parity (2:3 male to female) than in the CC group (2:5 male to female). Both RC and CC groups exhibited diverse racial and ethnic representation. In addition, as the prediction window lengthened, the number of cases decreased. Specifically, there were 560, 560, 383, and 225 RC cases, and 1358, 1358, 884, and 532 CC cases in prediction windows for 0 years, 1 year, 3 years, and 5 years, respectively.

Table . Descriptive statistics in case and control groups.

Variables	CC[a] cases (n=1358)	CC controls (n=6790)	RC[b] cases (n=560)	RC controls (n=2800)
Age, mean (SD)	36.54 (5.88)	36.69 (5.73)	37.70 (5.70)	36.80 (5.53)
Sex, n (%)				
Female	938 (69.07)	4461 (65.70)	323 (57.68)	1617 (57.75)

[a]CC: colon cancer.

[b]RC: rectal cancer.

Table 2 presents the results of CC prediction using 2 feature engineering strategies: 1 excluding CRC-related features and the other excluding cancer-related features. Additional evaluation metrics for CC prediction across all settings can be found in Tables S1-S2 in Multimedia Appendix 1. In most cases, tree-based models (XGBoost and RF) outperformed linear models (SVM and LR), yielding higher AUC values. Specifically, after removing CRC-related features, the RF model achieved the highest AUC for the 0-year prediction (0.811, 95% CI 0.808-0.814), while RF performed best for the 1-year (0.748, 95% CI 0.745-0.751), 3-year (0.689, 95% CI 0.684-694), and 5-year (0.686, 95% CI 0.68-0.692) predictions for CC. However, after removing features associated with previous cancers, the model performance decreased: LR achieved AUC values of 0.788 (95% CI 0.786-0.791) for 0-year prediction; RF achieved AUC values of 0.716 (95% CI 0.713-0.719) for 1-year, 0.684 (95% CI 0.679-0.688) for 3-year, and 0.663 (95% CI 0.658-0.668) for 5-year prediction. Performance metrics, including specificity, sensitivity, PPV, NPV, and F_1-score, exhibited similar trends.

Table . AUC[a] comparison for colon cancer prediction using machine learning models across different prediction windows (0, 1, 3, and 5 years).

Feature strategy and model	0-year AUC (95% CI)	1-year AUC (95% CI)	3-year AUC (95% CI)	5-year AUC (95% CI)
Excluding CRC-related[b] features				
LR[c]	0.809 (0.806-0.812)	0.733 (0.73-0.736)	0.683 (0.679-0.688)	0.674 (0.668-0.679)
SVM[d]	0.748 (0.745-0.751)	0.689 (0.685-0.692)	0.614 (0.61-0.618)	0.616 (0.61-0.621)
RF[e]	0.811 (0.808-0.814)	0.748 (0.745-0.751)	0.689 (0.684-0.694)	0.686 (0.68-0.692)
XGBoost[f]	0.802 (0.799-0.806)	0.745 (0.741-0.748)	0.689 (0.684-0.694)	0.657 (0.651-0.663)
Excluding cancer-related features

[a]AUC: area under the curve.

[b]CRC: colorectal cancer.

[c]LR: logistic regression.

[d]SVM: support vector machine.

[e]RF: random forest.

[f]XGBoost: Extreme Gradient Boosting.

Table 3 provides RC prediction results using the same feature engineering strategies and 4 prediction windows. Additional evaluation metrics for RC prediction across all settings can be found in Tables S3-S4 in Multimedia Appendix 1. Again, after removing CRC-related features, the XGBoost model achieved the highest AUC for the 0-year prediction (0.829, 95% CI 0.825-0.834), while RF performed best for the 1-year (0.771, 95% CI 0.766-0.777), and XGBoost did best for 3-year (0.727, 95% CI 0.721-0.732), and 5-year (0.721, 95% CI 0.713-0.729) predictions for RC. Eliminating cancer-related features resulted in a performance decrease: XGBoost achieved AUC values of 0.811 (95% CI 0.806-0.815) for 0-year prediction; RF achieved AUC values of 0.756 (95% CI 0.751-0.76) for 1-year, 0.724 (95% CI 0.718-0.73) for 3-year, and 0.711 (95% CI 0.704-0.719) for 5-year predictions. Performance metrics exhibited consistent trends. In both the CC and RC prediction tasks, we observed a decline in model performance as the prediction window length increased. Notably, when we removed cancer-related features, the AUC declined. This highlights the pivotal role these features play in enhancing prediction performance.

Table . AUC[a] comparison for rectal cancer prediction using machine learning models across different prediction windows (0, 1, 3, and 5 years).

Feature strategy and model	0-year AUC (95% CI)	1-year AUC (95% CI)	3-year AUC (95% CI)	5-year AUC (95% CI)
Excluding CRC[b]-related features				
LR[c]	0.819 (0.815-0.824)	0.763 (0.758-0.767)	0.722 (0.716-0.728)	0.693 (0.686-0.7)
SVM[d]	0.78 (0.774-0.785)	0.694 (0.689-0.699)	0.656 (0.649-0.662)	0.658 (0.65-0.665)
RF[e]	0.826 (0.822-0.83)	0.771 (0.766-0.777)	0.719 (0.713-0.726)	0.72 (0.712-0.727)
XGBoost[f]	0.829 (0.825-0.834)	0.766 (0.762-0.771)	0.727 (0.721-0.732)	0.721 (0.713-0.729)
Excluding cancer-related features				
LR	0.807 (0.803-0.812)	0.748 (0.743-0.752)	0.709 (0.703-0.715)	0.69 (0.683-0.697)
SVM	0.767 (0.761-0.772)	0.686 (0.68-0.691)	0.653 (0.646-0.659)	0.656 (0.648-0.663)
RF	0.806 (0.802-0.81)	0.756 (0.751-0.76)	0.724 (0.718-0.73)	0.711 (0.704-0.719)
XGBoost	0.811 (0.806-0.815)	0.749 (0.744-0.753)	0.724 (0.718-0.729)	0.679 (0.672-0.687)

[a]AUC: area under the curve.

[b]CRC: colorectal cancer.

[c]LR: logistic regression.

[d]SVM: support vector machine.

[e]RF: random forest.

[f]XGBoost: Extreme Gradient Boosting.

To further evaluate model performance, we integrated XGBoost and RF using soft voting. The AUC fluctuated around 0.01, showing no significant change from the best prevoting performance (Table S9 in Multimedia Appendix 1). For temporal validation, the overall AUC decreased slightly by around 0.02, suggesting potential distribution shifts over time that may have affected generalizability. While the model fit earlier data well, its weaker performance on newer data hints at possible drift (Tables S5-S8 in Multimedia Appendix 1).

To gain deeper insights into the risk factors associated with these findings, we present SHAP summary plots for CC and RC predictions using 2 feature engineering strategies and for 0-year and 3-year prediction windows in Figures 3 and 4. Supplementary SHAP summary plots for all other models can be found in Figures S1-S2 in Multimedia Appendix 1. Within the CC group, several predictors emerged as positively associated with the risk of CC. Notably, several diagnoses involving various tumors, such as suspected cancer, secondary malignant neoplasm, benign neoplasm of uterus, benign neoplasm of skin, neoplasm of uncertain behavior, neoplasm of uncertain behavior of skin, cancer of other female genital organs and myeloproliferative diseases were identified as influential factors. Gastrointestinal symptoms, encompassing conditions like gastrointestinal hemorrhage, other disorders of intestine, other symptoms involving the abdomen and pelvis, noninfectious gastroenteritis, appendiceal conditions, diverticulosis and diverticulitis, intestinal obstruction without hernia, and disorders of the intestine also exhibited a positive association with CC risk. In addition, medical procedures related to gastrointestinal diseases and symptoms, including upper gastrointestinal endoscopy, were significantly associated with the development of CC.

Figure 3. SHAP (Shapley Additive Explanations) summary plot of the top 20 features in CC prediction using best-performing models with 0-year and 3-year prediction windows: (**A**) excluding CRC-related features; (**B**) excluding cancer-related features. The prefix before the "_" in the y-axis labels of plots indicates the source of the corresponding features in the PCORnet data model. Specifically, these sources are: Diagnosis (Diag), Procedure (Proc), Medication (Med), Vital Signs (Vital), and Demographics (Demo). CC: colon cancer; CRC: colorectal cancer; LR: logistic regression; RF: random forest; XGBoost: Extreme Gradient Boosting.

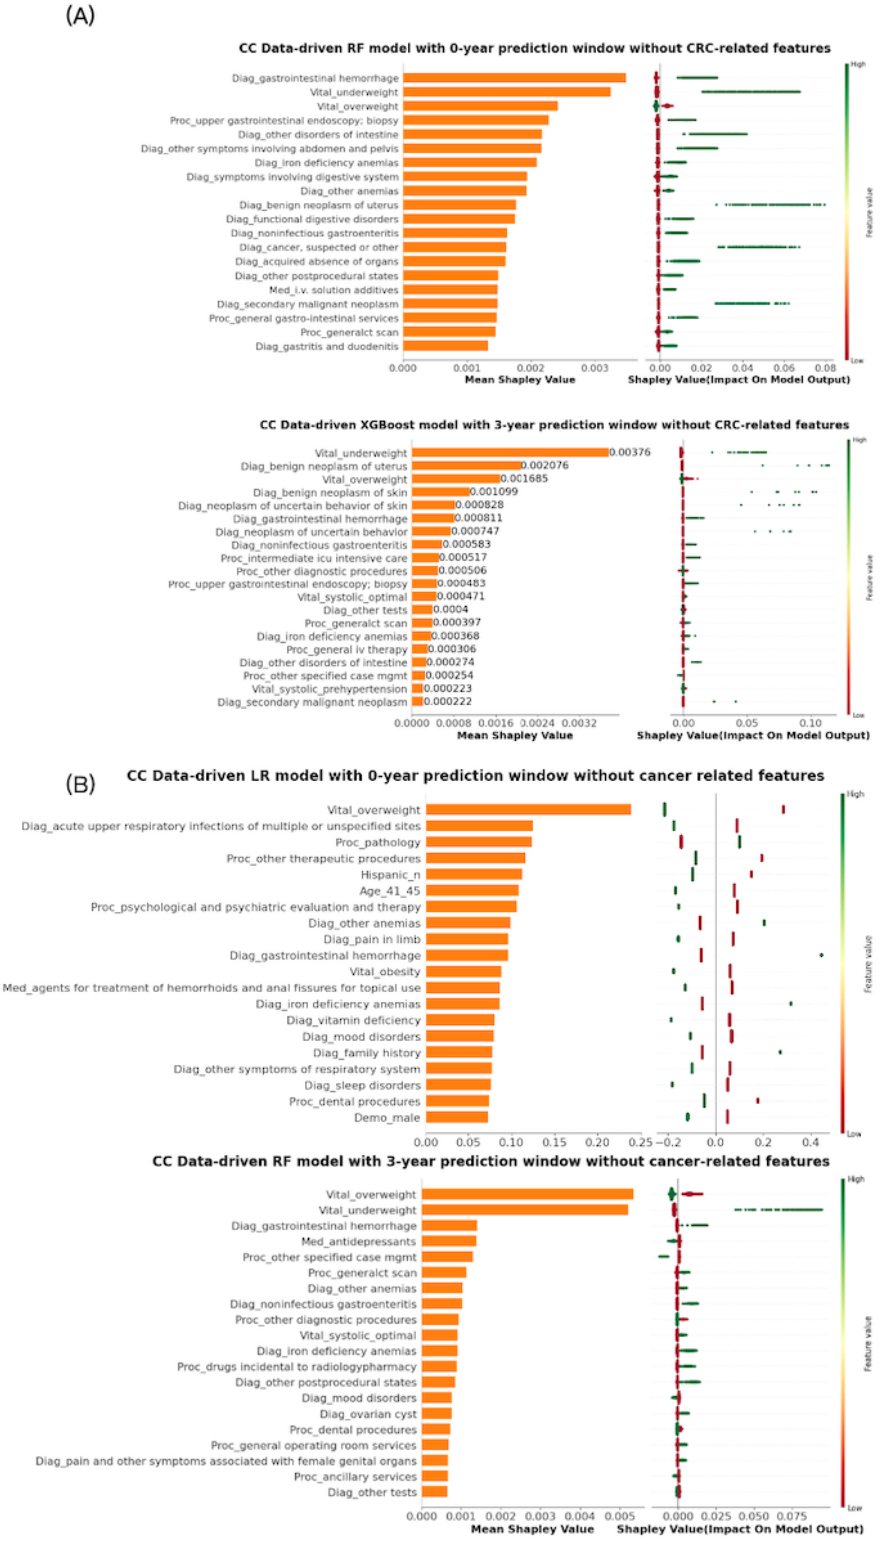

Figure 4. SHAP (Shapley Additive Explanations) summary plot of the top 20 features in RC prediction using best-performing models with 0-year and 3-year prediction windows: (**A**) excluding CRC-related features; (**B**) excluding cancer-related features. CRC: colorectal cancer; RC: rectal cancer; XGBoost: Extreme Gradient Boosting.

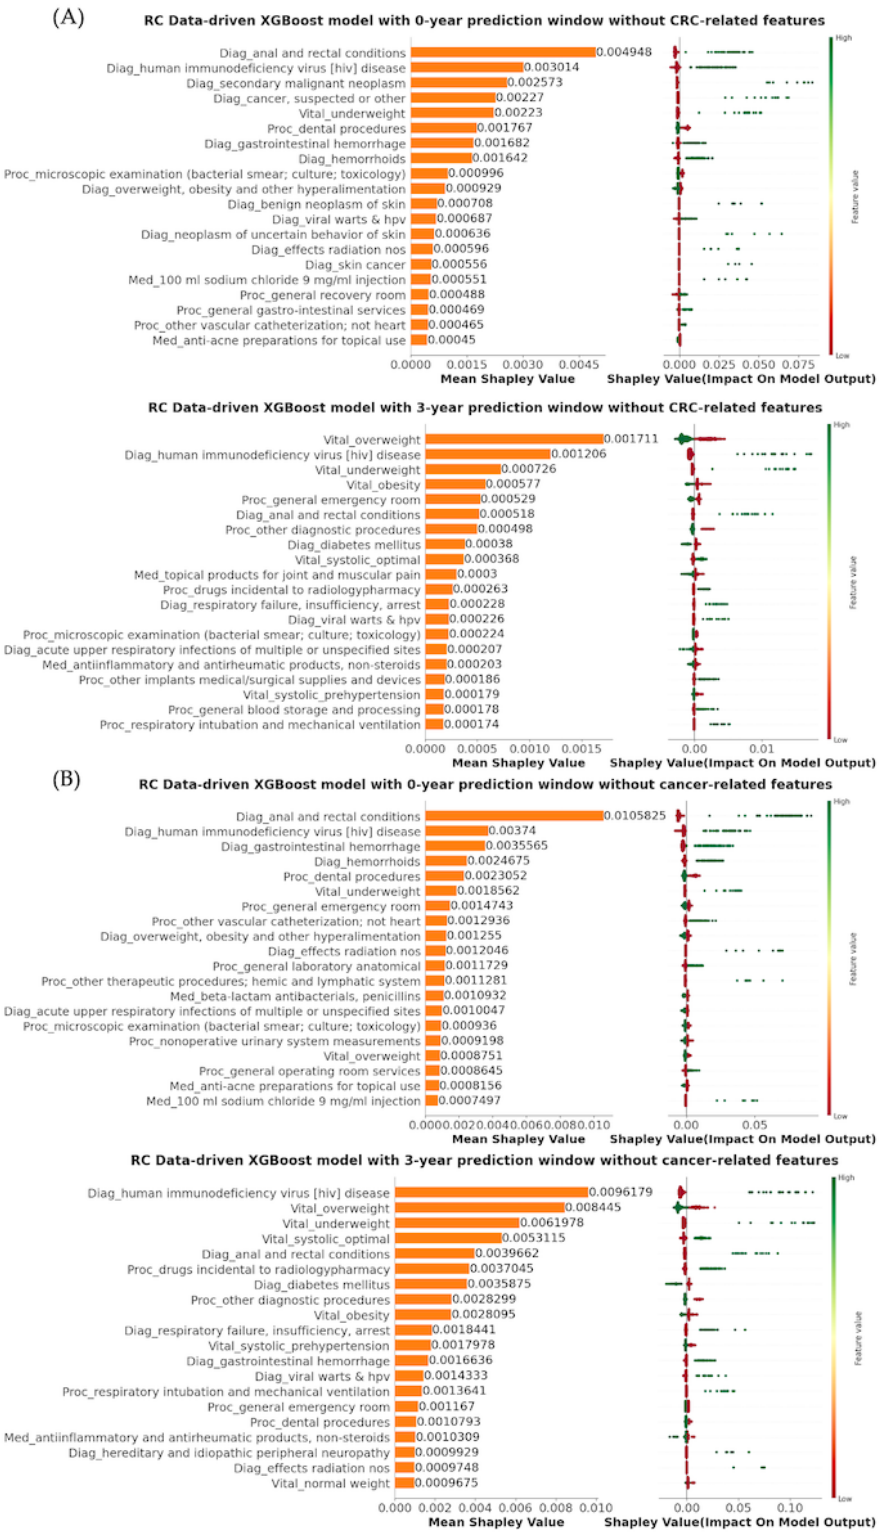

In the RC group, similar positive predictors were identified, mirroring the trends observed in the CC group, including gastrointestinal symptoms (eg, gastrointestinal hemorrhage, anal, and rectal conditions) and the presence of other cancers or tumors (eg, secondary malignant neoplasms and benign neoplasms of the uterus or skin). In addition, the presence of autoimmunity, diseases associated with a potentially weakened immune system (eg, HIV, viral warts, and human papillomavirus [HPV]), and conditions like hemorrhoids were linked to a heightened long-term risk of RC. Being underweight was a significant symptom associated with both CC and RC. Conversely, obesity, overweight, and normal weight appeared to be negatively associated with RC development. Importantly, after removing cancer-related features from consideration, the

significance of anemias surged to the forefront in both the CC and RC groups. These included indicators such as iron deficiency anemias and other anemias. Nevertheless, gastrointestinal diseases and immunodeficiency pathological changes remained substantial factors contributing to CC risk, while factors such as HPV and weight retained their significance as primary determinants of RC. The use of anti-inflammatory or antirheumatic medications were associated with decreased risk of RC.

Discussion

Principal Findings

In this study, we used 4 traditional ML algorithms (ie, XGBoost, RF, SVM, and LR) and obtained informative results predicting EOCRC using structured EHR data. In most cases, the tree-based models, (XGBoost and RF) outperformed linear models, achieving the best AUC scores for various prediction windows. In addition, even after excluding cancer diagnosis variables (eg, pancreatic, skin, and thyroid cancer), undergoing cancer-related procedures (eg, liver biopsy and bone marrow biopsy), cancer treatments (eg, cisplatin and doxycycline), our models continued to achieve acceptable AUC scores. Immune and digestive system disorders, blood diseases, and secondary cancers were identified as significant predictors.

Comparison to Previous Work

Most of our experimental findings were consistent with existing published research. Cancer-related diseases and diagnoses emerged as risk factors leading to the diagnosis of EOCRC, both for CC and RC. For example, uterine cancer was identified as a driver of EOCRC, suggesting a potential genetic association between these malignancies in younger patients [33]. Research also demonstrates that the incidence rate of second primary cancers among survivors is significantly higher than cancer in the general population, and survivors experience notable morbidity and mortality from their cancer treatment [34]. In addition, the use of CT scans for other medical reasons could contribute to the incidental identification of EOCRC cases [35]. Notably, we know that some forms of cancer treatment (eg, radiation) predisposes one to an increased risk for secondary malignancies, including EOCRC, particularly in patients surviving childhood cancer [36].

Inflammatory bowel diseases (IBDs) are well established risk factors for CRC, particularly during young adulthood. The chronic inflammation associated with IBD leads to the release of growth cytokines, excess blood flow, and metabolic free radicals, all of which contribute to the heightened risk of developing CRC [37]. Therapies for IBD sometimes involve immune suppression, another known risk factor for cancers. Furthermore, many gastrointestinal diseases can cause malabsorption or malnutrition [38], resulting in patients being underweight which can also contribute to immune dysfunction or suppression [39]. However, overweight patients were at low risk of EOCRC as our analysis demonstrated despite emerging evidence that being overweight may be associated with an increased risk of tumor recurrence and colorectal carcinogenesis [40,41]. The temporal use of antibiotics in relation to subsequent development of EOCRC is an interesting finding as it supports several previously reported roles that the gut microbiome may plan in CRC protection and development [42]. Our analysis highlighted that the diagnosis of iron deficiency anemia predated CC, but had less association with rectal cancers. It is logical, given that CC are situated more proximal in the gastrointestinal tract, causing occult chronic blood loss and subsequent anemia rather than overt gross bleeding as is typically evident from RC.

In addition, our study observed a significantly higher incidence of CRC cases among HIV-infected patients compared to HIV-uninfected individuals [43]. The heightened risk can be attributed to disruptions in immune function caused by immunodeficiency, which exposes individuals to a higher susceptibility against cancer-causing viruses, including HPV, Epstein–Barr virus, Kaposi sarcoma-associated herpesvirus, etc, as evidenced in our analysis [44]. Another notable finding was the association between CC and diseases of myeloproliferative disease. Similar to other cancers, the potential link could be related to genetics, treatments that induce DNA damage that could predispose to EOCRC, and chronic immune dysregulation. Overall, our study sheds light on the complex interplay between IBD, malnutrition, immune function, and specific blood-related diseases in the development of CRC. Understanding these relationships is crucial in advancing our knowledge of EOCRC risk factors and devising targeted interventions for at-risk populations. It can help health care providers identify individuals who may benefit most from screening between the ages of 18 and 44 years. In this case-control study, we identified several factors independently associated with an elevated risk of EOCRC. These findings could inform patient-provider discussions about the need for and approach to CRC screening and support targeted interventions to improve screening uptake among high-risk individuals.

Strengths and Limitations

The strength of our study is to develop an early diagnostic tool that can help identify individuals at higher risk for EOCRC before the onset of clinical symptoms or suspicion. To further clarify, we test the algorithm across different prediction windows—0, 1, 3, and 5 years—meaning we use data from these periods before a patient's first CRC diagnosis to predict whether they will develop CRC in the future. This approach enables us to assess how the algorithm can detect early risk signals well in advance of diagnosis, providing actionable insights for clinicians to consider for individuals who may not yet exhibit symptoms or be under suspicion for CRC. For individuals without clear clinical suspicion (ie, those who are not yet exhibiting symptoms or are below typical screening age), our algorithm could serve as a risk stratification tool. By analyzing real-world data, such as demographic information, medical history, and other relevant factors, the model can help identify patients who may benefit from earlier screening or closer monitoring, even in the absence of overt symptoms. This can be particularly important in populations with no established risk factors for CRC, but who may still be at risk for early-onset cases.

Our study does have several limitations. First, the mechanism through which identified medical factors are associated with

EOCRC is speculative. For example, CT scans contributed significantly to the model's performance, but the specific reasons are unclear. EHRs did not record the reason why patients underwent CT scans. Perhaps some patients obtained CT scans because of symptoms related to undiagnosed CRC while others received CT scans for other reasons with the incidental finding of CRC. It is less likely that CT scans could be associated with causing CRC due to radiation exposure. For that to occur, the cumulative lifetime exposure would need to be very high with exposure over a number of decades for that to occur. Perhaps CT imaging itself is just a surrogate for access to care whereby EOCRC is more likely to be eventually diagnosed as opposed to patients who might expire for other reasons with CRC, but before a diagnosis. Second, the exclusion of confounder samples and features posed difficulties, given the lack of universally accepted standards for phenotype definitions and ambiguous descriptions. These challenges hindered the design of the most optimal experiment [45]. Third, our experiments are carried out based on the EHR data, which inherently contains flaws, including missing values and potential mistakes in records. Efforts were made to fill in missing values, but comprehensive amendments remained challenging. The characteristics of the EHR data, such as temporality, irregularity, sparsity, and data imbalance, can result in abnormal outcomes when applying ML models [46,47]. Fourth, we primarily focused on metrics related to discrimination or classification (eg, AUC), as we believe these provide essential insights into how effectively the model differentiates between cases and noncases. We acknowledge that a more holistic evaluation—including calibration, fairness, stability, and net benefit—would provide a fuller picture of the model's real-world applicability.

Future Directions

Future research should focus on refining the experimental design, exploring alternative feature selection techniques, incorporating large language models based on both ambulatory and inpatient data, and integrating domain knowledge to enhance the performance of the prediction models. Ultimately, these efforts will contribute to early detection and better management of CRC, with the goal of improving patient outcomes. Using techniques like Synthetic Minority Over-sampling Technique or cost-sensitive learning could further improve the model's ability to detect the minority class. These methods were not used in this study but could be considered in future work to explore their potential impact on model performance, especially in terms of improving recall for the minority class.

Conclusion

In conclusion, our study demonstrated the potential of traditional ML algorithms in predicting EOCRC using real-world data for individuals below the screening age guideline. The identification of significant predictors and their consistency with academic research findings provide valuable insights for pursuing additional hypotheses or targeting potential patients at risk for EOCRC. However, addressing the challenges and limitations related to data quality, experimental design, and ML models' development is essential for improving the accuracy and reliability of EOCRC prediction models.

Data Availability

The variables used in this study can be found on GitHub [48].

Authors' Contributions

CS, EM, MQ, MP, RW, and JX were responsible for the overall design, development, and evaluation of this study. CS and JX did the initial drafts and the revisions of the manuscript. CS was responsible for rerunning all experiments and creating Shapley Additive Explanation plots. EM and MD were responsible for providing accurate *International Classification of Diseases* codes to define cases and filter colorectal cancer–related and cancer-related features. All authors reviewed the manuscript critically for scientific content and provided edits, and all authors gave final approval of the manuscript for publication.

Conflicts of Interest

TG serves on the Data and Safety Monitoring Board (DSMB) for Seagen, Nihon Medi-Physics, KAHR Medical, and Arbele and has served as a consultant for Avammune Therapeutics, BillionToOne, Exact Sciences, and Summit Therapeutics. Research support has been provided to his institution by Bristol-Myers Squibb, Merck, AstraZeneca, Lilly, Bayer, Incyte, Ipsen, Genentech, Astellas Pharma, GlaxoSmithKline, Amgen, OncoC4, BillionToOne, Jounce Therapeutics, Elicio Therapeutics, AMAL Therapeutics/Boehringer Ingelheim, Seagen, Regeneron, and Deciphera. Abstract

Background: The application of natural language processing in medicine has increased significantly, including tasks such as information extraction and classification. Natural language processing plays a crucial role in structuring free-form radiology reports, facilitating the interpretation of textual content, and enhancing data utility through clustering techniques. Clustering allows for the identification of similar lesions and disease patterns across a broad dataset, making it useful for aggregating information and discovering new insights in medical imaging. However, most publicly available medical datasets are in English, with limited resources in other languages. This scarcity poses a challenge for development of models geared toward non-English downstream tasks.

Objective: This study aimed to develop and evaluate an algorithm that uses large language models (LLMs) to extract information from Japanese lung cancer radiology reports and perform clustering analysis. The effectiveness of this approach was assessed and compared with previous supervised methods.

Methods: This study employed the MedTxt-RR dataset, comprising 135 Japanese radiology reports from 9 radiologists who interpreted the computed tomography images of 15 lung cancer patients obtained from Radiopaedia. Previously used in the NTCIR-16 (NII Testbeds and Community for Information Access Research) shared task for clustering performance competition, this dataset was ideal for comparing the clustering ability of our algorithm with those of previous methods. The dataset was split into 8 cases for development and 7 for testing, respectively. The study's approach involved using the LLM to extract information pertinent to lung cancer findings and transforming it into numeric features for clustering, using the K-means method. Performance was evaluated using 135 reports for information extraction accuracy and 63 test reports for clustering performance. This study focused on the accuracy of automated systems for extracting tumor size, location, and laterality from clinical reports. The clustering performance was evaluated using normalized mutual information, adjusted mutual information , and the Fowlkes-Mallows index for both the development and test data.

Results: The tumor size was accurately identified in 99 out of 135 reports (73.3%), with errors in 36 reports (26.7%), primarily due to missing or incorrect size information. Tumor location and laterality were identified with greater accuracy in 112 out of 135 reports (83%); however, 23 reports (17%) contained errors mainly due to empty values or incorrect data. Clustering performance of the test data yielded an normalized mutual information of 0.6414, adjusted mutual information of 0.5598, and Fowlkes-Mallows index of 0.5354. The proposed method demonstrated superior performance across all evaluation metrics compared to previous methods.

Conclusions: The unsupervised LLM approach surpassed the existing supervised methods in clustering Japanese radiology reports. These findings suggest that LLMs hold promise for extracting information from radiology reports and integrating it into disease-specific knowledge structures.

KEYWORDS

radiology reports; clustering; large language model; natural language processing; information extraction; lung cancer; machine learning

Introduction

Natural language processing (NLP) is vital in medicine as it allows the interpretation of textual content in medical documents. Radiology reports, written as free text by experienced radiologists, contain detailed information about medical imaging findings. While medical images are valuable, text-based analysis offers unique advantages in terms of computational efficiency and the ability to capture expert interpretations and observations of radiologists that may not be immediately apparent from images. Natural language processing can effectively extract this information, enhance its utilization, and provide new insights into medical imaging.

Advances in radiological NLP applications are driven by the availability of large datasets [1]. For example, the MIMIC Chest X-ray (MIMIC-CXR) includes more than 200,000 images, English-language reports, and structured data [2]. Numerous NLP models have been developed to summarize and extract clinical entities [3,4]. However, the availability of these datasets in languages other than English is limited.

To address this challenge, the NTCIR-16 Real-MedNLP shared task focused on clustering Japanese radiology reports by case basis. It is a set of Japanese radiology reports authored by different radiologists for the same case series of lung cancer, and the task was to cluster reports that describe the same medical case together [5]. This benchmark evaluates the detailed understanding of radiology reports, as NLP systems must extract sufficient information to recognize reports by diagnosing the same image without being affected by different writing styles.

Clustering is a powerful analytical tool in medicine and has been successfully applied in various clinical domains. Studies have demonstrated its effectiveness in clustering patients based on their clinical characteristics to guide medical decisions, ranging from cancer aftercare planning to pulmonary embolism risk assessment [6,7]. Semantic grouping has enabled efficient insight discovery in medical documents [8] and revealed specialty-specific sublanguages in clinical narratives [9]. Radiology reports are particularly suited for such analyses, as they provide high-quality annotated data despite their free-form nature, offering a more tractable alternative to direct image analysis.

While the participants in the NTCIR-16 (NII Testbeds and Community for Information Access Research) shared task used deep-learning models, their clustering performance was constrained by limited training data. Since then, large language models (LLMs) trained on extensive text corpora, such as ChatGPT and LLaMA [10,11], have emerged. These LLMs, which are adaptable to new tasks with minimal instructions or examples, have demonstrated high performance in extracting information from medical documents, even under zero-shot conditions [12].

This study aimed to evaluate the ability of LLM to understand real radiological reports through an information extraction task and apply this information to clustering, which is a clinically meaningful task.

Methods

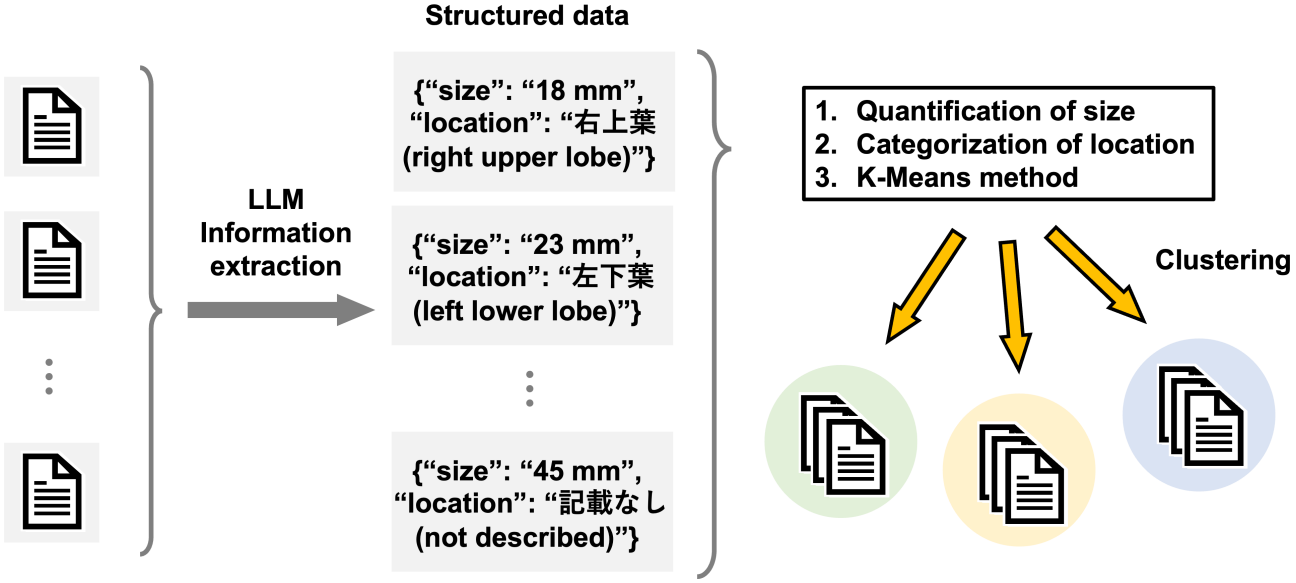
Study Design and Reporting Guidelines

This retrospective observational study followed the relevant items of the checklist for Artificial Intelligence in medical imaging (CLAIM) guidelines for methodology reporting [13,14]. Although this study analyzed text rather than images, CLAIM was followed because it is an established guideline for AI-based research in radiology and is deemed appropriate for NLP [15-17].

Algorithm Overview

The proposed algorithm is illustrated in Figure 1. Using the LLM, key lung cancer findings were extracted from radiology reports and quantified to obtain structured data. The structured data were subsequently used for clustering.

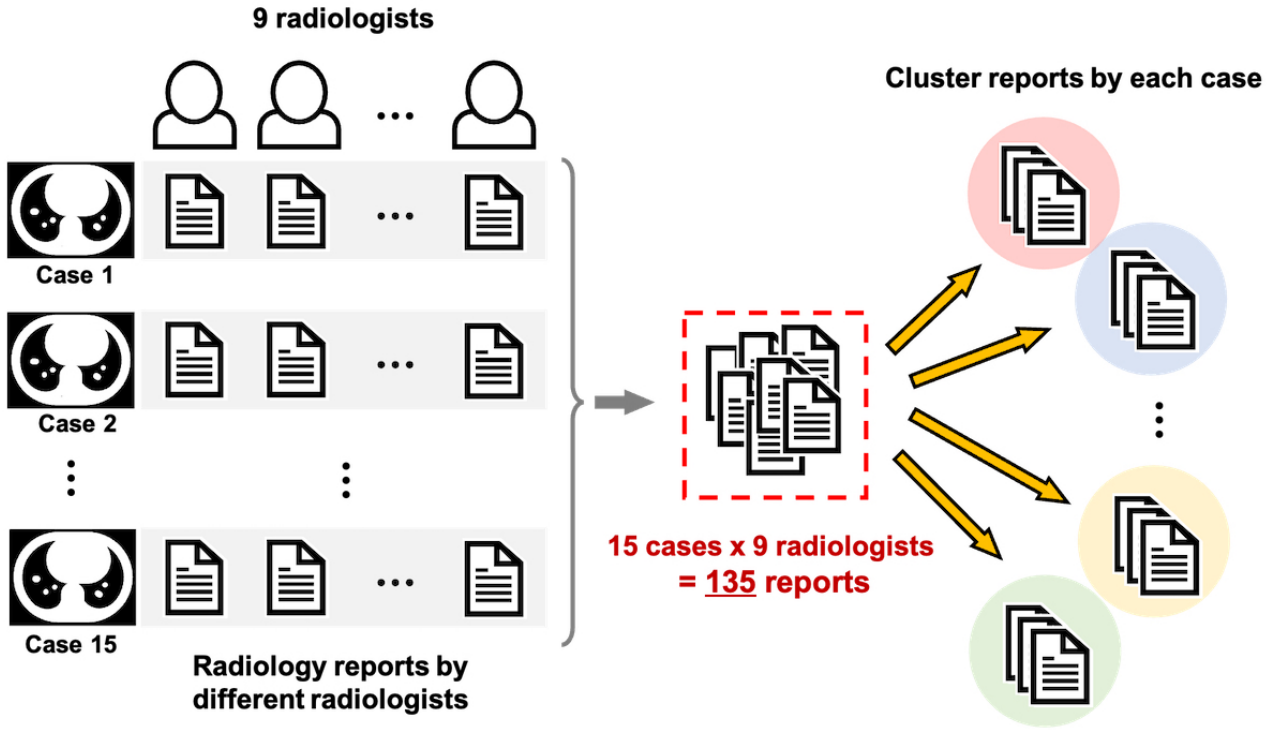
Figure 1. Flowchart of radiology reports clustering using LLM. LLM: large language model.



Dataset

The MedTxt-RR dataset was used in this study [5,18], comprising 135 Japanese radiology reports generated by 9 radiologists who interpreted CT images of 15 lung cancer cases sourced from Radiopaedia [19]. This dataset was used in an NTCIR-16 shared task [5], where participants competed to achieve optimal clustering performance. With each case comprising reports from 9 radiologists, the dataset was suitable for evaluating the clustering performance on a per-case (Figure 2). Eight cases and seven cases were assigned to the development and test sets, respectively. While no model training was conducted using the development set in this study, performance was evaluated on the same data split to facilitate comparison with the shared task results.

Figure 2. Overview diagram of the radiology report clustering task.



LLM Approach

Radiology reports contain confidential patient information; processing them using a cloud-based LLM, such as ChatGPT, could expose sensitive data externally, raising significant medical safety concerns. Therefore, a publicly available offline model was selected as an alternative approach.

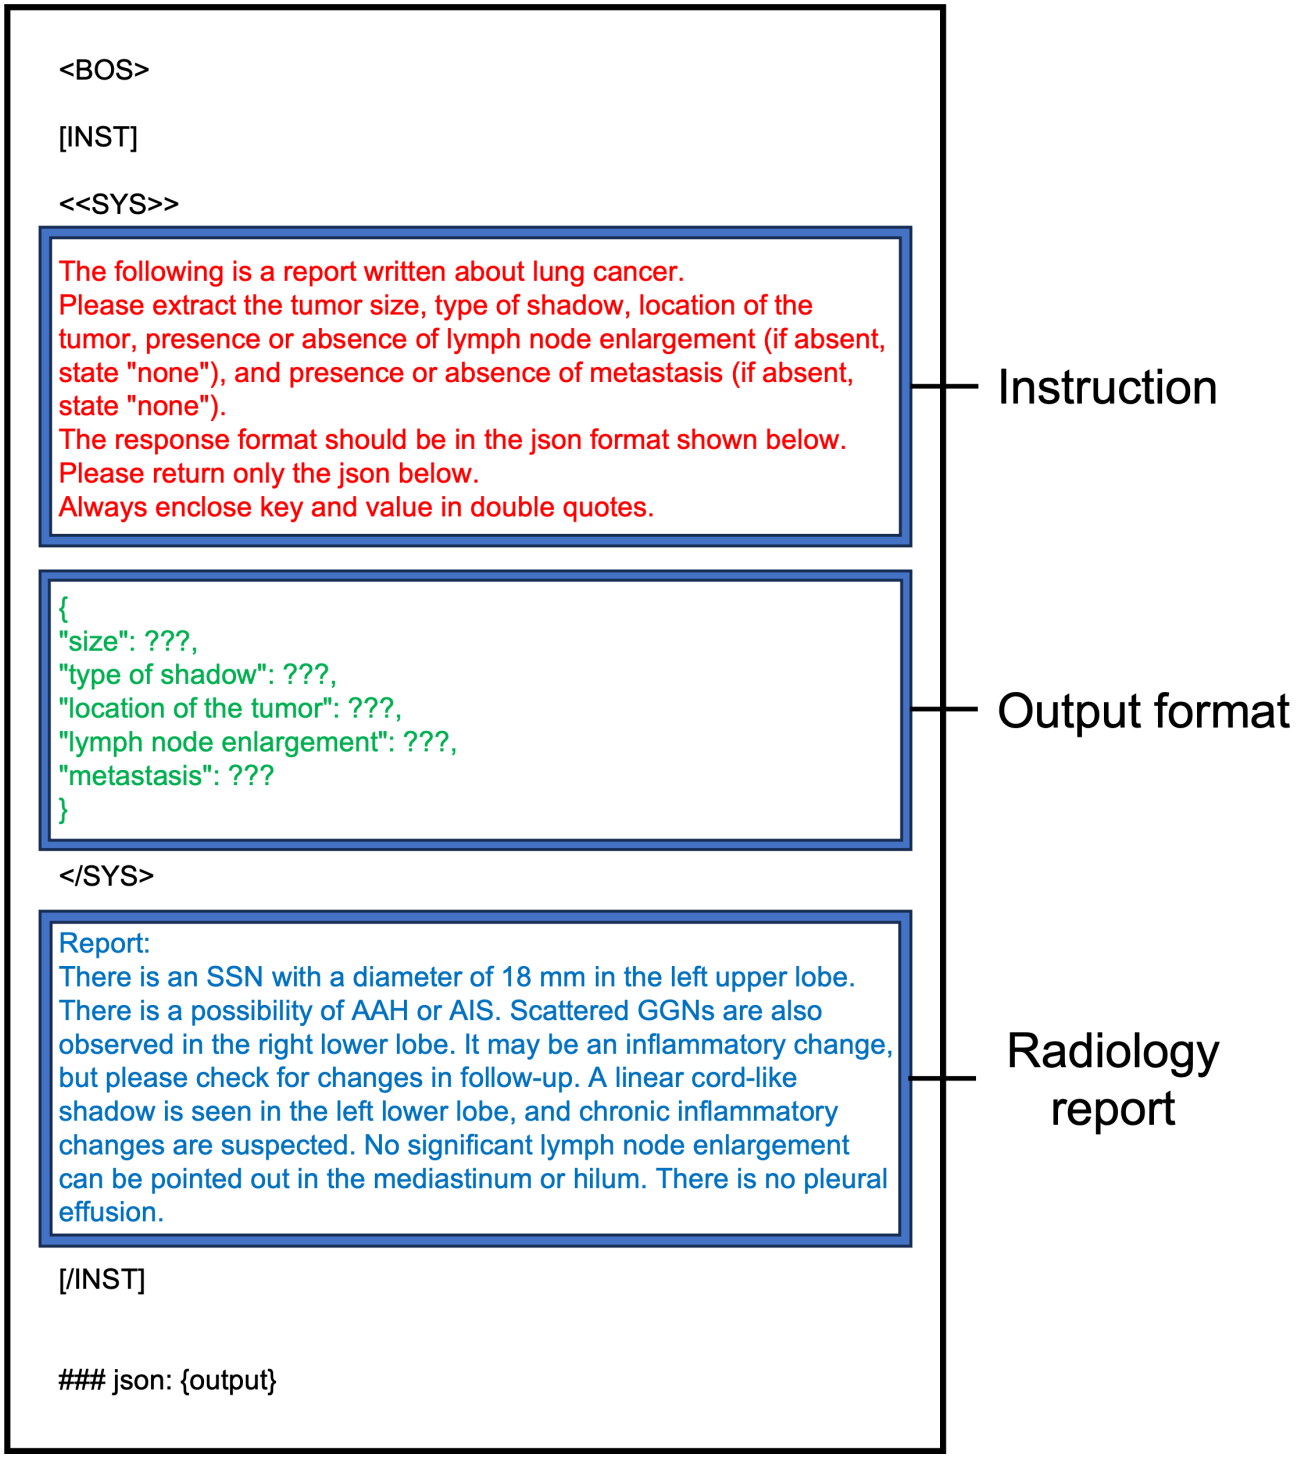
The ELYZA-Japanese-Llama-2-7b-fast-instruct model was employed as the LLM [20]. Adapted from Llama2 and pre-trained using Japanese datasets, this model demonstrated a performance comparable to that of GPT-3.5 on Japanese datasets [21-23].

Information Extraction

The LLM extracted multiple lung cancer staging parameters from radiology reports, including tumor size, tumor location, and the presence or absence of lymph node enlargement, suggesting metastasis and distant metastasis. To determine the optimal combination of features, clustering performance of the development set were repeatedly measured by using certain features. Consequently, sufficient clustering performance was confirmed achievable using only 3 parameters: tumor size, laterality (left or right), and lung location (upper, hilum, or lower region).

The prompt input into the LLM comprises system instructions and output format guidelines using json (JavaScript Object Notation), a standardized text-based format for structured information exchange, where data is organized in key-value pairs, such as {“size”: “45 mm,” “location”: “right upper lobe”}. These system instructions guided the LLM in extracting features from the radiology reports. The details of these prompts are shown in Figure 3 (English version) and Figure S1 in Multimedia Appendix 1 (original Japanese version).

Figure 3. Example of a prompt used as input for the LLM (English translated version). AAH: Atypical Adenomatous Hyperplasia; AIS: Adenocarcinoma in situ; GGN: Ground Glass Nodule; LLM: large language model; SSN: Subsolid Nodule.



The extracted data were converted into integer vectors comprising the tumor size and other categorical values. Unspecified tumor sizes only described as *large* were replaced with 71 mm, corresponding to the highest category in T classification, where T represents tumor categories in cancer staging. The details of this pipeline can be found in the GitHub Repository [24].

Moreover, a rule-based method was employed as the baseline approach and its performance was compared with that of the proposed method. The rule-based method performs context-sensitive word-based information extraction; the detailed algorithm is shown in Figure S2 in Multimedia Appendix 1.

Clustering

The resulting numerical matrices were clustered using the K-means algorithm in the scikit-learn library (version 1.3.1). The number of clusters was set to 8, aligning with expected classifications such as disease type or staging, since it was close to the number of test data cases. Centroid initialization used the k-means++ method, with default values for the centroid seed

and iteration count, because hyperparameter tuning was not conducted in this zero-shot study.

Information Extraction Evaluation

Two independent radiologists, a radiology resident with 1-year experience and a board-certified radiologist with 7 years of experience evaluated the accuracy of extracted information. In cases of discrepancy, the final assessment was determined by consensus. Evaluation focused on three key elements: tumor size, location (upper, hilum, or lower), and laterality (left or right). The performance of the LLM-based approach was compared to that of the rule-based method for information extraction. A detailed error analysis was conducted for cases with errors, categorizing them into missing information, false information generation, and extraction of multiple values.

McNemar's test was performed using Statsmodels (version 0.14.2) [25] to compare performance differences between the LLM-based and rule-based approaches for extracting tumor size and location.

Clustering Performance Evaluation

We assessed clustering performance using three metrics similar to those used in the shared task [5]: (1) normalized mutual information (NMI) that quantifies the mutual dependence between two clusters, normalized to a 0‐1 scale, with 1 indicating perfect clustering; (2) adjusted mutual information (AMI) which is an adjustment that corrects for NMI, accounting for its tendency to increase with the number of clusters; (3) Fowlkes-Mallows index (FM) that measures the similarity between two clusters by calculating the geometric mean of precision and recall, providing a balanced assessment of clustering accuracy.

Ethics Consideration

This study involved analysis of human subject data from publicly available radiology reports. All data were completely de-identified and accessible through MedTxt-RR [26]. In accordance with our institution's policy on research ethics, studies using exclusively de-identified, public datasets are exempt from institutional review board approval [27]. No additional privacy or confidentiality measures were required as the dataset contains no personally identifiable information, with all protected health information having been removed prior to public release.

Results

Information Extraction Performance

The details of the findings targeted at information extraction are summarized in Table 1 . The tumor size was correctly identified in 99 (73.3%) of 135 reports. Among the 36 outputs (26.7%) with errors, 23 (17%) lacked size information in their reports, and 22 (16.3%) contained false size information. The remaining errors were attributed to size inaccuracies or empty values despite size information being mentioned in the reports. Tumor location and laterality were accurately identified in 112 (83%) reports. All 23 (17%) reports with errors contained the necessary information but had empty values for laterality, location, or both, with one output indicating an incorrect location. The detailed error analysis is presented in Table 2.

Table . Summary of lung cancer cases.

Case no.	Side	Lobe	Size (mm)	Lymph node metastasis	Distant metastasis	Data split
Case 1	Left	Upper	18	No	No	Development
Case 2	Right	Lower	12	No	No	Development
Case 3	Left	Upper	28	No	No	Development
Case 4	Left	Upper	40	No	No	Test
Case 5	Left	Upper	48	Yes	No	Test
Case 6	Right	Hilum	Not measurable (due to invasion)	Yes	No	Development
Case 7	Right	Lower	55	Yes	No	Test
Case 8	Left	Upper	Not measurable (due to invasion)	No	No	Test
Case 9	Right	Hilum	43	No	Yes	Development
Case 10	Right	Upper	Not measurable (due to invasion)	No	No	Test
Case 11	Right	Upper	Not measurable (due to invasion)	No	No	Development
Case 12	Right	Lower	Not measurable (due to lung metastasis)	No	Yes	Development
Case 13	Left	Lower	78	Yes	No	Development
Case 14	Left	Upper	85	Yes	No	Test
Case 15	Left	Upper	Not measurable (due to invasion)	Yes	Yes	Test

Table . Detailed error analysis of tumor size, location, and laterality extraction from radiology reports using large language model (LLM) and rule-based methods.

Category	Extraction methods	
	LLM[a], n (%)	Rule-based, n (%)
Tumor size (details)		
Correctly identified	99 (73.3)	93 (68.9)
Errors (total)	36 (26.7)	42 (31.1)
Errors (no size information in reports)	23 (17)	0 (0)
False size information generated	22 (16.3)	0 (0)
T classification extracted instead of size	1 (0.7)	0 (0)
Errors (size mentioned in reports)	13 (9.6)	42 (31.1)
Size inaccuracies	8 (5.9)	3 (2.2)
Empty values	5 (3.7)	39 (28.9)
Tumor location and laterality (details)		
Accurately reported	112 (83)	46 (34.1)
Errors (total)	23 (17)	89 (65.9)
Empty values for laterality	9 (6.7)	0 (0)
Empty values for location	5 (3.7)	0 (0)
Empty values for both	8 (5.9)	80 (59.3)
Incorrect location	1 (0.7)	9 (6.7)

[a]LLM: large language model

The rule-based method correctly identified tumor size in 93 (68.9%) reports, whereas tumor location and laterality were accurately identified in only 46 (34.1%) reports. Among the errors in this method, only 1 case (0.7%) failed to accurately extract size information due to the extraction of multiple sizes. In contrast, for location, the number of errors reached 47 (34.8%) (Figure S3 in Multimedia Appendix 1). Unlike the LLM approach, due to the algorithmic nature of rule-based extraction, there were no cases of false-size information generation. Additionally, as the algorithm extracted laterality and location simultaneously as a single unit, there were no cases where only one of these values was empty; both were either extracted together or left empty.

McNemar's test showed that the LLM approach was significantly superior to the rule-based method in determining location (P<.001) but not size (P=.539).

Clustering Performance

The development data yielded an NMI score of 0.7152, an AMI score of 0.6516, and an FM index of 0.5959, whereas the test data yielded scores of 0.6414 (NMI), 0.5598 (AMI), and 0.5354 (FM).

The proposed method outperformed all previous methods in shared tasks across all evaluation metrics. The detailed results and methods are listed in Table 3. Further details of each method are available in a system paper describing this shared task [28-31].

Table . Clustering scores on the test data.

Method Description (System ID[a])	NMI[b]	AMI[c]	FM[d]	Supervised model	LLM[e]
Developed a matrix from word count in radiology reports and applied user-based collaborative filtering for case similarity and clustering, (D1) [28]	0.3569	0.1988	0.2674	No	No
Used paired radiology reports for BERT[f] input, fine-tuned for same-case identification and clustered based on predictions, (E1) [29]	0.5415	0.1489	0.1814	Yes	No
Generated embeddings from text via multilingual BERT trained on Wikipedia, followed by dimensionality reduction, and K-means clustering, (F1) [30]	0.1744	–0.0117	0.1170	No	No
Labels simplified from the TNM[g] classification of lung cancer were assigned to each document using BERT-based model for training, and in the test data, these predicted labels were used as groups for clustering, (J1) [31]	0.4622	0.3409	0.3622	Yes	No
This study	0.6414	0.5598	0.5354	No	Yes

[a]The System IDs are those used in previously shared tasks with the same dataset [5].

Discussion

Principal Findings

The extraction of lung tumor size showed minimal differences compared to the rule-based method, likely because size information is typically accompanied by standardized units (eg, mm or cm). However, the LLM method significantly outperformed the rule-based method in terms of location extraction, achieving over 80% accuracy and reducing the error rate by half. As demonstrated in Figure S3 in Multimedia Appendix 1, the rule-based method frequently generated multiple incorrect location extractions when reports mentioned various anatomical sites, whereas the LLM method successfully identified the correct tumor location. This finding empirically demonstrates the LLM's ability to understand and extract information based on context rather than predefined rules. This capability highlights its value for complex information extraction tasks in medical text analysis, where contextual understanding is crucial.

Comparison to Prior Work

This paper introduces a Japanese LLM algorithm for zero-shot information extraction and clustering that outperforms all previous methods [28-31]. The previous methods (E1, F1, and J1) relied on indirect features extracted by language models, whereas the current approach leverages accurate information extraction through unsupervised learning. The success of this method is particularly notable, given the historically low accuracy of unsupervised methods. By leveraging the LLM's contextual understanding of information extraction, this study demonstrated the potential for effective clustering of medical reports based on various attributes, including disease severity and lesion localization.

Strengths and Limitations

This study has several notable strengths including its methodology and implementation. Accurate information extraction and clustering without supervised learning requirements represent a significant advancement in the field. The flexibility of this method through prompt and algorithmic adjustments suggests broad potential applicability, with potential for further performance improvements through prompt optimization [32]. Furthermore, this method shows particular promise for languages with limited training data compared to English, by converting unstructured reports into language-independent structured data, thereby addressing a crucial gap in current medical text analysis.

However, the limitations must be acknowledged. First, validation was limited to small-scale Japanese datasets. While attempts were made to ensure the representativeness of the dataset by including diverse types of lung cancer cases, this limitation constrained the generalizability of the study findings and should be addressed in future studies through multi-institutional validation. Second, the evaluation focused primarily on clustering tasks; which although is a fundamental task in medical text analysis, its performance in other analytical tasks remains unexplored, suggesting the need for a comprehensive evaluation across various applications. Third, while this method shows promise for languages with limited training data, its generalizability to other languages and medical domains requires further investigation.

Conclusions

The LLM was used to successfully extract important findings from publicly available Japanese radiology reports as highly accurate structured data. By leveraging these structured data, superior results were achieved compared to existing supervised methods for clustering radiology reports. This indicates that employing existing LLMs is effective for solving specific tasks, particularly in languages with a significant shortage of training data compared to English.

Abstract

Background: Defining optimal adjuvant therapeutic strategies for older adult patients with breast cancer remains a challenge, given that this population is often overlooked and underserved in clinical research and decision-making tools.

Objectives: This study aimed to develop a prognostic and treatment guidance tool tailored to older adult patients using artificial intelligence (AI) and a combination of clinical and biological features.

Methods: A retrospective analysis was conducted on data from women aged 70+ years with HER2-negative early-stage breast cancer treated at the French Léon Bérard Cancer Center between 1997 and 2016. Manifold learning and machine learning algorithms were applied to uncover complex data relationships and develop predictive models. Predictors included age, BMI, comorbidities, hemoglobin levels, lymphocyte counts, hormone receptor status, Scarff-Bloom-Richardson grade, tumor size, and lymph node involvement. The dimension reduction technique PaCMAP was used to map patient profiles into a 3D space, allowing comparison with similar cases to estimate prognoses and potential treatment benefits.

Results: Out of 1229 initial patients, 793 were included after data refinement. The selected predictors demonstrated high predictive efficacy for 5-year mortality, with mean area under the curve scores of 0.81 for Random Forest Classification and 0.76 for Support Vector Classifier. The tool categorized patients into prognostic clusters and enabled the estimation of treatment outcomes, such as chemotherapy benefits. Unlike traditional models that focus on isolated factors, this AI-based approach integrates multiple clinical and biological features to generate a comprehensive biomedical profile.

Conclusions: This study introduces a novel AI-driven prognostic tool for older adult patients with breast cancer, enhancing treatment guidance by leveraging advanced machine learning techniques. The model provides a more nuanced understanding of disease dynamics and therapeutic strategies, emphasizing the importance of personalized oncology care.

Introduction

Breast cancer is more commonly diagnosed in older populations, particularly among women aged 65 years and older in wealthier countries. In the United States, the average age of breast cancer diagnosis is 62 years, and in 2020, women aged 70 years and older accounted for 30% of all new cases of the disease [1,2]. In the European Union, women older than 65 years made up about 44% of all breast cancer cases [3]. However, treatment approaches for early-stage breast cancer in these older age groups are often inadequate and unclear, largely due to a lack of solid evidence and the unreliability of web-based tools for making decisions about additional therapies, leading to less than ideal treatment outcomes [4,5].

The treatment plan for breast cancer is tailored based on the cancer's characteristics, the patients' overall health status, and their personal preferences. Standard care for early-stage breast cancer usually involves surgery, and may also include radiation, as well as neoadjuvant or adjuvant systemic therapy, used alone or in various combinations. Crafting postsurgical treatment strategies for older patients with breast cancer is complex due to their typically compromised health and the lack of data from

clinical trials, since older adults are seldom participants in such studies and are not well represented in meta-analyses that evaluate the effectiveness of adjuvant chemotherapy in reducing breast cancer mortality and improving survival rates [6,7]. Consequently, artificial intelligence (AI) has been investigated as a potential tool to support decision-making in the context of limited clinical trial evidence.

Early uses of AI in cancer treatment guidance involved knowledge-based systems [8,9]. Recently, a broader spectrum of machine learning methods has been examined to aid both clinicians and patients with breast cancer [10-15]. Nonetheless, most decision support tools are designed for patients aged between 18 and 65 years, reflecting the age group most studied, with limited research focusing on treatment outcomes for older patients with breast cancer [16-19]. The prognostic tool PREDICT [20], although popular, has shown limited effectiveness for older adult patients [21]. Adjutorium [22], which uses extensive datasets from the United Kingdom and the United States, provides more precise prognosis and treatment benefit predictions for breast cancer than PREDICT. Despite this, it primarily includes patients aged between 30 and 65 years, with fewer older patients in its datasets, and omits certain vital tumor information such as progesterone receptor (PR) status [19]. Another established tool, Adjuvant! Online, predicts 10-year overall survival, breast cancer survival, and recurrence rates, commonly used to inform expected outcomes from endocrine therapy and chemotherapy [23]. Its accuracy is questionable for older women with early-stage breast cancer, probably because it was trained on data with a maximum age limit of 69 years [24]. In a review by Engelhardt et al [25], various models could forecast breast cancer outcomes, typically based on genetic risk scores, but only Adjuvant! Online factored in comorbidity status. Yet, none had been thoroughly validated in older adult populations. The more recent PORTRET tool was designed to predict 5-year recurrence, overall mortality, and mortality from other causes in patients older than 65 years with early invasive breast cancer, as well as to estimate the benefits of adjuvant systemic treatment [26]. The tool's authors observed that their treatment effect estimates were based on data from pooled randomized clinical trials, which might not be entirely applicable to older adults due to the typically selective nature of older participants in these trials.

This study aims to develop models that overcome the shortcomings of past research by using cohorts that accurately reflect the demographic of older patients with breast cancer and by leveraging a detailed dataset that includes administrative, biological, treatment, primary tumor, and survival information. Our latest research uses manifold learning, an advanced tool for nonlinear dimensionality reduction that excels in unraveling complex geometric relationships within high-dimensional data, revealing intricate connections between clinical factors.

We introduce a new prognostic and predictive tool tailored for older adult patients with breast cancer, providing postoperative treatment recommendations. This tool is distinctive in its consideration of the interdependencies among variables within a patient population. It acknowledges the relative importance of prognostic factors in a way that many existing models do not. Our findings are set to be extremely beneficial for oncologists when determining suitable adjuvant treatment approaches for older adult patients with breast cancer, taking into account the nuances of both tumor-related and patient-specific characteristics.

Methods

Recruitment

In this retrospective study, we examined pseudonymized data from women aged 70 years and older who received a diagnosis of early-stage breast cancer and underwent surgery with the intent to cure (either lumpectomy or mastectomy, with or without axillary lymph node dissection) at the French Léon Bérard Cancer Center from January 1997 to December 2016. The French Léon Bérard Cancer Center is a 300-bed comprehensive cancer center located in Lyon, France, serving more than 30,000 patients annually, with a multidisciplinary team of 2000 health care professionals and a catchment area covering southeast France.

The inclusion criteria were not limited by the breast cancer's histological or molecular characteristics, the size of the tumor, or the status of the lymph nodes. However, the study did exclude patients who had noninvasive in situ carcinoma without invasive carcinoma, HER2 (human epidermal growth factor receptor 2) positive breast carcinoma, or who presented with distant metastases at the time of surgery. HER2-positive breast cancer cases were excluded because these patients typically receive trastuzumab-based targeted therapies, which dramatically improved their prognosis following its widespread adoption for nonmetastatic breast cancer around 2005. In contrast, chemotherapy protocols for HER2-negative cases remained consistent during the treatment period of the patients included in this study, ensuring uniformity in therapeutic strategies and outcomes across the cohort. The research concentrated on the 5-year survival rates, selecting only those who had at least 5 years of follow-up and whose vital status information was available.

The database was constructed using ConSore, a data-mining application developed by UNICANCER [27]. The ConSore platform extracts data from the electronic health records of the Léon Bérard Cancer Center, integrating patient demographics, clinical variables, and treatment details. To ensure accuracy, each record was also subject to a manual verification process. Data compiled included demographic details and clinical features of patients at diagnosis, alongside comprehensive biological and disease-specific information, and the treatments administered.

We included the following characteristics for patients diagnosed with early-stage breast cancer: age; Eastern Cooperative Oncology Group performance status; BMI; comorbidities such as diabetes, heart failure, coronary artery disease, chronic obstructive pulmonary disease, and cognitive impairments; history of hospitalizations; and polypharmacy. We also gathered biological indicators at the time of diagnosis, which included hemoglobin levels, lymphocyte counts, and creatinine clearance. We extracted data on disease attributes including histological subtype, hormone receptor status, HER2 status,

Scarff-Bloom-Richardson (SBR) grade, tumor count, size of the largest tumor, and the extent of lymph node involvement as per the Tumor," "Nodes," "Metastases (TNM) classification [28]. The statuses of estrogen receptors (ERs), PRs, and HER2 were determined from the histopathological analysis of pretreatment biopsies. Hormone receptor negativity was classified when fewer than 10% of cells were stained for ER and PR. HER2 negativity was assigned when immunohistochemistry staining was below 1+. For tumors scoring 2+, further in situ hybridization tests were conducted to assess HER2 amplification [29]. Treatment data collected encompassed the type of surgery performed, lymph node dissection, and adjuvant treatments including radiotherapy, chemotherapy, and endocrine therapy.

Outcome, Predictors, and Predictive Power

Outcome was overall survival in 5 years. Due to the high percentage of missing values for cause of death, cancer-specific survival was not considered. Nine predictors were selected: age, tumor size (mm), tumor grade (defined as either SBR low: 1 - 2; or high: 3), number of affected ganglions, hormone-receptor status (positive if either estrogen or PRs were immunohistochemically present in ≥10% of tumor cells; otherwise, patients were classified as triple negative), serum hemoglobin (g/dL) and lymphocyte count (G/L), BMI, and the presence of comorbidities.

The initial database, built using ConSore, compiled a range of clinical, biological, and disease-specific data, along with information on administered treatments. We aimed for a predictors representing a mixture of features typically tested before patients undergo treatment plans. Thus, we excluded features regarding treatments as (1) we wanted to gauge prediction accuracies based only on the initial testing of the patient, and (2) the efficacy of treatment strategies was also an outcome of interest in the study. We further excluded features with significant number of missing values so as to limit the loss of usable data. Creatinine was excluded due to its high correlation with patient's age and potential kidney disorders that are not uncommon in the study's demographic. The feature was found to correlate with negative patient outcome, but this was independent of cancer and introduced a bias. Following these steps, 9 predictors were isolated, a list comprising both continuous and categorical variables, as well as an acceptable mixture of relevant biological and clinical features. Random Forest Classification (RFC) and Support Vector Classifier (SVC) were used to evaluate the predictive power of the selected features. We used 5-fold cross-validation to mitigate overfitting and ensure the validity of our results.

Model Development and Validation

Patients in the initial cohort with missing values for any of the 9 predictors were cut from the study. The remaining patients comprised the model development cohort. This was divided into reference and model data.

Reference Data and Digital Twins

The reference data inclusion criteria were positive outcome for survival in 5 years and remission without relapse by the last follow-up. The purpose of this group was to calibrate the our patented algorithm, generating digital twins for future test subjects. Digital twins refer to synthetic patient data derived from the reference group specifically similar in profile to a new test subject. The model uses these synthetic profiles to recognize complex variations within the test profile. Thus, digital twins are generated and used in the model to provide recommendations on a new patient but do not themselves constitute the result that a physician would need to interpret.

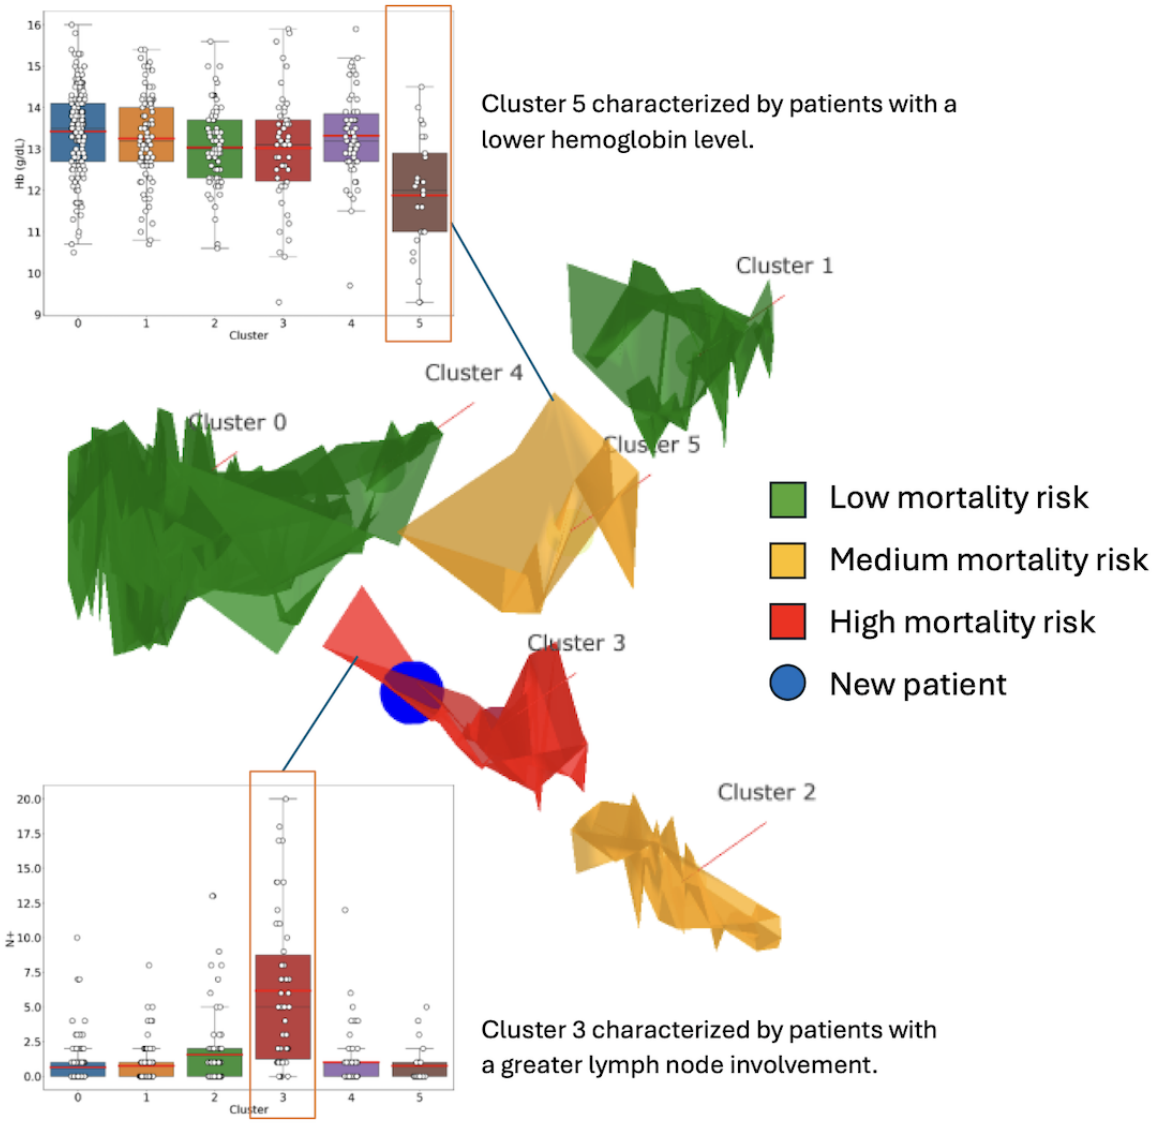
Model Data

The model data, distinct from the reference data to prevent data leaking, are the population that is run through the precalibrated model and scored against the reference group. The data are thus transformed from raw patient data to a numerical and standardized representation of their deviation from the reference group (their digital twins). The purpose of these transformed data is to populate the model with a range of patient profiles that will serve for future prognostic analysis.

PaCMAP, Mean-Shift Clustering, and Manifold Visualization

The transformed model data underwent dimensionality reduction using PaCMAP (Pairwise Controlled Manifold Approximation) [30] to generate 3D data referred to as a manifold, permitting easy visualization. The data were then stratified using mean-shift clustering [31], a nonparametric, density-based clustering algorithm that can be used to identify clusters in a dataset (Figure 1). Each cluster represents a local group of similar patients in the 3D space. Clusters represent typical patient profiles in the overall population. The advantage of clustering is that it captures the variability of subjects of a subgroup for easy analysis. A better understanding of the cluster and its variability allows clinicians to assess whether a new test subject aligns well with the cluster and to identify potential differences. When considering a new patient, estimates of prognosis and expected benefits of adjuvant treatment are ascertained by the examination of cluster-specific treatment outcomes pertinent to the patient's clinical profile.

Figure 1. Graphical representation of the 6 clusters of patients in the 3D manifold space. Patients in the reduced 3D space, or manifold, were grouped into clusters by their spatial distribution and profile similarity. Clusters were then colored based on the overall mortality rate of included patients. A newly tested patient is localized on the manifold and represented by a blue sphere.



Prediction of Chemotherapy Benefit

To estimate the benefit of chemotherapy, the position of a new patient is identified within the 3D manifold. Using the K-nearest neighbors algorithm, the 15 closest chemotherapy-treated patients and the 15 nearest non–chemotherapy-treated patients are pinpointed. Kaplan-Meier (KM) survival curves were plotted for each of these patient groups, providing a visual estimation of chemotherapy benefit for a clinical profile.

Validation of Treatment Benefit Predictions With Kullback-Leibler Divergence

To validate that the distributions of the 2 treatment subgroups are comparable, we used the Probability Density Function, which describes the spread of the data points in the 3D space. To measure the difference between these distributions, we applied the symmetrized Kullback-Leibler (KL) divergence, a statistical method that quantifies how much one distribution differs from another. To assess whether the observed difference was meaningful or just due to random chance, we conducted a permutation analysis. This technique works by randomly shuffling the data multiple times to create many new random comparisons; comparing the real result with the random results allows us to determine whether the observed difference between the distributions was statistically significant. If distributions of 2 different treatment groups were found to be similar, they could be compared to provide a prediction of treatment benefit.

Model Stability Validation

The original model data were split into 2 groups: 70% (327) of every cluster was pooled into the training group, and the remaining 30% (139) was pooled into the test group. A new manifold learning process was applied to the training group, and the test group was then projected onto this newly generated manifold. Patients in the test and model groups from the same cluster of origin were compared to evaluate whether data points would exhibit similar distributions (appear in proximity to each

other) in the new manifold space across 10 different manifold initializations.

Statistical Analysis

Kullback-Leibler Divergence and Permutation Test

The symmetrical KL divergence was used to measure the difference between 2 probability distributions. A permutation test was subsequently conducted to assess the significance of the observed KL divergence. This involved calculating the KL divergence for a large number of permutations of the combined datasets and comparing these values with the original KL divergence. The *P* value is calculated as the proportion of permutations where the KL divergence is as extreme as, or more extreme than, the original KL divergence calculated between the actual groups, thus providing a measure of how likely it was to observe a divergence as extreme as the original, under the null hypothesis of no difference between the distributions. Mathematically, this *P* value is the ratio of the number of permuted KL divergences that are equal to the original KL divergence or greater to the total number of permutations. A low *P*-value suggests that the observed difference in distributions is unlikely to have occurred by chance, thus indicating a significant divergence between the 2 groups.

Survival Analysis using the KM Estimator and Log-Rank Test

The KM estimator was used to generate survival curves for different treatment subgroups. The log-rank test, a nonparametric test, was applied to compare the survival distributions and a *P* value was calculated to determine the statistical significance of the differences observed between the groups. A low *P* value suggests that the observed survival curves are significantly different. The statistical package used for the analysis is Lifelines 0.30.0 (Lifelines Developers) [32].

Ethical Considerations

This retrospective study involving human subjects was reviewed and approved by the French data protection authority, the Commission Nationale de l'Informatique et des Libertés, under authorization number 9191415, dated October 10, 2019. According to institutional and national guidelines, no additional approval from a research ethics board was required, as the data used were previously collected for clinical purposes. No new informed consent was required for this study. The analysis was conducted using data for which participants had provided general consent at the time of data collection. All data were pseudonymized prior to analysis to protect patient confidentiality. No identifiable personal information was retained in the research dataset. No compensation was provided to participants.

Results

Cohort Characteristics

A total of 1229 patients comprised the initial cohort. Of these, 793 (65%) remained after entries with missing values were removed (Figure 2). Eliminating the risk of introducing a bias, the initial cohorts' demographic and clinical characteristics were found to be strictly similar to that of the final cohort and are summarized in Tables 1 and 2.

Figure 2. Flowchart of data construction.

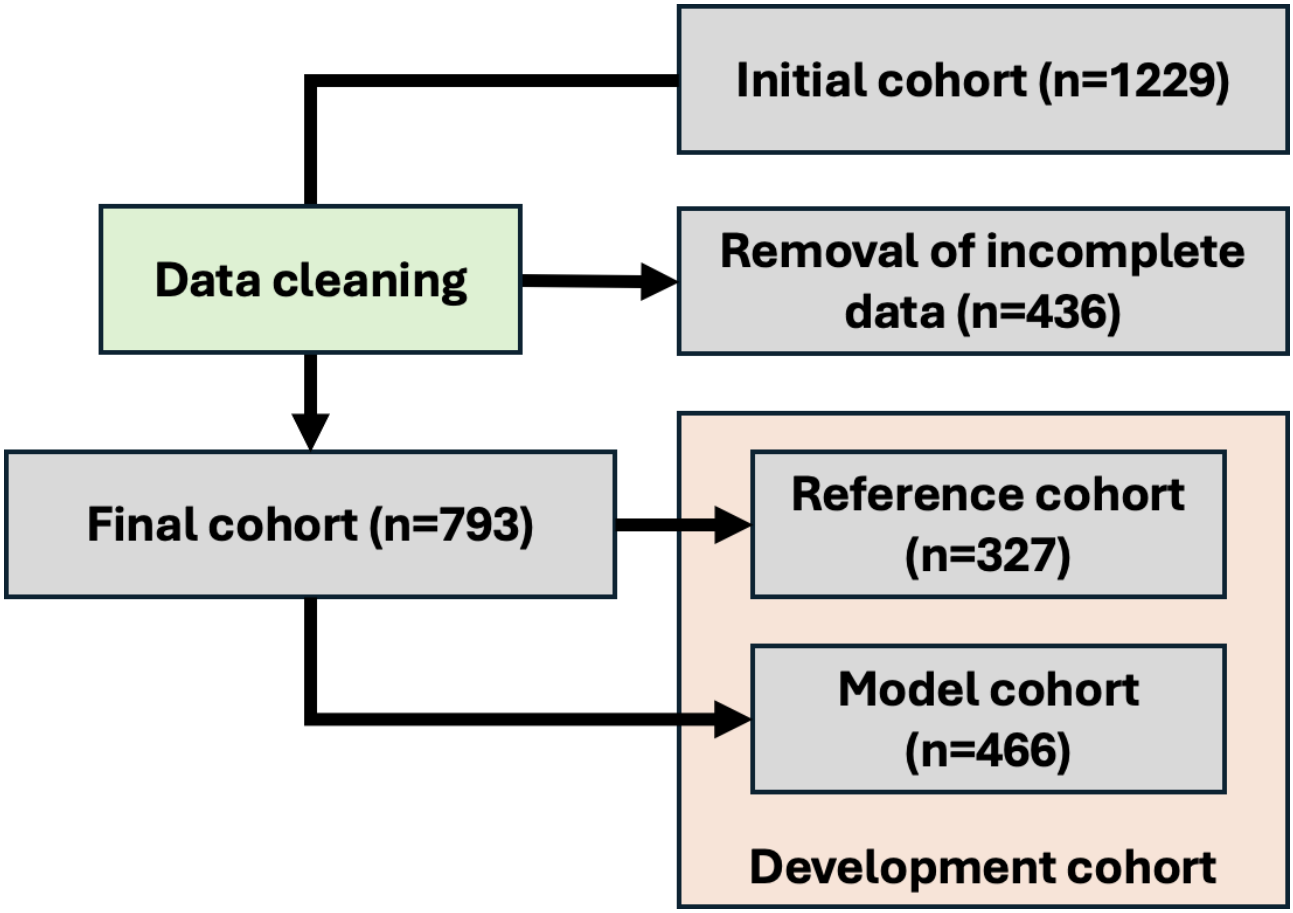


Table . Patient characteristics of the initial cohort (N=1229).

Characteristics	Participants
Age at diagnosis (years), n (%)	
70 - 74	580 (47)
75 - 79	331 (27)
80 - 84	204 (17)
85 - 89	93 (8)
>90	20 (2)
Performance status, n (%)	
0	339 (28)
1	322 (26)
2	48 (4)
3-4	23 (2)
Missing data	497 (40)
BMI, n (%)	
<18.5	32 (3)
18.5 - 25	446 (36)
25 - 30	409 (33)
>30	266 (22)
Missing data	76 (6)
Comorbidities, n (%)	
Creatinine clearance <40 mL/minute	57 (5)
Heart failure	105 (9)
Coronary artery disease	123 (10)
Chronic obstructive pulmonary disease	36 (3)
Diabetes	174 (14)

Table . Cancer characteristics of the initial cohort (N=1229).

Tumor size					
Status	T1	T2	T3	T4	Missing data
Participants, n (%)	567 (46)	286 (23)	36 (3)	250 (20)	90 (7)
Lymph nodes					
Status	N0	N1	N2	N3	Missing data
Participants, n (%)	614 (50)	243 (20)	55 (4)	55 (4)	262 (21)
Grade SBR[a]					
Status	I	II		III	Missing data

Status	Positive		Negative		Missing data
Participants, n (%)	978 (80)		145 (12)		106 (9)
Progesterone receptor					
Status	Positive		Negative		Missing data
Participants, n (%)	838 (68)		285 (23)		106 (9)

[a]SBR: Scarff-Bloom-Richardson.

Patient demographics and characteristics were evaluated on the date of breast cancer diagnosis (Table 1). Median age was 75 years (range: 70 - 100 years), with 317/1229 (26%) patients aged 80 years or older. Performance status was generally good, as most are categorized as 0 or 1. The main comorbidities were diabetes (174/1229 patients, or 14%), followed by coronary artery disease (123/1229 patents, 10%) and cardiac insufficiency (105/1229 patients, 9%).

The majority presented early-stage tumors (T1 in 567/1229 patients, with a prevalence of 46%), and lymph node involvement was mostly absent (N0 in 614/1229 patients, or 50%). The tumors were typically SBR grade II and 80% (978/1229 patients) were ER-positive. Progesterone receptor positivity was also high at 68% (838/1229 patients). Twelve percent of patients (149/1229) were reported to have received chemotherapy (Table 2).

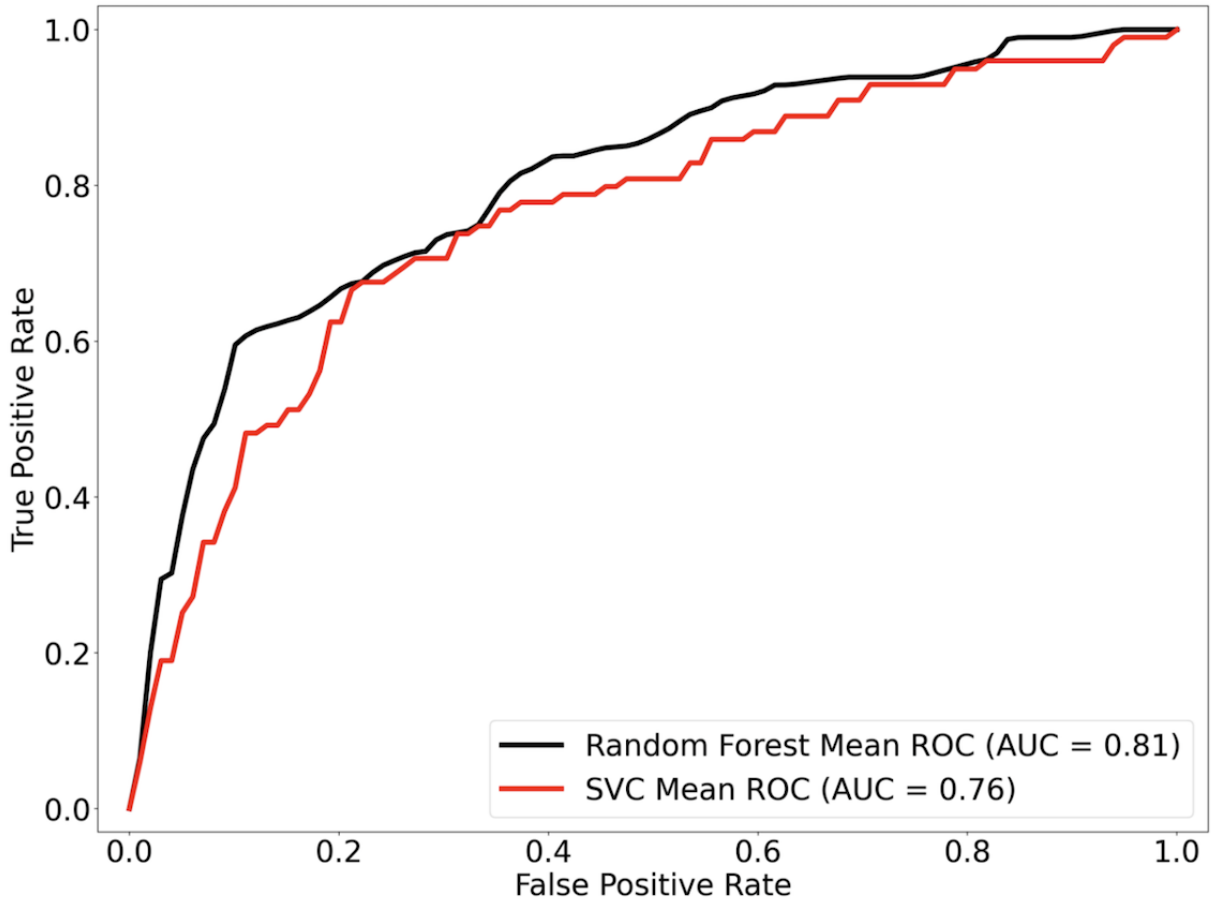
Development Cohort

The final cohort was divided into "reference" and "model" cohorts for model development (Figure 2). A total of 327 patients, that is, 50% of patients meeting the criteria for manifold-estimated derivation training were randomly selected. The purpose of this training group was to calibrate the manifold-estimated derivation–scoring algorithm. The model data comprised all remaining patients (466, 59% of the model development cohort).

Features Performance and Area Under the Curve Scores

In Figure 3, we ascertained the predictive efficacy of the selected variables using RFC and SVC. Analyzing the receiver operating characteristic curves, both models demonstrated commendable predictive capabilities. RFC yielded a mean area under the curve (AUC) of 0.81 (SD 0.06) and a mean accuracy of 0.82 (SD 0.02), while SVC followed closely with a mean AUC of 0.76 (SD 0.05) and a mean accuracy of 0.78 (SD 0.01). The overlapping SDs of these scores suggest that the differences in their performance are not statistically significant.

Figure 3. Receiver operating characteristic curves for 5-year mortality predictive models. The predictive efficacy of the selected features was ascertained using Random Forest Classification and Support Vector Classifier. Results are presented as the mean of ROC and AUC values derived from 5-fold cross-validation. AUC: area under the curve; ROC: receiver operating characteristic; SVC: Support Vector Classifier.



The overall relative importance of variables for the prediction of the 5-year outcome was also determined by RFC (Table 3). Age, tumor size, and hemoglobin were the top predictors, closely followed by lymphocyte count and BMI. Curiously, the cancer grade, axillary lymph nodes involvement, and the presence of comorbidities ranked low in overall importance. This indicates that although typically taken as important factors from a clinical perspective, comorbidities and cancer grade alone are not the best prognostic features in a patient; rather, a patient's overall

biological profile may be more valuable, underscoring the usefulness of manifold learning as a prognostic tool.

Table . Overall importance of predictors according to Random Forest Classification.

Variable	Importance (%)
Age	18.33
Tumor size	17.26
Hemoglobin (g/dL)	16.41
Lymphocytes (g/L)	14.84
BMI	13.06
Lymph nodes involvement	10.39
SBR[a] grade	4.06
ER[b] status	2.88
Comorbidities	2.78

[a]SBR: Scarff-Bloom-Richardson.

[b]ER: estrogen receptor.

Model Stability

Patients in the test and model groups from the same cluster of origin were compared to evaluate whether data points would exhibit similar distributions (appear in proximity to each other) in the new manifold space across 10 different manifold initializations. The distributions of the test group (n=140) consistently matched closely with those of the model group (n=326), with all *P* values being above the threshold of .05 indicating a lack of significant variation between groups (Figure S1 in Multimedia Appendix 1).

Prognostic Ability

The primary objective of our study is to evaluate the prognostic ability of the manifold learning model, as measured by the 5-year survival rate of our population. The 3D clusters in Figure 1 illuminated the landscape of our dataset, representing local groups of patients characterized by distinct clinical and prognostic profiles. Clusters are colored based on the overall mortality rate of included patients: Groups 0, 1, and 4 in green have the best prognosis with a 5-year survival rate of more than 80% while group 3 has the worst prognosis with a 5-year mortality rate of at least 35%.

Table 4 further elucidates the variability in values across the patient clusters, especially in BMI, tumor size (in mm), and median age, underscoring the diversity in our cohort.

Table . Characteristics of the 6 clusters defined by manifold learning.

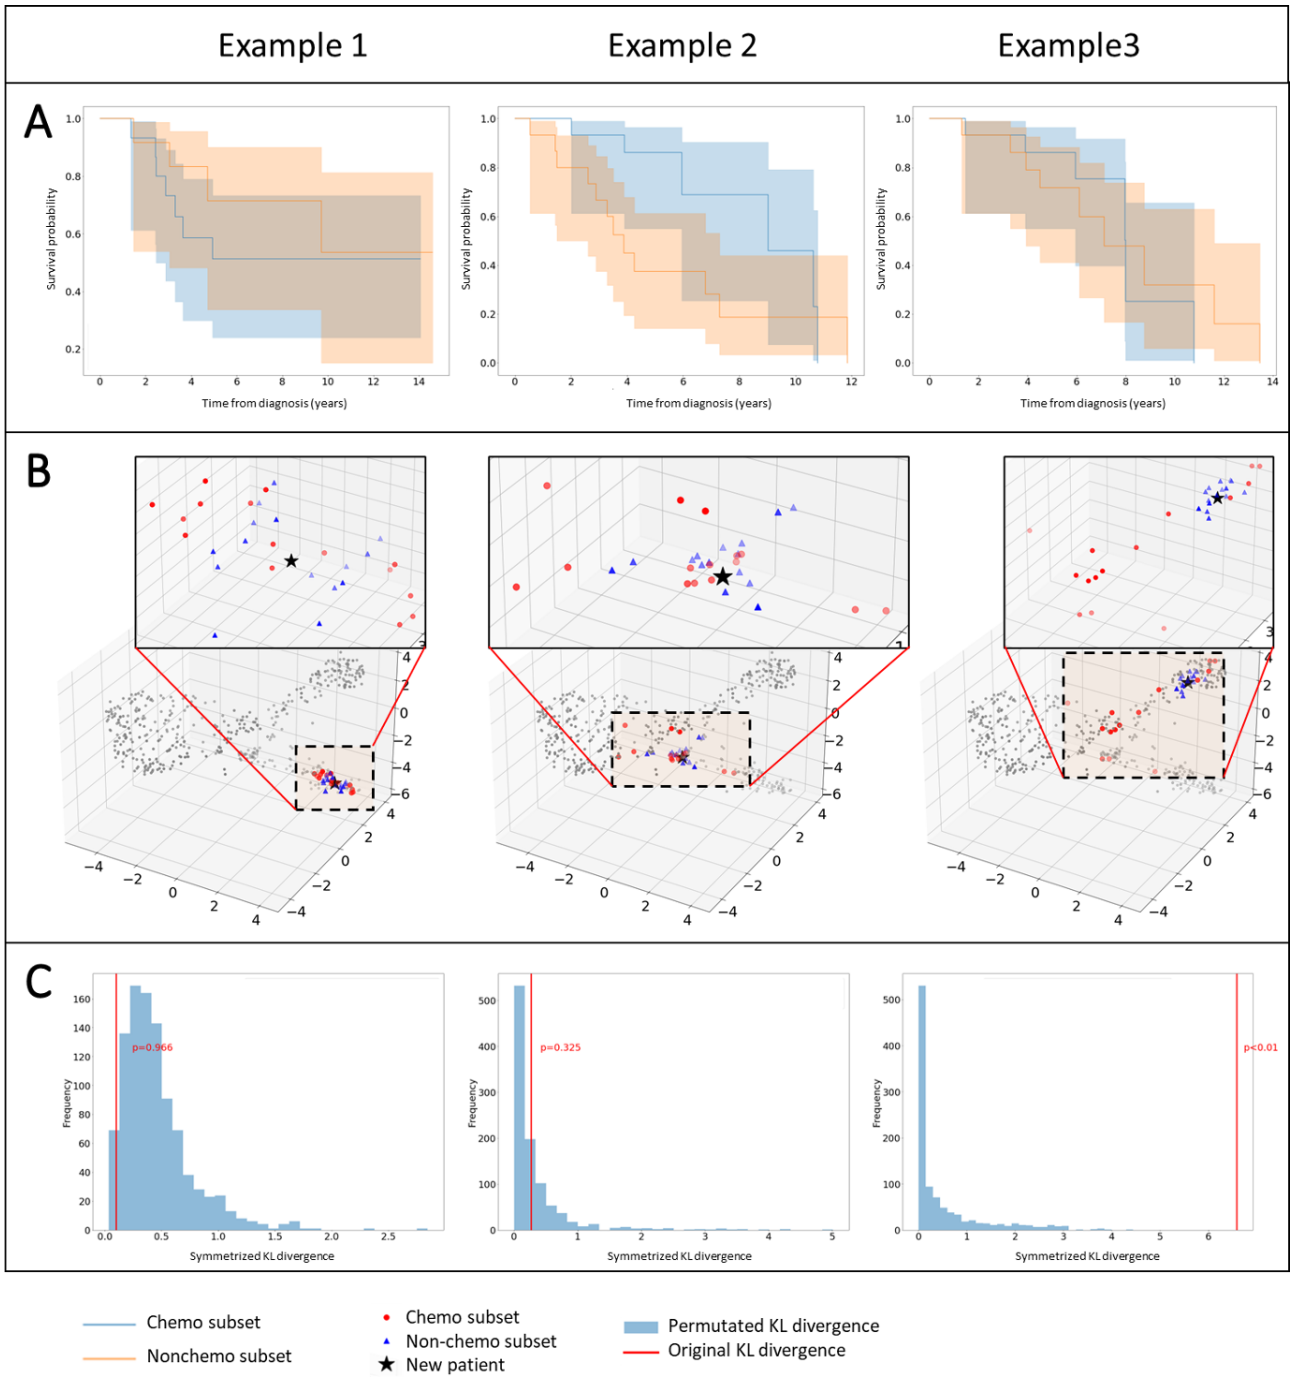
Feature	Cluster					
	0	1	2	3	4	5
Hemoglobin (g/dL)	13.4	13.3	13	13	13.3	11.9
BMI	25	28.4	24.9	28.9	25.6	23
Lymph nodes involved	0.6	0.8	1.6	6.2	1	0.8
Tumor size (mm)	19.6	19.3	26.1	65.8	23.1	30.6
Age (years)	75.8	76.3	77.8	77.4	79.2	80.5
Lymphocytes (g/L)	1.8	2.1	2.1	1.6	3.4	1.6
Comorbidities	0	1	0.4	0.3	0	0.9
Estrogen receptor status	1	1	0	0.8	1	1
SBR[a] (high/low)	0	0.1	0.7	0.5	0.8	0.6

[a]SBR: Scarff-Bloom-Richardson.

Predictive Ability

Next, we attempted to ascertain the individual benefit of performing adjuvant chemotherapy, demonstrated in Figure 4 with 3 examples.

Figure 4. Three case examples assessing the individual benefit of adjuvant chemotherapy. (A) The closest chemotherapy-treated and non–chemotherapy-treated patients to a new patient are identified in the 3D manifold and their survival curves are compared to show the treatment's potential benefit or lack thereof. (B) The new patient's position in the 3D manifold (black star), with the 15 closest patients of each treatment groups are shown, displaying varying distributions of treatment subgroups. (C) To quantify distances between the subgroups, the real calculated KL divergence between the treatment groups' distributions (red line) was compared with that of permutated data (blue histograms) to verify whether observed divergences between treatment subgroups are significant or not. KL: Kullback-Leibler.



When a target patient is localized in the 3D manifold, the closest patient profiles are identified. This is done for 2 treatment groups based on whether the patients received chemotherapy (chemo and nonchemo groups), permitting the visualization of KM survival curves that would show the treatment's potential benefit or lack thereof (Figure 4A).

Figure 4B shows the target patient's position in the 3D manifold (black star), with the 15 closest patients of each treatment groups also marked. In examples 1 and 2, the 2 treatment groups are found to be well "mixed" in the local vicinity of the target, indicating that the target profile is well represented by similar chemotherapy-treated and non–chemotherapy-treated patients. To quantify distances between the subgroups, we used

permutation analysis (Figure 4C). The real calculated KL divergences between the treatment groups' distributions (red line) for examples 1 and 2 fall well within the range of what could be expected by chance (blue histograms) ($P>.1$), indicating that the observed divergences are not significant.

Example 3 showcases a situation where patients from the 2 treatment groups are not well mixed in the local vicinity of the target patient. In this case, the real KL divergence is far right of the histogram ($P<.01$), suggesting a significant difference between the distributions. Thus, the KM survival curves and any conclusion drawn from them must be taken with consideration of the heterogeneity in the profiles of the treatment groups being compared.

Discussion

Principal Findings

From an initial cohort of 1229 patients, we used 793 (65%) to develop a model that clustered patients by their clinical and biological features. These clusters represent a potential prognostic tool for physicians, attributing a risk of mortality in 5 years to patients with consideration to multivariate profiles. The model is further able to indicate the potential benefit or lack thereof of chemotherapy treatment in older adult patients. We found that the predictors used in our model gave a good overall result of 0.81 and 0.76 AUCs with RFC and SVC, respectively.

In summation, our multifaceted approach, blending manifold learning with classical machine learning paradigms and intuitive data visualizations, has unveiled profound insights into the prognosis determinants of early-stage breast cancer in older adults. These revelations bring a more nuanced understanding of the disease and hold promise for tailoring patient-specific therapeutic strategies. Our study's utilization of manifold learning and advanced machine learning algorithms represents a significant contribution to oncology. The accuracy of 81% in differentiating patient subgroups through manifold learning is impressive, showcasing an advancement beyond traditional linear models [33]. This approach is in line with recent trends in personalized medicine [34,35], which discuss the potential of machine learning in cancer prognosis. The high AUC values achieved by RFC and SVC reflect the importance of our combined predictors in medical diagnostics, aligning with the findings of recent studies on the application of machine learning in cancer detection [36,37]. The application of data visualization techniques such as heatmaps and 3D scatterplots in elucidating complex clinical relationships is noteworthy. This approach is supported by advancements in data visualization in medical research, as seen in the study by Borkin et al [38] on how data visualization supports medical decision-making [39,40].

Limitations

The present results should be interpreted in the light of some limitations. First, the monocentric nature of the research may impact the representativeness of the cohort, potentially affecting the generalizability of our findings. Second, the exclusion of specific patient characteristics, such as the ONCODAGE score [41], from our datasets may have limited the comprehensiveness of our prognostic tools. Third, the retrospective design of the study constrains our ability to establish causality between clinical characteristics and patient outcomes. A fourth limitation concerns the fact that patients may present with or have a history of multiple comorbidities. We chose to group together patients with any number of comorbidities for reasons related to (1) the reduction of the sample size for each category of comorbidity, and (2) the potential skewing of patient distribution in the 3D manifold due to multiple related qualitative variables. PaCMAP is susceptible to "overseparate" the population if provided with too many binary features. These reasons in mind, we nonetheless acknowledge that omitting the consideration of multiple comorbidities is a limitation of the study. Other notable limitations include the absence of cancer-specific or treatment-specific survival metrics, a lack of detailed analysis on specific comorbidities, and the need for more data to enhance the less populated clusters. Furthermore, the external validation of our model remains pending, which is crucial for assessing its generalizability.

Future Prospects

Looking forward, the promising application of manifold learning in oncology, as demonstrated in our study, aligns with the burgeoning field of personalized medicine. The integration of machine learning in personalized cancer therapy, as discussed by Danishuddin et al [42], supports the potential of such approaches. The development of advanced AI-driven prognostic tools, particularly for older adult patients who are often underrepresented in clinical trials, could revolutionize treatment guidelines and care approaches. The rapid advancement of machine learning techniques poses a challenge in ensuring the longevity and relevance of models, necessitating continuous updates. This is echoed in the broader context of AI in health care, as discussed in Topol's [43] comprehensive review of AI in medicine. Concerns about the adoption of AI tools due to accuracy, explainability, and ethical considerations are also prevalent, as reflected in the exploration of implementing AI in clinical practice by Char et al [44]. Our findings may open up avenues for the personalized treatment specifically catered to neglected populations in oncology, starting with geriatric patients with breast cancer. We expect our software to provide rapid guidance to physicians in the process of charting treatment plans for their patients, going beyond simple monovariate statistics and instead considering patients' combined clinical and biological profiles.

Conclusions

Our study aimed to further the management of early breast cancer in older adult patients by integrating cutting-edge AI techniques. We proposed a technique that uses patient data to create a visualizable 3D map of pathology profiles that allow rapid prognostic estimations for new patients. These prognostic predictions include the potential benefits of treatment strategies such as chemotherapy, aiding clinical decision-making. It reflects the ongoing evolution in oncology, emphasizing the importance of tailored treatment strategies and highlighting both the potential and the challenges of AI applications in health care. This study also prompts considerations for future research

directions and ethical implications in the rapidly evolving field of AI in medicine.

Data Availability

The data that support the findings of this study are not publicly available due to privacy and confidentiality agreements. However, pseudonymized data may be made available upon reasonable request to the corresponding author and following approval by the French Commission Nationale de l'Informatique et des Libertés under the data-sharing agreements of the Léon Bérard Cancer Center.

Authors' Contributions

FR and PH contributed to conceptualization, methodology, project administration, validation, writing (review and editing). MA contributed to methodology, investigation, data curation, validation, and writing (original draft and editing). AA contributed to conceptualization, supervision, writing (review and editing), and resources.

Conflicts of Interest

The model described in this study was developed by GeodAIsics, who are listed among the authors. PH reports : grants; personal fees; and nonfinancial support from PFIZER, LILLY, DAICHII, and ASTRAZENECA grants, and nonfinancial support from NOVARTIS and ROCHE—personal fees and nonfinancial support from SEAGEN, GILEAD, and MSD—cofounder and chief medical officer of GEODAISICS. AA is the founder and CEO of GeodAIsics. The remaining authors have no conflicts of interest.

Multimedia Appendix 1

Stability analysis of manifold learning applied to clustered data. The original cohort data were divided into 2 groups; 70% of every cluster was pooled into the model group, and the remaining 30% was pooled into the test group. A fresh manifold learning process was applied to the model group, and the test group was then projected onto the newly generated manifold. Patients in the test and model groups from the same cluster of origin were compared to evaluate whether they would exhibit similar distributions (appear in proximity to each other) in the new manifold space. (A) Examples of permutation analysis of clusters 0 and 1. The permutation test determined whether the observed KL (red line) divergence was significantly different from what can be expected from random shuffling of the 2 groups (blue histograms). (B) Table summarizing the median *P* values of the stability tests across 10 different manifold initializations. All *P* values above .05 indicated a lack of significant variation between groups.

Abstract

Background: Progression-free survival (PFS) is a crucial endpoint in cancer drug research. Clinician-confirmed cancer progression, namely real-world PFS (rwPFS) in unstructured text (ie, clinical notes), serves as a reasonable surrogate for real-world indicators in ascertaining progression endpoints. Response evaluation criteria in solid tumors (RECIST) is traditionally used in clinical trials using serial imaging evaluations but is impractical when working with real-world data. Manual abstraction of clinical progression from unstructured notes remains the gold standard. However, this process is a resource-intensive, time-consuming process. Natural language processing (NLP), a subdomain of machine learning, has shown promise in accelerating the extraction of tumor progression from real-world data in recent years.

Objectives: We aim to configure a pretrained, general-purpose health care NLP framework to transform free-text clinical notes and radiology reports into structured progression events for studying rwPFS on metastatic breast cancer (mBC) cohorts.

Methods: This study developed and validated a novel semiautomated workflow to estimate rwPFS in patients with mBC using deidentified electronic health record data from the Nference nSights platform. The developed workflow was validated in a cohort of 316 patients with hormone receptor–positive, human epidermal growth factor receptor-2 (HER-2) 2-negative mBC, who were started on palbociclib and letrozole combination therapy between January 2015 and December 2021. Ground-truth datasets were curated to evaluate the workflow's performance at both the sentence and patient levels. NLP-captured progression or a change in therapy line were considered outcome events, while death, loss to follow-up, and end of the study period were considered censoring events for rwPFS computation. Peak reduction and cumulative decline in Patient Health Questionnaire-8 (PHQ-8) scores were analyzed in the progressed and nonprogressed patient subgroups.

Results: The configured clinical NLP engine achieved a sentence-level progression capture accuracy of 98.2%. At the patient level, initial progression was captured within ±30 days with 88% accuracy. The median rwPFS for the study cohort (N=316) was 20 (95% CI 18-25) months. In a validation subset (n=100), rwPFS determined by manual curation was 25 (95% CI 15-35) months, closely aligning with the computational workflow's 22 (95% CI 15-35) months. A subanalysis revealed rwPFS estimates of 30 (95% CI 24-39) months from radiology reports and 23 (95% CI 19-28) months from clinical notes, highlighting the importance of integrating multiple note sources. External validation also demonstrated high accuracy (92.5% sentence level; 90.2% patient level). Sensitivity analysis revealed stable rwPFS estimates across varying levels of missing source data and event definitions. Peak reduction in PHQ-8 scores during the study period highlighted significant associations between patient-reported outcomes and disease progression.

Conclusions: This workflow enables rapid and reliable determination of rwPFS in patients with mBC receiving combination therapy. Further validation across more diverse external datasets and other cancer types is needed to ensure broader applicability and generalizability.

Introduction

Background and Significance

Real-world evidence (RWE) is increasingly accepted to augment traditional clinical trial findings to better understand the effectiveness of oncological interventions. RWE can be leveraged to improve novel therapy development programs and provide better postmarket surveillance of approved therapies [1-3].

Response evaluation criteria in solid tumors (RECIST) is broadly used to ascertain disease progression in clinical trials. However, assessing RECIST in retrospective electronic health record (EHR) data is challenging due to its strict assessment indicators [4]. RECIST considers changes in the size of individual target lesions over time and the presence or absence of new lesions to categorize disease status into complete or partial response, stable disease, or progression [5]. A similar assessment paradigm is adopted in routine clinical practice, where clinicians document the occurrence of progression through serial clinical and radiological examinations. This clinician-confirmed cancer progression in unstructured text (ie, clinical notes) has been shown to serve as a reasonable surrogate for real-world indicators in ascertaining progression endpoints. This is also more practical for real-world studies than purely RECIST-based approaches [6].

In earlier studies across different types of solid tumors, real-world progression (rwP) was captured either through manual abstraction from unstructured data or proxy measures were evaluated based solely on structured drug data [7,8]. Recent studies have also used machine learning models specifically trained to automate the capture and characterization of clinician documentation of tumor response. These specialized models have shown varying accuracies [9,10]. In the past decade, health care natural language processing (NLP) frameworks like Google's Healthcare Natural Language application programming interface (API), Amazon Comprehend Medical, IBM Watson Health, and Microsoft Text Analytics for Health have emerged and shown promise in clinical concept recognition, entity linking, and sentiment analysis. However, these general-purpose NLP frameworks have shown varying degrees of performance on different data sources [11-13]. While large language models (LLMs) are rapidly advancing, they currently have limitations in clinical concept identification and medical relation extraction as structured outputs for direct application. Even specialized clinical LLMs require further fine-tuning for such use cases [14].

We aim to configure a pretrained, general-purpose health care NLP framework to transform free-text clinical notes and radiology reports into structured progression events. By combining these with structured drug records and encounter data, we will compute real-world progression-free survival (rwPFS) for metastatic breast cancer (mBC). This work can also guide other researchers in configuring a general-purpose health care NLP model to capture rwPFS. Developing a standardized and automated path for ascertaining rwP could help scale rwPFS computation across diverse subsets of solid tumors and maintain a better agreement across real-world studies.

Objectives

We aim to (1) develop and validate a novel semiautomated workflow that estimates rwPFS in patients with mBC, (2) explore the essentiality of each model in the general-purpose NLP framework through ablation analysis, and (3) investigate additional factors influencing rwPFS, such as the source of clinician-documented progressions (radiology reports versus routine clinical notes) and the presence of prior or concurrent medications during the observation period.

Method

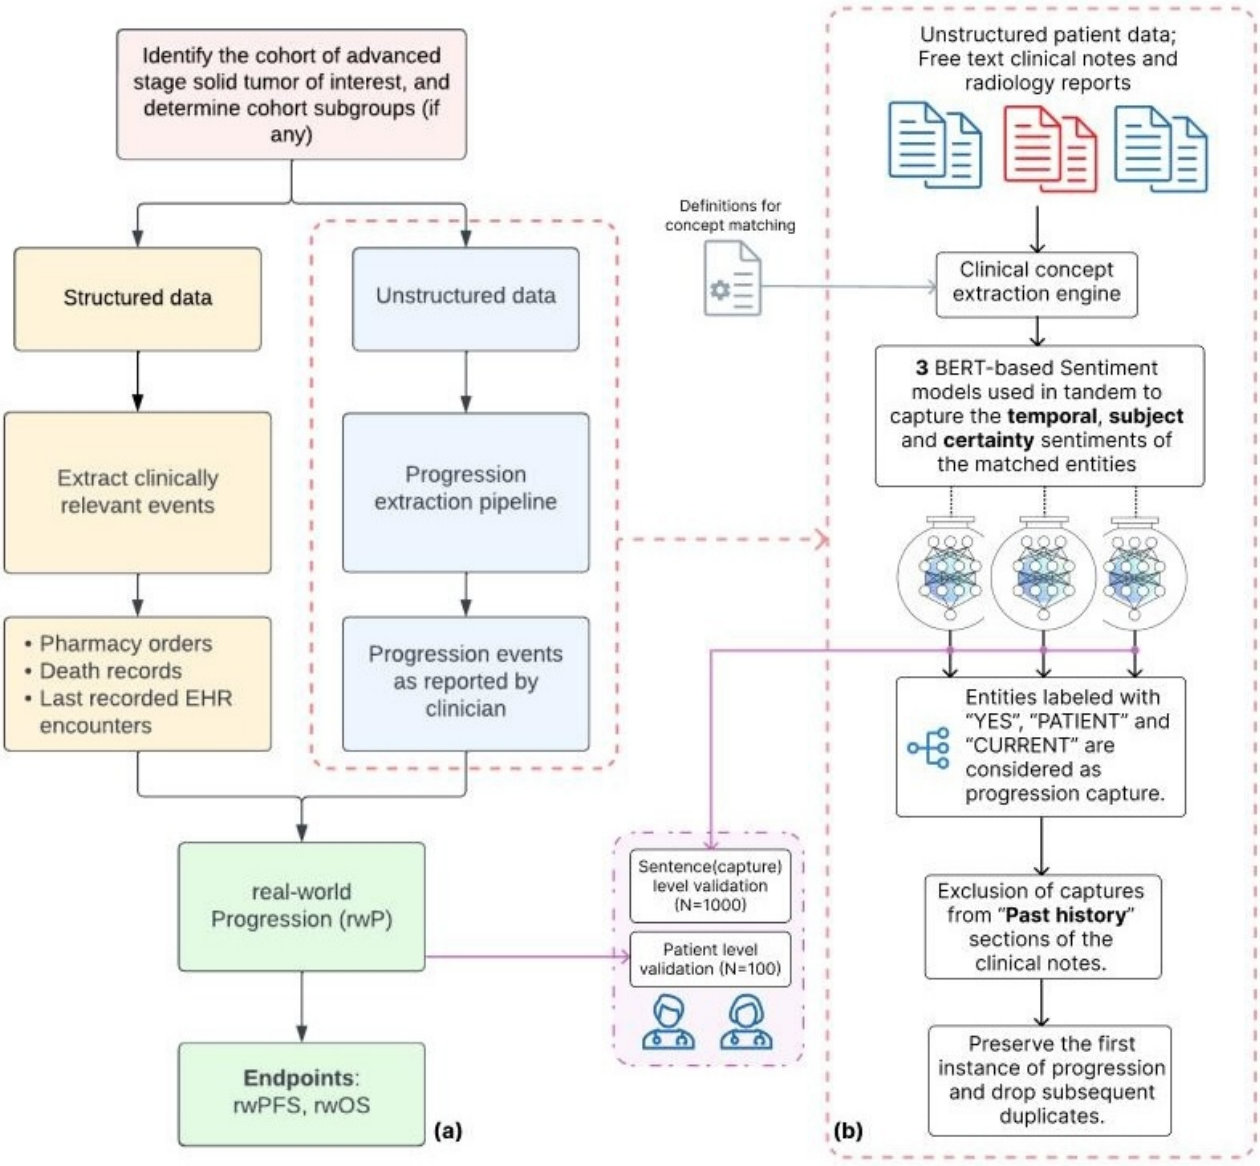
Data Source

This study analyzed deidentified EHR data from a network of tertiary clinical centers tied to an academic medical center (Mayo Clinic) in the United States through the Nference nSights Analytics Platform [15]. In-house tools were used for the deidentification of EHRs. The tool performs with a recall of 0.992 and a precision of 0.979 on the i2b2 2014 dataset at replacing protected health information (PHI) with plausible but fictional surrogates [16]. Overall, the platform hosts data from approximately 7 million patients from across the United States of America, with about 1.8 million patients having a mention of cancer across the structured data. The platform hosts an array of multimodal data, both structured and unstructured, such as clinical notes, radiology reports, Digital Imaging and Communications in Medicine headers, and pathology reports.

Study Design and Definitions

This retrospective observational study demonstrates the estimation of rwPFS with a workflow that integrates clinician-reported progression events from free text (unstructured data) in clinical and radiology documents with structured patient events like drug orders, clinic or hospital encounters, and mortality records. The workflow was developed to leverage the pretrained, general-purpose, deep learning–based health care NLP framework developed at Nference called the clinical NLP engine, which enables clinical concept recognition, sentiment analysis, and linking associated concepts. The models that are a part of the clinical NLP engine were initially trained on human-annotated datasets, and later further augmented by additional ground truth datasets generated by LLM agents from the same parent EHR data source. A high-level overview of the workflow is illustrated in Figure 1.

Figure 1. Methodology flow diagram illustrating the workflow. (**A**) Workflow for real-world progression (rwP) extraction and determining the real-world progression-free survival (rwPFS). (**B**) The methodology for capturing progression from unstructured texts in routine clinical documents and radiology reports using Nference's clinical NLP engine that performs clinical concept recognition, association, and sentiment analysis. BERT: Bidirectional Encoder Representations from Transformers; EHR: electronic health record.



Data Extraction and Augmentation

Breast cancer disease was identified using structured diagnosis codes 174 (*ICD-9* [*International Classification of Diseases, Ninth Revision*]), C50 (*ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*]), and NLP-based positive model confirmations (augmented curation) of the disease-related terms in clinical notes [17]. A similar approach was undertaken for identifying metastatic disease using structured codes 197, 198 (*ICD-9*), C78, and C79 (*ICD-10*). Further cohort attrition for the study population is outlined in Figure 2. Hormone receptor status, human epidermal growth factor receptor-2 (HER-2) status, and Eastern Cooperative Oncology Group scores were captured from clinical notes using the clinical NLP engine. A rule-based approach was used to identify the initiation date of first-line therapy in mBC by analyzing drug orders and administration records. To ensure reliability, only orders appearing for the first time after metastasis diagnosis were included. The same methodology was extended to identify second-line therapies.

Figure 2. Cohort attrition diagram: structured codes 174* (*ICD-9*) and C50* (*ICD-10*) or >4 positive disease sentiments from the augmented curation disease diagnosis model were used for breast cancer. For evidence of metastasis, 197*, 198* (*ICD-9*), C78*, and C79* (*ICD-10*) in conjunction with augmented curation were used; * represents all the children codes within the parent code. ECOG: Eastern Cooperative Oncology Group; EHR: electronic health record; HER-2: human epidermal growth factor receptor-2; HR: hormone receptor; *ICD-9*: *International Classification of Diseases, Ninth Revision*; *ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*; NLP: natural language processing.

Patient Population

The study cohort (N=316) consisted of female patients aged ≥18 years and diagnosed with mBC with hormone receptor–positive and HER-2–negative status with confirmed concurrent exposure to palbociclib and letrozole from January 1, 2015, to December 31, 2021 (study period), and with Eastern Cooperative Oncology Group performance scores of less than 3 around the start of the therapy (±60 d).

Demographics and baseline characterization of the study cohort, such as prior exposure to therapies, disease stage at the start of the study, stage at first cancer diagnosis, and other relevant metrics for the solid tumor of interest, were also documented.

Extracting Progression Events From Unstructured Text

To develop and evaluate our workflow, an initial rule-definition set of 200 cases from the overall mBC cohort (N=10,791) was sampled, and a preliminary manual abstraction was performed. This evaluation aimed to systematically identify a set of rules for configuring the baseline clinical concept extraction model to capture progression. Authors PKM, SKR, VK, and MM used internal clinical document (CD) exploration tools to cluster sentences based on initial pattern matches and iteratively refined these clusters to identify progression-indicative phrases. Independent reviews of oncology and radiology notes were conducted to extract commonly occurring phrases indicative of clinical progression. Authors GV and RHY subsequently collated these identified patterns into a set of regex search patterns. These patterns were tested on clinical notes to ensure they captured the appropriate progression-related contexts while removing duplicate or irrelevant verbatim such as general report headers, unrelated phrases (eg, “CR” for complete response or “PD” for progressive disease without patient-specific context), and noise. Downstream NLP models were applied to validate the extracted patterns by mapping the right set of label combinations that accurately reflected the progression status. This process was repeated iteratively until a consensus was reached among the authors, ensuring a robust set of rules for capturing progression events. The final progression capture configuration is detailed in Table S1 in Multimedia Appendix 1.

The rwP events were captured by configuring the clinical NLP engine. This baseline workflow is an ensemble of deep learning–based multi-BERT (Bidirectional Encoder Representations from Transformers) framework trained on unstructured patient data like CDs and radiology reports to perform named entity recognition and predict the sentiment labels for *subject*, *temporality*, and *certainty* of the captured named entities [18]. The ensemble also infers associations between related entities like disease-severity, drug-disease, and disease-anatomical_structure, among others. These proprietary models are fine-tuned versions of SciBERT-cased [19], a domain-specific transformer model pretrained on scientific text. The base models underwent further supervised fine-tuning for classification tasks on annotated sentences from CD texts of the overall Nference nSights database, but not specifically on the mBC patient note database. The details regarding their architecture, training, and performance of the individual models of the clinical NLP engine are detailed in Note S1 and Table S2 in Multimedia Appendix 1. The clinical NLP engine also uses a section header model to identify the clinical note sections from which the named entities were captured. The rules determined during the initial abstraction were used to capture cancer progression.

rwP Definitions

rwP events were identified by the earliest documentation of disease progression in a clinical or radiology note or by advancement to a new line of therapy. The addition of a new chemotherapy, endocrine therapy, or targeted therapy drug after 60 days of exposure to the initiating therapy of interest is considered line advancement. The following list of drugs were considered potential second-line drug candidates in the study period: tamoxifen, fulvestrant, elacestrant, paclitaxel, carboplatin, abemaciclib, docetaxel, cyclophosphamide, capecitabine, ribociclib, alpelisib, everolimus, doxorubicin, epirubicin, 5-fluorouracil, olaparib, talazoparib, ixabepilone, raloxifene, and toremifene. Censoring events included death, loss of follow-up, and the end of the observation period. Progression events captured within the first 30 days of therapy initiation were excluded as they occurred too early to reflect treatment effectiveness. The rwPFS was also assessed with variations in the origin of unstructured data, comparing radiology reports and CDs as data sources. The key contributing survival variables used for rwPFS were also stratified to understand the source of events.

Progression Capture Validation

Overview

For validation of the clinical progression captures, the manual review and abstraction were performed at 2 levels.

The raw progression captures were evaluated for accuracy independent of their temporality to the observation period. 1000 captures were sampled from the overall pool of progression captures for the sentence-level progression capture analysis.

A stratified sample (mBC validation set; n=100) was selected from the overall study cohort (N=316) to match the progression event occurrence observed in the overall set. This approach ensures that the sample mirrors the broader cohort’s characteristics for a valid comparison in patient-level evaluation for progression capture. These patients were not part of the initial rule-definition set and were evaluated for their first progression events. For the patient-level analysis, the elements of the confusion matrix were defined to account for temporality. We classified the captures into 4 categories: (1) true positives: automated progression captured is within ±30 days of manual capture; (2) false positives: progression was not found through manual capture, but automated progression was captured at any time or automated progression was captured >30 days before manual capture; (3) true negatives: progression was not found through manual review, nor was picked up by automated capture; and (4) false negatives: progression was identified through manual capture, but the automated method has not identified any progression (or) automated method captured progression >30 days after the date captured by manual review.

Ablation Analysis of the Progression Capture Pipeline

To evaluate the contribution of each workflow component to the overall performance, an ablation study was performed at 5 strategic points: (1) temporal model ablation, that is, the removal of the temporality assessment model; (2) subject model ablation, that is, the removal of the subject assessment model; (3) certainty model ablation, that is, the certainty assessment model was removed; (4) all 3 assessment models were removed; and (5) postprocessing ablation where the postprocessing steps, specifically the exclusion of specific note sections and dropping subsequent duplicate mentions of the same note contexts, were removed. Each ablation was analyzed in isolation to quantify its respective contribution to the final output's accuracy, aiding in identifying critical components of the pipeline and potential areas for optimization. This step is further illustrated in Figure S2 in Multimedia Appendix 1.

Validation on the External Dataset

To further assess the generalizability and robustness of the progression capture pipeline, external validation was performed using data from a different partner academic medical center (AMC). In the external dataset, 63 mBC patients on first-line therapy of the metastatic disease with palbociclib with or without aromatase inhibitors were identified for this analysis (see Figure S4 for cohort attrition in Multimedia Appendix 1). Similar NLP-based data augmentation techniques were applied on the external dataset for cohort identification. The proposed progression extraction workflow was applied on the external dataset for extraction of progression events during the defined study period (60 months) of the patients. For validation, similar to the primary cohort, a 2-tier approach was applied, including sentence-level and patient-level validation. For patient-level validation, the time of the first progression event in the patient cohort was manually abstracted and validated. Performance metrics such as precision, recall, accuracy, and F_1-score were calculated to evaluate the alignment of automated progression captures with manual annotations.

Sensitivity Analysis on rwPFS Estimates

Two sensitivity analyses were conducted to assess the robustness of rwPFS estimates: (1) to evaluate the effect of data incompleteness, 10%, 20%, and 30% of rows capturing progression events (missingness at random) were systematically removed from the Kaplan-Meier source data. Median rwPFS and survival probabilities were descriptively analyzed to quantify variations introduced by missing records. (2) The impact of treating death as a progression event versus censoring was assessed by generating Kaplan-Meier curves under both scenarios. Differences were evaluated using the log-rank test, with comparisons of median rwPFS and survival probabilities at predefined time points. These analyses ensured the robustness of rwPFS estimates by addressing potential biases from data structure and event definitions.

Patient-Reported Outcomes and Clinical Progression: Analysis Using the Patient Health Questionnaire-8

Patient-reported outcomes (PROs) were integrated by analyzing Patient Health Questionnaire-8 (PHQ-8) scores to complement clinician-documented progression events. Cumulative declines and peak reductions in PHQ-8 scores were compared between progressed and nonprogressed patients using a *t* test. Peak reduction was determined as the largest decrease observed between any 2 recorded scores during the study period. Cumulative decline, representing the total improvement over time, was calculated as the sum of all positive reductions (decline in PHQ-8 value) in scores across all pairwise comparisons during the study period. This approach aimed to provide a holistic perspective by linking patient-reported mental health outcomes to clinical progression.

Outcomes Assessment

The primary outcome was rwPFS, calculated as the time between the start of the intervention of interest and the first rwP event captured or a change in the line of therapy for the patient. The secondary outcome was real-world overall survival (rwOS), calculated as the time between the start of the intervention of interest and the date of death. A subgroup analysis was performed to assess the impact of prior and other concomitant medications on rwPFS and rwOS in the metastatic setting. The validation metrics of the primary outcome were reported as sensitivity, specificity, accuracy, precision, and F_1-scores.

Median follow-up time was computed from the date of the start of therapy till their last encounter in the EHR system. Time to treatment after the diagnosis of advanced disease (first evidence of metastasis) and follow-up after the start of therapy were imputed using *the date of the first evidence of metastasis* (identified by structured disease code or NLP-positive confirmation) and *the date of the first structured drug order for the combination therapy* (palbociclib and letrozole) as the anchor dates, respectively.

Ethical Considerations

This study analyzed deidentified primary patient-level data extracted from the Nference's, nSights electronic health record database under a data-use agreement that obviates the need for additional institutional review board review. Nference, in collaboration with the AMC data partner that provided the deidentified data for this study, has established a secure data environment, hosted by and within the AMC, that houses the AMC's deidentified patient data. The provisioning of and access to this data are governed by an expert determination that satisfies the Health Insurance Portability and Accountability Act Privacy Rule requirements for the deidentification of PHI. Each AMC's deidentified data environment is specifically designed and operated to enable access to and analysis of deidentified data without the need for institutional review board oversight, approval, or an exemption confirmation. Participants retain the right to opt out at any time. The data are accessible only to authorized users subject to a robust credentialing and authentication process. Data shown and reported in the manuscript have been extracted from this environment using an established protocol for data extraction, aimed at preserving patient privacy. The data have been deidentified pursuant to an expert determination in accordance with the Health Insurance Portability and Accountability Act Privacy Rule. No compensation was provided to individuals whose deidentified records were included.

Statistical Analysis

Data hosted on Nference's nSights environment were imported on demand into the secure code workspaces deployed with Python (version 3.10.6). Missing data imputation was not undertaken. The analysis workflow uses proprietary Python packages with APIs for database querying and data standardization. The descriptive statistics were reported as n (%) and median, IQR. Loss to follow-up was considered as a censoring event for survival estimates. The Kaplan-Meier estimator from the lifelines package 0.27.7 was used in this analysis. The median rwPFS and rwOS were reported, with a 95% CI.

Results

Workflow Configuration

We applied 3 selection conditions to ensure that the progression captures from the clinical NLP engine are relevant and up-to-date with the patient's current status with respect to the clinical note or report. First, entities labeled with "YES," "PATIENT," and "CURRENT," each having a sentiment prediction confidence of ≥0.9, were deemed relevant. Second, to address the issue of "copy-forwarding" in clinical notes, only the first chronological instance of each extracted sentence was retained. Finally, sentences from "Past History" sections were excluded, as they are unlikely to reflect events occurring at the time of documentation. The workflow configuration is illustrated in Figure 1.

Performance Evaluation

The accuracy of the progression capture was evaluated at 2 levels (Table 1): in level 1, sentence-level progression capture validation yielded an accuracy of 98.2% for the relevant progression captures, and in level 2, patient-level validation yielded an accuracy of 88.0%. Ablation analysis revealed the essentiality of the individual components of the clinical NLP engine for progression capture and selection conditions. All steps except the subject sentiment model labels substantially contribute to the overall model performance. This model can be disabled and the workflow performance remains the same. The patient-level workflow performance at each ablation step is outlined in Table 2.

Table . Manual validation was performed for progression at 2 levels.

	Values
Progression capture analysis in level 1[a] (manual validation of sampled raw progression captures [n=1000])	
Sensitivity	99.8%
Specificity	96.7%
Precision	96.6%
Accuracy	98.2%
F_1-score	98.2
First progression capture analysis in level 2[b] (manual validation of first progression [n=100])	
Sensitivity	92.5%
Specificity	83.0%
Precision	86.0%
Accuracy	88.0%
F_1-score	89.1

[a]Level 1: sentence-level review to validate the capture of progression sentiments at the sentence level. At this level, we reviewed the extracted sentences to ascertain the validity of the progression capture at a sentence level.

[b]Level 2: patient-level review to identify the first progression date. Here, we undertook a full review of patient records to ascertain the first progression capture of the metastatic disease.

Table . Output of the ablation analysis showcasing the performance metrics at each step.

	Validation against manually abstracted patient-level dataset (N=100)			
	Accuracy (%)	Sensitivity (%)	Specificity (%)	Median PFS[a] (months), value (95% CI)
Overall workflow	88.0	92.5	83.0	20 (18 - 26)
Temporal model ablation	79.0	91.5	67.9	19 (15 - 23)

Postprocessing ablation	87.0	96.2	76.6	19 (16 - 23)

[a]PFS: progression-free survival.

Cohort Description

The baseline characteristics are detailed in Table 3. The median age at metastasis was 59 (IQR 50.5 - 69) years. The median follow-up time after metastasis diagnosis was 43.3 (IQR 28.1 - 61.2) months and the median follow-up time after the start of the therapy was 39.8 (IQR 25.5 - 57.9) months. The starting dose of palbociclib and letrozole was available for 53.2% and 61%, respectively. The median number of drug orders for palbociclib and letrozole was 6 (IQR 3 - 12) and 4 (IQR 2 - 7), respectively. The treatment characteristics, including prior and concomitant exposure to other chemotherapy agents and a history of prior radiotherapy and breast surgery, are also detailed in Table 3. The breakdown of outcomes and censoring events that contributed to the Kaplan-Meier survival estimates are further detailed in Table 4.

Table . Study cohort characteristics.

Category and variable		Overall mBC[a] cohort (N=316)	mBC validation set (n=100)
Demographics			
	Age at metastasis (y), median (IQR)	59 (50.5 - 68.2)	59.1 (47.8 - 69.2)
	Female gender, n (%)	316 (100)	100 (100)
Ethnicity, n (%)			
	Not Hispanic or Latino	298 (94.3)	94 (94)
	Hispanic or Latino	11 (3.5)	3 (3)
	Unknown or choose not to disclose	7 (2.2)	3 (3)
Race, n (%)			
	Caucasian	293 (92.8)	95 (95)
	Asian	6 (1.8)	1 (1)
	African American or other	17 (5.4)	4 (4)
Tumor markers, n (%)			
	HR-positive[b]	316 (100)	100 (100)
	ER-positive[c] and PR-positive[d]	223 (70.6)	68 (68)
	ER-positive and PR-negative	27 (8.5)	11 (11)
	PR-positive and ER-negative	50 (15.8)	15 (15)
	ER, PR status unknown	16 (5.1)	6 (6)
	HER-2/neu-negative[e]	316 (100)	100 (100)
Disease severity, n (%)			
	Patients with confirmed stage IV [−30,+30] within 30 d of primary diagnosis[f]	196 (61.1)	62 (62)
	ECOG[g] performance score <3	316 (100)	100 (100)
Disease-related follow-up, median (IQR)			
	Follow-up after metastasis (months)	43.3 (28.1 - 61.2)	50.8 (38.6 - 64.2)
Treatment, n (%)			
	Prior systemic therapy	22 (7.5)	6 (6)
	Prior radiotherapy	125 (39.5)	38 (38)

Table . Breakdown analysis of outcomes and censoring events in the mBC[a] cohort.

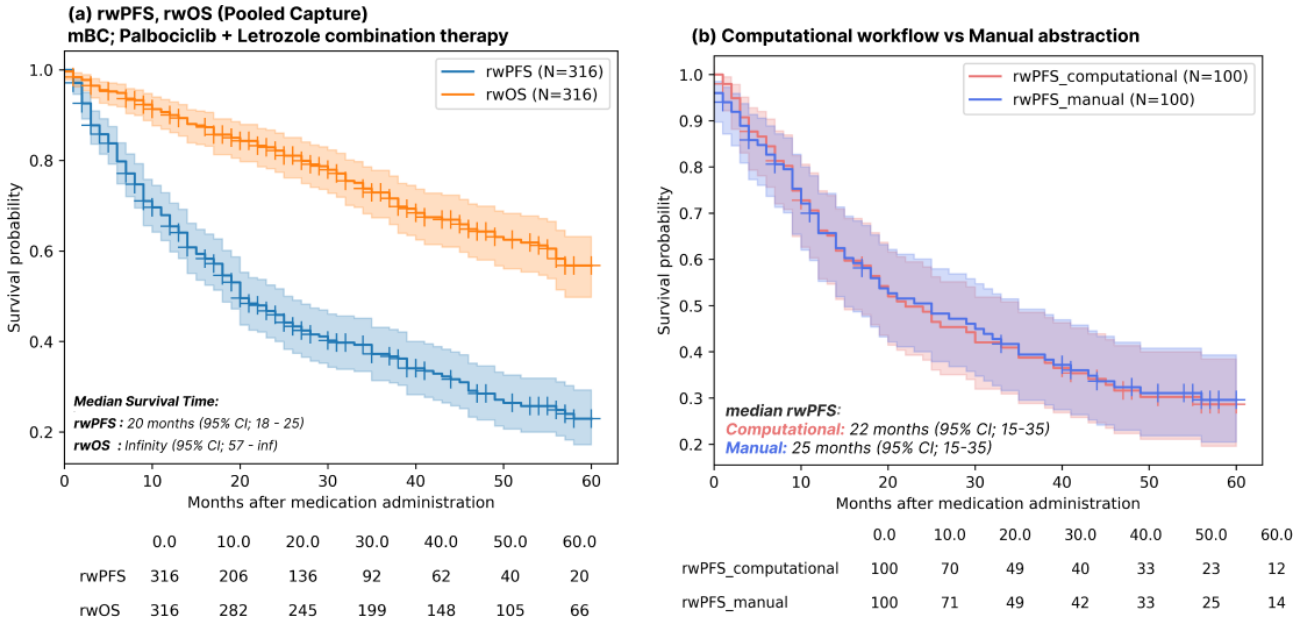
Source of capture		Events, n (%)
Breakdown of progression events (n=199)		
The first event is a progression capture from the pooled sources (n=152)		
	Radiology Reports	78 (51.3)
	Clinical documents	74 (48.7)
The first event is the start of a second-line drug (n=47)		
	Capecitabine	13 (27.7)
	Everolimus	11 (23.4)
	Abemaciclib	9 (19.1)
	Ribociclib	9 (19.1)
	5-Fluorouracil	3 (6.4)
	Olaparib	1 (2.1)
	Cyclophosphamide	1 (2.1)
Breakdown of censoring events (n=117)		
Last encounter date		76 (65)
Patient death date		22 (18.8)
End of study period		19 (16.2)

[a]mBC: metastatic breast cancer.

Outcomes

In the study cohort (N=316), 199 (62.9%) patients progressed during the observation period (60 mo starting from Jan 1, 2015). Out of the progressed patients, 152 (48.1%) were based on progression captures from unstructured data, and 47 (14.8%) were based on changes in the line of therapy from structured data. The median rwPFS for the overall cohort was 20 months (95% CI 18.0 - 25.0; Figure 3A). The median rwOS was not reached during the study period (95% CI 57- not reached [NR]).

Figure 3. Kaplan-Meier survival plots for the overall study cohort and validation sets: (**A**) Kaplan-Meier survival plots indicating the real-world progression-free survival (rwPFS) and real-world overall survival (rwOS) in the study cohort of patients with metastatic breast cancer using pooled note sources. (**B**) Patient-level validation of first progression capture and comparing outcomes estimated by computational workflow with manual curation. mBC: metastatic breast cancer.



In the mBC validation set of 100 patients, the median rwPFS was determined to be 25 (95% CI 15-35) months by manual curation and 22 (95%CI 15-35) months by the computational workflow outlined in Figure 3B. Based on the data source for progression capture, the rwPFS estimated exclusively from radiology reports was 30 (95% CI 24.0-39.0) months, compared to 23 (95% CI 19.0-28.0) months when estimated exclusively from CDs, as represented in Figure 4. Subgroup analysis on the

rwPFS based on prior or concomitant therapies is detailed in Figure 5.

Figure 4. Kaplan-Meier survival plots for real-world progression-free survival (rwPFS) based on the patient note source. Survival plots indicating the real-world rwPFS with progressions captured from solitary sources of radiology reports (RR) and routine clinical documents (CD). mBC: metastatic breast cancer.

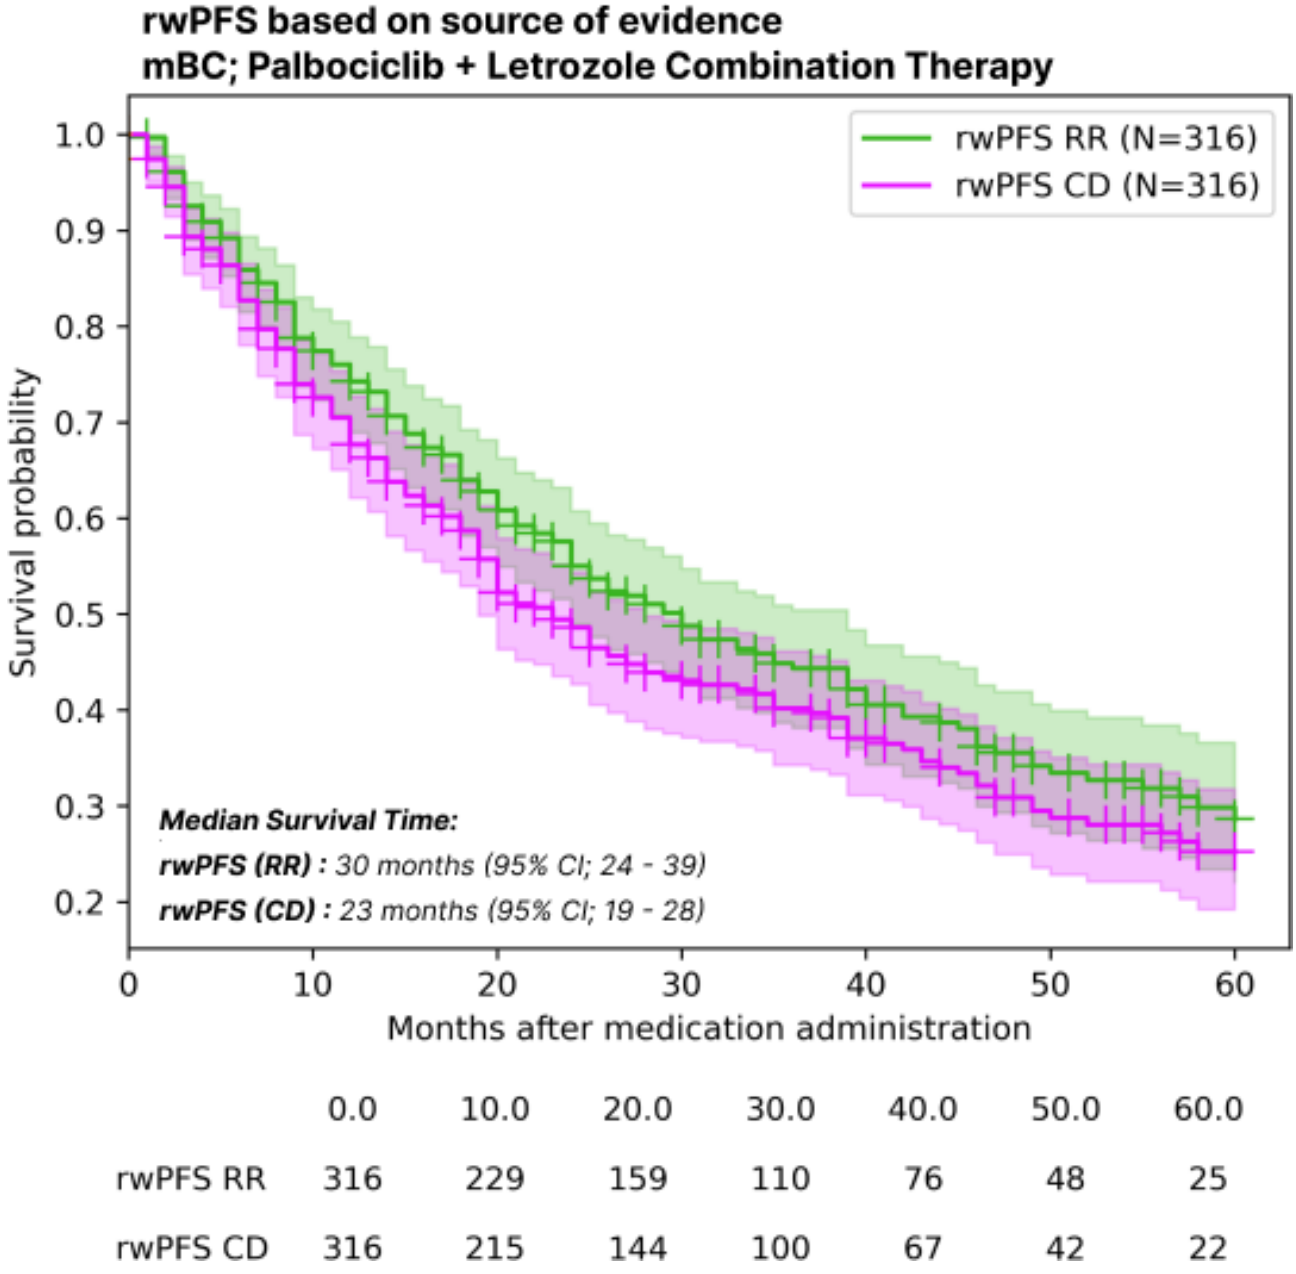


Figure 5. Kaplan-Meier survival curves for subgroup analysis. Each of the subgroups account for different variations in treatment patterns. The survival curves and risks table showcase the effect of other prior or concomitant systemic therapies on the median real-world progression-free survival (rwPFS).

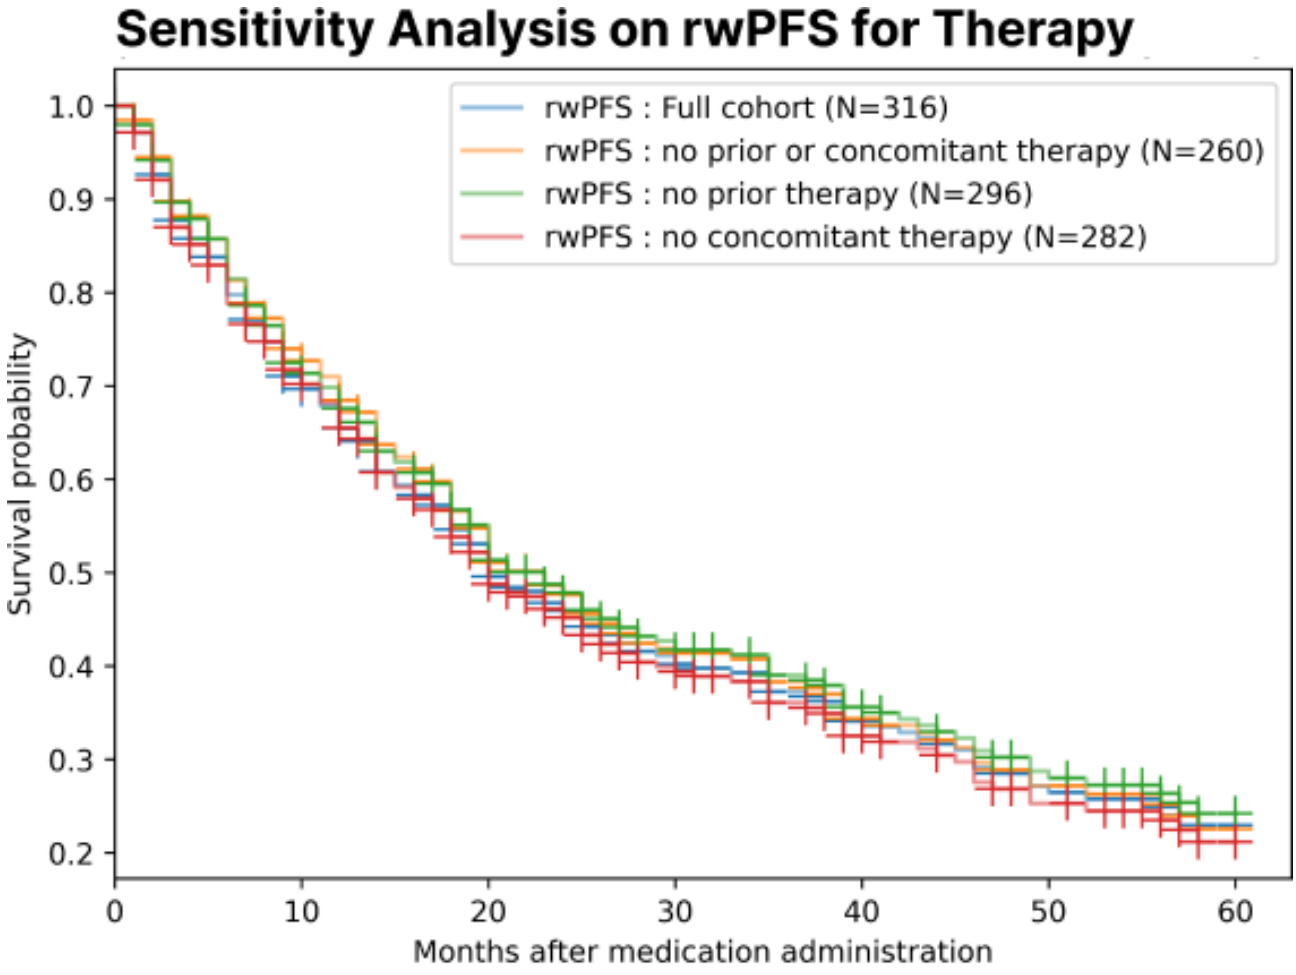

Time	Median rwPFS estimate	Time(months)						
		0(N)	10	20	30	40	50	60
rwPFS : Full cohort	20.00 months (95% CI 18.0-25.0)	316	206	136	92	62	40	20
rwPFS : no prior or concomitant therapy	23.00 months (95% CI 19.0-27.0)	260	176	118	78	50	34	14
rwPFS : no prior therapy	23.00 months (95% CI 19.0-28.0)	296	196	132	89	60	39	19
rwPFS : no concomitant therapy	20.00 months (95% CI 18.0-25.0)	282	186	122	81	52	35	15

External Dataset Validation

External validation was conducted using data from a partner AMC, representing a health system distinct from the main study, to assess the generalizability and robustness of the progression capture pipeline. At Level 1, manual validation of 200 sampled raw progression captures achieved an accuracy of 92.5% and an F_1-score of 92.8%, while Level 2 validation of the first progression in 61 patients reported an accuracy of 90.2% and an F_1-score of 92.5%. Two patients were excluded from performance metrics because the textual evidence identified during manual abstraction of the first progression event was unavailable to the automated extraction pipeline. Comprehensive performance metrics, including sensitivity, specificity, and F_1-scores, are detailed in Table 5.

Table . Manual validation of the progression capture workflow on the external dataset.

Validation step	Sensitivity	Specificity	Accuracy	Precision	F_1-score
Level 1					
Manual validation of sampled raw progression captures (n=200)	89.7%	95.7%	92.5%	96%	92.8%
Level 2					
Manual validation of first progression (n=61)	97.4%	78.3%	90.2%	88.1%	92.5%

Sensitivity Analysis on rwPFS Estimates

The sensitivity analysis demonstrated that rwPFS estimates were robust under varying conditions. Systematic removal of 10%, 20%, and 30% of progression events resulted in median rwPFS values of 20 (95% CI 18-26) months, 20 (95% CI 18-27) months, 22 (95% CI 18-28) months, and 23 (95% CI 19-29) months for the complete, 10%, 20%, and 30% datasets, respectively, with widening CIs indicating increased uncertainty. Similarly, median rwPFS estimates were comparable when death was treated as censorship versus a progression event, with values of 20 months (95% CI 18-25) and 18 months (95% CI 15-21) in the main dataset. These findings, along with overlapping CIs, indicate that the rwPFS estimates were not meaningfully affected by missing data or event definitions. See Figure S5 in Multimedia Appendix 1 for Kaplan-Meier curves and event tables.

PHQ-8 Outcomes and Disease Progression

Of the 316 patients, 94 had at least 2 PHQ-8 scores recorded during the study period, including 30 nonprogressed and 64 progressed patients. Nonprogressed patients showed greater mean peak reduction (5.57, SD 5.90 vs 2.95, SD 4.30; t_{92}=−2.397, P=.02) and cumulative decline (mean 8.00, SD 12.68 vs 3.66, SD 6.40; t_{92}=−2.201, P=.03) in PHQ-8 scores compared to progressed patients. See Table S3 in Multimedia Appendix 1 for details.

Discussion

Overview

The study showcases the development and validation of a novel semiautomated workflow for estimating rwPFS in patients with mBC using deidentified EHRs. One of its key strengths lies in the integration of NLP techniques to extract clinician-reported progression events from unstructured data sources such as clinical notes and radiology reports, combined with structured patient data like drug orders and clinical encounters. This approach enhances the accuracy and comprehensiveness of capturing progression events, as evidenced by the high sensitivity (99.8%) and specificity (96.7%) at the sentence level with good patient-level accuracy (88%).

While our initial goal was to develop a fully automated workflow for capturing disease progression, we have successfully implemented a semiautomated approach. This is advantageous because the semiautomated method allows for disease-specific adjustments to clinical concept recognition configurations, ensuring relevance across various cancer types. This flexibility underscores the potential for broader applicability beyond mBC, making it a valuable tool for oncological research and RWE generation.

Principal Findings

The median rwPFS of 20 months (95% CI 18 - 25) reported in this study is comparable to those reported in previous real-world studies and clinical trial results, validating the workflow's reliability and accuracy [20,21]. Subgroup analysis revealed the impact of prior and other concomitant medications on median rwPFS. For instance, the PALOMA-2 trial reported a median progression-free survival (PFS) of 24.8 months (95% CI 22.1-inf), which is comparable to the real-world observation in the study subcohort (N=260) of patients who received palbociclib and letrozole in the first-line metastatic setting (patients with no other prior or concomitant drugs), which was 23.00 months [22]. A matched comparison between the study cohort and other real-world cohorts or clinical trials could further establish the concordance between the survival estimates. Integrating progression events from both radiology reports and routine clinical or oncology notes standardizes the identification of disease progression, mitigating biases and overestimation that can arise from relying exclusively on a single data source. Ablation analysis also revealed the futility of using the subject sentiment analysis model in the workflow, as physicians are unlikely to describe the progression status of a family member or a blood relative in the patient's notes. While this model is useful for extracting other concepts using the clinical NLP engine, it has shown no benefit in its usage for progression capture.

The external validation further demonstrated the robustness and generalizability of the progression capture workflow across health systems. Manual validation on this dataset also achieves high accuracy at the sentence level (92.5%) and at capturing the first progression event (90.2%). Sensitivity analysis confirmed that rwPFS estimates were stable, regardless of whether death was treated as censorship or an event, with overlapping CIs observed across both scenarios. Sensitivity analysis confirmed that rwPFS estimates were stable across varying levels of missing data and event definitions, with slight increases in median rwPFS and wider CIs under data incompleteness and overlapping intervals when treating death as censorship or an event. Furthermore, integration of PHQ-8 outcomes revealed significant associations between patient-reported mental health and progression status,

highlighting the potential of PROs to provide complementary insights.

Comparison to Prior Work

The study also highlights the importance of source data used for determining rwPFS. Relying solely on radiology reports overestimated the median rwPFS compared to estimates derived from both clinical notes and radiology reports combined. The median rwPFS from the pool of free-text data excluding radiology reports (23 months) was closer to the median survival of the overall study cohort with all available pooled free-text data (20 months) when compared to the median rwPFS computed from free-text data exclusively from radiology reports (30 months). This discrepancy can be explained by the observation that patients can undergo radiological evaluations outside the EHR data network, with their findings being documented by treating physicians within the EHR network in patients' routine clinical notes. Similar findings were observed in a previous study that analyzed the impact of source data on real-world survival estimates [6]. Additionally, relying solely on structured data like drug records (time to discontinuation or time to next treatment) as a surrogate for rwPFS has been shown to underestimate the median rwPFS substantially in a prior study [23]. PROs provide direct insight into a patient's symptoms and quality of life and have been linked to progression-free and overall survival in prior studies. Although direct comparisons with alternative workflows were not performed, our method demonstrates performance metrics that are in line with those reported in previous studies, warranting further comparative analyses in future work.

Among other computational techniques for characterizing cancer response in real-world data (RWD), the use of LLMs has also shown promise. A prior study evaluating this has shown GatorTron to be the best-performing model, achieving an accuracy of 89% at the radiology report level upon fine-tuning [24]. However, applying LLMs across a broader patient corpus needs further investigation to fully ascertain their validity and generalizability. PROs provide direct insight into a patient's symptoms and quality of life and have been linked to progression-free and overall survival in prior studies [25-27]. We have observed significant associations between the decline in PHQ-8 scores and the patient's progression status.

Limitations

There are, however, limitations to this study. First, the reliance on clinician-reported events means that the accuracy of the workflow is reliant on the quality and completeness of clinical documentation. Incomplete or inconsistent documentation could lead to underestimation or overestimation of progression events. To mitigate this, careful validation of extraction patterns and data completeness checks were implemented. Second, although the semiautomated workflow reduces the resource-intensive nature of manual abstraction, it requires initial manual rule definition and configuration, which could introduce biases based on the selected rules and criteria. Representative evaluation samples were curated across the breast cancer cohorts to reduce the biases. Third, sensitivity analyses were limited primarily to variations in clinical text sources and censoring definitions. Expanding sensitivity analyses to include demographic factors, alternative definitions of progression, and data-source reliability could further strengthen the robustness of the findings. Fourth, augmenting the mortality data with commercial and federal death registries could enhance the accuracy of survival estimates. This was not feasible in the present analysis but represents an important area for future improvement. Fifth, integration of PROs could provide a more comprehensive understanding of patient well-being in relation to progression events. However, demonstrating this in RWD was challenging due to the limited availability of patient-reported records. Finally, the ensemble deep learning engine's performance was evaluated within a specific cohort of mBC patients; thus, further validation across more diverse external datasets and different cancer types is necessary to truly establish the generalizability of the workflow.

Future Directions

These findings align with the growing body of research advocating for integrating artificial intelligence and machine learning in health care data analysis, as these technologies can substantially enhance the speed, accuracy, and breadth of data processing capabilities. Future work will explore more advanced text data analysis and extraction methods, such as adaptive machine learning techniques and LLMs, to minimize manual import and enhance scalability. Furthermore, by using federated learning, insights and patterns from diverse populations across various institutions can be pooled securely, enriching the model's generalizability and performance across different health care settings. The successful implementation of this automated workflow demonstrates its potential to streamline the data extraction process from EHRs from various health systems. It also paves the way for its application in other oncological studies, where similar challenges in data abstraction exist.

Conclusions

Developing a practical and scalable method for capturing real-world progression from EHR data is crucial to improving oncological research and patient care. Overall, this technology represents a step forward in realizing the full potential of EHR data in oncology. Our findings establish a workflow for automated data capture to provide a more efficient and scalable method than traditional manual processes, particularly in handling complex, unstructured EHR data. Although the principles of progression capture remain the same across other cancer types, further research across other types of solid tumors is needed to ascertain the generalizability of the workflow.

Acknowledgments

We thank the peer reviewers for their thoughtful reviews and feedback, which greatly improved the quality of the final manuscript.

Data Availability

The deidentified patient-level EHR data that underpin the findings of this study are not publicly available due to the expert-determination process required to preserve Health Insurance Portability and Accountability Act–compliant deidentification and the terms of our data use agreement. Aggregate results and metadata supporting the conclusions are available from the corresponding author on reasonable request and subject to a data-sharing agreement. Qualified researchers may also request access via the Nference nSights Analytics Platform [15], under existing privacy and security controls. The analytic code and any training or validation datasets remain proprietary and are not publicly available.

Authors' Contributions

GV led data curation, formal analysis, visualization, writing of the original draft, review, editing, and contributed to the methodology. RKY contributed to the methodology, data curation, formal analysis, investigation, and visualization. PK was responsible for conceptualization, methodology, lead investigation, funding acquisition, lead supervision, and manuscript review and editing. BSA, SC, SKR, VK, and MM contributed to data curation and validation, with MM also involved in investigation. KP contributed to data curation, methodology, and investigation. AvA developed the clinical NLP engine software for NLP model inference. SJ developed the NLP models and software. AkA contributed to software development and provided feedback. RB and VT provided feedback, project administration, with VT also providing resources. PL and SAS contributed to validation, feedback, and writing review and editing; SAS also provided resources. VS provided supervision. All authors read and approved the final manuscript.

Conflicts of Interest

GV, PK, KP, SC, AvA, MM, SJ, AkA, RB, VT, PL, and VS are current employees of Nference, inc and hold a minority stake in the company. RKY, BSA, and VK are past employees of Nference. SAS is affiliated with Mayo Clinic, Rochester. The authors declare no further competing interests in the findings of the study.

Abstract

Background: Diagnosing and managing follicular thyroid neoplasms (FTNs) remains a significant challenge, as the malignancy risk cannot be determined until after diagnostic surgery.

Objective: We aimed to use interpretable machine learning to predict the malignancy risk of FTNs preoperatively in a real-world setting.

Methods: We conducted a retrospective cohort study at the Peking University Third Hospital in Beijing, China. Patients with postoperative pathological diagnoses of follicular thyroid adenoma (FTA) or follicular thyroid carcinoma (FTC) were included, excluding those without preoperative thyroid ultrasonography. We used 22 predictors involving demographic characteristics, thyroid sonography, and hormones to train 5 machine learning models: logistic regression, least absolute shrinkage and selection operator regression, random forest, extreme gradient boosting, and support vector machine. The optimal model was selected based on discrimination, calibration, interpretability, and parsimony. To address the highly imbalanced data (FTA:FTC ratio>5:1), model discrimination was assessed using both the area under the receiver operating characteristic curve and the area under the precision-recall curve (AUPRC). To interpret the model, we used Shapley Additive Explanations values and partial dependence and individual conditional expectation plots. Additionally, a systematic review was performed to synthesize existing evidence and validate the discrimination ability of the previously developed Thyroid Imaging Reporting and Data System for Follicular Neoplasm scoring criteria to differentiate between benign and malignant FTNs using our data.

Results: The cohort included 1539 patients (mean age 47.98, SD 14.15 years; female: n=1126, 73.16%) with 1672 FTN tumors (FTA: n=1414; FTC: n=258; FTA:FTC ratio=5.5). The random forest model emerged as optimal, identifying mean thyroid-stimulating hormone (TSH) score, mean tumor diameter, mean TSH, TSH instability, and TSH measurement levels as the top 5 predictors in discriminating FTA from FTC, with the area under the receiver operating characteristic curve of 0.79 (95% CI 0.77 - 0.81) and AUPRC of 0.40 (95% CI 0.37-0.44). Malignancy risk increased nonlinearly with larger tumor diameters and

higher TSH instability but decreased nonlinearly with higher mean TSH scores or mean TSH levels. FTCs with small sizes (mean diameter 2.88, SD 1.38 cm) were more likely to be misclassified as FTAs compared to larger ones (mean diameter 3.71, SD 1.36 cm). The systematic review of the 7 included studies revealed that (1) the FTA:FTC ratio varied from 0.6 to 4.0, lower than the natural distribution of 5.0; (2) no studies assessed prediction performance using AUPRC in unbalanced datasets; and (3) external validations of Thyroid Imaging Reporting and Data System for Follicular Neoplasm scoring criteria underperformed relative to the original study.

Conclusions: Tumor size and TSH measurements were important in screening FTN malignancy risk preoperatively, but accurately predicting the risk of small-sized FTNs remains challenging. Future research should address the limitations posed by the extreme imbalance in FTA and FTC distributions in real-world data.

KEYWORDS

follicular thyroid neoplasm; machine learning; prediction model; malignancy; unbalanced data; literature review

Introduction

Globally, thyroid neoplasms are becoming increasingly prevalent [1]. Among them, follicular thyroid neoplasms (FTNs) represent a major type but have garnered significantly less attention compared to papillary thyroid carcinoma. A key challenge is that over 95% of FTN cases cannot be reliably distinguished as benign (follicular thyroid adenoma [FTA]) or malignant (follicular thyroid carcinoma [FTC]) until diagnostic surgery [2]. This uncertainty often leads to both over- and undertreatment of patients with FTN. On one hand, it is estimated that over 80% of patients who undergo thyroidectomy might ultimately be diagnosed as benign FTN based on postoperative pathology [3]. On the other hand, those with malignant FTN may have already developed distant metastases to the lungs, bones, or other organs by the time they receive surgical treatment.

Several guidelines advocate for enhanced screening, accurate diagnosis, and appropriate treatment for patients with FTN [4,5]. One crucial solution is to develop prediction models to aid clinical decision-making for these patients. To date, machine learning has been proven effective in constructing predictive models for various cancers such as oral, gastrointestinal, and breast cancers [6-8]. Our literature review also indicated that machine learning technology excels at capturing complex, nonlinear relationships and high-dimensional intercorrelations among predictors [9-12].

However, our literature review revealed several limitations among most of the existing studies, mainly including (1) small sample sizes ranging from 18 to 888 participants [13-19], (2) the ratio of FTA to FTC deviating from the real population distributions, (3) reliance on simple linear models unable to capture the complex nonlinearity or interactions underlying predictor-outcome relationships [14,18], (4) using inappropriate metrics to evaluate model performance for the unbalanced data [13-19], (5) lack of assessing the extent to which a predictor influences the model's prediction (ie, model interpretability) [13,16,19], (6) not evaluating whether the predicted probabilities were consistent with actual outcomes (ie, model calibration) in the development and validation of clinical prediction models [20], and (7) predictors are predominantly confined to sonographic features with limited consideration of other factors such as the presence of Hashimoto thyroiditis (an autoimmune disease that may increase the risk for differentiated thyroid cancer [21]).

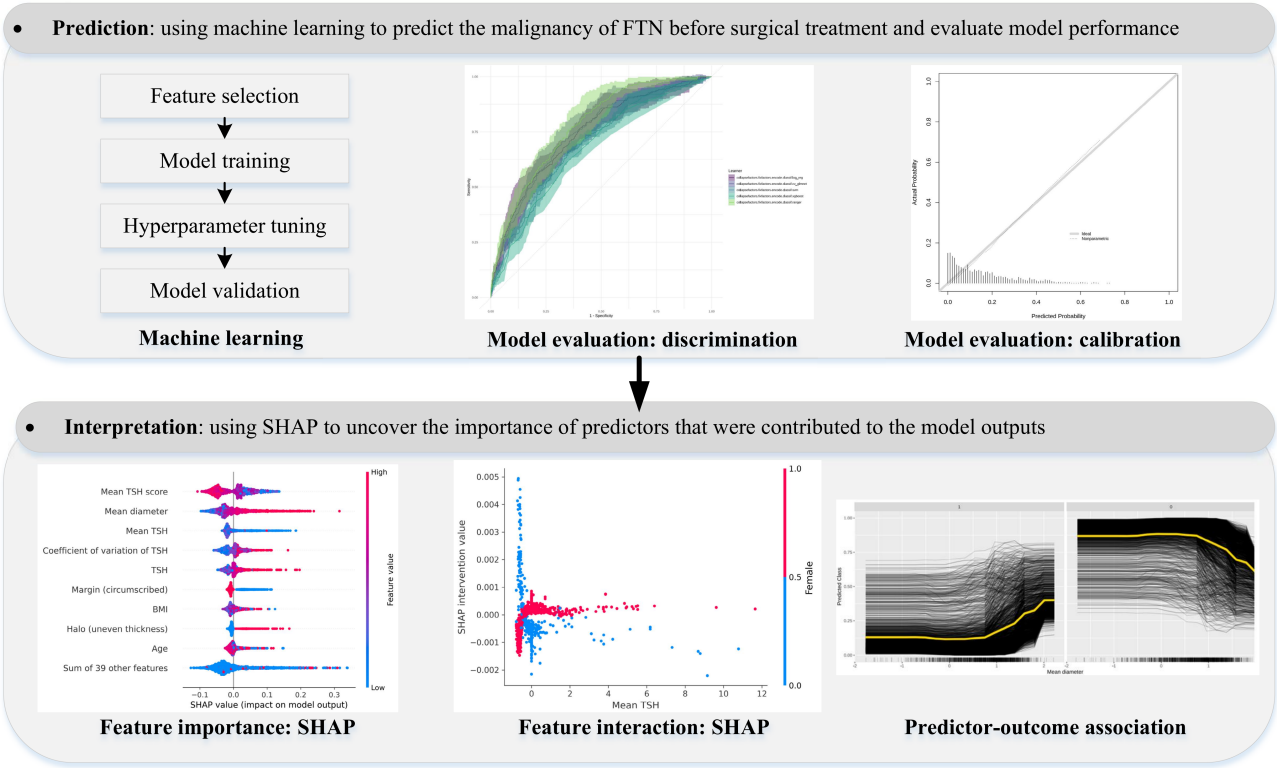
To address these limitations, our study has united a multidisciplinary treatment team for thyroid neoplasms and accumulated a cohort of over 1500 patients with FTN over the past decade [22]. This provided us a unique opportunity to develop and validate clinical prediction models to bridge the current research gaps in the field of FTN. Specifically, we aimed to individualize the clinical decision-making for patients with FTN by using interpretable machine learning to not only predict the malignancy risk of FTN but also identify the important predictors that might contribute to the prediction.

Methods

Study Design

This retrospective cohort study followed the suggestions of the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) statement [23]. Figure 1 shows the framework of our study.

Figure 1. Study framework of the machine learning–based modeling to facilitate the clinical decision-making for patients of FTN. FTN: follicular thyroid neoplasm; SHAP: Shapley Additive Explanations; TSH: thyroid-stimulating hormone.



Study Population

Our multidisciplinary research team included experts in the fields of epidemiology, surgery, pathology, ultrasound, and endocrinology. We conducted a retrospective cohort study at Peking University Third Hospital in Beijing, China, from January 2012 to September 2023. Eligible patients were those who underwent surgery and were pathologically diagnosed with FTA or FTC following the procedure. Patients were excluded if they did not undergo ultrasound examinations prior to surgery or if they had nodules classified as follicular tumors of uncertain malignant potential (UMPs). This exclusion was based on two considerations: (1) accurate diagnosis of FTNs required both an experienced pathologist and a complete biopsy sample. The key to distinguishing between benign and malignant FTNs was determining whether the tumor invaded the capsule. Tumors that invaded the capsule or blood vessels were classified as FTC, while those that did not were considered FTA. If the pathologist struggled to assess capsule invasion due to inexperience, or if the sample was inadequately collected during surgery, leading to capsule damage, the tumor might not have been accurately classified as either FTA or FTC. In such cases, it could have been labeled as a UMP. (2) Through a literature review, we found that all previous research had excluded UMPs [13-19]. Therefore, our study also excluded UMPs, enhancing comparability with prior research. We paid close attention to the accuracy of the pathological diagnosis of FTN due to its high professional requirements, which include not only complete sampling but also a thorough examination of all areas of the tumor margin. To ensure this, we invited pathologists with expertise in thyroid tumors to double-check all the postoperational pathological diagnoses in the study population, based on the most recent 2022, 5th edition WHO Classification of Thyroid Neoplasms [24].

It is important to note that our study population reflected the natural distribution of FTNs (ie, the ratio of FTA and FTC), resulting in imbalanced data, with 84.57% (n=1414) of cases was FTA. Specifically, we did not restrict the ratio of FTA to FTC to 1:1 or any other fixed ratio in the main analyses. This approach allowed the results from the developed prediction model to be more readily applicable to external populations with a similar natural distribution.

Data Sources and Processing

The data for this study were sourced from the electronic health records, extracted by professional information management personnel from the hospital's electronic information system. For critical data sources like thyroid pathology and neck ultrasound reports, a tailored data extraction form was designed using EpiData (EpiData Association), aligning with the study's research questions. The form was iteratively refined through discussions among researchers, surgeons, ultrasound specialists, and pathologists, followed by trial entries and revisions until finalized. Trained clinical doctors and medical students performed manual data entry, with researchers conducting 2 rounds of random checks to ensure accuracy and consistency. Senior doctors performed a final review to verify data quality. Missing values were imputed using the mean for continuous variables and the mode for categorical variables.

Predictors

We selected the predictors to develop the machine learning–based model based on our systematic review [17,18], domain knowledge [25-27], and data available. The predictors

included sonographic features, patients' age, sex, BMI, whether or not diagnosed as Hashimoto thyroiditis (an autoimmune disease that destroys thyroid cells by cell and antibody-mediated immune processes [28]), and measurements of thyroid hormones. Specifically, the sonographic features included mean diameter, composition (solid, predominantly solid, predominantly cystic, or cystic), echogenicity (hyperechoic, isoechoic, hypoechoic, or anechoic), taller-than-wide (the length in the vertical direction is greater than the width in the horizontal direction: absent or present), margin (circumscribed, ill-defined, irregular, or lobulated), calcifications (microcalcifications, macrocalcifications, peripheral calcifications, punctate echogenic foci of undetermined significance, microcalcifications with comet-tail artifacts, or no echogenic foci), halo (absent halo, even thickness halo, uneven thickness halo, or present halo without evenness of thickness reported), internal blood flow (absent or present), vascularity (mainly central vascularity, mainly peripheral vascularity, mixed vascularity, or avascularity), trabecular formation (typically appears as elongated, band-like, or fibrous echogenicity, arranged in a reticular or cord-like pattern: absent or present), and nodule-in-nodule appearance (a smaller nodule or an area with different echogenic characteristics is present within a larger thyroid nodule: absent or present); the measurements at the latest examination of thyroid hormones included thyroid-stimulating hormone (TSH), free triiodothyronine, and free thyroxine; additionally, TSH-related features derived from all examinations included mean TSH score (interval-adjusted detailed TSH score) [29], time-adjusted root mean square of successive differences of TSH [30], mean TSH (mean value of preoperative TSH), and coefficient of variation of TSH (the ratio of SD of preoperative TSH to mean value of preoperative TSH), and detailed definitions were introduced in previous publication [31]. All selected predictors were carefully checked by both clinicians and researchers to ensure the accuracy and reliability of the study results.

Development and Validation of Machine Learning–Based Models

We established the machine learning–based model as shown in Figure 1. We selected features, trained models, tuned hyperparameters, and validated models, as briefly described below. We used the mlr3 [32] ecosystem in R (version 4.3.3; R Foundation for Statistical Computing), scikit-learn [33], and Shapley Additive Explanations (SHAP) [34] in Python (version 3.11.1; Python Software Foundation) to conduct machine learning.

Feature selection, which aims to reduce the number of features, offers several benefits including minimizing overfitting, enhancing model robustness, and accelerating predictions. Notably, it is particularly advantageous for datasets with a high feature-to-sample ratio, where the number of features exceeds the limited size of data points. To identify a core set of predictors that could effectively predict the outcome without redundancy, we used a novel information-gain approach for feature selection [35]. To finalize the optimal model, we also compared model performance between that with full predictors and that with selected predictors.

We trained 5 classification models including logistic regression, least absolute shrinkage and selection operator (LASSO) regression, random forest, extreme gradient boosting, and support vector machine. We comprehensively considered and weighed (trade-off) the performance, calibration, parsimony, and interpretability of models and selected the most appropriate one as our prediction model.

The random search and cross-validation were combined to select model hyperparameters when training the machine learning model. We performed a random search over more than 45,000 hyperparameter combinations to select the best hyperparameter combination and trained the final classifiers. Additionally, to address the issue of imbalance, both oversampling (increasing the amount of minority class samples with producing new samples or repeating some samples) and undersampling (decreasing the amount of majority class samples) techniques were applied [36].

Evaluation of Model Performance

We evaluated the performance of the developed model in terms of discrimination (the ability of the model to distinguish between those with and without the outcome) and calibration (the consistency or agreement between the observed outcomes and predicted risks from the model). For discrimination, we first showed the confusion matrix including the numbers and percentages of true positive, true negative, false positive, and false negative. We then calculated both the threshold-free and threshold-sensitive metrics. Threshold-free metrics included the area under the receiver operating characteristic curve (AUROC) and the area under the precision-recall curve (AUPRC). While AUROC was a common performance metric for discrimination, AUPRC was considered more useful and informative for handling the unbalanced data in this study [37]. Threshold-sensitive metrics included sensitivity, precision, specificity, and accuracy. For calibration, we first plotted predicted risks (x-axis) against observed outcomes (y-axis) using a smoothed flexible calibration curve based on individual data. We also quantitatively assessed calibration using the calibration slope and calibration-in-the-large.

Interpretation of Model Prediction Results

First, we evaluated the feature importance (ie, the extent of the model depended on the feature) and the feature interaction by using the SHAP summary plot and SHAP interaction value dependence plot (see details in Multimedia Appendix 1) [34]. Second, we figured the partial dependence plots to visualize the direction of predictor-outcome associations, illustrate whether the risk of the outcome increased with a rise or decline in the predictor values, and assess whether this relationship is linear. Third, we plotted individual conditional expectations curves to explore potential modifiers that could influence predictor-outcome associations. Finally, we separated FTC into 2 groups based on whether they were correctly predicted and compared their characteristics. The significance of differences between the groups was tested using the Mann-Whitney *U* test, as the data did not follow to a normal distribution.

A Systematic Review of the Previous Studies

We conducted a systematic review of previous studies addressing similar topics. According to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [38] (see details in Checklist 1), we searched PubMed, Web of Science, Embase, and IEEE Xplore using the terms “follicular thyroid cancer” and “predict” for papers published up to October 1, 2023 (see details in Multimedia Appendix 2). Eligible studies included those that established prediction models to distinguish FTC from FTA before operation with various preoperative predictors. We included studies with either deep learning models, machine learning models, traditional statistical models, or other relevant methodologies. Studies were excluded if fewer than 50% of patients had FTN or if the papers were not written in English.

We evaluated the Thyroid Imaging Reporting and Data System for Follicular Neoplasm (F-TIRADS) scoring criteria developed by Li et al [18] to differentiate between benign and malignant cases in our dataset. These criteria are based on 6 key features: mean diameter, composition, echogenicity, margin, calcifications, and trabecular formation. Each specific characteristic of these features is assigned a corresponding point value, and the total points across the 6 features indicate the risk level of FTC. For instance, a total score of 12 points or higher suggests an FTC risk exceeding 90% (refer to Figure S1 in Multimedia Appendix 1).

Ethical Considerations

This study was classified as human participant research and was reviewed and approved by the medical research ethics committee of Peking University Third Hospital (IRB00006761-M2023168). As a retrospective analysis, the study was granted a waiver for additional informed consent. During the data extraction process, strict confidentiality measures were implemented to ensure patient privacy and data security. All extracted data were anonymized, with any information that could directly identify patients being removed.

Results

Characteristics of the Study Population

Altogether, we included 1539 patients, 1409 of whom had solitary tumors, and 130 had more than 1 tumor. Thus, a total of 1672 tumors were included and divided into 2 pathological types: FTA (n=1414) and FTC (n=258). The characteristics of the included tumors are listed in Table 1, and the characteristics of the study population are listed in Table 2. The age of the included population was 47.98 (SD 14.15) years (n=1530; missing value=9), the mean BMI was 24.18 (SD 3.66) kg/m^2 (n=1475; missing value=64), and the female population made up 73.16% (n=1126; male: n=342; missing value=71) of all patients.

Model Performance in Discrimination and Calibration

We compared performance among 5 models (logistic regression, LASSO regression, random forest, extreme gradient boosting, and support vector machine) using the AUROC and AUPRC. As shown in Multimedia Appendices 3 and 4, the random forest model performed better in both AUROC and AUPRC than the other 4 models. With comprehensive consideration of the discrimination, calibration, parsimony, and interpretability of models, we selected the random forest model as the optimal.

We developed a random forest model with a total of 22 features: age, sex, BMI, Hashimoto thyroiditis, thyroid hormones (TSH, free triiodothyronine, and free thyroxine), ultrasonic predictors (mean diameter, composition, echogenicity, taller-than-wide, margin, calcifications, halo, internal blood flow, vascularity, trabecular formation, and nodule-in-nodule appearance), and TSH-related variables (mean TSH score, time-adjusted root mean square of successive differences of TSH, mean TSH, and coefficient of variation of TSH). After 5-fold cross-validation, the AUROC of the prediction model was 0.79 (95% CI 0.77-0.81) and the AUPRC was 0.40 (95% CI 0.37-0.44). When the threshold is gradually lowered from 50%, 40%, 30%, 20%, and finally to 10%, the accuracy, specificity, and precision decreased step by step while the sensitivity increased progressively (Multimedia Appendix 5). The calibration slope and calibration-in-the-large were 1.16 and 0.13, respectively (Multimedia Appendix 6).

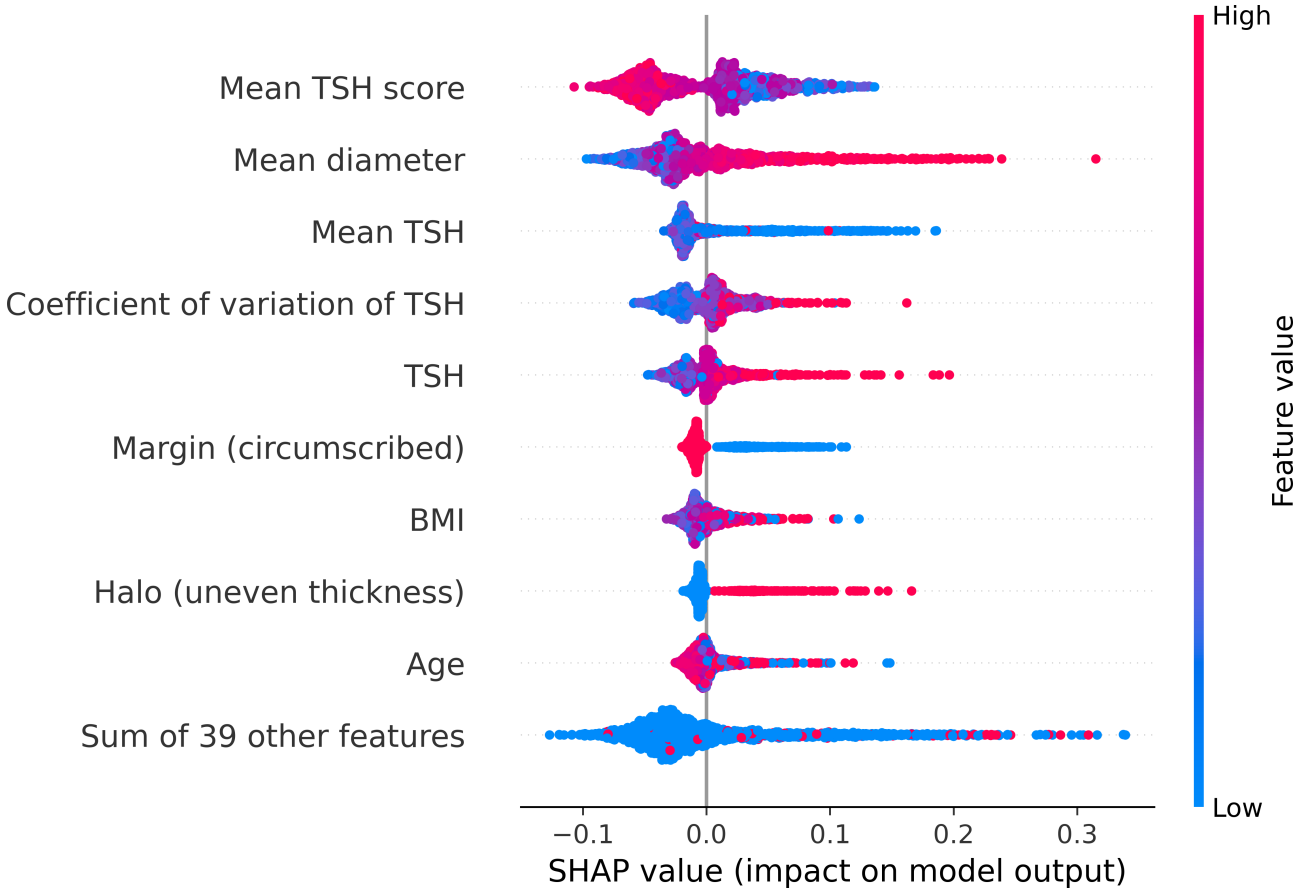
In addition, we implemented both oversampling and undersampling techniques to handle the imbalance in our models. However, following oversampling, the AUROC and AUPRC were 0.76 and 0.37, respectively, while after undersampling, the AUROC and AUPRC were 0.77 and 0.39, respectively. Notably, the model performed better before applying these sampling methods, with an AUROC of 0.79 and an AUPRC of 0.40.

Model Performance in Interpretation

The top 5 predictors were the mean TSH score, mean tumor diameter, mean TSH, coefficient of variation of TSH, and TSH level (Figure 2). The 5 top predictors did not show explicit

interactions with the sex or other predictors (Multimedia Appendix 7). Due to the strong correlation between TSH level and mean TSH score (correlation coefficient>0.6), we only plotted the partial dependence and individual conditional expectation plots for the top 4 features, excluding the TSH level. The associations between those 4 top continuous features and prediction probability were nonlinear (Multimedia Appendix 8). In general, the risk of malignancy tended to rise as the mean tumor diameter or the coefficient of variation of TSH increased, and the risk of malignancy tended to decrease as the mean TSH score or the mean TSH increased.

Figure 2. SHAP summary plot. SHAP: Shapley Additive Explanations; TSH: thyroid-stimulating hormone.



Moreover, we compared the characteristics of FTC groups with incorrect and correct predictions. FTC predicted as FTA by the model was classified into the incorrect-predicted group, while FTC predicted as malignant correctly by the model was then classified into the correct group. The mean diameter of the tumor was smaller in the incorrect-predicted group compared to the correct-predicted group (incorrect vs correct mean 2.88, SD cm 1.38 vs mean 3.71, SD 1.36 cm; mean diameter W=1474.5; P=.02).

A Systematic Review of the Previous Studies

After screening citations, we eventually included 7 studies in this systematic review (refer to Figure 3). The characteristics of the included studies are presented in Table 3. The sample sizes of the studies ranged from 18 to 888 patients [13-19]. The ratio of FTA to FTC in previous studies varied from 0.64 to 4.00 [13-19], which was much smaller than the ratio observed in our study (5.50) and in the real population, where the ratio of FTA to FTC can be as high as 5:1 [3]. In total, 3 studies even set the ratio close to 1 to address the imbalance [15,17,19]. As for the model selection, 4 studies developed deep learning models [13,16,17,19], 1 study used a random forest model [15], and the other 2 studies only established linear regression models [14,18], without concerning nonlinear associations or complicated interactions. Previous studies did not use gene mutations and other biomarkers as predictive variables. Except for 1 study from South Korea, which reported an AUROC of just 0.612 [13], the AUROC of the models in the other studies ranged from 0.75 to 0.96. However, none of them used AUPRC as a metric to assess discrimination. As for the interpretation of the models, Lin et al [15] assessed the feature importance, Tang et al [14] drew a nomogram, Li et al [18] developed F-TIRADS scoring criteria, and Yang et al [17] drew a heat map to visualize the importance of pixel regions, but the other 3 studies did not further explore interpretability, including feature importance, or the linear and nonlinear associations and interactions between features and targets.

Figure 3. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) study flow diagram. FTN: follicular thyroid neoplasm.

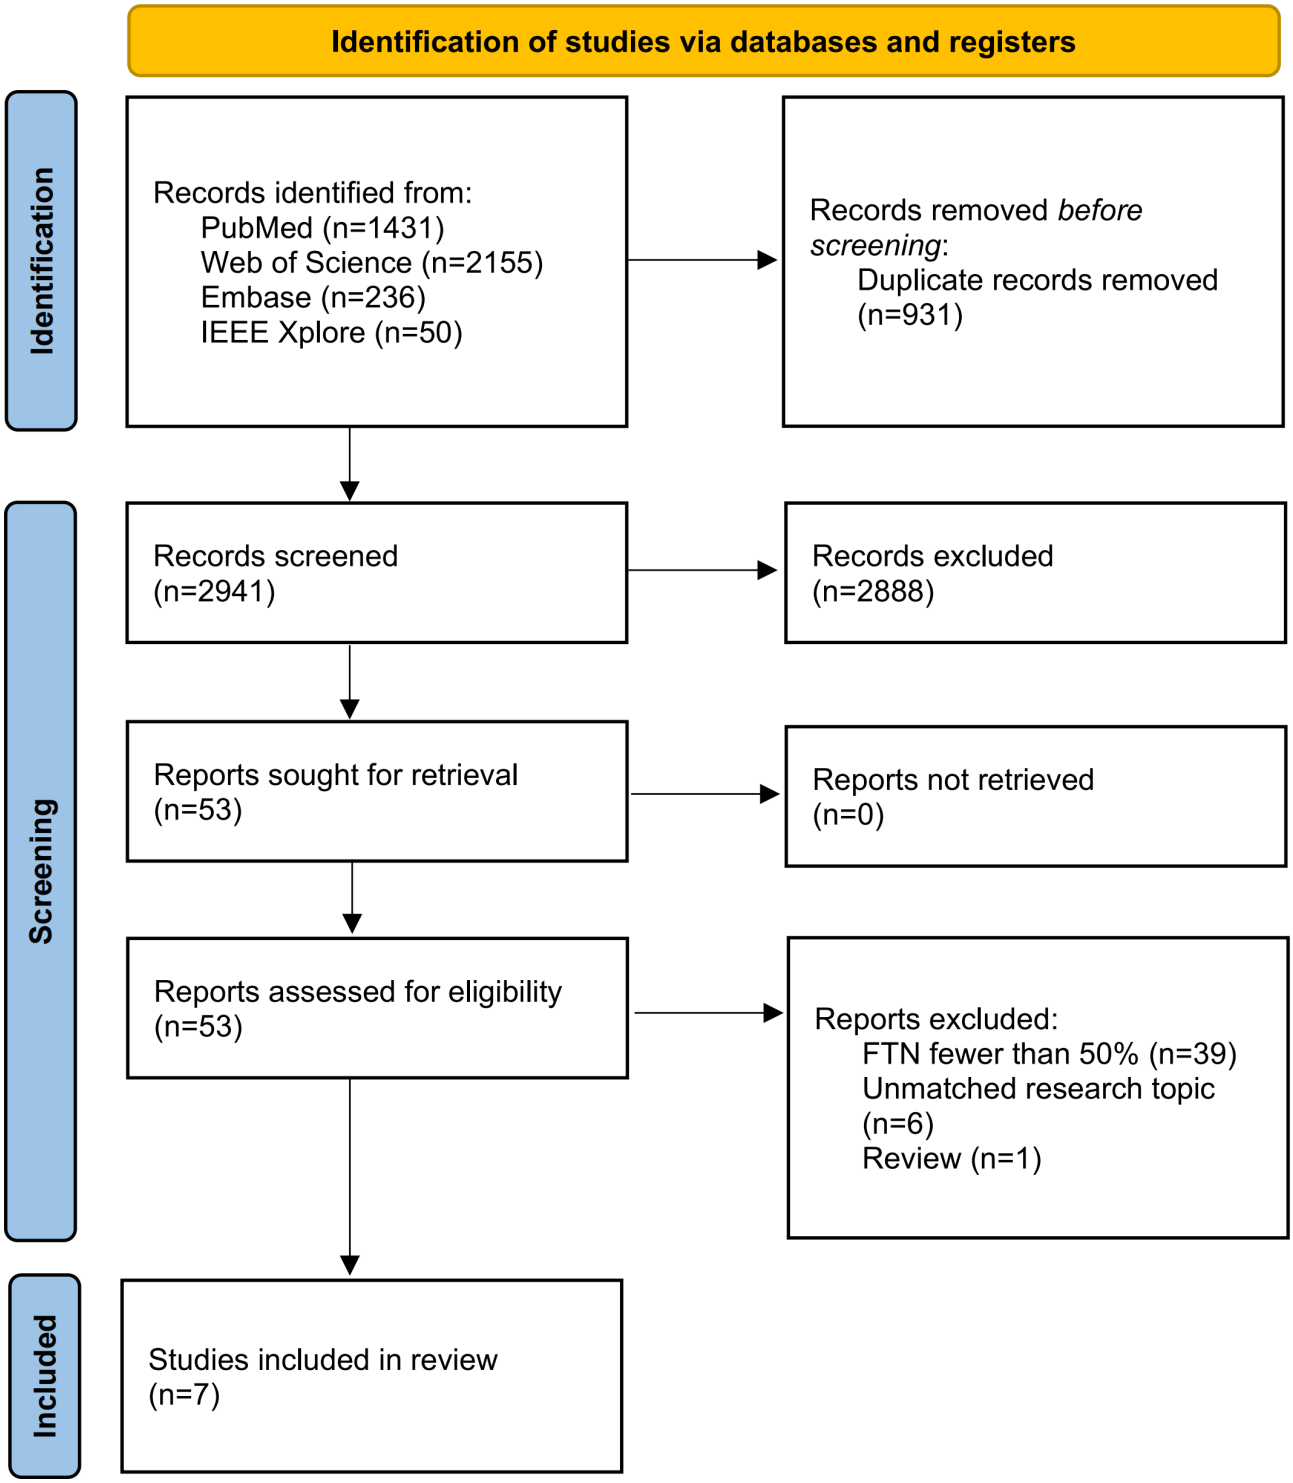


Table . Characteristics of the included studies.

Study	Country	Pathological ratio (FTA[a]/FTC[b]~ratio)	Features	Model	External test set	Sample size (n, patients)	Discrimination	Interpretation

[a]FTA: follicular thyroid adenoma.

[b]FTC: follicular thyroid carcinoma.

[c]CNN: convolutional neural network.

[d]AUROC: area under the receiver operating characteristic curve.

[e]ANN: artificial neural network.

[f]SVM: support vector machine.

[g]Yang et al (2020) [19] did not report the numbers of patients or nodules.

[h]LASSO: least absolute shrinkage and selection operator.

[i]F-TIRADS: Thyroid Imaging Reporting and Data System for Follicular Neoplasm.

Additionally, we tested the F-TIRADS scoring criteria developed by Li et al [18] with our dataset. The criteria specify 6 key features for scoring. After filtering our data to include only cases with complete information for these 6 features, we selected 1025 tumors from 993 patients as an external test set. When applying the F-TIRADS scoring criteria, the predictive performance was suboptimal. With a threshold for FTC risk set at >90%, the model achieved an accuracy of 0.82, sensitivity of 0.04, specificity of 0.99, and precision of 0.53. When using a >50% FTC risk threshold, the sensitivity increased to 0.27, while accuracy, specificity, and precision decreased to 0.79, 0.91, and 0.39, respectively. For threshold-independent metrics, the AUROC and AUPRC for the F-TIRADS scoring criteria were 0.47 and 0.59, respectively, in our external test set.

Discussion

Principal Findings

This study systematically established the interpretable machine learning–based model to address the challenge of clinical decision-making for the FTN before surgery. We developed a model using 22 readily available predictors with a preferable AUROC (0.79, 95% CI 0.77 - 0.81). Additionally, the model demonstrated excellent interpretability, identifying the mean TSH score, mean tumor diameter, mean TSH, coefficient of variation of TSH, and TSH level as the most important predictors. After comparing groups of incorrect-predicted and correct-predicted FTC, we found that smaller FTCs were more likely to be misclassified as FTA.

Comparison to Prior Work

It is crucial to evaluate the performance of clinical prediction models comprehensively, that is, the models should be well performed in discrimination and calibration. Concerning the discrimination, our developed model was comparable to that of previous studies aimed at predicting the malignancy risk of FTN before surgical treatment. For example, according to Li et al [18], the AUROC reached 0.76 in the LASSO regression model consisting of ultrasound features (the ratio of FTA to FTC: training set: 2.74 and validation set: 3.70); also, in the LASSO regression model, the AUROC reached 0.913 in discriminating FTA from FTC on selected clinical parameters, computed tomography signs, and radiomic features referring to Tang et al [14] (the ratio of FTA to FTC: 4.00). However, neither study used AUPRC as the evaluation metric. We also acknowledge that the model was derived from extremely imbalanced data (the ratio of FTA to FTC: 5.50), and in this context, the AUPRC metric for assessing model performance is more informative and intuitive than the AUROC [37]. For example, the prediction model might perform relatively well when measured by AUROC but may perform unsatisfactorily when measured by AUPRC, in the scenario of imbalanced data. Furthermore, to address the imbalance in our models, we applied oversampling and undersampling techniques, but both failed to improve performance. Our findings were in line with the previous research, which found that oversampling and undersampling generally did not enhance prediction models in large observational health datasets [39]. The possible reasons might be as follows: (1) oversampling and undersampling would modify the outcome proportions in the training data, leading to miscalibration, such as overestimated risks [39]; (2) the synthetic data generated by oversampling may not accurately represent

the original distribution of minority class, potentially affecting classification performance [40]; and (3) undersampling reduced the number of majority class samples, limiting the model's ability to fully use the features of the majority class during training [41].

As one previous systematic review indicated, calibration was commonly overlooked during the development and validation of clinical prediction models [20]. However, calibration metrics are also important to assess the size of the gap between the predicted risk probability and the true risk probability. For instance, grouping can be manipulated to obscure the evaluation of miscalibration in a particular range without a calibration curve and its numerical quantification [42]. In general, our model had relatively good calibration, as the calibration slope was close to 1 and the calibration-in-the-large close to 0.

Based on the results of our systematic review, most of the previous studies show relatively satisfying AUROC, but none of them reported AUPRC. Although Li et al [18] reported a handy score-risking tool for clinicians to assess the malignancy risk of FTN at the diagnosis stage, this tool seemed to not perform ideally in the practice of our data (AUROC 0.47; AUPRC 0.59; sensitivity 0.04 [threshold 90%] and 0.27 [threshold 50%]).

Limitations and Strengths

We should interpret the study findings cautiously. As with other single-center studies, the results from this study were limited in generalizability to patients and clinical settings with distinct characteristics. However, the pathological diagnosis of FTC was highly heterogeneous across different clinical settings due to its challenge in sufficient sampling and accurate diagnosis. Therefore, we advocated for the standardization of FTC diagnosis before the conduction of a multicenter study soon. Additionally, the prediction performance of models, comparable to the previous work with similar predictors, had room to further improve. The clinical utility of the screening stage was also less than ideal. Building on the experiences and lessons learned from this study, we are conducting a prospective cohort study to further optimize the model performance through collecting other costly multidimensional predictors including genomics, ultrasound images, and videos. Besides, our study was retrospective in nature, which may introduce selection bias. Furthermore, we excluded patients with nodules of UMPs, potentially limiting the model's accuracy in identifying borderline follicular tumors. Moreover, our models did not incorporate other potential predictors, such as genetic markers (eg, BRAF, TRET, and RAS mutations), computed tomography or magnetic resonance imaging characteristics, or family history, due to constraints in data availability.

Our study had several strengths. Our models were advantageous in the large sample size for the present topic, the clinically easy-accessible and clinician-validated predictors, and the comprehensive evaluation with the metrics appropriate for the nature of the data (imbalanced data) [43]. Furthermore, the disease distribution of FTA and FTC in the study population was fully consistent with that of patients with FTN in real-world settings, that is, we did not deliberately over- or undersample patients with any type of disease in the model development, as commonly seen in previous studies [17,18]. As such, findings from our study had theoretically better fidelity and generalizability in real-world settings. In addition, we conducted a systematic review to synthesize findings from previous studies, comprehensively integrate the evidence, and identify research gaps.

Future Directions

Our study paved the way for future research in terms of predictors, models, and targets. Concerning predictors and models, further studies might consider taking advantage of the rapidly developing deep learning models and fully using high-dimension predictors such as ultrasound images and genomics. In terms of targets, it is important to standardize the pathological diagnosis of FTC across multiple centers before conducting a future multicenter study.

Our study is also important for future clinical practice. First, findings from the interpretation of our models indicate that clinicians should comprehensively consider patients' variables such as thyroid hormones in addition to the ultrasound results. Second, in a natural distribution population with severely unbalanced data (FTA is far more than FTC), preoperative prediction of FTA and FTC by thyroid hormone and ultrasound features alone may face challenges, especially for relatively small-sized FTCs, which are easy to miss detection.

Conclusions

In clinical practice, it remained challenging to sensitively screen, precisely diagnose, and appropriately treat patients with FTN. Interpretation of our developed machine learning–based model suggests that clinicians should also pay attention to patients' variables such as TSH along with tumor size. However, it may be hard to correctly predict FTNs preoperatively with thyroid hormone and ultrasound features alone, especially for FTCs with small sizes. The findings of our study bridged the gaps of previous work and paved the way for connecting machine learning to interpretation in the field of FTN research. We call for subsequent studies to further examine the generalizability to other contexts.

Acknowledgments

This work used the data of the Peking University Third Hospital. The authors sincerely thank the research team of Thyroid Tumor Multi-Disciplinary Treatment. We appreciate the health professionals at Peking University Third Hospital for data collection and management. Funding support was received from the National Natural Science Foundation of China (82373694), Young Elite Scientists Sponsorship Program by CAST (2023QNRC001), Beijing Education Sciences Planning Program during the 14th

Five-Year Plan (BECA23111), Proof of Concept Program of Zhongguancun Science City and Peking University Third Hospital (HDCXZHKC2022210), and the Fundamental Research Funds for the Central Universities (BMU2021YJ030).

Abstract

Background: Next-generation sequencing (NGS) has become a cornerstone of treatment for lung cancer and is recommended in current treatment guidelines for patients with advanced or metastatic disease.

Objective: This study was designed to use machine learning methods to determine demographic and clinical characteristics of patients with advanced or metastatic non–small cell lung cancer (NSCLC) that may predict likelihood of receiving NGS-based testing (ever vs never NGS-tested) as well as likelihood of timing of testing (early vs late NGS-tested).

Methods: Deidentified patient-level data were analyzed in this study from a real-world cohort of patients with advanced or metastatic NSCLC in the United States. Patients with nonsquamous disease, who received systemic therapy for NSCLC, and had at least 3 months of follow-up data for analysis were included in this study. Three strategies, logistic regression models, penalized logistic regression using least absolute shrinkage and selection operator penalty, and extreme gradient boosting with classification trees as base learners, were used to identify predictors of ever versus never and early versus late NGS testing. Data were split into D1 (training+validation; 80%) and D2 (testing; 20%) sets; the 3 strategies were evaluated by comparing their performance on multiple m=1000 splits in the training (70%) and validation data (30%) within the D1 set. The final model was selected by evaluating performance using the area under the receiver operating curve while taking into account considerations of simplicity and clinical interpretability. Performance was re-estimated using the test data D2.

Results: A total of 13,425 met the criteria for the ever NGS-tested, and 17,982 were included in the never NGS-tested group. Performance metrics showed the area under the receiver operating curve evaluated from validation data was similar across all models (77%-84%). Among those in the ever NGS-tested group, 84.08% (n=11,289) were early NGS-tested, and 15.91% (n=2136) late NGS-tested. Factors associated with both ever having NGS testing as well as early NGS testing included later year of NSCLC diagnosis, no smoking history, and evidence of programmed death ligand 1 testing (all P<.05). Factors associated with a greater chance of never receiving NGS testing included older age, lower performance status, Black race, higher number of single-gene tests, public insurance, and treatment in a geography with Molecular Diagnostics Services Program adoption (all P<.05).

Conclusions: Predictors of ever versus never as well as early versus late NGS testing in the setting of advanced or metastatic NSCLC were consistent across machine learning methods in this study, demonstrating the ability of these models to identify factors that may predict NGS-based testing. There is a need to ensure that patients regardless of age, race, insurance status, and geography (factors associated with lower odds of receiving NGS testing in this study) are provided with equitable access to NGS-based testing.

Introduction

The care of patients with non–small cell lung cancer (NSCLC) has changed dramatically since the early 2010s, from a chemotherapy-based approach that was tailored only to the disease histology (squamous or nonsquamous tumors) to becoming a disease with multiple actionable biomarkers that can identify targeted therapies associated with superior outcomes based on individual patient genomic characteristics [1,2]. This has led to the adoption of next-generation sequencing (NGS) recommendations included in treatment guidelines for patients with NSCLC [3].

Unfortunately, despite these recommendations, multiple studies have shown that NGS-based testing is not being used for all patients with advanced or metastatic NSCLC, and only about half of all patients in some studies receive comprehensive biomarker testing [4-6]. The reasons for the lack of testing are unclear but may include barriers to ordering tests, insufficient tissue, clinical deterioration, or a crisis that requires immediate care [6]. More recent studies have also demonstrated a racial disparity in receipt of biomarker testing; patients who are Black are significantly less likely than those who are White to receive NGS-based testing in the United States [7].

Studies evaluating the barriers to testing have typically taken a specific hypothesis-driven a priori categorization of potential barriers to investigate the lack of testing [6,7]. While certainly this approach is critical to investigate specific issues such as racial disparities, this falls short when trying to evaluate the complexity of care and the multiple and potentially interacting factors. Clinical prediction models are an alternative approach to using patient-level evidence to help inform health care decision makers about patient care. These models have been used for decades by health care professionals [8]. Traditionally, prediction models combine patient demographic, clinical, and treatment characteristics in the form of a statistical or mathematical model, usually regression, classification, or neural networks, but deal with a limited number of predictor variables (usually below 25). Flexible machine learning methods can be used, by which the researcher does not force the model to evaluate a limited set of covariates, but rather the models themselves learn by trial and error from the data to make predictions, without having a predefined set of rules for decision-making. Simply, machine learning can be better understood as “learning from data” [9]. The setting of biomarker testing provides an opportunity to apply these methods to more thoroughly explore the factors that are associated with the lack of recommended biomarker testing.

While machine learning methods have been more commonly used for biomarker identification and treatment selection, there is little evidence of these methods applied to the prediction of biomarker testing itself. To date, the investigations surrounding the gaps in biomarker testing have remained largely limited to descriptive research and opinion pieces [10-13]. Therefore, this study was designed to fill this gap in evidence by applying machine learning methods to the question of biomarker testing for patients with advanced or metastatic nonsquamous NSCLC to determine demographic and clinical characteristics that may predict receipt of NGS-based testing. A second objective was to further determine the characteristics that predict receipt of NGS-based testing (early testing) in accordance with clinical guidelines that can inform first-line therapy (vs those who receive NGS-based testing after the first-line therapy is underway). These objectives were pursued to better understand factors associated with experiencing barriers to recommended testing and the timing of such testing to inform future intervention strategies.

Methods

Data Source

This study used the Advanced NSCLC Analytic Cohort from the nationwide Flatiron Health electronic health record–derived longitudinal database, comprising deidentified patient-level structured and unstructured data, curated via technology-enabled abstraction [14,15]. The data are deidentified and subject to obligations to prevent reidentification and protect patient confidentiality and are not considered human participants in accordance with the US Code of Federal Regulations [16]. These deidentified data originate from approximately 280 cancer clinics (~800 sites of care) in the United States. Patients in this database are those who have lung cancer *ICD* (*International Classification of Diseases*) codes 162.x (*ICD-9* [*International Classification of Diseases, Ninth Revision*]), C34x, or C39.9 (*ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*]) on at least 2 documented clinical visits on different days occurring on or after January 1, 2011. Longitudinal patient-level data were available through November 2021. Patients must further have had pathology consistent with NSCLC and have advanced or metastatic disease (diagnosed with stage IIIB, IIIC, IVA, or IVB disease or diagnosed with early-stage NSCLC and subsequently developed recurrent or progressive disease).

Definitions of NGS Testing Cohorts

Patients were included in this analysis if they were in the Flatiron Health Advanced NSCLC Analytic Cohort, had nonsquamous NSCLC, evidence of receipt of systemic therapy, and at least 3 months of follow-up in the database. Receipt of testing by NGS is a field recorded in the electronic medical record database by the health care provider that was used for testing identification in this study. The method of NGS testing (tissue or circulating tumor) is not specified. Patients were excluded who had evidence of NGS-based testing more than 20 days prior to initial NSCLC diagnosis. Patients meeting the

inclusion criteria for this study were categorized into 2 groups. The ever NGS-tested group included patients with at least 1 NGS test recorded in the database. All remaining patients were included in the never NGS-tested group, as this group was comprised of patients with no evidence of any NGS test recorded in the database. Among those in the ever NGS-tested group, individuals were further subgrouped by the timing of NGS-based testing. Each patient in the ever NGS-tested group was either included in the early NGS-tested subgroup, including patients whose first or only NGS-based test occurred prior to the start of first-line therapy through day 7 of first-line therapy, or the late NGS-tested subgroup, all remaining patients whose first NGS-based test occurred 8 days or later after the start of first-line therapy. The date of advanced or metastatic diagnosis was considered the index diagnosis date.

Candidate Predictors

Candidate predictors for receipt and timing of NGS-based testing were prespecified based on published literature, analyses of real-world data, and expert input from the field of cancer diagnostics [4,7,17]. These variables included patient age at advanced or metastatic diagnosis date (years), sex (male or female), race (Asian, Black, White, and other), insurance type (public, private, or other), Eastern Cooperative Oncology Group (ECOG) performance status (0-4), smoking history (ever vs never smoker), body weight (kilograms), BMI (kg/m^2), practice setting (academic or community), practice volume (the average number of those with NSCLC receiving care at the site where the included patient received care by index year over the period 2011 to 2021), biomarker result (positive, not positive, and not tested) by each available biomarker (anaplastic lymphoma kinase [ALK]; epidermal growth factor receptor [EGFR]; V-Raf murine sarcoma viral oncogene homolog B [BRAF]; Kirsten rat sarcoma virus [KRAS]; c-ros oncogene 1 [ROS1]; mesenchymal epithelial transition [MET]; neurotrophic tyrosine receptor kinase [NTRK]; rearranged during transfection [RET]; and programmed death ligand 1 [PD-L1]), stage of disease at initial diagnosis (0-IV), laboratory value (low, normal, high, or not tested) by blood test (alkaline phosphatase, alanine transaminase, aspartate transferase, bilirubin, creatinine, lymphocyte count, red blood cell count, hematocrit, platelet count, white blood cell count, and hemoglobin), number of non-NGS biomarker tests received (total number of fluorescence in situ hybridization, immunohistochemistry, polymerase chain reaction, or other non-NGS–based tests), as well as 2 variables to identify periods of environmental changes. The first of these variables categorized the status of National Comprehensive Cancer Network (NCCN) Clinical Guidelines: prior to 2016, before NGS was recommended in the guidelines; 2016-2019, when broad-based testing was recommended; and 2020 and later, when NGS-based testing was recommended [18]. The second variable evaluated the timing of US Food and Drug Administration approval of drugs that targeted the available biomarkers: period (1) January 1, 2011-August 25, 2011 (EGFR drugs only); period (2) August 26, 2011-March 10, 2016 (EGFR+ALK); period (3) March 11, 2016-June 21, 2017 (EGFR+ALK+ROS1); period (4) June 22, 2017-November 25, 2018 (EGFR+ALK+ROS1+BRAF); period (5) November 26, 2018-May 5, 2020 (EGFR+ALK+ROS1+BRAF+NTRK); period (6) May 6, 2020-May 26, 2021 (EGFR+ALK+ROS1+BRAF+NTRK+MET+RET); and period (7) May 27, 2021, and later (EGFR+ALK+ROS1+BRAF+MET+NTRK+RET+KRAS) [19]. Additionally, candidate predictors of Medicare Administrative Contractor (MAC) region [20] and Molecular Diagnostics Services (MolDX) Program adoption (yes or no) [21] were included. These variables explored the policies in place at the geography in which the patient received care. MACs are private companies that process claims for Medicare beneficiaries. These companies are geographically distinct and identifiable by unique alphanumeric designations (eg, J8=jurisdiction 8) and by private company names (eg, Noridian and Palmetto) [22]. The MolDX Program determines the coverage of diagnostic testing in 4 MACs across 28 states [20,21]. Importantly, all candidate predictor variables were required to be recorded prior to the end of the early NGS testing period to ensure that no covariates were recorded after the measurement of the NGS testing outcome.

The following interactions were deemed to be clinically relevant and forced into the models for evaluation: smoking and sex, smoking and NCCN guideline periods, race and insurance type, age and ECOG performance status, MAC region and public insurance, and MolDX region and public insurance. The estimates of the expected direction of these relationships were defined in the study protocol and are summarized in Table 1.

Table 1. Expected direction of candidate predictors for next-generation sequencing (NGS) testing.

Candidate predictor variable	Expected direction
Year of advanced or metastatic diagnosis	As year increases, NGS testing is more likely.
Smoking status (yes vs no)	Smoking=no, NGS testing is more likely.
Sex (male vs female)	Sex=female, NGS testing is more likely.
Race (Asian, Black, White, other)	Race=Asian or White, NGS testing is more likely.
Practice volume (continuous)	As practice volume increases, NGS testing is more likely.
BMI (using WHO[a] categories)	BMI=underweight, NGS testing is less likely.
ECOG[b] performance status (0, 1, 2, 3, or 4)	As ECOG performance status increases, NGS testing is less likely.
Body weight (continuous, in kilograms)	As weight increases, NGS testing is more likely.
Stage at initial diagnosis (0-I, II, III, or IV)	Stage 0-II=NGS is more likely than stage III; stage IV=NGS is more likely than stage III.
EGFR[c] (not tested, positive, not positive) by non-NGS test	EGFR=positive, NGS less likely.
ROS1[d] (not tested, positive, not positive) by non-NGS test	ROS1=positive, NGS less likely.
ALK[e] (not tested, positive, not positive) by non-NGS test	ALK=positive, NGS less likely.
BRAF[f] (not tested, positive, not positive) by non-NGS test	BRAF=positive, NGS less likely.
KRAS[g] (not tested, positive, not positive) by non-NGS test	KRAS=positive, NGS less likely.
PD-L1[h] (not tested, positive, not positive)	PD-L1=positive, NGS less likely.
Number of single-gene tests (continuous)	As the number of single-gene tests increase, NGS less likely.
Practice setting (academic, community)	Practice setting=academic, NGS more likely.
Insurance status (public, private, other)	This relationship is unknown. It is possible that insurance status=public, NGS less likely; however, it is possible that in some cases, insurance status=private only, NGS could be less likely.
MAC[i] region	No direction is known.
MolDX[j]	While this only applies to Medicare, states may adopt broader policies, and the relationship is uncertain. MolDX may make NGS more likely, but it is largely unknown.
NCCN[k] guidelines (pre, broad, or NGS)	NCCN guidelines=NGS, NGS more likely.
Drug approval periods (1, 2, 3, 4, 5, 6, 7)	As drug approval periods increase, NGS more likely.
Laboratory values (high, normal, low, not tested) for alkaline phosphatase, alanine transaminase, aspartate transferase, bilirubin, creatine, lymphocyte count, red blood cell count, hematocrit, platelet count, white blood cell count, hemoglobin	The direction of a single laboratory value is unknown. However, generally one would expect multiple out-of-range values to reflect poor health and may make NGS less likely, but the a priori assumed direction is unknown.

[a]WHO: World Health Organization.

[b]ECOG: Eastern Cooperative Oncology Group.

[c]EGFR: epidermal growth factor receptor.

[d]ROS1: c-ros oncogene 1.

[e]ALK: anaplastic lymphoma kinase.

[f]BRAF: V-Raf murine sarcoma viral oncogene homolog B.

[g]KRAS: Kirsten rat sarcoma virus.

[h]PD-L1: programmed death ligand 1.

[i]MAC: Medicare Administrative Contractor.

[j]MolDX: Molecular Diagnostics Services.

[k]NCCN: National Comprehensive Cancer Network.

Statistical Analysis

Descriptive analyses were conducted to summarize available data and to understand the extent of missingness in the database. Categorical variables were assessed using a 1-sided chi-square test or Fisher exact test and continuous variables using a 2-sided *t* test. Missing values were imputed using the random forest

missing data algorithm (impute.rfsrc function in R package *randomForestSRC*) [23].

Three modeling strategies were used to identify potential predictors of NGS-based testing with 2 sets of outcomes for ever versus never NGS-tested (model 1) and early versus late NGS-tested (model 2). The 3 modeling strategies included logistic regression (LR) models, penalized logistic regression (PLR) using least absolute shrinkage and selection operator (LASSO) penalty, and extreme gradient boosting (XGBoost) with trees as base learners. LR was implemented using forward selection on the main effects and predefined interactions (listed earlier), starting with the predefined variables and adding the most significant terms to the model. PLR was implemented using sparse group LASSO on the main effects and predefined interactions, forcing some predefined variables into the model with the penalty selected using 5-fold cross-validation. XGBoost is a decision tree–based machine learning algorithm [24]. The model matrix for XGBoost was built using main effects and predefined interactions. Hyperparameters were selected based on 5-fold cross-validation over a grid search, and hyperparameters included the shrinkage (learning rate), the number of trees, and tree depth. Table S1 in Multimedia Appendix 1 contains the full list of hyperparameters used in this study. The data extraction approach and modeling process is summarized in Figure 1.

In step 1, data were extracted based on the prespecified inclusion and exclusion criteria. Step 2 involved variable recoding, which included transforming all categorical variables with missing information by creating an additional level to represent missing data. Step 3 was a data quality method used to identify any unusual observations that needed to be excluded or recoded in addition to any imputation that was required. Steps 4 to 6 outline the implementation of models, evaluation of the performance of these models, and interpretation of the final features selected using LR. Figure 2 provides an overview of the model strategy evaluation process for the 2 outcomes mentioned in step 4 of Figure 1.

First, the data were split into D1 (training+validation; 80%) and D2 (testing; 20%) sets. Then, the 3 strategies were evaluated by comparing their performance on multiple m=1000 splits in the training (70%) and validation data (30%) within the D1 set. Specifically, for each split, all 3 strategies were fit to training data, and performance measures (eg, area under the receiver operating curve) were computed on the validation data. Modeling was done using R packages, sparsegl was used for LASSO, XGBoost for gradient boosting, and PRROC, which computes the areas under the precision-recall and ROC curve, for performance measures. PLR and XGBoost involved hyperparameters that were fine-tuned using 5-fold cross-validation nested within training datasets. Prediction models were developed on 2 different groups: ever versus never and early versus late NGS-tested groups. In total, 146 features (including all levels of all variables) were entered into both the XGBoost and LASSO models, with only 36 features (main effects and interactions) being used in the LR model. Preselection of features consisted of excluding variables that have little to no association with the outcomes of interest.

The final model was selected by evaluating performance as described earlier (area under the receiver operating curve from validation data) and by considering the simplicity and clinical interpretability. Model performance was re-estimated using the test data D2. For the final model choice, the features with nonzero coefficients selected by PLR were run on the D1 data. These variables were fitted to an LR model within the test data D2 to calculate model estimates (odds ratios, 95% CIs, and P values). Odds ratios for main effects in the presence of interaction terms were calculated using the analytical formula presented in Multimedia Appendix 2. All analyses were conducted using SAS (version 9.4; SAS Institute Inc) and R (version 4.0.3; R Foundation for Statistical Computing).

Figure 1. Data extraction and modeling flow. AUC: area under the curve; CI: confidence interval; NSCLC: non–small cell lung cancer; OR: odds ratio; ROC: receiver operating curve.

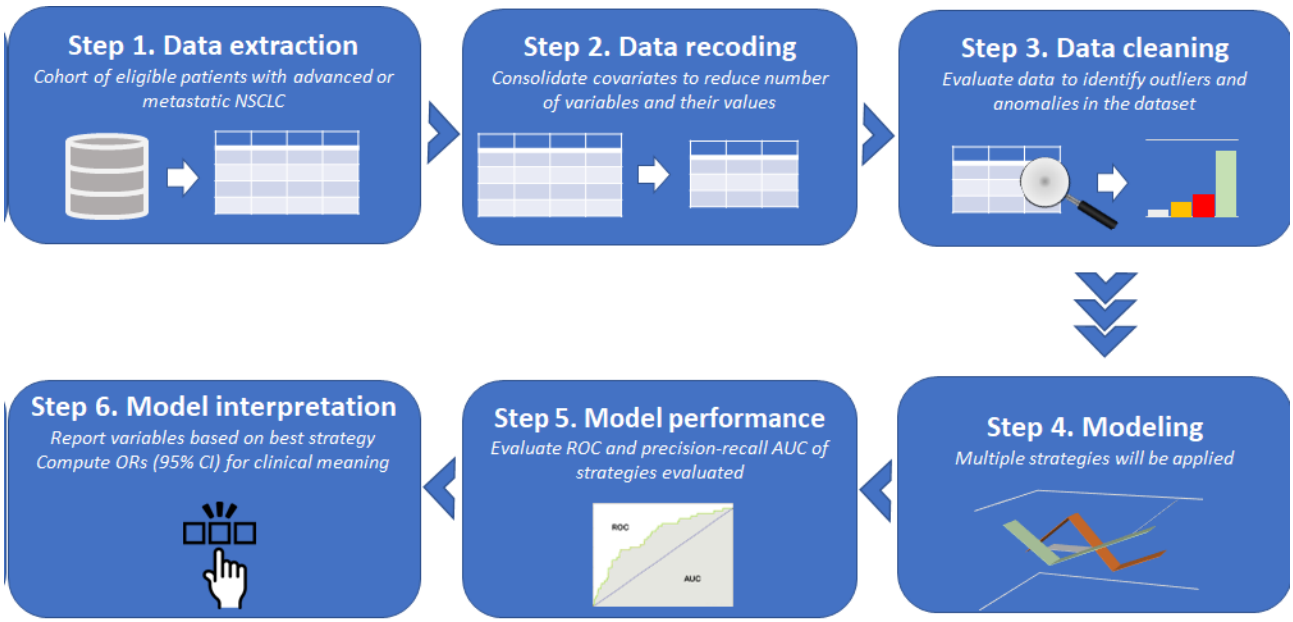

Figure 2. Modeling evaluation flow. EHR: electronic health record; NGS: next-generation sequencing.

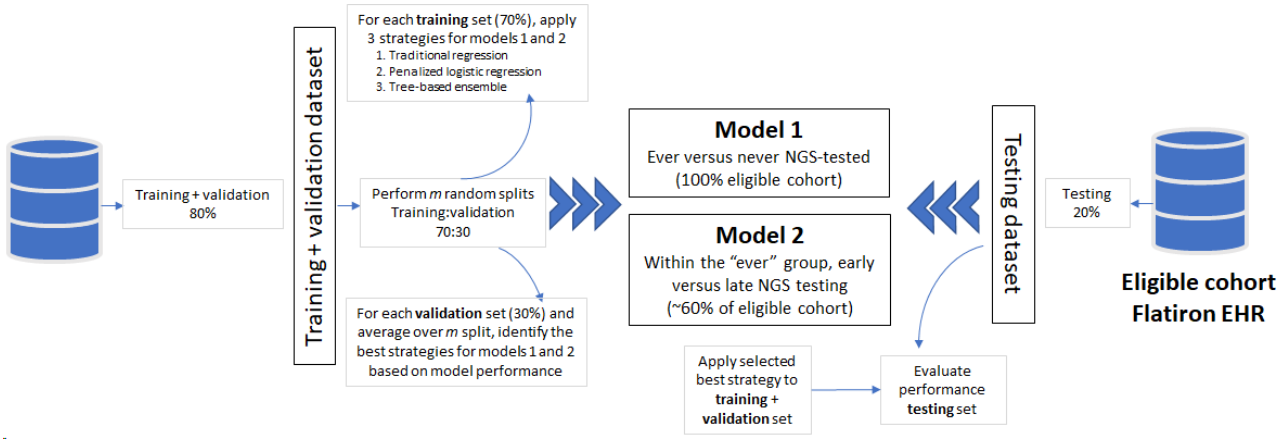

Ethical Considerations

The data used for this study are deidentified and subject to obligations to prevent reidentification and protect patient confidentiality, and as such are not considered human subjects research and are exempt from review in accordance with the US Code of Federal Regulations [16].

Results

A total of 74,211 patient records were available in the Flatiron Health NSCLC dataset for this analysis. After applying eligibility criteria, a total of 31,407 patients were included in this analysis. Of all patients, 42.75% (n=13,425) were included in the ever NGS-tested group and 57.25% (n=17,982) were included in the never NGS-tested group. Among those in the ever NGS-tested group, 84.08% (n=11,289) were early NGS-tested, and 15.91% (n=2136) late NGS-tested. Characteristics of these groups and subgroups used as features in the machine learning models are listed in Tables 2-11.

Most features were significantly different between both the ever and never NGS-tested as well as the early NGS versus late NGS-tested groups. Of note, smoking rates and testing conducted during the NCCN prerecommendations period were lower for the ever NGS-tested group (n=10,589, 78.88% vs n=14,987, 83.34% and n=2663, 19.84% vs n=10,734, 59.69%, respectively), and ECOG status of 0 (n=4410, 32.85% vs n=4665, 25.94%) was higher for the ever NGS-tested group versus those who were never tested. Similarly, for the early versus late NGS-tested groups, there was a higher proportion of patients with a history of smoking (n=9025, 79.95% vs n=1564, 73.22%) and a lower proportion of testing conducted during the NCCN prerecommendations period (n=1746, 15.47% vs n=917, 42.93%) as well as a lower proportion of ECOG status of 0 (n=3606, 31.94% vs n=804, 37.64%) for the early tested group.

Comparison of performance metrics for each model showed that the percent AUC was similar across models (80%-84% and 77%-80%) and marginally better when the models were fit on the ever versus never NGS-tested groups. In addition, other metrics were also comparable (Table S2 in Multimedia Appendix 1). The final model chosen was the LASSO model, as it was able to identify important features including interactions (those with nonzero coefficients after shrinkage) and the metrics for each model were highly comparable (Table S2 in Multimedia Appendix 1). Figures S1 and S2 in Multimedia Appendix 1 show the feature importance plots for both groups. The most important factors associated with ever versus never testing included year of diagnosis, observation of a PD-L1 test, Black or African American race, and number of single-gene tests observed. The most important factors associated with early versus late testing included the observation of a PD-L1 test, a positive single-gene test result, the year of diagnosis, and the geographical region of care. Later year of diagnosis, evidence of PD-L1 testing, patient race, positive single-gene test results, and region were among the top 5 predictors of NGS testing for both ever versus never as well as early versus late NGS testing.

Table 2. Demographic characteristics of the overall, ever, and never NGS[a]-tested study cohorts prior to imputation.

Characteristic	Overall (N=31,407)	Ever NGS-tested[b] (n=13,425)	Never NGS-tested[c] (n=17,982)	Ever NGS-tested versus never NGS-tested, *P* value[d]
Age at initial diagnosis (years), mean (SD)	67.2 (9.8)	67.2 (10.1)	67.3 (9.5)	.66
Sex, n (%)				.0007

[e]ALP: alkaline phosphatase.

[f]ALT: alanine transaminase.

[g]AST: aspartate aminotransferase.

Over the 1000 bootstrap samples over the training data D1, an average of 135 and 89 features were identified by the LASSO models for the ever versus never and early versus late NGS-tested groups, respectively. These variables were then entered into an LR model using the testing set. The final model was established after removing any nonsignificant interaction terms, as explained earlier in the study methods. Details of the model fit statistics are shown in Table S3 in Multimedia Appendix 1. All main effects identified from the modeling for each group are shown in Figures 3-9.

There were lower odds of ever receiving NGS testing among patients with later age at initial diagnosis, bilirubin not tested, worse ECOG performance status, treated in geographies under the MolDX Program, a total higher number of genetic tests received, had only public insurance, and who were of Black or African American race as compared with those who were never tested. Patients who were obese, had a later year of initial NSCLC diagnosis, were from larger practices, had evidence of PD-L1 testing, no results for platelet testing, no history of smoking, had stage II disease, and were treated in a MAC region other than JH Novitas or J6 NGS had higher odds of ever receiving NGS-based testing.

For early versus late NGS testing (Figures 10-17), there were greater odds of receiving early NGS-based testing among patients with a later year of initial NSCLC diagnosis, who had no history of smoking, who were in later drug period approval periods, had a PD-L1 test, treated in the MAC J8 WPS, and who had no other biomarker tests or inconclusive testing.

Discussion

Overview

This study applied machine learning methods and traditional statistical tools that identified several factors that were significantly associated with not only receiving NGS-based testing but also receiving the testing early when there is a potential for early intervention with targeted therapies. Factors associated with both ever having NGS testing as well as early NGS testing included later year of NSCLC diagnosis, no history of smoking, and evidence of PD-L1 testing. These factors were consistent with the hypothesized direction of candidate variables, as NGS-based testing has been increasing over time, and it was not unexpected that the rate of testing has increased in recent years [4,25]. In addition, consistent with the hypothesized direction of these relationships, patients without a smoking history were more likely to undergo NGS-based testing. The lack of environmental causal factors would lead one to seek other explanations for the onset of lung cancer, including certain genomic abnormalities, which are frequently observed among nonsmokers with lung cancer [26]. PD-L1 testing is generally conducted alongside the NGS test and was only available in later years, so the observation of these relationships was also not unexpected.

Principal Findings

Factors associated with a greater chance of never receiving NGS testing included older age, lower ECOG performance status, Black race, higher number of single-gene tests, public insurance, and treatment in a geography associated with MolDX Program adoption. Patient age and public insurance are factors that are closely related. Patients aged 65 years and older generally have Medicare coverage, whereas younger patients will have private insurance. The median age of lung cancer diagnosis is 71 years [27], and it is highly likely that a younger patient presenting with NSCLC could raise questions about the genomic aspects of the disease that should be investigated as a result be associated with a higher likelihood of receiving early NGS-based testing as noted in the published literature [28]. Importantly, patient race, similar to prior research [7], remains a significant factor that continues to demonstrate the lack of equity in receipt of NGS-based testing. Of all factors evaluated in this study, racial inequity cannot be explained by any reasonable clinical factors and requires immediate attention by the health care community.

Several factors that did not have a clear association with NGS-based testing were those that also did not have a hypothesized direction associated with a potential relationship. While blood test results may have captured some aspect of well-being, there was no consistent relationship identified. Similarly, while patients with better performance status were more likely to receive NGS-based testing, this relationship was not strong, and the factor was not among those with the highest importance scores observed in this study. Therefore, this study suggests that these factors are likely not largely factored into a decision to receive NGS-based testing and could be why little data were observed in the published literature related to these factors.

The roles of the MolDX program and the MAC region are unclear. The emergence of MAC region J8 WPS as a predictive factor for greater odds of receiving early NGS testing and both JH Novitas and J6 NGS at lower odds of receiving any NGS testing could be an artifact of a large dataset with multiple subgroups or could reflect underlying factors related to this region that could not be explored, given the available data in the electronic data used for this study. Additionally, the timing of MolDX program adoption was not taken into account, so the patients in these regions could have had the decision made at a time that was unrelated to this variable (“yes” or “no”). Other geographic factors such as distance to a clinic, access to testing resources, and site of care could certainly have played a role as well; therefore, the relationship with MolDX should not be overinterpreted. Additionally, not all patients in these regions had Medicare coverage, so there is a great deal of uncertainty in these variables. A study with more comprehensive variables related to patient care in these regions would be needed to come to any clear conclusion about these relationships.

Limitations

First, this study is based on real-world data. The Flatiron Health deidentified data, as with most other electronic health record–based datasets, do not contain all potentially relevant variables to investigate all aspects of the complex question of NGS-based testing. Factors such as tissue availability, tissue quality, a patient crisis requiring immediate care, and other health care system–related factors were not recorded and may be additional factors that could impact access and receipt of NGS-based testing. The availability of these data, however, would not invalidate the factors that were observed in this study. Second, there were some patients who could have received NGS-based testing at an early stage diagnosis who were not included in this study due to our eligibility criteria, requiring testing within the time frame of advanced or metastatic diagnosis. Therefore, this study may not be generalizable to those diagnosed and tested at earlier stages of the disease. Third, as with all real-world data sources, missingness is a potential issue. However, the rates of NGS-based testing in this study are very similar to other estimates from different data sources, which provides confidence in the outcome variable assessed within the database used for this study [10]. Finally, when evaluating predictive models, a cutoff of 0.5 was applied to the predicted probability of events. While this may result in a suboptimal trade-off of specificity versus sensitivity for certain models (eg, for modeling “early vs late” NGS testing, it resulted in low specificities of ~20% and very high sensitivity of ~98%; Table S2 in Multimedia Appendix 1), the objective of this study was to identify predictors of NGS testing rather than optimizing predictive rules. The probability cutoffs could be further calibrated to strike a desired balance between false positives and negatives.

Conclusions

Despite the limitations of these data, this study reinforces the need to assure equity in access to NGS-based testing that has been observed in prior research. Black race is consistently associated with lower biomarker testing rates [7]. Other factors may be more associated with disease trajectory (eg, age, lower

ECOG performance status, and single-gene tests), emphasizing the flexibility needed in testing for those patients who may not be well enough for systemic therapy or who have an actionable biomarker previously identified. While efforts must be made to ensure all patients diagnosed with NSCLC have equal access to NGS-based testing early in the trajectory of the disease, there may be consideration for the specific patient needs in these cases.

Abstract

While patient-reported outcome measures are regularly incorporated into phase 3 clinical trials, they have been infrequently used in early phase trials. However, the patient's perspective is vital to fully understanding dose toxicity and selecting an optimal dose. This viewpoint paper reviews the rationale for and practical approach to collecting patient-reported outcome data in early phase oncology drug development and the rationale for electronic collection.

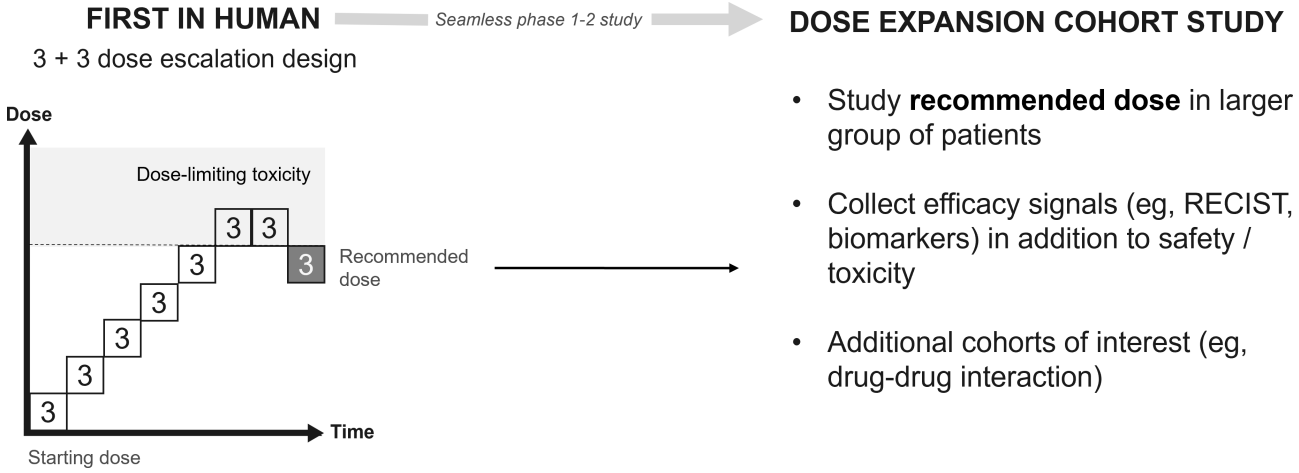
Dose Finding in Oncology Drug Development

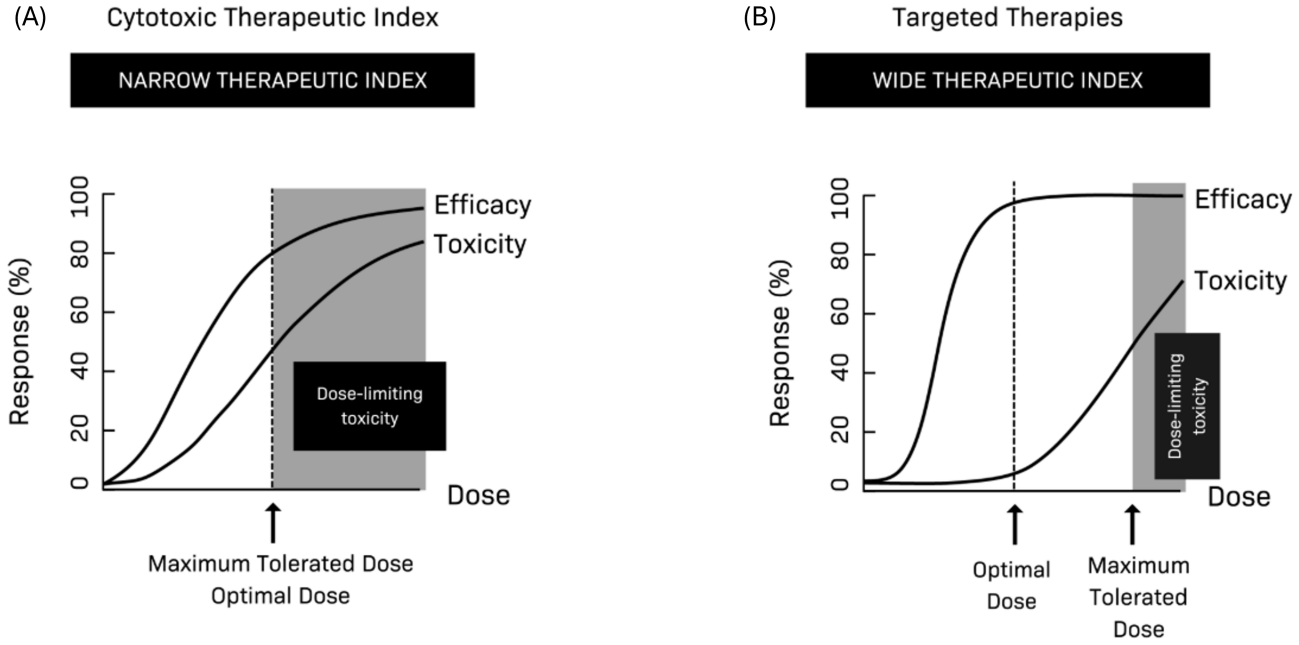
Traditional dose findings in oncology clinical drug development have focused on determining the maximum tolerated dose, assuming that the efficacy-dose relationship follows a steep monotonic increasing curve. By this assumption, the recommended dose is defined as the highest dose in which dose-limiting toxicity is not observed. Typical early phase programs (Figure 1) often use a 3 + 3 dose escalation design in which subsequent cohorts of 3 patients are studied, each receiving a higher dose than the last. Dose levels often follow a modified Fibonacci sequence whereby dose increments become smaller as the dose increases [1]. When dose-limiting toxicity is observed in at least one patient, the dose level is repeated in a further cohort of 3 patients, and if dose-limiting toxicity is observed again, further escalation stops, identifying the previous dose as the recommended maximum tolerated dose to take forward. Further study of the recommended dose is achieved, often using a seamless phase 1-2 design, by recruiting an additional larger group of patients into a dose expansion study. The primary end point in an expansion cohort is usually to determine efficacy, most frequently according to the radiological response rate. Additionally, further safety data is gathered, and pharmacodynamic markers may also be developed.

Figure 1. Traditional early phase oncology dose-finding studies. RECIST: Response Evaluation Criteria in Solid Tumors.



This approach has been acceptable for cytotoxic chemotherapy drugs due to their steep dose-response relationships, their limited drug target specificity, and the willingness of patients to trade off substantial toxicity to treat serious, life-threatening diseases [2]. However, it may lead to the recommendation of higher doses and a suboptimal tolerability profile when used in dose finding for modern, more targeted oncology drugs such as kinase inhibitors and monoclonal antibodies (Figure 2). In these cases, the wider therapeutic index means that a range of doses may show relevant efficacy, and doses below the maximum tolerated dose may have similar efficacy with reduced toxicity [3]. This can be particularly important because targeted therapies are often taken for much longer periods, during which lower grade, persistent symptomatic toxicities can present a greater challenge to patients [2]. Dose finding limitations have been illustrated in 26% of Food and Drug Administration (FDA)–approved kinase inhibitors (2001‐2015) requiring postmarketing requirements/commitments to study alternative doses [4].

Figure 2. Dose-response relationships and optimal dose selection for cytotoxic chemotherapy drugs and targeted therapies.



Better characterizing dose response to optimize dose finding has been underlined by the FDA's Project Optimus, which aims to reform how doses are selected in oncology clinical trials, with a particular focus on maximizing efficacy and optimizing safety and tolerability [5]. This led to their subsequent guidance on dose optimization for new cancer treatments [2]. Studying more dose levels in the dose expansion study may be one approach to enable this and may better enable characterization of the dose-response relationship, albeit qualitatively given the likely small cohort sizes.

Understanding Tolerability

Tolerability is defined in good clinical practice as "the degree to which overt adverse effects can be tolerated by the subject" [6]. In oncology, assessment of tolerability typically comprises clinician-reported treatment-related adverse events (AEs) using, for example, the Common Terminology Criteria for Adverse Events (CTCAE) [7], along with other data such as dose modifications, discontinuations and interruptions, safety biomarkers, hospitalization, and death [8]. However, these tools and data fail to fully account for the patient's perspective or to

fully measure the impact of AEs on the patient's activities and quality of life. Many studies comparing physician and patient reports of treatment-related AEs have consistently shown underreporting and reduced severity rating in physician interpretations compared to patient reports [9-16]. This represents a challenge for drug developers in accurately quantifying the dose-toxicity relationship and limits the ability to define optimal doses, leading to a greater risk of exposing greater numbers of patients to doses that are too high, potentially resulting in increased discontinuation and a less favorable safety profile.

For example, measuring the frequency of individual AEs reported by early phase patients using the full Patient-Reported Outcomes version of the CTCAE (PRO-CTCAE) item bank [17], Veitch and colleagues [9] evaluated the associated frequency of reporting of the same AEs by physicians using the CTCAE. They found that all 50 AEs reported by at least 10% of patients undergoing cancer treatment (n=243) were consistently underreported by physicians using the CTCAE, in some cases markedly. For example, 9 AEs were identified at least 50 times less frequently by physicians: decreased libido (31.4% vs 0.1%), palpitations (14.7% vs 0.1%), wheezing (14.5% vs 0.2%), voice alteration (14.1% vs 0.2%), hiccups (13.9% vs 0.1%), hyperhidrosis (23.9% vs 0.4%), vaginal dryness (11.0% vs 0.1%), nail ridging (10.0% vs 0.2%), and urinary incontinence (10.0% vs 0.2%). Further, 19 CTCAE items were reported 1% or less of the time by physicians, compared to 10%-31.4% by patients.

A further study in 1933 patients with a variety of oncology conditions treated in various routine care settings reported an underestimation of AE severity by clinicians in comparison to patient reports [10]. The frequency of symptoms assessed as moderate or severe by patients and physicians, respectively, were pain (67% vs 47%), fatigue (71% vs 54%), generalized weakness (65% vs 47%), anorexia (47% vs 25%), depression (31% vs 17%), constipation (45% vs 30%), poor sleep (32% vs 21%), dyspnea (30% vs 16%), nausea (27% vs 14%), vomiting (14% vs 6%), and diarrhea (14 vs 6%). While this study was not conducted in an early phase setting, it is likely that the discordance in clinician and patient assessments, consistent with Veitch et al [9], would be similarly reflected in early phase research.

These examples demonstrate that physician assessment of patient AEs may be both incomplete and underestimated in comparison to the patient perspective. Reasons for this may include patient difficulties in spontaneously raising or describing AEs, patient fears of delay or discontinuation of treatment options in which they have high expectations of positive results, introduction of clinician subjectivity, and time constraints and practical limitations with current physician tools.

While valuable in addressing the underreporting and lower scoring of AE severity by physicians, the PRO-CTCAE alone fails to assess the cumulative impact of the AE profile and the effects on functioning and quality of life. The cumulative impact may be especially important in newer treatments taken for sustained periods, where multiple, concurrent, low-grade but persistent AEs may together represent an intolerable burden for the patient. As we describe later, supplementing the rating of individual AEs with an overall single-item measure of the cumulative impact of AEs (eg, using the Functional Assessment of Cancer Therapy–Item GP5 [FACT GP5] [18] or item 168 from the European Organisation for Research and Treatment of Cancer [EORTC] item library [19]) and the adverse impact on patient physical function and role function (eg, measured using the associated subscales of the EORTC Quality of Life Questionnaire—Core Questionnaire [EORTC QLQ-C30] [20]) provides a valuable assessment of the impact of the AE profile experienced.

Using Patient-Reported Outcomes in Early Phase Oncology Trials

Overview

While the use of patient-reported outcome measures (PROMs) is increasingly incorporated into phase 3 clinical trials, and regulatory recommendations on measurement strategy have been recently published by the FDA [21], there is little use of PROMs in early phase trials [22]. Barriers to adoption in early phase oncology studies include a lack of guidance regarding PROM selection, concerns relating to dealing with missing patient-reported outcome (PRO) data, overburdening site staff and patients, handling patient and data queries [23], and low power associated with small sample sizes. Nonetheless, the patient perspective is a vital element of fully understanding dose toxicity and selecting an optimal dose for later phase development.

Adverse Events

In later phase trials, there is typically enough understanding of the AE profile of the investigational treatment to enable a reliable preselection of items for measurement (eg, using a small subset of PRO-CTCAE items). The same is not true for first in human and other early phase trials. Preclinical data may provide some signals to drive thinking, but these are unlikely to be robust and comprehensive, and while the AE evidence from other drugs with the same mechanism of action may be available and relevant, this is not always the case. The full PRO-CTCAE instrument contains 124 items across 78 distinct terms [17], and this is impractical to use in a full list format for regular ongoing measurement.

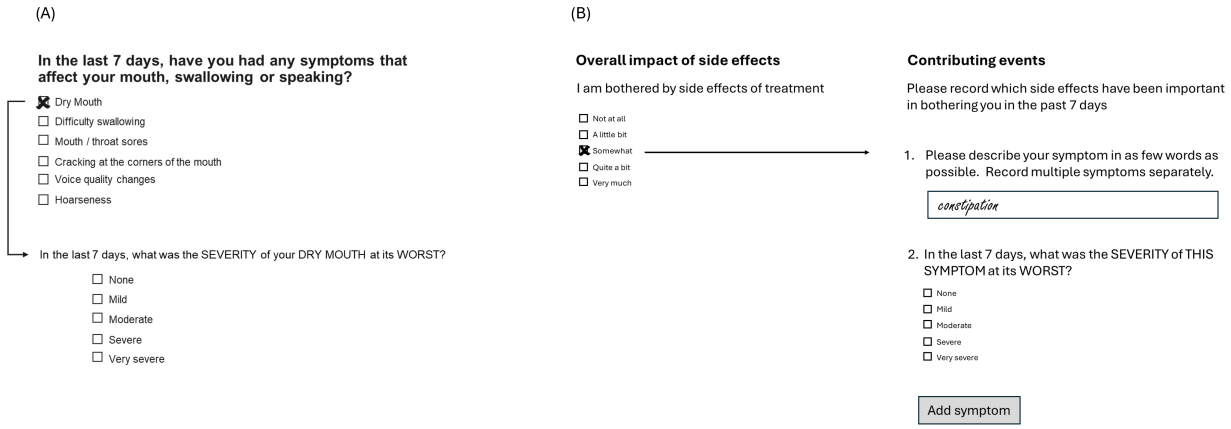
Janse van Rensburg and colleagues [24] used a statistical approach to develop a reduced list of PRO-CTCAE items considered most likely to occur in a phase 1 population using the same dataset reported by Veitch et al [9]. Using that dataset, they eliminated AEs recorded less than 5% of the time; those recorded as "mild" severity by at least 75% of patients; and AEs associated with interference scores of "not at all," frequency scores of "never," or amount scores of "not at all" by at least 80% of patients. Finally, terms with the lowest internal reliability within each organ system domain, as measured using Cronbach α, were also eliminated. With further refinements from physician perspectives, this led to a tailored PRO-CTCAE survey consisting of 58 items assessing 30 terms. While a useful and interesting approach, the generalizability of this reduced survey may be limited by the relatively small sample size, the limited

set of treatments and tumor types represented, and the risk that using historical data may miss important aspects of tolerability for new targeted therapies.

When selecting a reduced set of predefined items, it is helpful, as PRO-CTCAE recommends and allows, to include a free-text item to capture other important AEs not listed [25] and to use this information to allow the item list to adapt with the emerging understanding gained through continued study.

Because the PRO-CTCAE items are grouped by organ system domains, it is possible to optimize the completion of the full item list compared to an individual symptom-by-symptom approach (Figure 3A). Alternatively, a free-text approach asking patients to list and rate the AEs that contribute most to their overall impact rating (scored using the FACT GP5 item, for example) might provide a less burdensome approach (Figure 3B). Leveraging an electronic PRO (ePRO) solution, using a smartphone app, for example, would enable free-text symptom text to be resurfaced as a list of existing AEs to be easily rescored at future time points.

Figure 3. Approaches to simplify adverse event capture and scoring (A) using organ system grouping and (B) collecting the most bothersome adverse events associated with overall impact score.

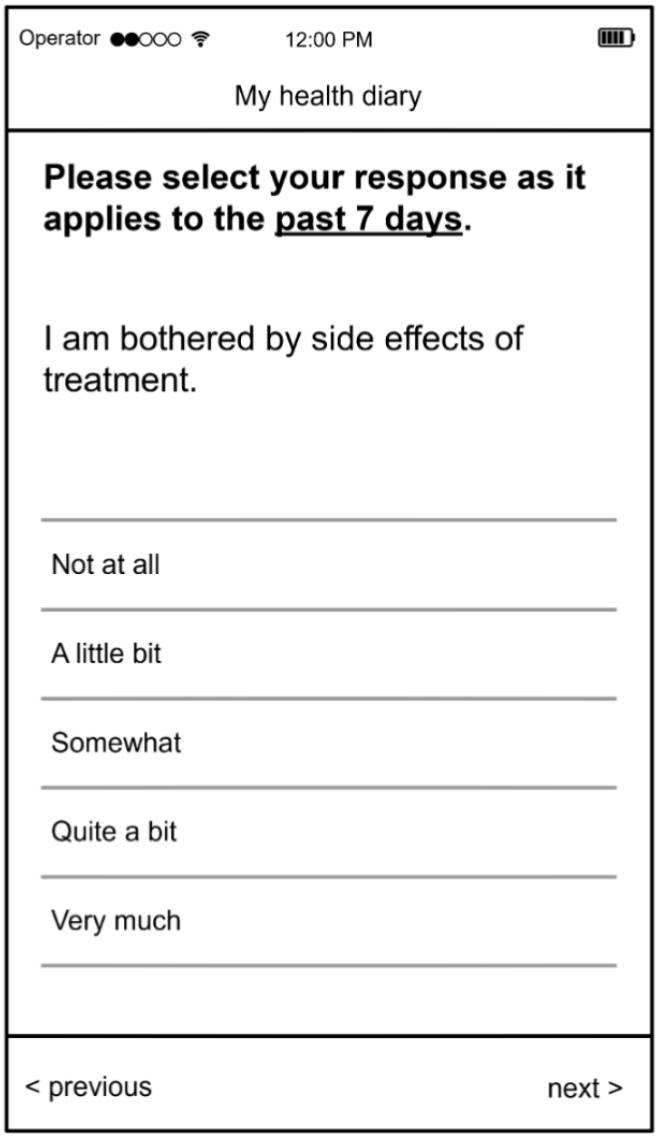


Collecting the most bothersome AEs (Figure 3B) has similarities to some existing PROMs that measure the most bothersome symptoms (MBSs). For example, MBS has been shown to be a useful patient-centric measure of migraine symptoms [26,27] and is referred to in the patient-focused drug development guidance published by the FDA [28]. Challenges with collecting an MBS include how to pool data in the statistical analysis and different symptoms becoming the most bothersome over time. However, these challenges may be less relevant when collecting the set of most bothersome AEs to understand the dose-toxicity relationship in early phase cancer trials.

Other Recommended PROMs

The Friends of Cancer white paper [8] and FDA guidance on PROs in cancer trials [21] both recommend that in addition to the collection and scoring of individual AEs, an overall measure of the AE impact is included, along with measures to assess the impact of treatment on physical function and role function, although the FDA guidance is more focused toward use in confirmatory trials. A single item to score the overall impact of AEs, such as the FACT GP5 [18] (Figure 4) or Q168 of the EORTC item bank [19], is important as it enables the patient to account for the impact of any AEs not covered by PRO-CTCAE administration and to attach greater importance to the combined impact of multiple low-level AEs. This understanding may be particularly important in assessing the impact of newer treatments taken over longer periods. The FDA has identified measures of physical function and role function they consider suitable, including the EORTC QLQ-C30 physical function and role function subscales [20] and the Patient-Reported Outcomes Measurement Information System (PROMIS) physical function scale [29].

Figure 4. Functional Assessment of Cancer Therapy–Item GP5 (FACT GP5). An example of a single-item measure of the impact of adverse events. FACT GP5 is reproduced with permission, copyright of Dr David Cella, and licensed by FACIT.org [18].



Mitigating Barriers to PROM Adoption in Early Phase Trials

As described earlier, barriers to the adoption of PROMs in early phase cancer trials include a lack of guidance regarding PROM selection, concerns relating to dealing with missing PRO data, overburdening site staff and patients, handling patient and data queries [23], and low power associated with small cohorts. We address PROM selection in the discussion above. Dealing with missing data is always an important consideration in clinical research, as different missing data approaches rely on assumptions that, if violated, can lead to biased estimates. Although researchers in early phase trials may use less formal approaches to interpreting the data and determining the optimal dose, it will remain important to consider the impact of missing data using a variety of sensitivity evaluations.

In terms of patient burden, the UK National Cancer Research Institute Consumer Forum survey indicated that most patients and carers affected by cancer and involved in research activities (n=57) were willing to spend up to 15 minutes per day completing PROMs [23]. This time duration seems high for frequent collection but perhaps reflects the value that patients see in communicating this data to their treating physician. The measures we have discussed above typically use a 7-day recall period, and it is, therefore, most likely that a weekly completion schedule would be recommended. Recall bias using the weekly recall periods associated with these validated measures is unlikely to be a concern, but ensuring completion times do not overburden patients with the debilitating effects of the disease and treatment is an important consideration. Median per-item completion rates of PROMs commonly used in oncology trials have been reported as 6 - 14 seconds [30], which suggests that a weekly PROM assessment of, for example, the PRO-CTCAE implemented using the approach outlined in Figure 3A, an overall AE impact item, and the physical function and role function subscales of the QLQ-C30 (items 5 and 2, respectively) might translate to an average completion time of less than 5 minutes per week. This seems to be a feasible assessment strategy, and ensuring a flexible completion window across more than 1 day may drive higher completion rates.

The remaining barriers cited may be mitigated by electronic collection of PRO data, for example, by using an ePROs smartphone app. The burden on site staff and patients during busy clinic visits can be mitigated by enabling at-home completion, and electronic tools can eliminate data queries by prohibiting ambiguous or invalid entries. The easy implementation of longer lists of items using branching logic to speed completion is only practical using an electronic approach. Further, the use of ePRO solutions can also lead to reduced missing data through alarms, reminders, and remote monitoring to drive on-time completion.

Electronic collection of PRO data may be perceived as a significant additional cost relative to the smaller numbers of patients involved in early phase studies, but this should be considered in the context of the value of the data. The more frequent assessment schedules and the nature of the measures implemented drive the use of electronic solutions. In the context of the increased expense of studying more patients in early phase trials due to the need to better characterize dose response, the use of ePROs to drive more accurate, reliable data may lead to accurate decision-making using relatively smaller sample sizes and offset the cost of ePROs many times over.

Smaller sample sizes associated with early phase studies may limit the robust characterization of the dose-response relationship, but this limitation is not unique to PRO data and also applies to other measures of efficacy and tolerability that inform dose selection. A thoughtful approach is required to balance the cost of increased sample size with the statistical robustness of dose-response characterization. Supplementary qualitative data collected using in-trial patient interviews may be a valuable addition to understanding the AEs experienced by the patients and aid the interpretation of PROM data when limited by small sample sizes.

Conclusion

There is growing interest in more completely quantifying the dose-response relationship to inform optimal dose determination for new oncological treatments. PROs play a vital role in understanding dose tolerability profiles, especially as treatment-related AEs tend to be underreported and underscored by physicians. While AE profiles are less understood in early phase drug development, this should not prevent the capturing of this data to inform dose selection decisions as early as the first in human study using some of the approaches discussed in this paper.

Of course, we lack experience in interpreting PRO tolerability data from such early studies and need to remember that we may not have adequately defined the patient population at this early stage, and so the clinical interpretation of dose-response relationships associated with the PROs and other efficacy and tolerability data needs to be interpreted with this in mind.

With newer targeted therapeutics, there is a need to learn much more about safety and tolerability across a wide range of doses, and the current dose-finding models focusing on a single “optimal” dose may no longer work. A fundamental element of the decision-making process for determining safety and tolerability currently missing is the patient experience. It has been assumed that the physician, through patient interaction and AE reporting, can provide a sufficient reflection of the patient experience, but the evidence demonstrates that this is not reliable. Some important symptoms for patients are missed completely. The severity of other symptoms is underreported. Further, with newer targeted agents, AEs may accumulate over time, and the chronic nature or combination of events may make a dose become intolerable for the patient later. If the patient’s perspective is not considered, there is a risk of selecting dose groups that are too high, leading to reduced compliance. It is, therefore, necessary to build a PROM assessment strategy for early phase trials that combines elements of well-established scales to assess safety and tolerability in a package that is practical and not burdensome, yielding vital data to support decision-making as the trial progresses. Maximizing the value of the early patient experience is ethically appropriate and feasible, and drives efficiency in development programs and patient exposure.

Abstract

This study describes patients' interaction with a personalized web-based visualization displaying daily electronic patient-reported outcomes and wearable device data during outpatient chemotherapy.

(JMIR Cancer 2025;11:e62711) doi:10.2196/62711

KEYWORDS

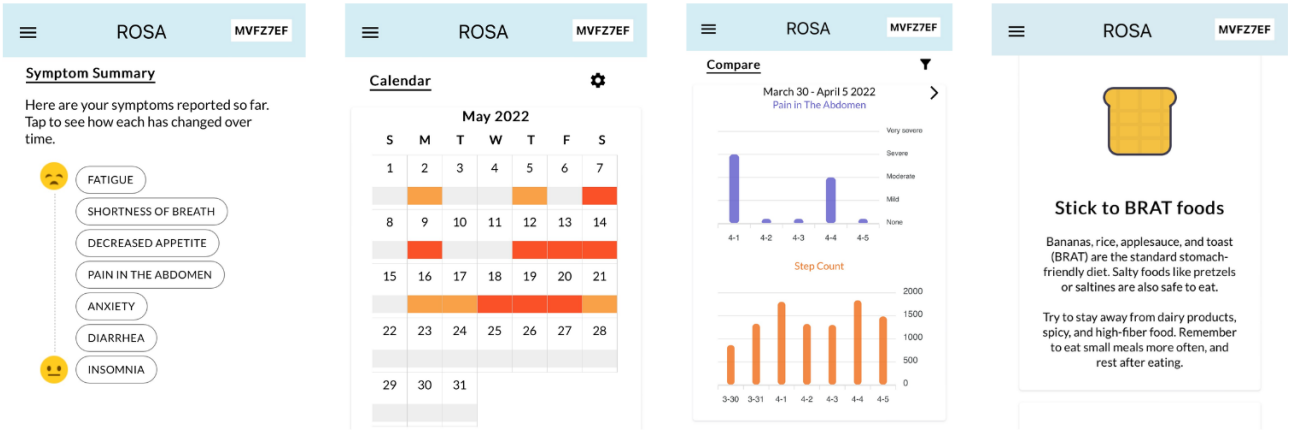
oncology; cancer; data visualization; remote monitoring; mobile technology; patients; outpatient; chemotherapy; symptoms; side effects; cancer treatment; electronic patient-reported outcome; online; monitoring; self-management

Introduction

Chemotherapy can cause significant symptoms that impact the quality of life [1]. Although electronic patient-reported outcome (ePRO) systems for collecting symptom ratings from patients have become increasingly common in cancer care, most of these are designed for clinicians, and fewer than half share data visualizations with the patients [2,3]. Visualization of ePRO and other data (eg, wearable device data) may help patients undergoing cancer treatment find patterns that help them to prepare for future treatment cycles, manage side effects, and have productive conversations with clinicians [4,5].

As part of a prospective longitudinal National Cancer Institute–funded study to develop a remote symptom monitoring system during chemotherapy [6], we created mobile-friendly web visualizations of each patient's daily symptom ratings and wearable device data (Figure 1). The aim of this paper is to describe patterns of use of these novel visualizations.

Figure 1. Visualizations of daily symptom ratings and wearable data with self-care resources.



Methods

Recruitment and Study Design

Participants undergoing chemotherapy for any solid tumor and who owned smartphones were recruited from oncology clinics at a single academic center in Pittsburgh, Pennsylvania. During the study, the participants wore a Fitbit device (Inspire; Google LLC) and reported 16 symptoms commonly experienced during chemotherapy (eg, nausea, fatigue) daily, using the patient-reported version of the Common Terminology Criteria for Adverse Events [7]. The website also included

evidence-based symptom self-management resources as described by Donovan et al [8].

At the time of enrollment, we provided each patient with a personalized link to their real-time visualizations; however, no instructions about viewing frequency for the visualizations or usage reminders were given during the study. At the end of the 3-month study, 141 patients completed an electronic- or paper-based 11-question survey (mean completion time was 5 min) to assess whether they used the visualizations, frequency of use, helpful information, and suggestions for improvement. Data were collected between February 2022 and April 2024.

Ethical Considerations

The University of Pittsburgh's Institutional Review Board approved all study activities (19070011). At the time of enrollment, all participants provided informed written consent. All data were stored in secure locations and identified only by anonymized study ID numbers. Participants received US $100 and could keep the Fitbit device (estimated value $100).

Results

Characteristics of the participants can be found in Table 1. Survey respondents were heterogeneous in age (mean 61, SD 12; range 29-92 years), race (113/141, 80% White; 28/141, 20% other races), and cancer stage (75/135, 56% stage IV). Approximately half (76/141, 54%) of the participants accessed the link to their data visualizations. Participants with non-binary gender (n=1, 0.7%) and unknown cancer stage (n=6, 4.3%) were excluded from χ^2 analysis while comparing participants who accessed their visualizations. There were no significant differences between the participants who clicked on the link and those who did not during the study in terms of mean age (P=.74), gender (P=.66), race (P=.50), or cancer stage (P=.31). Of those who accessed the platform, most (54%, 41/76) viewed it a few times (ie, less than monthly), while 13% (10/76) used it daily. The 10 daily users were within 3 months of starting chemotherapy for the first time. Most participants (58/75, 77%) found the visualizations *somewhat* or *very helpful/informative*. Few participants shared their data with family members or friends (11/141, 8%) and with others (2/141, 1%); none shared data with their providers or other patients. Participant–suggested improvements included reminders to view graphs and the ability to enter treatment and surgery dates.

Table . Participant characteristics.

Characteristics	Overall (N=141)	Did not click the link (n=65)	Clicked the link (n=76)	Test statistic (*df*)[a]	*P* value
Age (years), mean (SD)	61 (12)	61 (13)	60 (11)	t (130.1)=0.68	.74
Gender, n (%)				$\chi^2(1)=0.2$	.66[b]
Female	94 (66.7)	45 (69.2)	49 (64.5)		
Male	45 (31.9)	19 (29.2)	26 (34.2)		
Non-binary	1 (0.7)	0 (0)	1 (1.3)		
Unknown	1 (0.7)	1 (1.5)	0 (0)		
Race, n (%)				$\chi^2(1)=0.45$	.5
White	113 (80.1)	50 (76.9)	63 (82.9)		
Others[c]	28 (19.8)	15 (23.1)	13 (17.1)		
Stage IV cancer, n (%)				$\chi^2(1)=1.04$	.31[d]
Yes	75 (53.2)	39 (60.0)	36 (47.4)		
No	60 (42.5)	25 (38.5)	35 (46.0)		
Unknown	6 (4.3)	1 (1.5)	5 (6.6)		

[a]Welch two sample *t*-test and Pearson's χ^2 test were used, as appropriate; degrees of freedom (*df*) are provided in parentheses.

[b]Participants with non-binary or unknown gender were excluded from this test.

[c]Other race category included Black or African-American (n=24), Asian (n=2), and more than one race (n=2).

[d]Participants with unknown cancer stage were excluded from this test.

Discussion

Overview

Providing real-time visualizations of ePRO and activity data throughout chemotherapy may help patients anticipate and manage symptoms effectively and potentially identify patterns between activity or other sensor data and symptoms. These preliminary findings suggest that patients are motivated to view their data, and these visualizations were accessible to patients of different ages, races, and cancer stages. Daily users, who were mostly new to chemotherapy, may have higher levels of

anxiety and a greater need for health information [9]. Future studies should investigate the potential benefits of patient-facing visualizations for patients beginning chemotherapy.

Limitations

The visualizations and other website content were developed as part of an ancillary project in an ongoing study, and participants received no instructions or reminders regarding website usage. Survey respondents represented a subset (141/158, 89%) of participants, who received personalized visualizations, and the results may be influenced by selection, response, and recall biases.

Conclusion

This study describes initial efforts to share real-time ePRO and wearable device data visualizations with patients undergoing chemotherapy. Further research is needed to improve the usability of data visualizations and evaluate their impact on symptom management, self-efficacy, and other outcomes.

Conflicts of Interest

Abstract

Background: Cancer is the second leading cause of death in the United States. Compelling evidence shows screening detects colorectal cancer (CRC) at earlier stages and prevents the development of CRC through the removal of precancerous polyps. The Healthy People 2030 goal for CRC screening is 68.3%, but only 36.5% of Missouri federally qualified health center patients aged 50 - 75 years are up-to-date on CRC screening. For average risk patients, there are three commonly used screening tests in the United States—two types of stool tests collected at home (fecal immunochemical test [FIT]–immunochemical fecal occult blood test [FOBT] and FIT-DNA, such as Cologuard) and colonoscopies completed at procedural centers.

Objective: This study aims to examine variation by month for the three types of CRC testing to evaluate consistent patient care by clinical staff.

Methods: Data from 31 federally qualified health center clinics in Missouri from 2011 to 2023 were analyzed. A sample of 34,124 unique eligible "average risk" patients defined as persons not having a personal history of CRC or certain types of polyps, family history of CRC, personal history of inflammatory bowel disease, and personal history of receiving radiation to the abdomen or pelvic to treat a previous cancer or confirmed or suspected hereditary CRC syndrome. Another eligibility criterion is that patients need to be seen at least once at the clinic to be included in the denominator for the screening rate calculation. Descriptive statistics characterize the sample, while bivariate analyses assess differences in screening types by month.

Results: Completion of CRC screening yielded statistically significant differences for patients completing the different types of CRC screening by month. October-January had the highest proportions of patients (644-680 per month, 8.5% - 10.2%) receiving a colonoscopy, while February-April had the lowest (509-578 per month, 6.9% - 7.8%), with 614 being the average monthly number of colonoscopies. For FIT-FOBT, June-August had the higher proportions of patients receiving this test (563-613 per month, 8.9% - 9.6%), whereas December-February had the lowest (453-495 per month, 7.1% - 8%), with 541 being the average monthly number of FIT-FOBT kits used. For FIT-DNA, March was the most popular month with 11.3% (n=261 per month) of patients using the Cologuard test, followed by April, May, and November (207-220 per month, 8.7% - 9.4%), and January and June (168-171 per month, 7.2%-7.3%) had the lowest proportion of patients using Cologuard, with 193 being the average monthly number of FIT-DNA kits used. Combining all tests, February had the fewest CRC tests completed (1153/16,173, 7.1%).

Conclusions: Home-based tests are becoming popular, replacing the gold standard colonoscopy, but need to be repeated more frequently. Monthly variation of screening over the course of a year suggests that CRC screening efforts and patient care may be less than ideal. Months with lower rates of screening for each type of CRC test represent opportunities for improving CRC screening.

KEYWORDS

colorectal cancer screening; federally qualified health center; FQHC; fecal immunochemical test; FIT; FIT-DNA; colorectal cancer; CRC; cancer; cancer screening; colonoscopy; United States; health center; quality improvement

Introduction

Colorectal cancer (CRC) is the third most common cancer in the United States and the second leading cause of cancer deaths [1]. Evidence shows that screening detects CRC at earlier stages, and its development can be prevented by removing precancerous polyps. For average risk patients, there are three common screening tests—two types of stool tests collected at home (fecal immunochemical test [FIT]–immunochemical fecal occult blood test [FOBT] and FIT-DNA, like Cologuard) and colonoscopies

completed at procedural centers. The revised Healthy People 2030 goal for CRC screening among people aged 45 - 75 years changed from 74.4% to 68.3% [2]. Federally qualified health centers (FQHCs) provide low-cost care for approximately 30 million people, and 90% of FQHCs' patient population (n=17,562,189) have an income less than 200% of the federal poverty level [3,4]. The CRC screening rate of patients using FQHCs in Missouri (n=95,191) is 36.5% compared to 74.1% for patients not using FQHCs (n=1,657,026) [5].

Colonoscopy is considered the gold standard of CRC screening since precancerous polyps can be removed at the time of the test, preventing cancer. However, numerous patient and health system barriers to colonoscopies have been identified [6]. Home-based testing is becoming more common, and FIT-DNA use has increased post COVID-19 [7]. The increased FIT-DNA use may reflect patient preference for home-based testing that does not incur being wait-listed for months to get a colonoscopy [8]. Additionally, the manufacturer of FIT-DNA provides a full service in facilitating patients' completion of the test. This service includes a patient follow-up to encourage returning the kits and results sent directly to the patient's electronic medical record. For the FIT tests, a clinic is responsible for patient follow-ups regarding stool collection and sending the kit in for analysis [9].

Since screening opportunities take place at patients' routine visits to health centers, determining screening variation by month can assist health care systems adjust outreach efforts, targeting low use months to establish consistently high CRC screening opportunities throughout the year.

Objective

This quality improvement project aims to determine if there is variation in the 3 types of CRC testing by month. Identifying variations by month can support targeted attention. The global aim of the quality improvement project was to support FQHCs' in providing CRC screening opportunities with consistent screening rates each month.

Methods

Overview

Starting in 2020 as part of a 5-year Centers for Disease Control and Prevention–funded quality improvement program, our project supported eight health care systems' initiation or enhancement of four evidence-based interventions to increase CRC screening rates of age-eligible patients using a practice facilitator model. As part of this quality improvement program, up to 4 years of annual data on CRC screening by type and date of completed CRC test for the eligible patient population in the selected health care system were available. Patient characteristics including age, race/ethnicity, primary language, and sex were gathered. Screening compliance was defined as a colonoscopy recommended every 10 years, FIT-FOBT every year, and FIT-DNA every 3 years. Screened for CRC was defined as having a medical record of being up-to-date on one of the three types of tests. For this analysis, eligible patients were aged 50 - 75 years with no prior diagnosis of CRC, adenomatous polyps, or inflammatory bowel disease, and no personal diagnosis or family history of known genetic disorders that predispose them to a high lifetime risk of CRC such as Lynch syndrome or familial adenomatous polyposis [10]. Descriptive statistics characterize the sample, while bivariate analyses assess differences in screening types by month. While examining monthly CRC screening rates, data were limited to exclude years where fewer than 10 screenings occurred for any given month. Monthly totals were first calculated, and the average number of tests across all months was used to calculate the average percentage change (increase or decrease) month to month. A χ^2 test for equal proportions of the CRC screening tests by month among the 3 types of CRC tests was then examined. Month was chosen as the unit of analysis since it is easily understood, helping plan and implement activities. A weekly analysis has fewer observations leading to less stable numbers, and holidays influence the days in any week. SAS 9.4 (SAS Institute) was used for the analysis.

Ethical Considerations

This project was approved by University of Missouri's Institutional Review Board (IRB 2034264), which allowed analysis of clinical data extracted from electronic medical records without additional consent for the secondary analysis. The data were deidentified for the analysis. All data were transmitted and stored in a Health Insurance Portability and Accountability Act (HIPAA)–compliant secure system (REDCap) [11].

Results

A total of 31 clinics servicing predominately rural residents yielded 34,124 unique eligible patients from 2011 to 2023. Among these, 6238 (18.3%) were up to date on their CRC screening, another 5170 (15.2%) had received a CRC screening at some time in the past but were not up to date, and the remaining 22,716 (66.6%) patients had no record of being screened for CRC. Most participants were 50 - 64 years old (n=24,014, 70.4%), were female (n=19,229, 56.4%), used English as their primary language (n=31,686, 92.9%), and were White (n=27,677, 81.1%; Table S1 in Multimedia Appendix 1). Fewer participants younger than 65 years were up to date on their CRC screening than those 65 years and older. Patients with the highest proportion of ever being screened were Hispanic (837/2032, 41.2%), compared to White (9391/27,677, 33.9%) and Black (533/1385, 38.5%), but fewer Hispanic participants (n=260, 12.8%) were up to date compared to White (n=5386, 19.5%) and Black (n=268, 19.4%) participants (Table S1 in Multimedia Appendix 1). The FQHC systems in this analysis served 87% of patients who were at or below 200% of the federal poverty guidelines. Most clinics (n=28, 90.3%) were located in rural areas of Missouri. Among the clinics, the 2023 annual CRC screening rates ranged from 13.7% to 63.1% (62/451 and 238/377 eligible patients, respectively).

Table S2 in Multimedia Appendix 1 breaks down the descriptive statistics on monthly CRC screenings. There were 7368 patients who were up to date on CRC screening by colonoscopy with an average of 614 screenings per month from 2014 to 2023. A χ^2 test for equal proportions found significant differences across

monthly colonoscopy screenings (χ^2_{11}=38.9; *P*<.001). January was the highest month for colonoscopy screenings (n=680, 11% higher than the average), while February was the lowest (n=509, 17% lower than the average; Figure 1). For FIT-FOBT (n=6486), there were an average of 540.5 screenings per month from 2017 to 2023. A χ^2 test for equal proportions found significant differences across monthly FIT-FOBT screenings (χ^2_{11}=51.7; *P*<.001). August was the highest month for FIT-FOBT screenings (n=613, 13% higher than the average) compared to January (n=468, 14% lower than the average) and February (n=453, 16% lower than the average; Figure 2). There were 2319 FIT-DNA screenings, with an average of 193.3 per month from 2020 to 2023. A χ^2 test for equal proportions found significant differences across monthly FIT-FOBT screenings (χ^2_{11}=49.2; *P*<.001). March was the highest month (n=261, 35% higher than the average) while January (n=168, 13% lower than the average) and August (n=153, 21% lower than the average) were the lowest months for FIT-DNA testing (Figure 3).

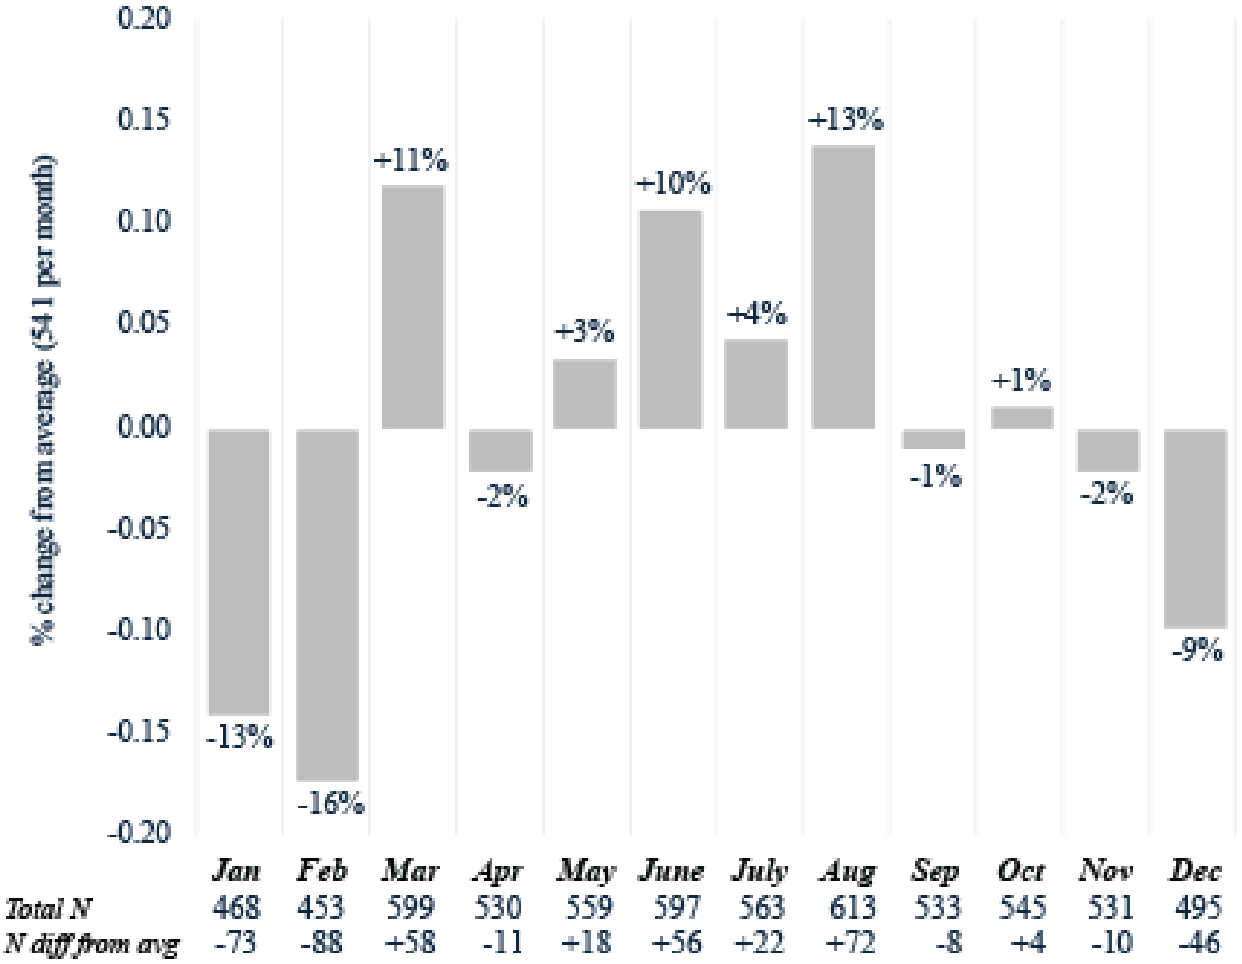

Figure 3. Fecal immunochemistry test–DNA by month (2020 - 2023).

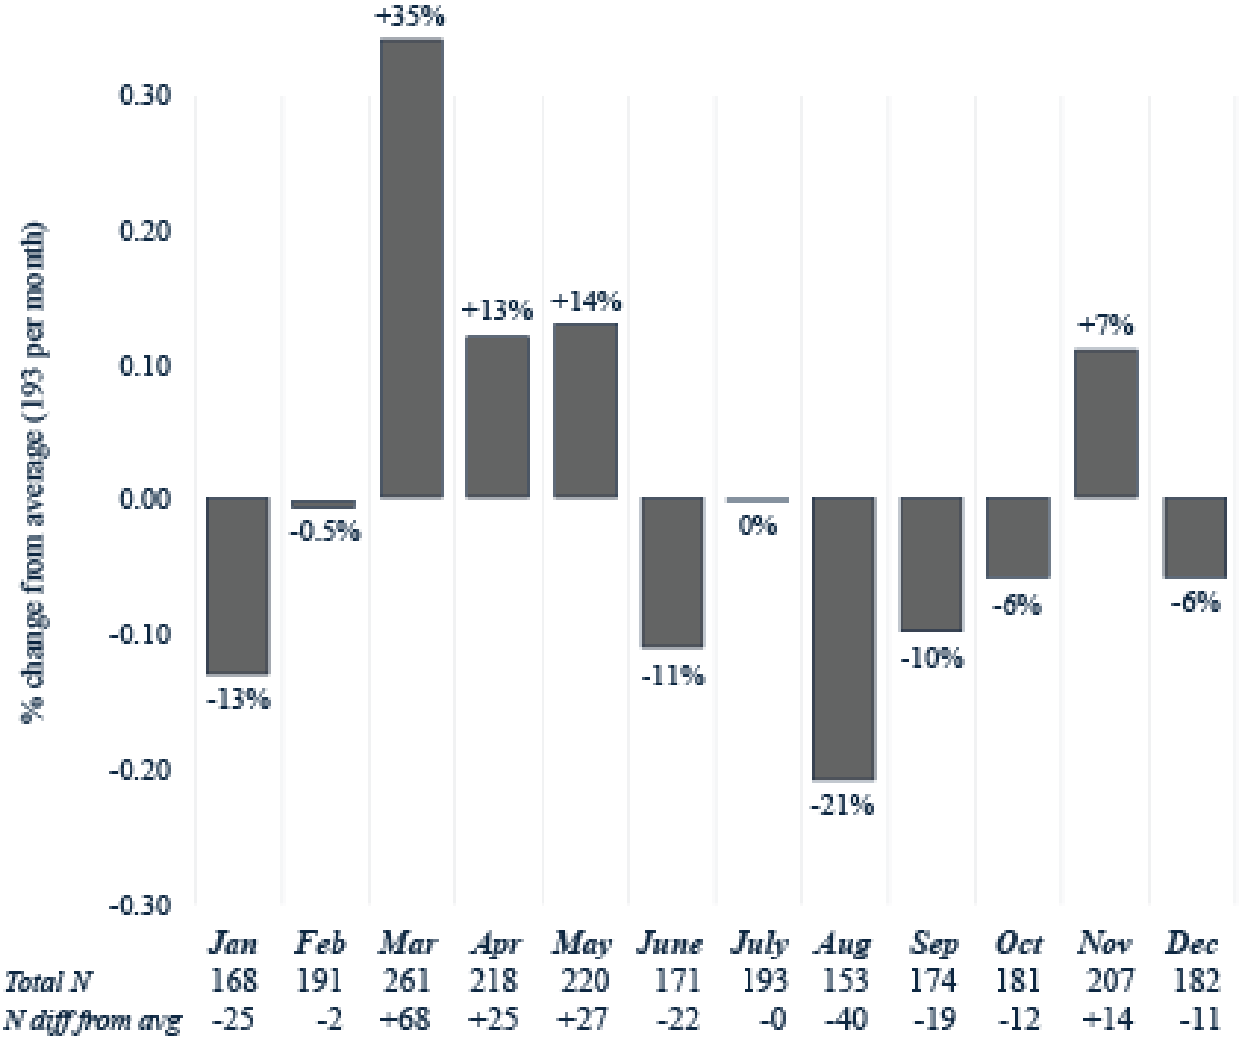

Discussion

Principal Findings

Among the 3 types of CRC screening for average risk patients seen at our FQHCs in the United States, no test was completed consistently by month, and each test had different peak months of completion. We were not able to find any research that compared variation by month in CRC screening test types of colonoscopy, FIT-FOBT, and FIT-DNA. To our knowledge, this is the first study that provides results of CRC screening type by month.

As reflected in our screening choices by patients seen at FQHC clinics, home-based CRC screening increased during the COVID-19 pandemic's closures of specialty care including elective procedures (eg, colonoscopies) [7]. This change in CRC screening options allowed for testing at the discretion of the patient rather than appointment availability.

Strengths and Limitation

One strength of this study was evaluating patients over 12 years from several FQHCs. These data were snapshots of each year's CRC screening behavior by the health care systems. This also captured screening behavior before and after the pandemic.

One limitation of this study was our inability to explain the variability by month of the different screening tests. For example, FIT-DNA and FIT-FOBT tests peaked in CRC awareness month in March but not colonoscopies. Additionally, while the results are informative, only a simple analysis of screening variability was performed, which excluded an examination of temporal changes over time.

The preferences of clinicians on which CRC screening test is recommended and their patient care style were not captured. For example, some clinicians only recommend colonoscopy [12-14]; however, some patients who decline a colonoscopy [15] would be willing to complete a home-based CRC screening test if offered. Further reasons for CRC screening refusal of any test were also not captured. These could be a factor in the CRC test variation by month.

Future Direction

Among the selected participant characteristics, attention is needed on those younger than 65 years to encourage CRC screening. Similarly, while 41.2% of Hispanic participants showed a positive attitude toward CRC screening, only 12.8% were up to date with their screening. This suggests that tailored campaigns and outreach programs could encourage greater participation in CRC screening. For all populations, screening matters since the variance in testing over a year can impact the

health care system's capacity for timely preventive patient care. Gastroenterologist availability to complete colonoscopies may be limited in some regions of the country, but home-based tests can be completed each month [8]. Undoubtedly, individual-level barriers influence CRC screening rates, such as transportation, medical mistrust, financial issues, and low health literacy [16]. However, organizational factors, including monitoring and feedback, have been identified as implementation facilitators [16]. Rockwell and colleagues [6] described health system barriers, especially for colonoscopies, as sludge, "frictions or administrative burdens that make it difficult for people to attain what they want or need." Providing clinical staff information on completed CRC screening rates by month for each test type may facilitate addressing these "sludge" issues and increase CRC screening [8,17].

Abstract

Background: Generative artificial intelligence (AI) chatbots may be useful tools for supporting shared prostate cancer (PrCA) screening decisions, but the information produced by these tools sometimes lack quality or credibility. "Prostate Cancer Info" is a custom GPT chatbot developed to provide plain-language PrCA information only from websites of key authorities on cancer and peer-reviewed literature.

Objective: The objective of this paper was to evaluate the accuracy, completeness, and readability of Prostate Cancer Info's responses to frequently asked PrCA screening questions.

Methods: A total of 23 frequently asked PrCA questions were individually input into Prostate Cancer Info. Responses were recorded in Microsoft Word and reviewed by 2 raters for their accuracy and completeness. Readability of content was determined by pasting responses into a web-based Flesch Kincaid Reading Ease Scores calculator.

Results: Responses to all questions were accurate and culturally appropriate. In total, 17 of the 23 questions (74%) had complete responses. The average readability of responses was 64.5 (SD 8.7; written at an 8th-grade level).

Conclusions: Generative AI chatbots, such as Prostate Cancer Info, are great starting places for learning about PrCA screening and preparing men to engage in shared decision-making but should not be used as independent sources of PrCA information because key information may be omitted. Men are encouraged to use these tools to complement information received from a health care provider.

KEYWORDS

generative artificial intelligence; chatbot; chatGPT; prostate cancer; cancer screening; shared decision making; artificial intelligence

Introduction

Generative artificial intelligence (AI) chatbots such as ChatGPT, Google Gemini, and Microsoft Copilot have become highly publicized for enhancing work efficiency and effectively responding to diverse queries. These sophisticated programs leverage large language models, machine learning, and natural language processing to understand and respond to a query with publicly available or third-party information [1]. Over the past 2 years, researchers have demonstrated a growing interest in evaluating generative AI chatbots for providing quality health and cancer information [2-4]. While the performance of generative AI chatbots has varied depending on the disease queried, complexity of the query, and brand of chatbot used, these tools show promise for being reliable health information resources in the future [3,5,6].

In terms of prostate cancer (PrCA), the second leading cause of cancer mortality among men in the United States [7], the American Cancer Society (ACS) [8], American Urological Association (AUA) [9,10], and the United States Preventive Services Task Force (USPSTF) [11] recommend that men make shared PrCA screening decisions with their health care providers. To prepare for this important decision, men need access to credible, readable, and culturally-appropriate (eg, African Americans have a higher mortality risk [12]) PrCA screening information [13]. Multiple studies have investigated the quality of PrCA information generated by AI chatbots [14-22]. Overall, these studies show that PrCA information produced by chatbots can be accurate, reliable, and moderately comprehensive, but readability and credibility are often compromised. In a recent study by the authors, Owens and Leonard [23] discovered that soliciting plain-language responses from chatbots to PrCA screening inquiries significantly enhanced the response's readability. Conversely, credibility was difficult to ascertain because generative AI chatbots do not consistently reference authoritative information sources [23]. To create a reliable and credible plain-language resource for

PrCA screening information, we have developed "Prostate Cancer Info" (PCI), a generative AI chatbot using Open AI's custom GPT platform [24]. PCI is unique because it only responds to inquiries from credible, PrCA expert-curated websites (like the ACS). This method is different from current generative AI chatbots, which search the entire web and produce responses from a variety of expert-vetted and non-vetted sources. In addition, we have programmed PCI to always provide a source for responses, which is uncommon for current generative AI chatbots. Finally, we have programmed PCI to provide responses that do not exceed 6th to 8th grade readability as recommended by the American Medical Association [25]. The study's purpose is to evaluate the accuracy, completeness, and readability of PCI responses to 23 frequently asked PrCA screening questions. The study will contribute insight into the safety and efficacy of using AI chatbots for shared PrCA screening decision-making and the usefulness of developing customized AI chatbots for PrCA decision-making.

Methods

Intervention Development

Author MSL developed PCI using a multistep process. Websites published by the ACS, AUA, USPSTF, and Centers for Disease Control and Prevention (CDC) were programmed into the GPT builder [24]. The rationale for limiting our search to these websites is that these organizations are globally recognized for providing timely, evidence-based PrCA screening education and recommendations. In particular, the PrCA screening recommendations from the ACS, AUA, and USPSTF are the most widely recognized in US PrCA research and clinical practice. PCI was then directed to draw responses exclusively from these websites in the order listed. Therefore, PCI relied on the ACS website as a primary source unless the information was unavailable or was requested from a non-ACS source. Strict directives were given to PCI to (1) only retrieve information from websites provided, (2) respond with language at or below 8th grade readability, (3) ignore non-PrCA queries, and (4) provide sources for responses. PCI was pretested to confirm its adherence to these directives.

PCI answers user questions through a well-defined process: first, it limits itself to information from preapproved websites. Then, it indexes these sites, reading and organizing their content. When a user asks a question, PCI searches its indexed data for relevant details, analyzes the information to understand the context, and creates a concise, accurate answer from approved sources. This ensures consistent and trustworthy answers.

Study Protocol

A total of 23 frequently asked PrCA questions were adopted from previous studies by Zhu et al [15] and Owens and Leonard [23]. One author entered questions into PCI. Responses were saved in a document for rating by both authors. The authors used a coding form containing questions with key points and answers from ACS and CDC education resources[26,27], along with screening recommendations from the ACS, AUA, and USPSTF [8-11], and checkboxes to evaluate whether a response was accurate (contained correct statements) and complete (presented all salient facts without significant omissions). For example, a response to "What is the prostate?" would be considered accurate if it stated that the prostate is a gland that is a part of the male reproductive system. However, to be considered complete, the response would also need to include information on the size of the prostate, its location, and its purpose. If any parts of the response were not correct, they were rated as inaccurate. Table 1 shows the key points used to determine accuracy and completeness. Each of these key points is critical to a shared PrCA decision because a patient must consider factors such as the risks, benefits, and uncertainties of screening; their age, race, family history; and their personal values and preferences. Our chatbot responses have been included in Multimedia Appendix 1. Additional space was allotted on the coding form to record details about inaccuracies or omissions. The authors had 100% interrater agreement. The readability of responses was determined via a web-based Flesch Kincaid Reading Ease Scores calculator. Each response was copied and pasted into the calculator, excluding the reference website. The Flesch Kincaid Reading Ease Score uses total words, sentences, and syllables in an excerpt of text to calculate a score between 0 and 100, which corresponds to grade-level readability. Scores of 60 to 100 are considered easy to read by someone possessing an education at or below 8th to 9th grade. Scores of 50 to 60 require a 10th to 12th grade education (ie, fairly difficult) and scores below 50 require a college education (ie, very difficult) to comprehend.

Table . Key points for determining accuracy and completeness[a].

Questions	Key points
Basic Questions	
What is the prostate?	• Male reproductive organ. • The size of the prostate increases with age but is walnut-sized in younger men. • Located below the bladder and in front of the rectum. • Produces some of the fluid in semen.
How common is prostate cancer?	• About 313,780 new cases of prostate cancer (1 in 8 men). • About 35,770 deaths from prostate cancer (1 in 44 men).
What are the risks for prostate cancer?	• Risk increases with age. • More common among African-American men. • More prevalent in North America, northwestern Europe, Australia, and the Caribbean islands. • Risk is doubled if a man has a first-degree relative (eg, father, brother, or son) with prostate cancer gene mutations can increase the risk for prostate cancer. • Less common risk factors are diet, obesity, smoking, chemical exposure, inflammation of the prostate, STIs[b], and vasectomy.
When and how often should a man be screened for prostate cancer?	• ACS[c]: ages 50 years (average risk), 45 years (high risk), and 40 years (very high risk). • AUA[d]: ages 45 to 50 years (average risk) and age 40 years (high risk). • USPSTF[e]: age 55 to 69 years (average risk).
What are the symptoms of prostate cancer?	• Can have no symptoms in early stages. • Urinary problems. • Blood in urine or semen. • Erectile dysfunction. • Pain in hips, back, chest, or other areas. • Weakness or numbness in legs or feet. • Loss of bladder or bowel control.
What are the types of screenings for prostate cancer?	• DRE[f] and gloved finger test are not 100% accurate. • PSA[g], a blood test, is not 100% accurate and can produce false positives and false negatives.
What are the benefits and harms of prostate cancer screening?	• Benefit: can find cancer early. • Harms: tests, especially PSA can produce false positives or negatives, which can lead to unnecessary tests or treatments, which carry risks.
How is prostate cancer diagnosed?	• Biopsy: tissue samples from the prostate.
What are the risks of a prostate biopsy?	• Pain, blood in the semen, or infection.
How long can I live if I have prostate cancer?	• The 5-year relative survival rate is 97% on average, but depends on how far the cancer has spread.
Difficult Questions	
Is the PSA or DRE more effective for finding prostate cancer?	• PSA is more effective.
My father had prostate cancer. Will I have prostate cancer too?	• Having a father or brother with prostate cancer can more than double a man's risk of prostate cancer.
I have a high PSA level. Do I have prostate cancer?	• The probability of having prostate cancer increases with PSA level but there is no set PSA level that can definitively indicate the presence of prostate cancer.
What does a PSA level of 4 mean?	• Men with a PSA level between 4 and 10 have about a 1 in 4 chance of having prostate cancer.

Questions	Key points
What does a PSA level of 10 mean?	• The chance of having prostate cancer is 50% with a PSA of 10 or more.
What does a PSA level of 20 mean?	• The chance of having prostate cancer is more than 50% with a PSA of 20 or more.
What newer tests for prostate cancer may be more accurate than the PSA test?	• The prostate health index (PHI). • 4Kscore test. • IsoPSA test. • Urine-based tests.
If my biopsy sample is positive for cancer, should I receive genetic testing?	• Some men who have a strong family history or certain inherited genes, prior cancer diagnosis, or cancer that has spread to other parts of the body, should speak to their health care provider about this option.
If my biopsy sample is positive for cancer, how soon should I start treatment?	Will depend on the stage and grade of the cancer and their: • Age and expected lifespan. • Other serious health conditions. • Feelings about treatment. • The likelihood of a cure and doctor's opinion. • Feelings about treatment side effects.
Are there any cons to taking an at-home PSA test?	• At home PSA tests do not give a man an opportunity to make a shared decision with their health care provider about the risks, benefits, and uncertainties of the PSA test.
I am an African-American male, aged 40, with a family history of prostate cancer, at what age should I begin receiving prostate cancer screening?	• Screening should begin at age 40 based on both the ACS and AUA screening guidelines.
I am an African-American male, aged 40, with a family history of prostate cancer, can you provide me with all of the information I need to know to make a shared decision about prostate cancer screening?	Response should include all key points such as: • Prostate cancer incidence and mortality statistics. • Prostate cancer risks for African-American men. • Symptoms for prostate cancer. • Screenings for prostate cancer for African-American men. • Risks and uncertainties of prostate cancer screening. • Meaning of PSA results. • Biopsy for diagnosis. • Risk of biopsy. • Steps after a positive biopsy.
What are the differences in screening recommendations between major health organizations?	• ACS: ages 50 years (average risk), 45 years (high risk), and 40 years (very high risk). • AUA: age 45 to 50 years (average risk) and age 40 years (high risk). • USPSTF: age 55 to 69 years (average risk).

[a]Key points developed from web sources produced by ACS, CDC, AUA, and UPSTF.

[b]STI: sexually transmitted infection.

[c]ACS: American Cancer Society.

[d]AUA: American Urological Association.

[e]USPSTF: United States Preventive Services Task Force.

[f]DRE:digital rectal exam.

[g]PSA: prostate specific antigen test.

Data Analysis

Data was transferred from coding forms to Microsoft Excel spreadsheets for analysis. Descriptive statistics were calculated to determine the percentage of questions answered accurately and completely. An average mean readability score was also calculated.

Results

Accuracy and Completeness

Responses to all questions were accurate. In total, 17 of 23 questions (74%) were answered completely. Of the 6 questions with less complete responses, one lacked information about geography as a risk for PrCA and the higher prevalence of PrCA in North America. Of note is that this response recognized that

African Americans may be at greater risk for the disease, but statistics were not provided in any responses that substantiated the burden of incidence and mortality among African-American men. A total of 3 questions related to the meanings of PSAs of 4, 10, and 20 lacked statistics about the probability of PrCA, but did state men's greater chance of being diagnosed with PrCA at PSAs higher than 4. A fifth question about how soon a man should start treatment after a positive biopsy lacked information about how age, expected life span, comorbidities, and patient feelings about side effects factor into treatment decisions. Finally, a sixth question about what information an African-American male, aged 40 years with a family history of PrCA needs to know to make a shared screening decision yielded an answer that lacked information about what PSA results mean or the purpose and risks of a prostate biopsy.

Readability

The average readability was 64.5 (SD 8.7), which indicates most responses were written at an 8th-grade level or below. However, 5 of 23 responses (22%) were written at a 10th to 12th grade reading level and 1 response was written at a college level. In addition, 3 of the 5 responses addressed difficult questions. Scores ranged from 48.6 to 81.3. The lowest readability score (ie, 48.6) was in response to a basic question about symptoms of PrCA (see Table 2).

Table . Accuracy, completeness, and readability of Prostate Cancer Info responses to questions about prostate cance.

Questions	Accurate?	Complete?	Readability score
Basic questions			
What is the prostate?	Yes	Yes	81.3
How common is prostate cancer?	Yes	Yes	79.4
What are the risks for prostate cancer?	Yes	No	65.5
When and how often should a man be screened for prostate cancer?	Yes	Yes	70.3
What are the symptoms of prostate cancer?	Yes	Yes	48.6[a]
What are the types of screenings for prostate cancer?	Yes	Yes	70.8
What are the benefits and harms of prostate cancer screening?	Yes	Yes	64.6
How is prostate cancer diagnosed?	Yes	Yes	71.5
What are the risks of a prostate biopsy?	Yes	Yes	56.1[b]
How long can I live if I have prostate cancer?	Yes	Yes	63
Difficult questions			
Is the PSA[c] or DRE[d] more effective for finding prostate cancer?	Yes	Yes	74.7
My father had prostate cancer. Will I have prostate cancer too?	Yes	Yes	60.4
I have a high PSA level. Do I have prostate cancer?	Yes	Yes	70.7
What does a PSA level of 4 mean?	Yes	No	67.5
What does a PSA level of 10 mean?	Yes	No	67.2
What does a PSA level of 20 mean?	Yes	No	67.5
What newer tests for prostate cancer may be more accurate than the PSA test?	Yes	Yes	63.1
If my biopsy sample is positive for cancer, should I receive genetic testing?	Yes	Yes	52.4[b]
If my biopsy sample is positive for cancer, how soon should I start treatment?	Yes	No	58.8[b]
Are there any cons to taking an at-home PSA test?	Yes	Yes	65
I am an African-American male, aged 40, with a family history of prostate cancer, at what age should I begin receiving prostate cancer screening?	Yes	Yes	51.8[b]

Questions	Accurate?	Complete?	Readability score
I am an African-American male, aged 40, with a family history of prostate cancer, can you provide me with all of the information I need to know to make a shared decision about prostate cancer screening?	Yes	No	51.6[b]
What are the differences in screening recommendations between major health organizations?	Yes	Yes	60.6
Total (yes), %	100	74	—[e]
Readability score, mean (SD)	—	—	64.5 (8.7)
Readability score, median (range)	—	—	65 (48.6-81.3)

[a]Readability was very difficult (requires a college education).

[b]Readability was fairly difficult (requires a 10th to 12th grade education).

[c]PSA: prostate specific antigen test.

[d]DRE: digital rectal exam.

[e]Not applicable.

Discussion

Principal Findings

PCI had pristine accuracy and average completeness and readability. On average, completeness and readability were higher on responses to basic questions as compared to difficult questions. Specifically, 9 of 10 (90%) of the responses to basic and 8 of 13 (62%) of the responses to difficult questions were complete. In addition, 8 of 10 or (80%) and 9 of 13 (69%) of readability scores for basic and difficult questions, respectively, were below an 8th to 9th grade level. Difficult questions often contained longer and more complex responses, which likely affected readability. Furthermore, 4 of the 6 incomplete responses only lacked 1 key point which did not significantly dilute these responses. For example, 3 responses on PSA levels at 4, 10, and 20 did not effectively highlight differences in cancer likelihood (eg, over 50% chance), but each response indicated a greater chance of prostate cancer. Therefore, men would be informed that a PSA over 4 is concerning and warrants counsel from a provider. Key points missed in responses about when to start treatment for any man and about shared decision-making for African-American men are more concerning as the omitted information (eg, biopsy as a diagnosis tool) is focal to a PrCA screening decision. Not possessing this knowledge could lead to a PrCA screening decision that is not ideally informed and may not truly be shared between the patient and their healthcare provider. Specifically, knowing that the biopsy, not the PSA, is the only definitive means to diagnose PrCA may somewhat lessen the fear of an increased PSA score because another diagnostic step exists. Being informed about the biopsy could also prompt shared discussion about the relevance of a biopsy for the patient's circumstance. In addition, providing African-American men with all the information necessary to share a PrCA screening decision based on their demographic profile could be exceptionally useful for those men who may lack access to a question list, and not have time to ask multiple questions to an AI chatbot, or simply want a more tailored answer to their given circumstance. This tailored information can also facilitate a shared PrCA screening decision that is more patient-centered.

Limitations

The 23 questions we used may not reflect the full breadth of inquiries someone may have about PrCA screening. PCI was programmed to seek information from a finite set of websites from key medical authorities, but several equally credible websites were not included (eg, Mayo Clinic), which may have slightly improved PCI's performance. While much of the general information about PrCA on these additional websites (eg, signs, symptoms, and prostate anatomy) would likely be similar, there may be cutting-edge research on new PrCA screenings that may not yet be publicized on ACS or similar websites but could provide additional context for more difficult questions like those related to newer tests for PrCA. Finally, although rigorous research methods, such as interrater reliability, were used to mitigate any study bias, we acknowledge that as the developers of PCI, we may be susceptible to unconscious biases that could have affected our ratings. For transparency, we have included all PCI responses in Multimedia Appendix 1. Future studies to evaluate PCI and similar chatbots should include external raters and user feedback.

Comparison With Previous Work

Similar to our previous research [23] and research by others [15-19,21,22], generative AI chatbots like PCI can be highly accurate when responding to PrCA and PrCA screening inquiries. The completeness and readability of Prostate Info's responses to PrCA screening questions varied. PCI generally performed better than Lombardo et al [20] and comparable with Geantă et al [20-22], both of whom investigated chatbot performance on non-US PrCA guidelines. As compared with studies using US PrCA guidelines, PCI performed better than ChatGPT-3.5 (OpenAI), ChatGPT-4 (OpenAI), Microsoft Co-Pilot, Google Gemini, and Google Gemini Advanced, but equal to Microsoft Copilot on completeness of responses to basic PrCA screening queries posed in our previous comparative study, which solicited both standard and plain-language (ie low

literacy) responses [23]. However, the average readability on basic questions was lower than all, but one (ie, Microsoft Co-Pilot) generative AI chatbot when considering plain language responses only [23]. Otherwise, PCI outperformed all, but one (ie, Google Gemini Advanced) chatbot when we asked it to provide a standard response [23]. Compared to Zhu et al [15], who evaluated multiple generative AI chatbots' performance on a similar combination of basic and difficult questions to our study, PCI did not perform nearly as well as ChatGPT and ChatGPT Plus (earlier versions of ChatGPT) on completeness. PCI outperformed all other chatbots evaluated by Zhu et al [15] including Perplexity (by Perplexity AI), YouChat (by You.com), Chatsonic (by Writesonic), and NeevaAI (by Neeva). However, PCI's average readability may have been (but not definitively) lower than all generative AI chatbots evaluated in Zhu and colleagues' [15] study. It is important to note that Zhu et al [15] used a slightly different method for calculating completeness and readability than this study or the study by Owens and Leonard [23]. Zhu et al [15] determined the percentage of comprehensiveness using a Likert approach as opposed to indicating whether a response was simply complete or not complete. Numbers listed in Table 3 for Zhu et al [15] represent the percentage of questions that were "very comprehensive" (ie, fully complete). Readability was rated by reviewers as opposed to using a validated readability measure. Percentages reported in Table 3 for Zhu et al [15], represent that percentage of total responses that were "very easy to read." SDs for Zhu et al [15] were not reported.

Table . Comparison of completeness and readability of chatbot responses on US prostate cancer screening guidelines.

Study	Chatbot name	Completeness, n/N (%)	Average readability score	
			mean (SD)	%, mean (SD)
This study	PCI[a]	17/23 (74)	64.5 (8.7)	—[b]
Zhu et al [15]	ChatGPT	21/22 (95)[c]	—	100 (NR[d])
Zhu et al [15]	ChatGPT Plus	20.3/22 (92)[c]	—	100 (NR)
Zhu et al [15]	ChatSonic	14.3/22 (65)	—	95 (NR)
Zhu et al [15]	YouChat	10.34/22 (47)	—	98 (NR)
Zhu et al [15]	Neeva AI	8.8/22 (40)	—	84 (NR)
Zhu et al [15]	Perplexity Detailed	6.6/22 (30)	—	95 (NR)
Zhu et al [15]	Perplexity Concise	6.6/22 (30)	—	95 (NR)
Owens et al [23]	ChatGPT 3.5 standard response	6/11 (54)	38.0 (7.6)	—
Owens et al [23]	ChatGPT 3.5 low literacy response	4/11 (34)	70.3 (7.2)[e]	—
Owens et al [23]	ChatGPT 4.0 standard response	7/11 (63)	43.1 (9.2)	—
Owens et al [23]	ChatGPT 4.0 low literacy response	7/11 (63)	74.1 (9.9)[e]	—
Owens et al [23]	Google Gemini standard response	6/11 (54)	55.7 (10.4)	—
Owens et al [23]	Google Gemini low literacy response	5/11 (45)	81.0 (3.6)[e]	—
Owens et al [23]	Google Gemini Advanced standard response	6/11 (54)	66.3 (9.4)[e]	—
Owens et al [23]	Google Gemini Advanced low literacy response	6/11 (54)	79.4 (5.1)[e]	—
Owens et al [23]	Microsoft Copilot standard response	8/11 (72)	50.8 (9.3)	—
Owens et al [23]	Microsoft Copilot low literacy response	6/11 (54)	65.1 (6.6)[e]	—
Owens et al [23]	Microsoft Copilot Pro standard response	7/11 (63)	61.2 (9.5)	—
Owens et al [23]	Microsoft Copilot Pro low literacy response	6/1 (54)	78.8 (4.7)[e]	—

[a]PCI: Prostate Cancer Info.

[b]Not applicable.

[c]Chatbot had a higher completeness score than PCI.

[d]NR: not reported.

[e]Chatbot had definitively higher readability scores than PCI based on the Flesch-Kincaid readability. Other scores may also be higher but were not based on a validated measure.

We expected PCI to outperform most other commercially available generative AI chatbots on completeness because of its development using the latest ChatGPT-4.0 technology and its directive to secure information from specific websites, but PCI underperformed earlier versions of ChatGPT. Therefore, additional training of the large language model that undergirds ChatGPT-4.0 will be needed for this niche area. In addition, unexpected was the lower average readability of responses from PCI, especially compared to our previous work, which solicited plain-language responses from multiple chatbots including ChatGPT-3.5 and ChatGPT-4. Nonetheless, the average readability of PCI is suitable for an audience with a middle school education.

Conclusions and Future Directions

Generative AI chatbots, such as PCI, are great starting places for learning about PrCA screening and preparing for shared decision-making but should not yet be used as sole sources of PrCA information because of their periodic omission of key information. Nevertheless, with further testing and validation,

model training, and refinement of the source selection process, we hope PCI can be a publicly available resource for credible, evidence-based, and culturally appropriate information for PrCA screening decisions. In the future, PCI could be integrated into the decision-making workflow by prompting patients to use PCI before their medical visit via an emailed link or a 1-page hard copy with a QR code. This same email or document could contain multiple frequently asked questions about PrCA. Men should be encouraged to pose as many of these questions as possible, but especially those on our list that are more complex (eg, Is the PSA or DRE more effective for finding prostate cancer?) PCI questions and responses could then be saved on their mobile device or printed, notated to indicate areas of concern or need for clarity, and then taken to their appointment to be used to guide the shared PrCA screening discussion. During this discussion, the health care provider should ensure that men understand their personal PrCA risk; screening options; and risks, benefits, and uncertainties of PrCA screening. The discussion should then shift to focus on men's questions and their screening preferences. Using this method of generative AI integration into the shared decision process could fortify men's PrCA knowledge and identify patient values and preferences.

To improve the overall performance of PCI in the future, it will be necessary to iteratively fine-tune our model which will include expanding the sources from which PCI retrieves data, which could include the most current peer-reviewed journal articles in addition to websites of major research hospitals and international health organizations. All sources will be curated by a PrCA expert who will review each data source to ensure it contains quality information. Equally important will be soliciting routine feedback from health care providers and patients through an embedded satisfaction survey that can enable them to comment on the quality of questions developed by the research team, potential questions that should be added to the database, and the quality of the responses generated by the PCI. Additional model training will come from tracking common follow-up questions from users to incorporate them into the initial responses. Based on these continuous feedback loops, PCI's performance could be improved significantly and always remain up-to-date. Future research should focus on the clinical deployment of PCI and testing to assess its acceptability, ease of use in a clinical workflow, and usefulness in the shared PrCA screening decision process.

(JMIR Cancer 2025;11:e71958) doi:10.2196/71958

In "Benefits of Remote-Based Mindfulness on Physical Symptom Outcomes in Cancer Survivors: Systematic Review and Meta-Analysis" (JMIR Cancer 2025;11:e54154) an error was noted.

Reference 46 was previously a duplicate of reference 26, as follows:

Nissen ER, O'Connor M, Kaldo V, et al. Internet-delivered mindfulness-based cognitive therapy for anxiety and depression in cancer survivors: A randomized controlled trial. Psychooncol. Jan 2020;29(1):68-75.

All in-text citations to reference 46 have been changed to 26, the repeated reference information removed, and all subsequent references renumbered accordingly.

The correction will appear in the online version of the paper on the JMIR Publications website on February 13, 2025, together with the publication of this correction notice. Because this was made after submission to PubMed.

Submitted 30.01.25; this is a non–peer-reviewed article;accepted 31.01.25; published 13.02.25.
