Abstract

Background: The relationship between assisted reproductive technology (ART) and childhood cancer risk has been widely debated. Previous meta-analyses did not adequately account for the impact of infertility, and this study addresses this gap.

Objective: Our primary objective was to assess the relative risk (RR) of childhood cancer in infertile populations using ART versus non-ART offspring, with a secondary focus on comparing frozen embryo transfer (FET) and fresh embryo transfer (fresh-ET).

Methods: A literature review was conducted through PubMed, Embase, Cochrane, and Web of Science, with a cutoff date of July 10, 2024. The study was registered with the International Platform of Registered Systematic Review and Meta-Analysis Protocols (INPLASY 202470119). Inclusion criteria were based on the PICOS (Population, Intervention, Comparison, Outcomes, and Study Design) framework: infertile or subfertile couples (population), ART interventions (in vitro fertilization [IVF], intracytoplasmic sperm injection [ICSI], FET, and fresh-ET), non-ART comparison, and childhood cancer risk outcomes. Data abstraction focused on the primary exposures (ART vs non-ART and FET vs fresh-ET) and outcomes (childhood cancer risk). The risk of bias was assessed using the Newcastle-Ottawa Quality Assessment Scale, and the evidence quality was evaluated with the Grading of Recommendations Assessment, Development, and Evaluation (GRADE). Pooled estimates and 95% CIs were calculated using random effects models.

Results: A total of 18 studies were included, published between 2000 and 2024, consisting of 14 (78%) cohort studies and 4 (22%) case-control studies, all of which were of moderate to high quality. The cohort studies had follow-up periods ranging from 3 to 18 years. Compared with non-ART conception, ART conception was not significantly associated with an increased risk of childhood overall cancer (RR 0.95, 95% CI 0.71 - 1.27; GRADE quality: low to moderate). Subgroup analyses of IVF (RR 0.86, 95% CI 0.59 - 1.25), ICSI (RR 0.76, 95% CI 0.26 - 2.2), FET (RR 0.98, 95% CI 0.54 - 1.76), and fresh-ET (RR 0.75, 95% CI 0.49 - 1.15) showed similar findings. No significant differences were found for specific childhood cancers, including leukemia (RR 0.99, 95% CI 0.79 - 1.24), lymphoma (RR 1.22, 95% CI 0.64 - 2.34), brain cancer (RR 1.22, 95% CI 0.73 - 2.05), embryonal tumors (RR 1, 95% CI 0.63 - 1.58), retinoblastoma (RR 1.3, 95% CI 0.73 - 2.31), and neuroblastoma (RR 1.02, 95% CI 0.48 - 2.16). Additionally, no significant difference was observed in a head-to-head comparison of FET versus fresh-ET (RR 0.99, 95% CI 0.86 - 1.14; GRADE quality: moderate).

Conclusions: In conclusion, this study found no significant difference in the risk of childhood cancer between offspring conceived through ART and those conceived through non-ART treatments (such as fertility drugs or intrauterine insemination) in infertile populations. While infertility treatments may elevate baseline risks, our findings suggest that whether individuals with infertility conceive using ART or non-ART methods, their offspring do not face a significantly higher risk of childhood cancer. Further research, especially comparing infertile populations who conceive naturally, is needed to better understand potential long-term health outcomes.

KEYWORDS

assisted reproductive technology; childhood cancer; infertility; subfertile; risks; systematic review

Introduction

Over the last century, global fertility rates have significantly declined, and it is projected that by 2060, fertility will fall below replacement levels [1,2]. This trend is closely linked to an increase in infertility, which can be caused by factors such as ovulation disorders, tubal abnormalities, uterine issues, and sperm abnormalities [3]. Assisted reproductive technology (ART) has helped many infertile couples achieve parenthood. Since ART's introduction in 1978, over 10 million children have been born using this technology [4], with approximately 1 million children conceived via ART each year. As ART usage increases, monitoring the long-term health risks associated with it, particularly childhood cancer, becomes crucial [5].

The relationship between ART and childhood cancer has been widely studied, but the results remain controversial due to inconsistent findings [6,7]. One of the key reasons for this inconsistency is the use of different reference groups. Few studies distinguish between children born to parents with infertility and those born to parents who conceived naturally [5,8]. It is essential to differentiate the effects of parental infertility from those of ART treatment, particularly given the challenge of small sample sizes in many studies. Furthermore, most studies are conducted within a single health care system or region, which limits their ability to fully assess cancer risk in offspring conceived through ART.

Previous reviews and meta-analyses have not adequately addressed infertility as a factor, possibly due to the limited availability of relevant studies [9-14]. However, recent large national cohort studies have compared offspring of parents with infertility with controls, and follow-up periods have extended beyond 10 years [15-22]. Given these advances, we conducted a systematic review and meta-analysis to assess the relative risk (RR) of childhood cancer in ART versus non-ART offspring in infertile populations and to compare frozen embryo transfer (FET) with fresh embryo transfer (fresh-ET). This study provides new insights into the relationship between ART modalities and pediatric cancer risk, which could help guide clinical ART fertility treatments.

Methods

Overview

This study was retrospectively registered with the International Platform of Registered Systematic Review and Meta-Analysis Protocols (INPLASY 202470119). The systematic review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines and included all published articles on ART exposure and childhood cancer risk in the offspring of parents with infertility [23].

Search Strategy and Inclusion Criteria

We conducted a systematic literature search with a deadline of July 10, 2024, using PubMed, Embase, Cochrane, and Web of Science. The electronic search strategy was initially developed by the author (GS) and subsequently reviewed by the author with extensive search experience (MQC). We first tested the search by adapting it for each database and validating it against previously published meta-analyses on relevant topics to ensure the comprehensiveness of our approach. The validated search strategy was implemented simultaneously across each database on July 10, 2024, using the search terms "ART," "children," "cancer," and "risk." The detailed Boolean expressions of the search strategy are presented in Multimedia Appendix 1.

The inclusion criteria were constructed using the PICOS (Population, Intervention, Comparison, Outcomes, and Study Design) framework:

- Population: infertile or subfertile couples.
- Intervention: ART, including in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), FET, and fresh-ET.
- Comparison: non-ART, defined as infertile or subfertile couples who did not conceive through ART but may have conceived naturally or with induced ovulation induction (OI) or intrauterine insemination (IUI).
- Outcomes: risk of childhood cancer, including overall childhood cancers and specific types such as leukemia, lymphomas, brain cancer, embryonal tumors, retinoblastoma, and neuroblastoma.
- Study design: randomized controlled trials and observational studies (eg, cohort or case-control studies).

Studies lacking sufficient data to calculate RR estimates and their 95% CIs were excluded. Additionally, conference abstracts, reviews, non-English articles, duplicate data, and non–peer-reviewed publications were excluded.

Study Selection

On July 10, 2024, 2 researchers (CQZ and RL) conducted literature searches, reviewed the results, and imported them into Endnote X8 (Clarivate Analytics). CQZ was responsible for deduplication and the initial screening of studies, while RL reviewed CQZ's selections. Both researchers then independently performed further screening based on the predefined inclusion criteria. Any disagreements were resolved through discussion between CQZ and RL. If a consensus could not be reached, a third researcher, GS, was consulted.

Data Extraction

Data extraction was carried out by CQZ using a prespecified and tested form in Microsoft Excel. RL then reviewed the extracted data for accuracy. The information extracted included the first author, year of publication, age at follow-up, study design, study timeframe, country, data source, duration of follow-up, type of cancer reported, ART type (IVF, ICSI, FET, or fresh-ET), and case-control or exposure-nonexposure data. If any data were missing, the authors were contacted to obtain the necessary information.

Quality Assessment and Risk of Bias

The Newcastle-Ottawa Quality Assessment Scale (NOS) was used for the quality assessment of the included studies [24]. Two authors (CQZ and RL) independently conducted the NOS evaluation, and any disagreements were resolved through discussions with the corresponding author or GS. Studies were categorized into low (total score ≥7), moderate (total score 5 - 6), and high (total score ≤4) risk of bias.

Publication bias for the primary outcomes, such as ART versus non-ART and FET versus fresh-ET, was assessed using funnel plots and the Egger test. If the points on the funnel plot were symmetrically distributed, it indicated no or low bias; asymmetry suggested the presence of publication bias. The Egger test was performed to quantitatively assess publication bias, with a $P<.05$ indicating significant bias. Sensitivity analyses were conducted for the primary outcomes.

Data Analysis and Synthesis

The RR and 95% CIs were chosen to assess the association between ART and childhood cancer in infertile offspring. Outcomes were combined using the DerSimonian and Laird random effects model [25]. All analyses were visualized using Stata 17 statistical software, and in meta-analyses, $P<.05$. Heterogeneity was analyzed using the I^2 statistic. A high degree of heterogeneity was indicated if the I^2 value was greater than 50%. Subgroup analyses were conducted based on the following four criteria: (1) continents, (2) duration of follow-up, (3) reported cancer type, and (4) operational versus nonoperational. Subgroup differences were assessed using the Q test, and statistical significance was defined as a $P<.05$. Regardless of the level of heterogeneity, a random-effects model was consistently applied to ensure the robustness of the analysis across different study designs and populations. Sensitivity analyses were performed by excluding each study individually.

Quality of Evidence

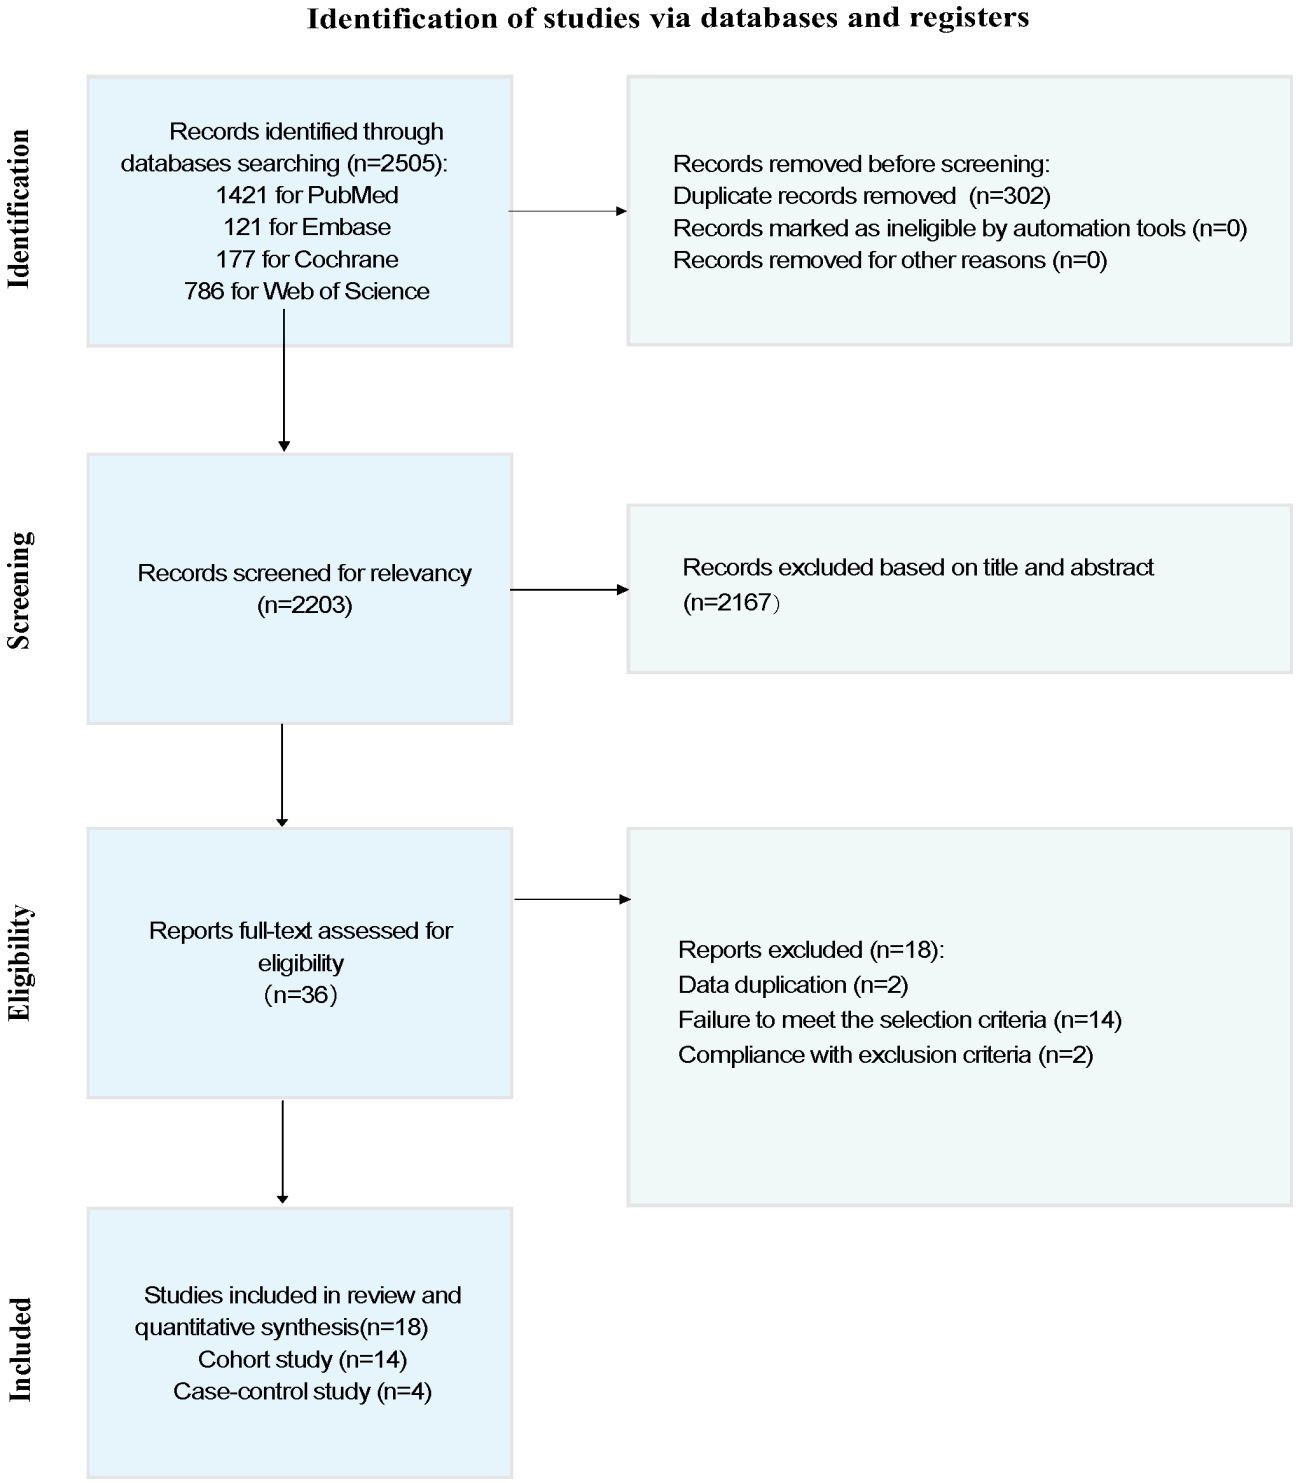
GRADE (Grading of Recommendations Assessment, Development, and Evaluation) is a systematic approach for evaluating the quality of evidence by assessing 5 domains: methodological limitations (eg, risk of bias), heterogeneity of results (eg, inconsistency), generalizability of findings (eg, indirectness), precision of estimates, and risk of publication bias [26]. The overall certainty of the evidence is categorized into 4 levels, ranging from high to very low.

Results

Search Results and Study Characteristics

A total of 2505 articles were obtained from the systematic search, of which 302 (12.06%) were duplicates. We screened the titles and abstracts to exclude 2167 (86.51%) articles that did not meet the eligibility criteria and subsequently removed them. The full manuscripts of the 36 articles were screened to exclude 18 (50%) articles that did not meet the eligibility criteria. These included different papers by the same authors with duplicate data. Data that did not involve subfertile offspring were excluded. A total of 18 studies [15-22,27-36] were thus included in this review. The NOS quality of the included studies was either moderate or high (Table S1 in Multimedia Appendix 2) [15-22,27-36]. The PRISMA flowchart depicts the article screening process (Figure 1).

Figure 1. Flowchart illustrating the article selection process.



Of the 18 included studies, 14 (77%) were cohort studies [15-22,27-32] and 4 (22%) were case-control studies [33-36]. All cohort studies reported overall cancer occurrence risk, while the 4 case-control studies focused only on specific types of cancer, including retinoblastoma, leukemia, and neuroblastoma. All studies were published in English and covered multiple countries and regions, including Australia, Israel, Denmark, the United States, France, Finland, Sweden, the Netherlands, Taiwan, the United Kingdom, and Norway. The studies were published across nearly 2 decades, with the earliest study published in 2000 [27] and the most recent study published in 2024 [16]. Most cohort studies had follow-up durations ranging from 3 to 18 years, with the shortest follow-up period being 3 years [30] and the longest extending to 18 years [17].

Of the 18 studies, 10 (56%) [15-20,33-36] compared ART with non-ART and 11 (61%) [16,17,20-22,27-32] compared FET with fresh-ET. Of the 10 studies comparing ART with non-ART, 6 (60%) were cohort studies [15-20] involving 480,852 ART patients and 716,144 non-ART patients. Four (4/10, 40%) [33-36] were case-control studies involving 563 ART patients and 1521 non-ART patients. Of the 18 studies, 11 (61%)

comparative studies of FET versus fresh-ET were cohort studies involving 176,800 FET patients and 723,327 fresh-ET patients.

Comparison of Childhood Overall Cancer Risk by ART Conception and Non-ART Conception

Of the 18 studies, 6 (33%) studies have compared the risk of childhood overall cancer in offspring of ART versus non-ART conceptions (Table S2 in Multimedia Appendix 2) [15-20]. The results showed that there was no significant increase in the risk of childhood overall cancer in ART-conceived offspring compared with non-ART conception (RR 0.95, 95% CI 0.71 - 1.27; I^2=82%) (Figure 2). A high degree of heterogeneity was observed. We performed subgroup analyses based on continent, follow-up duration, reported cancer types, and whether artificial insemination procedures were involved. No significant differences were observed within the subgroups (Table 1). However, when the non-ART control group was defined as nonoperational (ie, using only OI or fertility drugs), the RR for childhood overall cancer in the ART group was 1.23 (95% CI 0.98 - 1.54). Based on the GRADE evidence quality assessment, the quality of the comparison between ART and non-ART was rated as "low to moderate" due to serious risk of bias and inconsistency (Table S3 in Multimedia Appendix 2). The Egger test did not detect significant publication bias (*P*=.66), and the adjusted RR was 0.812 (95% CI 0.549 - 1.074), indicating robust results (Figure S1 in Multimedia Appendix 3).

[a]ART: assisted reproductive technology.

[b]RR: relative risk.

[c]Not applicable.

[d]We set non-ARTs that only use fertility drugs or ovulation induction as a nonoperational factor, and those that involve artificial insemination or intrauterine insemination operations as an operational factor.

In addition, we compared IVF, ICSI, FET, and fresh-ET conceptions with non-ART conceptions separately. The results showed no significant differences between either (P≥.05). The corresponding RRs were for IVF (RR 0.86, 95% CI 0.59 - 1.25; I^2=70.18%), ICSI (RR 0.76, 95% CI 0.26 - 2.2; I^2=94.61%), FET (RR 0.98, 95% CI 0.54 - 1.76; I^2=83.18%), and fresh-ET (RR 0.75, 95% CI 0.49 - 1.15; I^2=81.85%) (Figures S1-S4 in Multimedia Appendix 4) [15-18,20].

Comparison of Childhood Overall Cancer Risk by FET Conception and Fresh-ET Conception

Of the 18 studies, 11 (61%) cohort studies compared the risk of childhood overall cancer in FET versus fresh-ET conceived offspring (Table S4 in Multimedia Appendix 2) [16,17,20-22,27-32]. The results showed no significant increase in the risk of childhood overall cancer for FET-conceived offspring compared to fresh-ET (RR 0.99, 95% CI 0.86 - 1.14; Figure 3). The interstudy heterogeneity was low (I^2=24.45%). Subgroup analyses by continent, follow-up duration, and cancer type revealed no significant differences (Table 2). Funnel plots and the Egger test indicated no publication bias (t=0.53, P=.61; adjusted RR 0.98, 95% CI 0.856 - 1.125; Figure S2 in Multimedia Appendix 3). Based on the GRADE assessment, the quality of the comparison between FET and fresh-ET was rated as “moderate” due to a serious risk of bias (Table S3 in Multimedia Appendix 2).

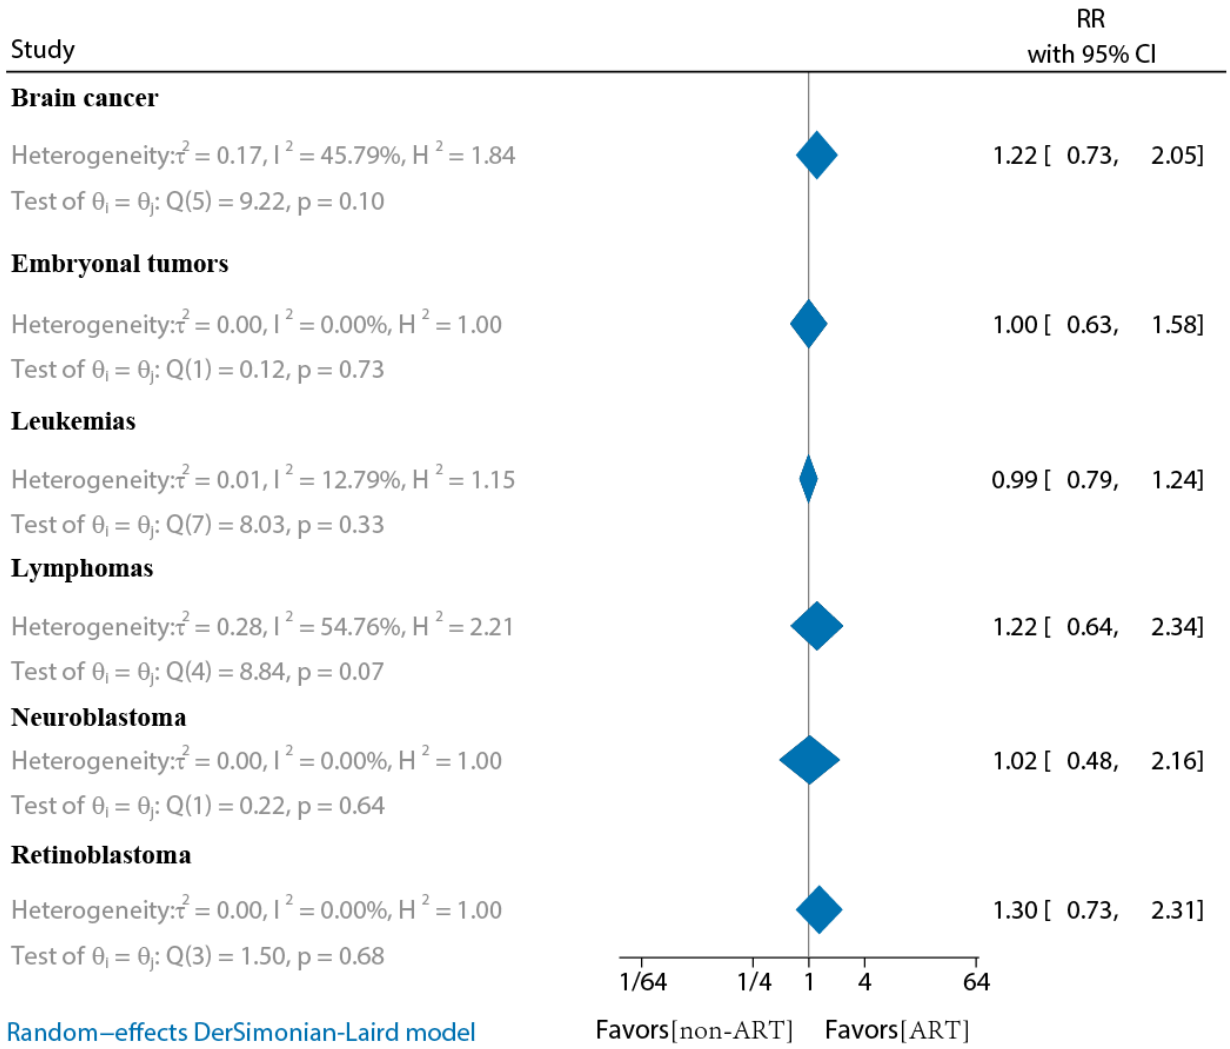
Comparison of Childhood-Specific Cancer Risk by ART Conception and Non-ART Conception

In total, 10 studies compared the risk of childhood-specific cancer in the offspring of ART versus non-ART conceptions (Tables S5 and S6 in Multimedia Appendix 2) [15-20,33-36]. The main studies included 6 cohort studies and 4 case-control studies. The results showed that none of the ART-conceived offspring had a significantly increased risk of childhood-specific cancer compared to non-ART conception (P≥.05). The main ones included leukemia (RR 0.99, 95% CI 0.79 - 1.24;

I^2=12.79%), lymphoma (RR 1.22, 95% CI 0.64 - 2.34; I^2=54.76%), brain cancer (RR 1.22, 95% CI 0.73 - 2.05; I^2=45.79%), embryonal tumors (RR 1, 95% CI 0.63 - 1.58; I^2=0%), retinoblastoma (RR 1.3, 95% CI 0.73 - 2.31; I^2=0%), and neuroblastoma (RR 1.02, 95% CI 0.48 - 2.16; I^2=0%) (Figure 4).

Figure 4. Comparison of childhood-specific cancer risk by ART conception and non-ART conception. ART: assisted reproductive technology; RR: relative risk.



Sensitivity Analysis

To explore the stability of the meta-analysis results, sensitivity analyses were performed by excluding each study individually. The results demonstrated the robustness of findings for both ART versus non-ART conception and FET versus fresh-ET conception regarding childhood cancer risk. The results remained consistent even after excluding the study by Spaan et al [17] (RR 1.1, 95% CI 0.95 - 1.26; Figure S3 in Multimedia Appendix 3) [15-22,27-32].

Discussion

Principal Findings

This study, to our knowledge, is the first systematic review and meta-analysis to use infertile or subfertile populations as the reference group. We found no significant increase in childhood overall cancer risk in ART-conceived offspring compared to non-ART. This result was consistent across different ART methods, including IVF, ICSI, FET, and fresh-ET. Furthermore, no significant differences were observed between FET and fresh-ET in terms of childhood cancer risk. Despite the heterogeneity of the studies included, the results were robust across sensitivity analyses, supporting the stability and reliability of our findings.

Comparison to Prior Work

To date, 6 meta-analyses have examined the association between ART fertility treatments and childhood cancer risk. The meta-analyses by Wang et al [12], Chiavarini et al [14], and Hargreave et al [10] found a significant correlation between ART and childhood cancer risk, while those by Raimondi et al [9], Gilboa et al [11], and Zhang et al [13] did not support such an association. Recent large-scale cohort studies have yet to reach a consensus on this issue. Some studies report a significant association between ART conception and increased childhood cancer risk [19,21,30,37,38]. For instance, a large Nordic study by Sargisian et al [21], which included data from Denmark, Norway, Sweden, and Finland, found a significantly increased risk of childhood cancer in ART-conceived offspring compared

to naturally conceived offspring (RR 1.13, 95% CI 1.01 - 1.26). However, other studies have not observed this association [16,17,20]. The inconsistencies in these findings may be due to differences in control group selection, sample size, and follow-up duration [5,6,8,39].

Recent evidence suggests that epigenetic changes may play a key role in causing infertility, rather than being simply a result of fertility treatments [40,41]. Couples experiencing infertility may already have a higher risk of epigenetic defects in their gametes, which fertility treatments have only helped to reveal [42]. The present meta-analysis provided new insights, and we selected an appropriate control group to eliminate the effects of infertile or subfertile. We included 6 large cohort studies involving 480,852 ART conceptions and 716,144 non-ART conceptions. In our analysis of the non-ART control group, we performed subgroup analysis by categorizing it into operational (IUI or artificial insemination) and nonoperational (OI or fertility drugs) groups. When the non-ART control group was defined as nonoperational, the RR for childhood overall cancer in the ART group increased to 1.23 (95% CI 0.98 - 1.54), approaching the statistical significance threshold. The review by Berntsen et al [5] suggested that a scientific control group should consist of children of low-fertility parents who conceived naturally. However, obtaining such controls is challenging because they are rarely included in registry data. Additionally, it was noted that children born through fertility measures, such as ovarian stimulation or IUI, could also serve as suitable controls. Due to limitations in current published studies, we focused on studies with the latter control group approach. Future research should aim to include offspring born to low-fertility parents who conceived naturally to better understand the long-term effects of both infertility and fertility treatments.

ICSI has become increasingly common worldwide, with approximately one-third of fresh ART cycles using conventional IVF and two-thirds using ICSI [43,44]. Despite the invasive nature of ICSI and ongoing concerns about the health of children born through this method, our meta-analysis, which included 2 eligible studies, showed that the risk of childhood overall cancer in ICSI-conceived offspring was not significantly higher compared to non-ART offspring (RR 0.76, 95% CI 0.26 - 2.2; I^2=94.61%). However, there was considerable heterogeneity between the studies, and further research is needed to confirm the long-term safety of ICSI regarding childhood cancer risk.

FET accounts for 32.6% of all ART treatment cycles in Europe, showing a clear increasing trend [45]. Large cohort studies and meta-analyses have provided short-term health data on FET, such as perinatal outcomes [46-50]. Compared to singletons born after fresh-ET, infants born after FET generally have higher birth weights and a higher risk of LGA (large for gestational age) in suprapregnant children but lower perinatal mortality. Singletons born after FET are at an increased risk of LGA and preterm labor compared to naturally conceived offspring [50]. However, data on the long-term health of FET offspring are limited. Studies comparing FET with naturally conceived offspring suggest an increased cancer risk in FET-conceived children [20,21].

In our meta-analysis, which included 4 large cohort studies with infertile populations as the comparison group, we found no significant increase in childhood overall cancer risk in FET-conceived offspring compared to non-ART offspring (RR 0.98, 95% CI 0.54 - 1.76; I^2=83.18%). Given the high heterogeneity, these results should be interpreted with caution. Additionally, to our knowledge, no meta-analyses have compared childhood cancer risk between FET and fresh-ET conceived offspring. Our analysis, which included 11 cohort studies with 176,800 FET-conceived and 723,327 fresh-ET-conceived individuals, found no significant difference in cancer risk between the 2 groups (RR 0.99, 95% CI 0.86 - 1.14), with low heterogeneity (I^2=24.45%). No significant bias was found, and sensitivity analyses confirmed the stability of the results.

Several studies have explored the association between ART conception and specific childhood cancers, including leukemia [16,51], lymphoma [52], hepatoblastoma [31,53], retinoblastoma [54], and central nervous system tumors [15]. A 2013 meta-analysis by Hargreave et al [10] reported an increased risk of cancers such as leukemia (RR 1.65), neuroblastoma (RR 4.04), and retinoblastoma (RR 1.62). A 2019 meta-analysis by Chiavarini et al [14] found that ART significantly increased the risk of hematological neoplasms (odds ratio [OR] 1.3, 95% CI 1.08 - 1.58) and neurological cancers (OR 1.21, 95% CI 1.01 - 1.46). Furthermore, a 2020 study by Zhang et al [13] showed a significantly increased risk of hematologic cancers (RR 1.39), other solid tumors (RR 1.57), and leukemia (RR 1.31). Leukemia is one of the most common childhood cancers and a leading cause of death in children, followed closely by lymphoma and central nervous system tumors [55]. Although several studies have suggested that ART is associated with an increased risk of childhood leukemia, most compared ART offspring with those conceived naturally [16,19,20,30,56]. In contrast, our analysis included 8 studies on leukemia, 3 of which had follow-up durations of more than 10 years, and 2 were case-control studies. The results showed no significant increase in leukemia risk in ART offspring compared to non-ART offspring (RR 0.99, 95% CI 0.79 - 1.24; I^2=12.79%). When cohort studies were analyzed separately, the results remained unchanged (RR 1.1, 95% CI 0.87 - 1.4; I^2=4.05%). Additionally, no significant differences were found in further analyses of other specific childhood cancers, including lymphoma (RR 1.22, 95% CI 0.64 - 2.34), brain cancer (RR 1.22, 95% CI 0.73 - 2.05), embryonal tumors (RR 1, 95% CI 0.63 - 1.58), retinoblastoma (RR 1.3, 95% CI 0.73 - 2.31), and neuroblastoma (RR 1.02, 95% CI 0.48 - 2.16).

Strengths and Limitations

Strengths

One strength of this study is the use of a more appropriate control group, that is, infertile or subfertile populations, which enhances the reliability of the comparisons and helps address the risk of epigenetic defects associated with infertility. Additionally, our estimates were not significantly affected by recall bias, which is common in case-control studies [57]. Parents of children with cancer may be more likely to recall

past events, potentially overestimating cancer risk. We combined 4 eligible case-control studies, mainly focusing on specific cancer types, and performed subgroup analyses, showing no significant differences across subgroups. Furthermore, large cohort studies with long-term and comprehensive data were recently included, reducing the risks of selection, attrition, and recall bias, while providing more opportunities to observe rare cancer exposures, thus enhancing the credibility of the findings.

Limitations

First, the sample size of infertile or subfertile populations was small. Despite a comprehensive search, the limited number of studies, especially on ICSI and FET offspring, may reduce confidence in the findings. Larger sample sizes are needed in future research for greater statistical power. Second, this meta-analysis did not classify the non-ART control group further. The lack of distinction between naturally conceived offspring from low-fertility parents and those conceived through ovarian stimulation or IUI may introduce confounding, affecting the cancer risk baseline. Future studies should differentiate these groups to better assess ART's impact on childhood cancer risk. Third, while some studies reported male infertility, gender-specific analyses were not performed, preventing separate calculations for male and female infertility. Future studies should address this to explore gender-specific effects on offspring health after ART. Fourth, the included studies used raw data without adjusting for factors like age, gender, birth order, socioeconomic status, and history of abortion. This lack of adjustment may affect result interpretation. Future studies should include adjusted data for more accurate conclusions.

Conclusions

This study found no significant difference in the risk of childhood cancer between offspring conceived through ART and those conceived through non-ART treatments (such as fertility drugs or OI/IUI) in infertile populations. While infertility treatments may elevate baseline risks, our findings suggest that whether individuals with infertility conceive using ART or non-ART methods, their offspring do not face a significantly higher risk of childhood cancer. Further research, especially comparing infertile populations who conceive naturally, is needed to better understand potential long-term health outcomes.

Abstract

Background: Natural language processing systems for data extraction from unstructured clinical text require expert-driven input for labeled annotations and model training. The natural language processing competency of large language models (LLM) can enable automated data extraction of important patient characteristics from electronic health records, which is useful for accelerating cancer clinical research and informing oncology care.

Objective: This scoping review aims to map the current landscape, including definitions, frameworks, and future directions of LLMs applied to data extraction from clinical text in oncology.

Methods: We queried Ovid MEDLINE for primary, peer-reviewed research studies published since 2000 on June 2, 2024, using oncology- and LLM-related keywords. This scoping review included studies that evaluated the performance of an LLM applied to data extraction from clinical text in oncology contexts. Study attributes and main outcomes were extracted to outline key trends of research in LLM-based data extraction.

Results: The literature search yielded 24 studies for inclusion. The majority of studies assessed original and fine-tuned variants of the BERT LLM (n=18, 75%) followed by the Chat-GPT conversational LLM (n=6, 25%). LLMs for data extraction were commonly applied in pan-cancer clinical settings (n=11, 46%), followed by breast (n=4, 17%), and lung (n=4, 17%) cancer contexts, and were evaluated using multi-institution datasets (n=18, 75%). Comparing the studies published in 2022 - 2024 versus 2019 - 2021, both the total number of studies (18 vs 6) and the proportion of studies using prompt engineering increased (5/18, 28% vs 0/6, 0%), while the proportion using fine-tuning decreased (8/18, 44.4% vs 6/6, 100%). Advantages of LLMs included positive data extraction performance and reduced manual workload.

Conclusions: LLMs applied to data extraction in oncology can serve as useful automated tools to reduce the administrative burden of reviewing patient health records and increase time for patient-facing care. Recent advances in prompt-engineering and fine-tuning methods, and multimodal data extraction present promising directions for future research. Further studies are needed to evaluate the performance of LLM-enabled data extraction in clinical domains beyond the training dataset and to assess the scope and integration of LLMs into real-world clinical environments.

Introduction

The advent of electronic health records (EHR) has allowed clinicians to leverage their access to vast amounts of longitudinal, patient-level clinical text data that inform patient diagnoses, prognoses, and management [1]. However, the majority of useful clinical data are stored as unstructured free text that requires manual extraction into meaningful clinical features; therefore, clinicians spend more time on administrative work reviewing EHRs instead of practising patient-facing medicine [1]. To address this task of extracting key attributes from unstructured clinical text, natural language processing (NLP) methods have classically applied rule-based and machine-learning methods to identify important entities in text and categorize them based on categories of interest [2]. For instance, the extraction of cancer staging information from clinical text requires an NLP algorithm to recognize references to cancer staging in clinical texts and categorize these references

according to defined cancer staging nomenclature, such as the TNM classification of malignant tumors system.

Rule-based classification relies on domain expert-designed rules, heuristics, ontologies, and pattern-matching techniques to extract information from text. In contrast, machine learning-based approaches use statistical models trained on large-scale labeled text data to automatically learn patterns and generalize these learned competencies in data extraction to unlabeled testing data. The emergence of deep learning models, a subfield of machine learning that focuses on artificial neural network models with multiple processing layers, has been particularly effective at modeling the hierarchical structure of natural language and demonstrated superior performance across diverse NLP tasks, including but not limited to data extraction [3].

One particularly promising deep learning architecture, known as the transformer model, has gained worldwide attention for its generative language competency and strong performance in question answering, sentence completion, and sentence classification tasks compared to other deep learning models [4]. Deep learning–based transformer models may require less time and fewer resources needed to manually annotate training datasets compared to classical machine learning models and can better address nuanced edge cases in data extraction that may not be explicitly accounted for in rule-based data approaches [5,6]. However, these models are often limited by their need for large-scale computational resources and training data [7,8].

Modern LLMs are commonly built using adaptations of the transformer architecture and trained on large corpora of text to enable human-like natural language competency. Due to their extensive training dataset, LLMs such as BERT and GPT may have zero-shot capabilities, meaning they can perform tasks without prior task-specific training [9]. Emerging research on fine-tuning LLMs with custom datasets and prompt engineering for conversational LLMs has yielded promising performance improvements for specialized NLP tasks compared to baseline LLMs.

Given the longitudinal nature of cancer care, the vast amount of clinical text associated with cancer patient EHRs necessitates the development of automated methods for data extraction from these clinical records into structured data, which is useful for review by oncologists. The broad natural language competency of LLMs encourages the design of specialized LLM applications for data extraction from unstructured clinical text, reducing the oncologists' time and effort spent in manually reviewing patient EHRs to extract key information to inform their clinical decision-making.

The emergence of several recent pilot studies of LLM-enabled data extraction prompts the need for a scoping review to map the current landscape, including definitions, frameworks, and future directions for this novel tool in clinical data extraction. This review seeks to address this gap in the literature by characterizing primary research articles that evaluated an LLM tool applied to data extraction from unstructured clinical text into structured data.

Methods

We queried OVID Medline on June 2, 2024, using oncology ("neoplasms," "cancer," "onco," "tumor") and generative LLM ("natural language processing," "artificial intelligence," "generative," "large language model") keywords in consultation with a librarian. Non-English articles, nonprimary research articles, articles published before 2000, and articles published in nonpeer-reviewed settings were excluded. The full search strategy is detailed in Multimedia Appendix 1. Following the deduplication of articles (n=10) using the Covidence review management tool, the literature search yielded 817 articles for manual screening.

We conducted abstract screening followed by full-text screening of articles in duplicate (KA and SA), including primary research articles that tested a large language model, were applied in oncology contexts, and evaluated the performance of data extraction from text. The articles that evaluated an NLP-based algorithm that did not assess an LLM, were secondary research articles, applied in only nononcology settings, and did not evaluate or report the performance of data extraction from the clinical text were excluded. Screening conflicts were resolved through consensus discussion with a third reviewer (DC).

We extracted key study attributes from the included full-text papers in duplicate (KA and SA), including clinical domain, LLM attributes (eg, model, use of fine-tuning, use of prompt engineering), the dataset used for training and testing, primary study outcomes, model training methodology, and model evaluation processes. The LLMs were coded as baseline if they were applied "out of the box" without additional fine-tuning. LLMs were coded as (1) fine-tuned LLMs: the study described training the baseline LLM on a custom dataset intended to yield improved data extraction performance compared to the baseline LLM alone; (2) zero-shot LLMs: they were applied "out-of-the-box" without additional prompt engineering, (3) prompt engineered LLMs: the study described adaptations to prompting procedures, such as one-shot or few-shot prompting, designed to yield improved data extraction performance compared to the baseline LLM alone. Data extraction conflicts were resolved through consensus discussion with a third reviewer (DC).

The synthesis of extracted data involved grouping studies based on similarities in the evaluated specific model, clinical domain applied, and shared themes of strengths and limitations, based on outcomes reported by the studies. The appraisal process involved the completion of a standardized data extraction form to systematically code in duplicate (KA and SA) which articles commented on which themes of strengths and limitations, and the discrepancies were resolved through discussion (DC and SR). The risk of bias was assessed using ROBINS-I (Version 2) in duplicate (KA and SA), with conflicts resolved through consensus discussion with a third reviewer (DC). Cohen κ score was used to assess inter-rater concordance. This scoping review followed the PRISMA-ScR reporting guideline.

Results

The literature search yielded 817 papers, of which 24 papers met the inclusion criteria (Figure 1). Most included papers exhibited moderate (n=15, 62.5%) risk or low (n=9, 37.5%) risk of bias (Figure 2). The most common domains for moderate risk of bias included bias due to confounding (n=21, 87.5%) and bias in the selection of the reported result (n=21, 87.5%). No papers scored a high risk of bias in any domain. ROBINS-I risk of bias assessment exhibited moderate inter-rater concordance based on an κ score of 0.43.

Figure 1. Search and filtering strategy used to select large language model studies evaluating data extraction performance for inclusion in this review. LLM: large language model.

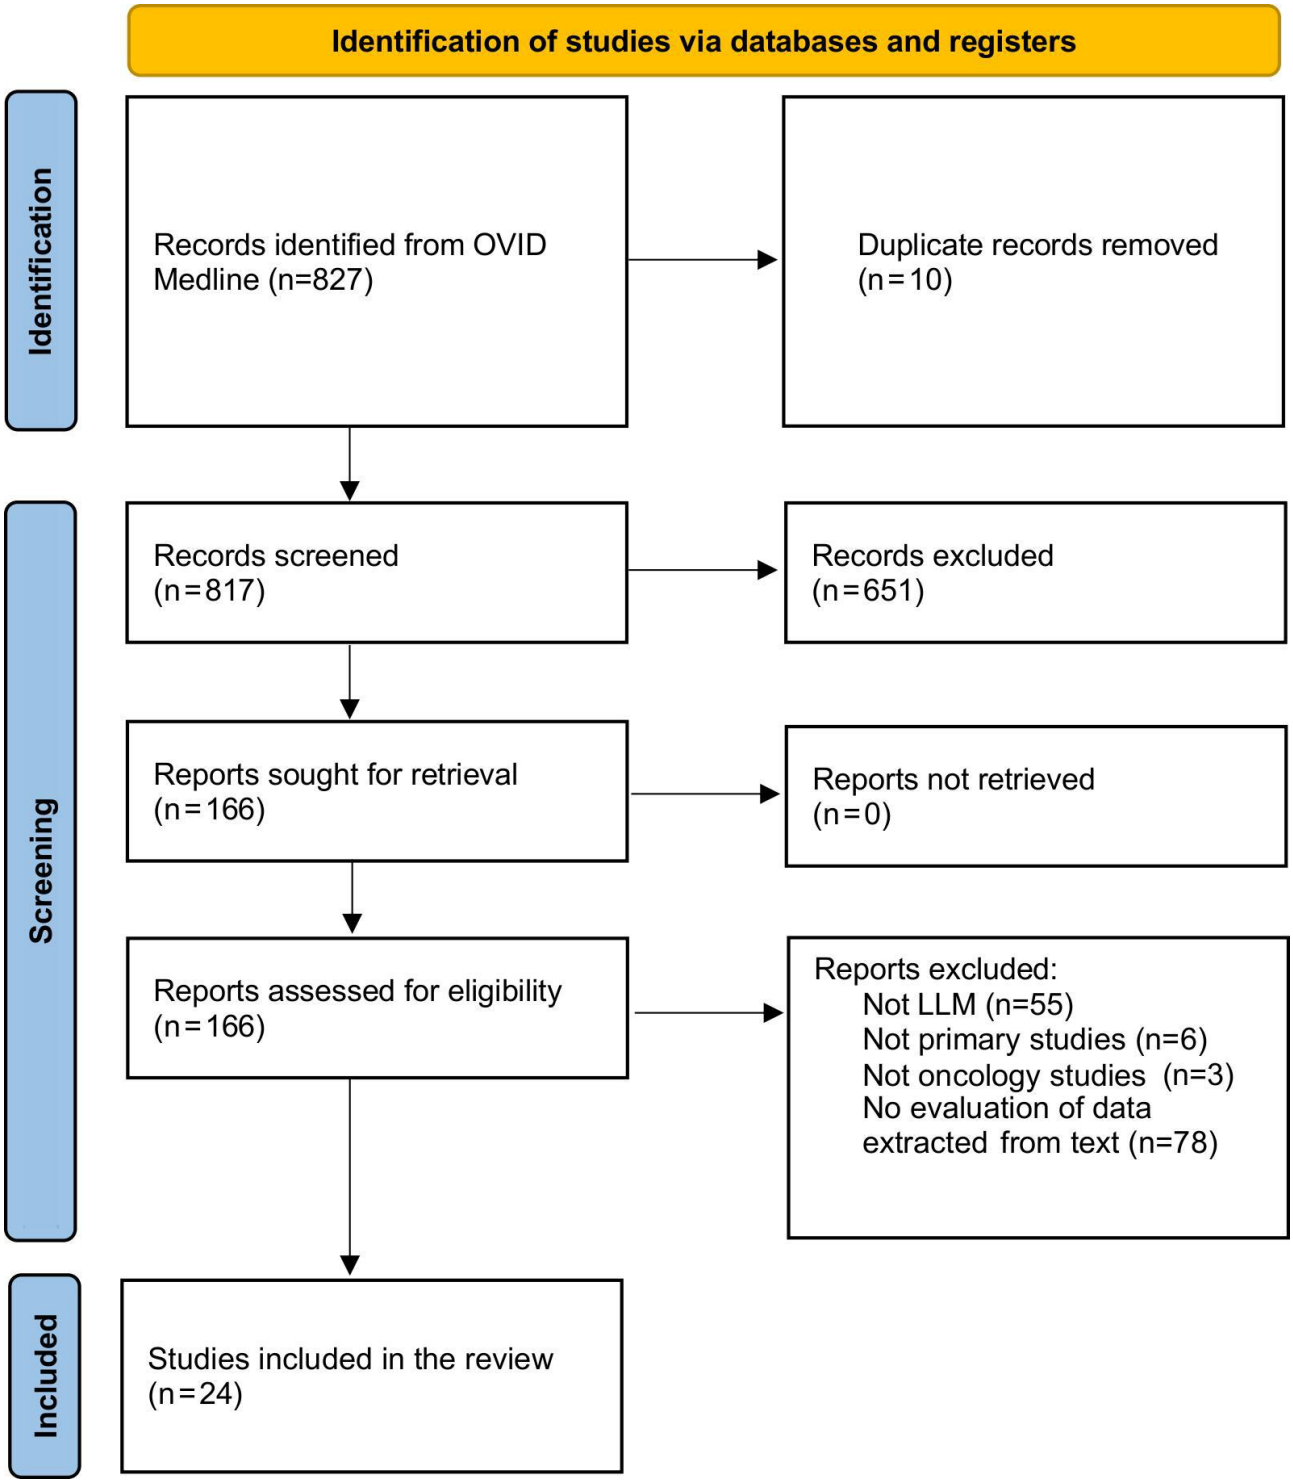

Figure 2. Risk of bias assessment using the ROBINS-I tool displayed as a traffic light plot for each included study [1,3,5,6,7,8-12,13,14-16,17,18,19,20-26].

Characteristics of the studies included in the study and published between 2019 - 2024 are shown in Table 1. The most common LLMs reported in these studies included BERT and its variants, as well as ChatGPT. Additional details related to methodology are reported in Multimedia Appendix 2.

Table . Characteristics of studies included in the review.

Study ID	Clinical domain	Baseline model	Baseline or fine-tuned LLM[a]	Zero-shot or prompt - engineered LLM	LLM main outcomes
Solarte-Pabon 2023[10]	Breast	BERT; RoBERTa	Fine-tuned	Zero-shot	F-scores: BETA: 0.9371; Multilingual BERT: 0.9463; RoBERTa Biomedical: 0.9501; RoBERTa BNE: 0.9454
Choi 2023 [11]	Breast	ChatGPT-3.5	Baseline	Prompt-engineered	Accuracy: 87.7%

[a]LLM: large language model.

[b]NER: named entity recognition.

[c]Bi-LSTM-CRF: bidirectional-long short term memory-conditional random field.

[d]AUROC: area under the receiver operating characteristic.

[e]AUPRC: area under the precision-recall curve.

[f]APHE: hyperintense enhancement in the arterial phase.

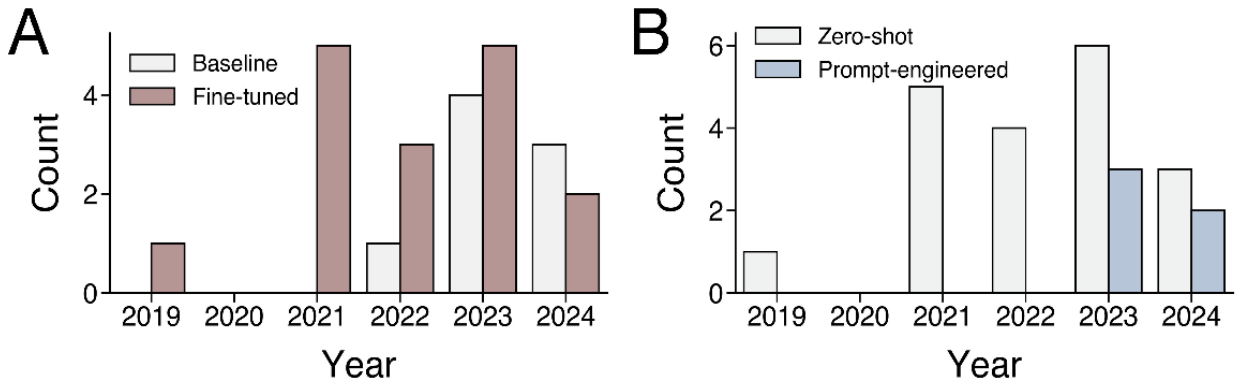
[g]PDPH: hypointense in the portal and delayed phases.

[h]PMK-EN: Prior Medical Knowledge-English Prompt

[i]ROC: receiver operating characteristic.

Most studies evaluated either the original or fine-tuned variants of the BERT LLM (n=18, 75%) in studies published between 2019 - 2024, followed by the Chat-GPT conversational LLM (n=6, 25%), upon application to data extraction from clinical texts in oncology, in studies published between 2023 - 2024. The LLMs for data extraction were commonly applied in pan-cancer clinical settings (n=11, 46%), followed by breast (n=4, 17%), lung (n=4, 17%), neurological (n=2, 8%), colorectal (n=1, 4%), gynecological (n=1, 4%), and liver (n=1, 4%) cancer contexts. The author teams of these studies belonged to institutions in the United States (n=11, 46%), China (n=4, 17%), Korea (n=3, 12%), Germany (n=2, 8%), Spain (n=2, 8%), the United Kingdom (n=1, 4%), and Singapore (n=1, 4%). Most studies were evaluated on datasets sourced from multiple institutional centers (n=18, 75%) compared to a single institutional center (n=6, 25%). Regarding the year of study publication, we observed a higher number of studies published between 2022 - 2024 (n=18, 75%) compared to 2019 - 2021 (n=6, 25%) (Figure 3). Notably, upon a comparison of studies published between 2022 - 2024 with studies between 2019 - 2021, the proportion of studies that reported the use of the fine-tuning method was lower (10/18, 55.6% vs 6/6, 100%) (Figure 3A), whereas the proportion of studies that reported the use of prompt engineering was higher (5/18, 28% vs 0/6, 0%) (Figure 3B).

Figure 3. Number of studies that evaluated (A) fine-tuning and (B) prompt engineering methodologies to optimize large language model data extraction performance.



Discussion

Principal Findings

Our scoping review of 24 studies highlights significant research interest in designing, evaluating, and deploying LLMs for data extraction from clinical text in oncology. The most commonly used LLMs for data extraction from clinical text in oncology include BERT and Chat-GPT, two of the most well-known LLMs in NLP research. These LLMs were most frequently applied in pan-cancer clinical contexts, reflecting their generalized natural language competency, regardless of clinical domain and context-specific terminologies and nomenclature. We observed a notable trend toward increasing utilization and refinement of LLM techniques over time, particularly in the areas of fine-tuning and prompt engineering. Given the common application of fine-tuning [26-28] and prompt-engineering [1,29,30] techniques in the design of deep learning- and LLM-based models in oncology, respectively, the emergence of optimized LLMs using these techniques represents a promising future direction for enhancing their data-processing capabilities. Despite these advancements, mixed reports of data extraction performance underscore the imperative for further assessment of these models across specific topics and use cases before their deployment as tools in cancer research and clinical care. Compared to historical statistical NLP and machine learning-based methods for data extraction in oncology, LLMs have been broadly evaluated for comparable applications, such as extracting tumor and cancer characteristics and patient-related demographic data [31].

The data processing competency of LLMs makes them a useful tool for automating repetitive, rule-based tasks, such as data extraction from clinical text on EHRs, to generate medical evidence about specific patients and patient populations that can inform patient care and population health guidelines respectively. Notably, LLMs have already shown competency in pilot studies of automated data extraction in biology [32], materials science materials science [33], and pharmacology [33], suggesting their generalized ability to extract relevant named entities from the clinical text that may be useful to synthesize medical knowledge. Across the included studies in this review, we found that LLMs offer several benefits for data extraction in clinical oncology, though further benchmarking against representative datasets and classical machine learning or statistical NLP approaches is required to determine their superior performance. In general, LLMs exhibited positive performance metrics compared to baseline human or statistical NLP approaches or were deemed feasible and acceptable in cross-sectional studies. These LLMs harbor the potential to balance accuracy and efficiency when processing large-scale, complex, unstructured text datasets found in EHRs [19]. Using LLM approaches for clinical data extraction as a supportive tool along with a human reviewer may reduce the potential for errors associated with human-led manual data extraction alone, thereby enhancing the reliability of clinical data analyses and interpretations [34].

Moreover, LLMs may curtail the resources required for data extraction, which is traditionally a labor- and time-intensive process [35]. For instance, our review highlighted the generalized performance of LLM-enabled data extraction across various text types in oncology, including histological and pathological classification [9,36], imaging report classification [8,14], and data extraction from postoperative surgery reports [5]. By automating the extraction and preliminary analysis of clinical text data, these models may free up valuable time for health care professionals, allowing them to focus more on patient-facing care and synthesis of medical knowledge from LLM-extracted information rather than the burden of administrative data management [10,12,37]. This shift not only improves clinical efficiency and cost-effectiveness but also reduces the serious risks of burnout among clinical staff by mitigating some of the repetitive administrative tasks associated with data handling [11,38].

Additionally, the versatility of LLMs across different clinical text contexts is notable. Whether dealing with structured data formats or the myriad forms of unstructured data present in EHRs, such as physician's notes and diagnostic reports, the general human-like natural language competencies of LLMs enable these "out-of-the-box" solutions to automatically adapt to and extract relevant information from varied data sources. This adaptability is crucial in precision oncology, where data from multiple data formats—such as imaging reports, next-generation sequencing results, and laboratory results—must be integrated and analyzed to generate personalized patient profiles and treatment strategies [39]. Our review highlighted

that current state-of-the-art evaluations of LLMs for data extraction in oncology have primarily focused on clinical text as input. However, we also highlight the recent emergence of multimodal LLMs capable of processing both image- and text-based inputs, serving as a new frontier for clinical decision support [40]. Taken together, future research to optimize data extraction for specific text formats in oncology—each with their own nuances—may improve extraction accuracy, enhance reliability, and produce results that can be trusted by clinicians and readily inform clinical decision-making [41].

The distribution of studies included in our scoping review reflects a predominant application of LLMs in pan-cancer clinical domains, accounting for nearly half of all research studies. This suggests that researchers leverage the versatility of LLMs to address broad oncological challenges across multiple cancer types, likely due to the generalizable nature of these models for various cancer data [42]. Breast and lung cancer also constituted a large portion of the studies, which can likely be attributed to their high prevalence and extensive clinical data availability, providing a rich dataset for deploying and testing the efficacy of LLMs [43]. The focus on these specific cancers indicates a targeted approach, where models are fine-tuned to address unique data extraction challenges, such as cancer type-specific nomenclature and lexicons. This underscores the potential of LLMs to be customized for specialized medical fields while also highlighting their broad "out-of-the-box" utility in general oncology. For instance, Gao et al [44] reported that BlueBERT did not outperform baseline nonLLM models in pan-cancer contexts, while Fang et al [22] and Mitchell et al (2022) [23] reported that the data extraction performance of BERT exceeded 90% accuracy in pan-cancer contexts. The mixed performance reported by different pilot studies of data extraction performance within the same clinical domain may be confounded by study-specific factors, including the prompting methodology, benchmark dataset, and definitions of performance metrics. These findings align with similar reports of mixed performance across different tasks and clinical text datasets within cancer type-specific domains [45-47], highlighting the need for systematic benchmarks to assess LLM data extraction reliability and domain-specific limitations. Standardizing performance metrics and defining critical thresholds for acceptable performance of data extraction accuracy remain open research questions to be addressed.

Our analysis reveals an increasing trend in the use of fine-tuning and prompt-engineering techniques in studies on LLMs, with 16 (67%) studies incorporating fine-tuning and 5 (21%) using prompt engineering. This progression suggests a maturation in the application of LLMs in clinical settings, where research has transitioned from developing baseline models for simple data extraction to the optimization of existing models using novel model adaptations and prompting methodologies tailored to the intricacies of medical data extraction. Fine-tuning allows models to adapt to the unique linguistic and contextual challenges presented by medical texts, potentially improving the accuracy and relevance of extracted information [29]. In comparison, prompt engineering enables the creation of more effective queries that align closely with the specific information needs of specialty fields such as oncology, steering LLMs toward more precise data retrieval [48]. For instance, Huang et al [19] demonstrated that providing LLMs with example outputs for few-shot learning and chain-of-thought reasoning methods for prompting yielded higher classification performance compared to baseline zero-shot applications of LLMs for data extraction. The careful design of prompting methodologies personalized to specific tasks and clinical domains within oncology may yield more accurate and efficient data extraction performance [49].

Despite the promising applications of LLMs in clinical oncology, our review also highlights notable disadvantages, particularly in cases of poor data extraction accuracy and performance [8,9]. Among the 24 reviewed studies, 9 (38%) cited accuracy as a limitation of LLMs for data extraction. These shortcomings underscore the critical need for cautious integration of LLMs into clinical workflows. The variability in performance can be attributed to the complex and diverse nature of clinical data, which may include nuanced medical terminologies and varied presentation styles across different documents [50]. These challenges emphasize the necessity for ongoing refinement and testing of these models under real-world conditions. Another minor disadvantage is the token limit of many LLMs, including both BERT and ChatGPT [20,42,44]. This limitation may complicate the extraction process, requiring models to be adapted to longer texts and resulting in reduced performance of these models [51]. Future research directions, as indicated by the reviewed studies, should involve performance benchmarks against existing statistical and machine learning–based methods and the extension of LLM tool validation to external, hold-out cohorts from additional clinical domains beyond those used in initial training datasets [7,16,24]. This would help ensure that the models are robust and reliable across various medical specialties and global oncology patient populations. While LLMs hold significant potential to revolutionize data management in oncology, their integration into clinical practice must be approached with careful planning and systematic evaluation to truly harness their capabilities without compromising patient care quality and privacy. The interpretation of both advantages and disadvantages of LLMs requires individualized consideration of each study, on a case-by-case basis given the heterogeneity in benchmark datasets, study designs, and reported outcomes.

Limitations

We acknowledge the limitations inherent in our scoping review. First, the rapid evolution of LLM technologies means that newer advancements may not have been fully represented in the reviewed studies due to the delays in publication cycles, leading to the omission of recent models. Second, the heterogeneity in study designs, datasets, and methodologies across included articles may affect the generalizability of findings in external contexts not evaluated in the same conditions as the original studies. Third, the majority of included studies originated from high-resource settings, primarily the United States, which may limit the applicability of results to lower-resource or structurally different health care systems. Fourth, while the risk of publication bias was not formally evaluated in our review, the tendency to publish studies with positive results may overrepresent the strengths of these LLMs without an

understanding and consideration of their limitations and nonpublished, negative results. Fifth, more recent journals that publish artificial intelligence research may not be indexed in the search databases yet, limiting the completeness of the search results in this scoping review. Sixth, this scoping review searched only one literature database, which may have resulted in the omission of relevant studies from other sources and limited the comprehensiveness of the findings.

Conclusion

In conclusion, the application of LLMs in oncology represents a forward leap in the digital transformation of health care data management. The potential to enhance data extraction processes and improve clinical decision-making is significant yet tempered by the current technological and methodological limitations. Ongoing research and development will be vital in harnessing the full potential of these models, ultimately leading to their more widespread adoption in clinical practice.

Abstract

Background: Digital interventions have been increasingly applied in multidisciplinary care plans to improve medication adherence to oral systemic anticancer therapy (SACT), the crucial lifesaving treatments for many cancers. However, there is still a lack of consensus on the efficacy of those digital interventions.

Objectives: This systematic review and meta-analysis aimed to investigate the efficacy of digital interventions in improving adherence to oral SACTs in patients with cancer.

Methods: This systematic review and meta-analysis followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement guidelines. The protocol has been registered at PROSPERO (no. CRD42024550203). Fully published, randomized controlled trials (RCTs) in English on adults with cancer assessing digital interventions for improving adherence to oral SACTs were retrieved from MEDLINE, Embase, APA PsycINFO, and CINAHL Plus up to May 31, 2024. Adherence measures compared between digital intervention users and nonusers were extracted. The proportions of poor adherence were synthesized using a random-effects model. The pooled results were reported as the odds ratio and 95% CI. The heterogeneity was assessed with the I^2 test (%). The mean difference and 95% CI were calculated from the mean adherence score and SD. A risk of bias assessment was conducted using version 2 of the Cochrane Risk of Bias Assessment Tool (RoB 2) for RCTs, which ensured that a quality assessment of all included studies was conducted as recommended by the Cochrane Collaboration.

Results: This study included 13 RCTs on digital interventions for improving adherence to oral SACTs in patients with cancer. The 13 RCTs, published between 2016 and 2024, were conducted in the United States, South Korea, France, Egypt, Finland, Australia, Colombia, Singapore, and Turkey. The technologies used were mobile apps (n=4), reminder systems (n=4), telephone follow-ups (n=3), and interactive multimedia platforms (n=2). Adherence was measured by surveys (n=8), relative dose intensity (n=2), pill count (n=1), self-reported missed doses (n=1), a smart pill bottle (n=1), and urine aromatase inhibitor metabolite assays (n=1). Concerns regarding risk of bias primarily involved randomization, missing outcome data, and outcome measurement, including nonblinded randomization, subjective patient-reported data, and difficulties in distinguishing between missed appointments and actual medication nonadherence. Pooled results from 11 trials showed that digital technology users had significantly lower risk of poor adherence (odds ratio 0.60, 95% CI 0.47 - 0.77). Two studies reported positive mean differences in adherence scores comparing digital intervention users and nonusers. However, due to considerable heterogeneity (I^2=73.1%), it is difficult to make a definitive conclusion from the pooled results about the effect of digital interventions upon adherence to oral anticancer therapy.

Conclusions: Digital intervention users exhibited significantly lower risk of poor oral SACTs adherence than nonusers. Acknowledging individual variation and tailoring digital technologies to prioritize patient needs is essential.

Trial Registration: PROSPERO CRD42024550203; https://www.crd.york.ac.uk/PROSPERO/view/CRD42024550203

Introduction

Medication adherence is a major public health concern, and nonadherence is responsible for 8% of global health expenditure and imposes a substantial economic burden on health care systems [1]. The advance in innovative treatments has led to an increasing number of cancers being classified as a long-term condition [2]. There is an increasing amount of research on measuring adherence [3], quantifying adherence rates in various drugs and cancer [4,5], investigating how to improve drug adherence [6], and identifying predictors of nonadherence [7].

Oral systemic anticancer therapy (SACT) has become increasingly accessible over the past 10 years, comprising 25% of oncology prescriptions globally [8] due to the advantages of being noninvasive, less intrusive, and more convenient [9]. However, they are prone to nonadherence as patients take medicines away from the medical setting. Many patients struggle to adhere to daily oral SACTs, with an adherence rate varying from 16% to 100% based on the settings and types of medicine [10].

Adherence is crucial to aiding successful patient outcomes of oral SACTs, while nonadherence can lead to disease progression, increased hospitalizations, and higher health care costs [11]. Factors such as complicated regimens, insufficient monitoring, poor communication, a lack of community support, mental health concerns, drug efficacy views, adverse effects, and financial load might contribute to nonadherence to oral SACT [6]. Clinicians may also neglect to mention the need for adherence and possible adverse effects, and patients may not have an adequate support system or understand the necessity of the medication [12]. Meanwhile, it has been asserted that interventions, including patient education and counseling, can improve treatment adherence [13].

Educational resources and various forms of communication have been used to build educational programs for patients in health care [14]. It is suggested that there is a link between continuous patient education and optimal adherence after a study showed that almost 50% of patients forgot their doctors' instructions immediately after being told them [15]. Patient-centered care and individualized interventions incorporating digital strategies have emerged as promising directions for research and development [16].

Innovative digital approaches include telemedicine, which refers to the provision of clinical services remotely using communication tools such as video or telephone. It encompasses activities such as diagnosis, monitoring, advice, reminders, education, interventions, and remote admissions, offering benefits such as reduced travel costs and time [17]. Smart home technology is another app that integrates computing solutions into living spaces to provide various services, including health care. Using telecommunication and web technologies can involve remote monitoring systems that enable patients to receive support while remaining in their homes [18].

Recent evidence suggests that digital interventions improve medication adherence in patients with chronic conditions. A meta-analysis involving 11 studies across various diseases demonstrated that reminder-based interventions, including text messages, phone calls, and video calls, significantly improved adherence, with 65.94% of prescribed doses taken in the reminder groups compared with 54.71% in control groups (P=.04) [19].

In oncology, digital tools such as apps [20], text messages [21], mobile games [22], phone calls [23], and multimedia interactive information technologies [14] have been used to increase medical adherence. Specific benefits of the digital approach include aiding in treatment recall, promoting healthy lifestyle habits, and suggesting that patient-focused educational initiatives could enhance treatment adherence and quality of life [14,24]. According to Karaaslan-Eşer and Ayaz-Alkaya [25], digital apps are easy to use, safe, provide access to medical professionals, offer guidance on managing symptoms with real-time feedback, and send timely notifications to enhance treatment adherence.

However, previous publications on the digital approach to increasing adherence have been limited to targeted oral SACT [26], specific digital tools (such as mobile [27], app-based design [20], text message [28], or telemedicine [23]), and specific diseases [29,30], with previous reviews lacking synthesized results from a meta-analysis [31,32]. Furthermore, medications for cancer treatment differ from those for other chronic conditions, as dosing is often less stable. SACTs are often adjusted by clinicians in response to treatment-related side effects and disease progression, leading to fluctuating dosages that complicate patient adherence [33].

Given these unique challenges, further investigation is warranted to evaluate the efficacy of digital interventions on adherence, specifically for patients with cancer taking oral SACT. This knowledge gap can be explored by undertaking this systematic review and meta-analysis examining their efficacy.

Methods

Protocol Registration

This systematic review and meta-analysis followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement guidelines (Multimedia Appendix 1) [34]. The protocol has been registered at PROSPERO (no. CRD42024550203). There were no deviations from the registered protocol.

Selection Criteria

The inclusion and exclusion criteria of this study are summarized as follows (Table 1).

Table . Inclusion and exclusion criteria of this study.

	Inclusion criteria	Exclusion criteria
Population and conditions	• Patients with cancer aged 18 years and older. • Patients diagnosed with cancer. • Patients with cancer taking oral SACTs[a].	• Patients with cancer including pediatrics, children, adolescents, neonates, or infants. • Studies that include mixed age groups of participants with cancer. • Patients with cancer taking nonoral SACTs[a]. • Patients with cancer exclusively receiving injectable SACTs[a].
Intervention and comparator	• The use of digital interventions such as: 1. Mobile apps 2. Web-based platforms 3. Wearable devices 4. Telemedicine interventions 5. Reminder systems (eg, text message reminders) 6. Virtual support groups or web-based communities • Comparator: standard or usual care without digital interventions.	• Studies that use nondigital interventions to improve adherence. • Studies with no suitable or appropriate comparator.
Outcome	• Adherence measures such as: 1. Medication possession ratio 2. Proportion of days covered 3. Self-reported adherence measures (eg, questionnaires and surveys) 4. Pharmacy refill data 5. Medication event monitoring systems (eg, smart pill bottles and electronic pill caps) 6. Biological markers	• The study does not contain outcome measures related to adherence. • Adherence measures are based solely on subjective reporting (unless validated self-reported measures were used).
Study type	• Human studies	• Animal or in vitro studies
Language	• English	• Non-English language
Publication	• Randomized controlled trials and clinical trials (comparative interventional trials)	• Review papers, systematic reviews, meta-analyses, cross-sectional studies, case-control studies, pilot studies, feasibility studies, editorials, commentaries, letters, opinion pieces, conference abstracts, gray literature, and non–peer-reviewed sources.

[a]SACTs: systemic anticancer therapies.

Types of Studies

Randomized controlled trials (RCTs) and clinical trials (nonrandomized, comparative interventional trials) were included. Review papers, systematic reviews, meta-analyses, cross-sectional studies, case-control studies, pilot studies, feasibility studies, editorials, commentaries, letters, opinion pieces, conference abstracts, gray literature, and non–peer-reviewed sources were excluded.

Types of Participants

This study included participants who met the following criteria: (1) patients aged 18 years and older, (2) patients diagnosed with cancer, and (3) patients taking oral SACTs. Patients younger than 18 years, studies that included mixed-age groups of participants, patients with cancer taking nonoral SACTs, and patients with cancer exclusively receiving injectable SACTs were all excluded.

Types of Interventions

The digital interventions were categorized according to the existing literature and the Cochrane Effective Practice and Organisation of Care (EPOC) taxonomy of health system interventions. EPOC outlined 4 categories of information and communication technology that health care organizations use for managing and delivering health care: health information systems, the application of information and communication technology, smart home technologies, and telemedicine [35].

To improve their adherence to oral SACTs, patients with cancer who used digital interventions, such as mobile apps, web-based platforms, wearable devices, telemedicine interventions, reminder systems (eg, text message reminders), virtual support

groups, or web-based communities, were included. Studies using nondigital interventions to enhance adherence were excluded.

Types of Outcome Measures

As there is no gold standard for measuring adherence and its associated outcomes, studies that reported adherence to oral SACTs, measured by various methods including self-reported adherence measures (such as the Morisky Medication Adherence Scale Score [36]), pharmacy refill data, medication event monitoring systems (including smart pill bottles and electronic pill caps), and biological markers, and presented as continuous or dichotomous data, such as the medication possession ratio [37], the proportion of days covered [37], or the proportion of adherence or nonadherence, were included in this review. Any studies that did not contain outcome measures related to adherence and studies that used adherence measures based solely on subjective reporting (unless validated self-reported measures were used) were excluded.

Data Sources and Search Strategies

A comprehensive electronic database search was conducted on MEDLINE, Embase, APA PsycINFO, and CINAHL Plus from their inception to May 31, 2024, as this review began in June 2024. MEDLINE and Embase are widely recommended for studying health care interventions [38], while APA PsycINFO and CINAHL Plus, although narrower in scope, are also well suited for this field. These databases focus on subject-specific rather than population-based information. Although there is no established guideline for the number of databases to include in a search, the combination of 2 broad and 2 focused databases is considered appropriate for the subject area of this review. Various structured search strategies were used, using controlled vocabulary and keywords based on the study's inclusion and exclusion criteria (Table 1) (Multimedia Appendix 2).

Study Selection

The title and abstract of papers retrieved from the electronic databases search were first screened by 2 reviewers (FA and WCL) independently according to the selection criteria (Table 1) using the predesigned electronic screening form. Each paper was rated as "included," "further check," or "excluded." The intraclass correlation coefficient (2-way mixed-effects model with absolute agreement [39]) and 95% CI were calculated for the consistency between 2 reviewers (FA and WCL) in record screening. Any discrepancy was resolved by discussing between reviewers and, if necessary, with a third reviewer (LCC) to reach a consensus. The full texts of potentially eligible papers were further reviewed independently by 2 reviewers (FA and WCL) to conclude the selection of studies.

Data Extraction and Management

The data for each study were independently extracted by 2 reviewers (FA and WCL) using the standardized and piloted electronic data extraction sheet. Disagreements were adjudicated by a third reviewer (LCC). Study information (study title, lead author, country, and year of publication), study design, setting, targeted population (cancer and oral SACT), intervention (digital apps), comparison, outcome measures, and follow-up period were extracted. Study results, including continuous data (such as mean adherence scale score and SD) and dichotomous data (such as the proportion of adherent or nonadherent patients), were retrieved. If raw data are unavailable, risk ratio, hazard ratio, mean (SD), median (range) of adherence duration, or any other results that can be converted into raw data were extracted. Duplicates were identified using EndNote 20 (Clarivate Analytics) through its default 1-step auto-deduplication process, which applies the matching criteria of "author," "year," and "title." This process was used to aid in screening the studies.

Risk of Bias Assessment

Controlling the risk of bias in a systematic review is crucial, as bias can distort the true effect of interventions [40]. Quality assessment of all included studies was conducted using version 2 of the Cochrane Risk of Bias Assessment Tool (RoB 2) for RCTs as recommended by the Cochrane Collaboration [41]. By assessing bias across 5 critical methodological aspects of each RCT, namely, the randomization process, deviations from the intended intervention, missing outcome data, outcome measurement, and selection of reported results [41], the included studies were categorized into "'low risk of bias," "some concerns," or "high risk of bias" using the RoB 2 tool. The results were subsequently tabulated. Risk of bias assessment was conducted independently and in duplicate by the 2 reviewers (FA and WCL).

Data Analysis

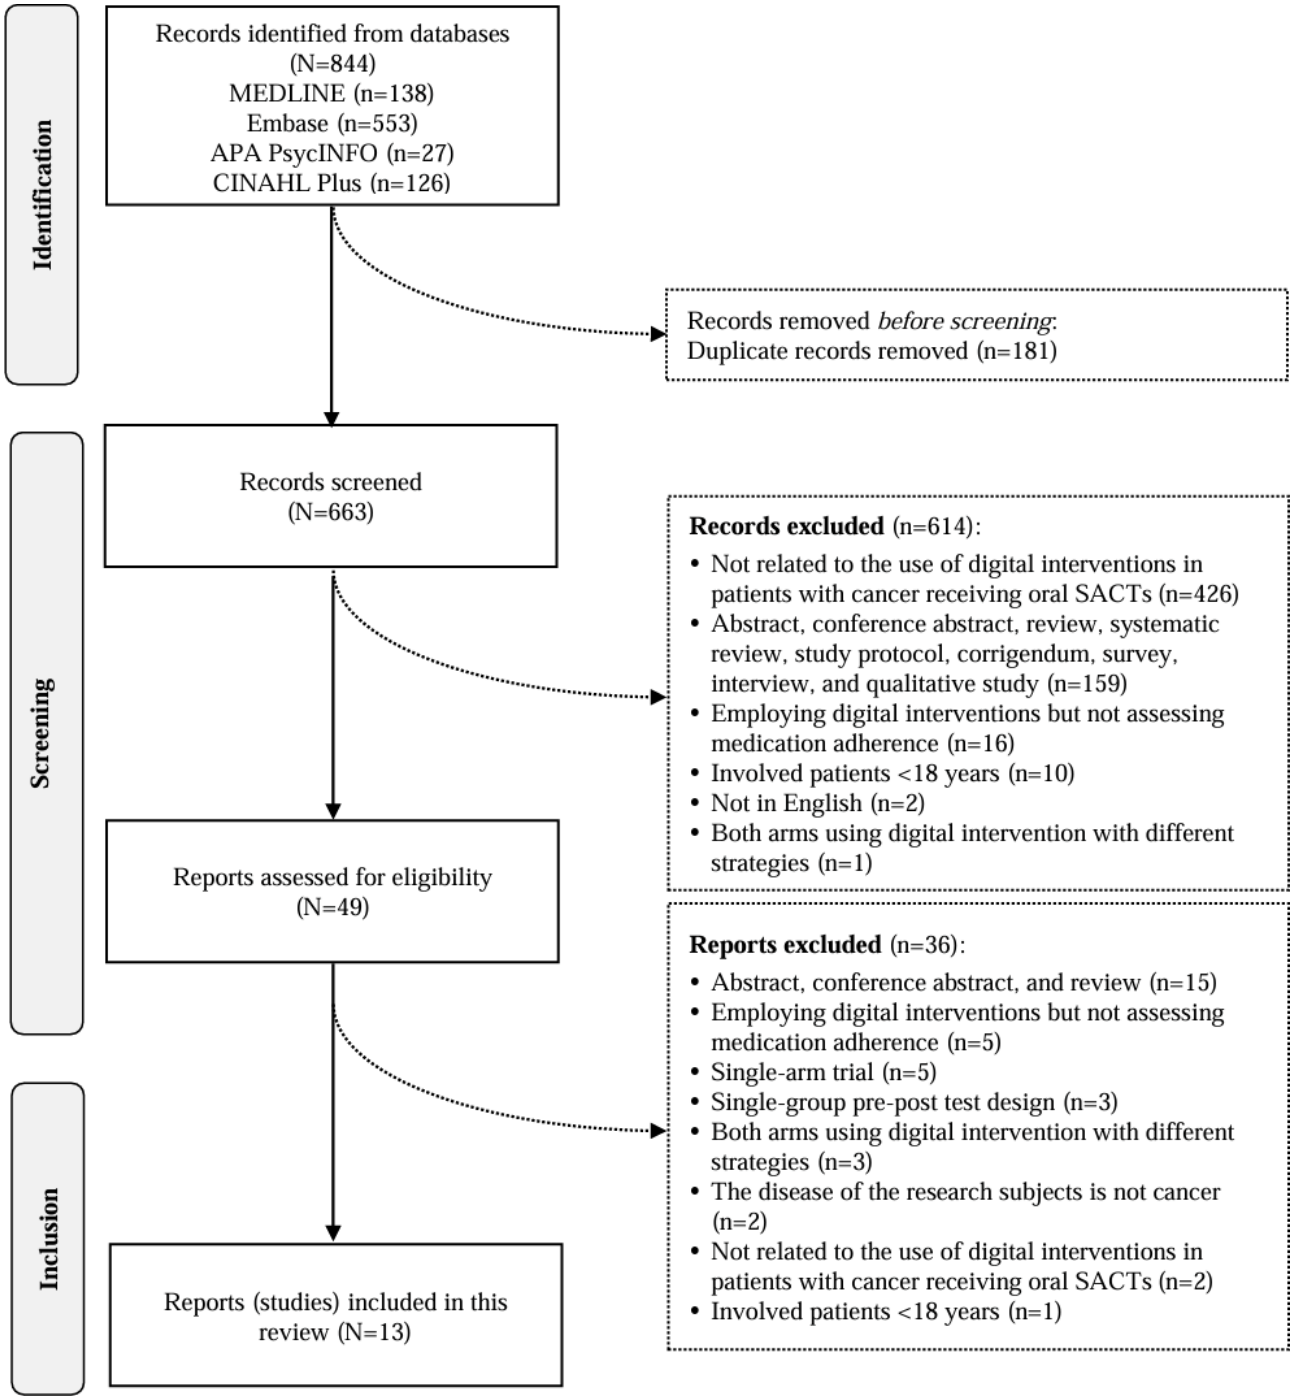
All outcomes were compared between the exposed group (digital intervention users) and the nonexposed group (those receiving standard care). The proportions of poor adherence were synthesized using a random-effects model (Der-Simonian and Laird method [42]). The pooled results were reported as odds ratio and 95% CI. The heterogeneity was assessed with the I^2 test (%). If appropriate, the mean difference and 95% CI of the adherence scale scores between the exposed and nonexposed groups were calculated and synthesized. The meta-analysis was conducted in STATA (Release 14; StataCorp LLC).

Results

Selection of Study

Of the 844 records identified from the electronic databases search, 181 duplicates were deleted. After screening titles and abstracts, 614 records were removed due to the irrelevance to digital interventions in patients with cancer receiving oral SACTs (n=426), being not fully published original interventional papers (n=159), not assessing medication adherence (n=16), involving patients younger than 18 years (n=10), not being in English (n=2), and both arms using digital interventions (n=1). After the full-text screening of the remaining 49 studies, 36 were excluded, leaving 13 studies (2611 participants) for inclusion in this review (Figure 1). The intraclass correlation coefficient between the 2 reviewers (WCL and FA) is 0.886 (95% CI 0.868-0.902), indicating good consistency. Since both authors demonstrated consistency and agreement at the full-text screening stage, the intraclass correlation coefficient was calculated solely for the abstract screening.

Figure 1. Selection of studies. APA: American Psychological Association; SACTs: systemic anticancer therapies.



Characteristics of Study

The 13 included RCTs, published from 2016 to 2024, were conducted in various countries: the United States (n=3) [21,33,43], South Korea (n=2) [22,24], France (n=2) [44,45], Egypt (n=1) [23], Finland (n=1) [46], Australia (n=1) [47], Colombia (n=1) [14], Singapore (n=1) [48], and Turkey (n=1) [25]. The studies involved patients with breast cancer (n=5) [21,22,24,47,48], various types of cancer (n=5) [25,33,43-45], chronic myeloid leukemia (n=1) [46], colorectal or gastric cancer (n=1) [23], and multiple myeloma (n=1) [14]. Digital interventions included mobile apps (n=4) [22,24,25,43], reminder systems (n=4) [21,33,47,48], telephone follow-ups (n=3) [23,44,45] and interactive multimedia platforms (n=2) [14,46]. According to the EPOC taxonomy [35], 7 RCTs used smart-home technologies [22,24,25,33,43,47,48], 4 used telemedicine [23,33,44,45], and 2 used information and communication technology [14,46] (Table 2). There were 1305 patients in the digital intervention group and 1306 patients in the control group.

Table . Characteristics of included studies.

Author, year, country	Cancer type, age of patients (years)	Digital intervention Tools or technology and intensity of intervention	EPOC[a]	Control	Adherence measure
Kekale et al (2016), Finland [46]	Chronic myeloid leukemia, median (range): 60 (25-83).	30-minute face-to-face counseling and multimedia interactive information technologies comprising a 5-minute video and daily text messages for 9 months.	Information and communication technology	Standard treatment	MMAS[b]
Kim et al (2018), South Korea [22]	Metastatic breast cancer, mean (SD): 50.9 (7.0)	Mobile game. Play the game for >30 minutes, 3 times weekly, for 3 weeks.	Smart-home technologies	Routine care	K-MARS[c]
Sikorskii et al (2018), United States [33]	Various types of cancer[d], mean (SD): 61 (12).	Reminder phone calls consisting of daily adherence reminder calls.	Telemedicine	Standard care	RDI[e]
Eldeib et al (2019), Egypt [23]	Metastatic colorectal or gastric cancer, mean (SD): intervention group: 49.98 (10.7); control group: 44.8 (12.65)	Follow-up phone calls involving weekly phone calls for the 11 cycles of treatment.	Telemedicine	Standard care	Pill count method
Greer et al (2020), United States [43]	Various types of cancer[f], mean (SD): 53.30 (12.91)	Mobile app with patients using the app for 12 weeks.	Smart-home technologies	Standard care	MMAS[b]
Hershman et al (2020), United States [21]	Early-stage breast cancer, median (range): 60.9 (30.7 - 82.4)	Text message twice a week for 3 years.	Smart-home technologies	No text messaging	Urine test
Tan et al (2020), Singapore [48]	Breast cancer, median (range): 61 (32-80)	Text message weekly for 1 year.	Smart-home technologies	Standard care	SMAQ[g]
Bouleftour et al (2021), France [44]	Various types of cancer[h], median (Q1-Q3): 70 (62-78)	Follow-up phone calls with calls at baseline, 3rd, 6th, 12th, and 24th weeks.	Telemedicine	Routine care	MMAS[b]
Karaaslan-Eser and Ayaz-Alkaya (2021), Turkey [25]	Various types of cancer[i], mean (SD): intervention group: 60.33 (9.31); control group: 62.14 (9.97)	Mobile app, which was a weekly record of symptoms and severity for 6 months.	Smart-home technologies	Standard care	OCAS[j]
Mir et al (2022), France [45]	Various advanced or metastatic cancer[k], median (range): 62 (20-92)	Follow-up by phone or internet (web portal) weekly for first month, biweekly from second to fourth month, and then 3 weekly from the fifth month onward.	Telemedicine	Usual care	RDI[e] and questionnaire
Park et al (2022), South Korea [24]	Breast cancer, mean (SD): 53.33 (8.71)	Mobile app and smart pill bottle reminder with smart pill bottle reminder daily for 4 weeks.	Smart-home technologies	Usual care	Automatic smartphone records
Singleton et al (2023), Australia [47]	Breast cancer, mean (SD): 55.1 (11.1)	Text messages comprising 4 text messages weekly for 6 months.	Smart-home technologies	Usual care	Self-reported missed doses within the last 7 days

Author, year, country	Cancer type, age of patients (years)	Digital intervention Tools or technology and intensity of intervention	EPOC[a]	Control	Adherence measure
Guio et al (2024), Colombia [14]	Multiple myeloma, mean (SD): intervention group: 65.19 (10.45); control group: 62.25 (11.89)	Multimedia interactive information technologies. Contents are presented to patients and caregivers at the start of each 4-month cycle.	Information and communication technology	Conventional educational approach	MAQ[l]

[a]EPOC: Effective Practice and Organisation of Care.

Quality Assessment

The 13 included RCTs raised concerns primarily related to the randomization process, missing outcome data, and outcome measurement; there were no high risks identified in any of the 5 areas of bias. The randomization was conducted by the principal investigator (KM) in one study [46] and lacked blinding in another [23]. In several studies, adherence outcomes were derived subjectively from patient-reported data via self-completed questionnaires [14,22,25,43-48]. In addition, challenges in differentiating missed appointments from actual medication nonadherence [21] and the possibility of smart pill bottles being opened without medication intake [24] further compounded measurement bias (Multimedia Appendix 3).

The challenges in recording outcome measures were found in 2 studies [21,24]. The authors of these RCTs made assumptions about the absence of urine samples as an indicator of nonadherence and the correlation between opening smart bottles and actual medication intake. While both studies used a sampling check or additional survey to support their assumptions, these diverse approaches contributed to increased heterogeneity and potential biases in this meta-analysis.

Characteristics of the Interventions

Four studies used mobile apps to integrate educational materials into their platforms [22,24,25,43]. Although the app (ILOVEBREAST) by Kim et al [22] functioned as a game, it still served as an educational tool for patients. Standard features of these mobile apps include side effects and symptom management [22,25,43], lifestyle guidance [43], and addressing adherence concerns [24,43]. Two of these studies incorporated additional digital technologies into their mobile apps, such as smart pill bottle reminders [24] and integrated Fitbit for monitoring physical activity [43] (Multimedia Appendix 4).

Moreover, standard features across mobile apps and other digital technologies included disease management and patient education about specific cancer types. Three studies directly targeted adherence through their digital technologies, either by questioning patients about their adherence [23,44] or by measuring it [24]. The remaining studies indirectly addressed adherence by focusing on related features. Some text messages covered a variety of content related to not only medication adherence but also physical activity, healthy diet, well-being, side effects management, physician recommendations, and providing support [21,47]. In addition, 3 studies used digital interventions to identify problems, particularly symptoms and toxicities [25,44,45]. In 1 study, health care professionals were able to access patient data and communicate with nurse navigators via a web portal [45] (Multimedia Appendix 4).

The delivery mode of digital technologies in the 13 RCTs varied. Mobile apps involve self-administration by patients, constituting a passive delivery method, although 2 studies personalized the app experience with features such as customized medication dosing timetables and symptom recording [25,43]. Reminder systems, either via text message or phone call, were passively delivered through telecommunication companies [48] or an interactive voice response system [33], with reminders predominantly generic. Telephone follow-ups were tailored to individual patients and proactively delivered by trained nurses [44,45] or a single principal investigator [23]. Interactive multimedia platforms, although passively delivered, provided bespoke content. One study combined multimedia interactive

platforms with face-to-face counseling sessions delivered by trained nurses [46] (Multimedia Appendix 4).

The duration of digital interventions in the 13 RCTs ranged from 3 weeks [22] to 3 years [21], with 1 study comprising 44 months in 11 undefined-length cycles [23]. Reminder systems were predominantly weekly, except for some studies conducted daily [33] or biweekly reminders [21]. Several studies used reminder systems to enhance adherence to oral SACTs. These systems varied, with some studies using smartphone messages [25,46,48], smart pill boxes [24], or telephone calls [33] to remind patients about their medication. Mobile apps were recommended for daily [22,24] or weekly use [25], except 1 study with unspecified frequency [33]. Telephone follow-ups varied from weekly [23] to less regular pattern [44,45]. One study combined follow-up phone calls with a web portal for web-based communication and patient information sharing [45]. Multimedia interactive platform engagement varied from monthly [14] to unspecified frequencies [46], with text messages being sent daily in 1 study [46] (Table 2).

Adherence Measurement

Adherence was the primary outcome in 11 RCTs, while 2 studies assessed it as a secondary outcome [45,47]. Various subjective measures, including surveys [14,22,25,43-46,48], relative dose intensity (RDI) [33,45], pill count [23], self-reported missed doses [47], and a smart pill bottle [24], were used across the 13 RCTs. One study used a more objective measure of adherence using time-to-adherence failure, defined by urine aromatase inhibitor metabolite assay results [21] (Table 2).

Adherence Rate

The pooled result from 11 studies [14,21,23-25,33,43,45-48] showed that users of digital technology had a significantly lower risk of poor adherence to oral SACTs than nonusers (odds ratio 0.60, 95% CI 0.47-0.77; I^2=73.1%) (Table 3). A trend was observed where smaller studies favored the digital intervention group [14,25,46], while larger studies favored the control group or showed no significant difference [21,33,43,45,48]. However, definitive conclusions cannot be drawn due to substantial heterogeneity (I^2=73.1%) [40]. In 1 study, only the proportion of medium adherence was reported, with no significant difference observed between the intervention (92/183, 77.2%) and control (91/183, 81.3%) groups [44].

Table . Proportion of patients with poor adherence in the included studies.

Study	Type of digital technology	Follow-up	Event rate[a]	Odds ratio (95% CI)
Kekäle et al (2016) [46]	• Face-to-face counseling • Interactive multimedia platforms	9 months	1/35 vs 9/33	0.08 (0.01 - 0.66)
Sikorskii et al (2018) [33]	• Reminder phone calls • Disease self-management tool kits	12 weeks	0/106 vs 0/108	1.02 (0.02 - 51.82)
Eldeib et al (2019) [23]	• Follow-up phone calls	11 cycles	0/44 vs 3/38	0.13 (0.01 - 2.73)
Greer et al (2020) [43]	• Mobile app	12 weeks	11/80 vs 20/86	0.53 (0.23 - 1.18)
Hershman et al (2020) [21]	• Text message	3 years	238/290 vs 268/313	0.77 (0.50 - 1.19)
Tan et al (2020) [48]	• Text message	1 year	59/123 vs 55/121	1.11 (0.67 - 1.83)
Karaaslan-Eser and Ayaz-Alkaya (2021) [25]	• Text message	6 months	16/38 vs 28/39	0.29 (0.11 - 0.74)
Mir et al (2022) [45	• Follow-up by phone or internet (web portal)	6 months	15/255 vs 26/265	0.57 (0.30 - 1.11)
Park et al (2022) [24]	• Mobile app integrated with a smart pill bottle reminder	4 weeks	1/30 vs 3/27	0.28 (0.03 - 2.83)
Singleton et al (2023) [47]	• Text message	6 months	3/42 vs 8/47	0.38 (0.09 - 1.52)
Guio et al (2024) [14]	• Interactive multimedia platforms	At least 100 days following transplantation or 3 months after maintenance	1/16 vs 13/16	0.02 (0.01 - 0.17)
Overall	N/A[b]	N/A	345/1059 vs 433/1093	0.60 (0.47 - 0.77); I^2=73.1%

[a]Event rate refers to the proportion of poor adherence in each study, measured by the specific method used in the study. Digital intervention users versus nonusers. Some event rate values have been converged based on the adherence data provided by studies.

[b]N/A: not applicable

Adherence Scale Score and RDI

Two studies reported adherence scale scores [22,44]. Although the results were not pooled, the mean difference was calculated (Table 4). These 2 studies generated positive mean differences, indicating that digital technology users experienced an increase or improvement in oral SACT adherence compared with nonusers. The mean (SD) of the RDI for the intervention group and the control group were 0.89 (0.03) (n=122) and 0.92 (0.03) (n=117) in one study [33], and 0.84 (0.26) (n=255) and 0.80 (0.21) (n=265) in another study [45]. A value of RDI<0.8 indicated underadherence, as reported in 1 study [33].

Table . Adherence scale score and mean difference of the included studies.

Study	Digital technology	Follow-up	Adherence scale	Mean (SD) score[a]	Mean difference[b] (95% CI)
Kim et al (2018) [22]	Mobile game	3 weeks	Korean version of the medication adherence rating scale	7.6 (0.7) (n=34) vs 6.5 (0.5) (n=38)	1.10 (0.82-1.38)[c]
Karaaslan-Eser and Ayaz-Alkaya (2021) [25]	Text message	6 months	Oral chemotherapy adherence scale	81.22 (8.05) (n=38) vs 73.36 (10.44) (n=39)	7.86 (3.81-11.91)[c]

[a]Digital intervention users versus nonusers.

[b]Mean difference represents the adherence score difference between digital intervention users and standard care patients, with higher scores indicating better adherence.

[c]P<.01.

Discussion

Principal Results

This study investigated the efficacy of digital interventions in improving adherence to oral SACTs and found that digital intervention users had a significantly lower risk of poor adherence to oral SACTs than nonusers. In addition, digital technology users demonstrated improved or increased adherence scores compared with nonusers.

Interactive and patient-focused digital supports have revolutionized the possibilities for improving medication adherence [16]. An overview of reviews indicates that incorporating digital technologies with direct clinician contact is likely to increase adherence [31]. A systematic review confirmed the efficacy of digital interventions in improving short-term treatment adherence among patients with cancer receiving oral chemotherapy [32]. Our pooled meta-analysis results also support this, as they showed a significantly reduced risk of poor adherence to oral SACTs among users of digital tools.

The efficacy of digital tools in achieving success can be attributed to various factors, for example, providing instructional resources, dosage aids, engagement with health care providers, digital medicine, self-monitoring, and quickly implementable technical methods [16]. Patient awareness of their drug regimen and the goals, benefits, and potential adverse events is critical for optimal adherence [49]. Digital can offer medication information and instructional help as educational resources [22,24,25,43]. Digital-based interventions such as personalized dosing schedules help patients organize and improve drug adherence [43]. Face-to-face counseling, proposed as a single consultation experience, was also included in our review for its potential to enhance patient adherence [46,50].

Implications

Medication adherence is crucial in oncology therapy, yet low adherence rates, as low as 14% for some cancer regimens, significantly impact patient health outcomes and strain health care systems and budgets [51]. This indicates that personalized interventions may improve adherence [51,52]. With more than 4.57 billion web users globally, 91% are accessing it via mobile devices, and smartphone usage—projected to increase by 8% annually [53], as well as digital health tools including phones and wearable devices—offer promising avenues for enhancing health care outcomes, cost-effectiveness, and patient acceptance [27].

Telemedicine offers greater flexibility than in-person interventions, allowing for addressing nonadherence wherever and whenever it occurs, such as between appointments or outside of clinic settings [54]. Telemedicine for reminder and follow-up phone calls was also a method of implementation used in several studies examined [23,33,44]. Digital medicine involves tools such as electronic pill bottles and wearable electronic devices. These devices enhance adherence and can track when containers are opened, although this does not verify intake [55]. Moreover, digital treatments may have drawbacks, including the cost and time needed for transferring or connecting with electronic equipment [16].

One study investigated whether using 1 or 2 digital tools improved adherence [56]. Both groups received weekly automated voice responses over 8 weeks, with the intervention group receiving additional daily text messages for 21 - 28 days. Results suggested that the extra text messages improved adherence and symptom management in patients taking oral anticancer agents. Another similar study showed that additional text messages could positively impact patients by promoting behavior change and improving self-care [28]. This highlights the potential for diverse clinical outcomes with varying types and quantities of digital tools.

Furthermore, social inequality is often correlated with the reduced use of digital technology in health care, contributing to a digital health divide [57]. For instance, older adults are less likely to use the web [58] or smartphones [59], and individuals with lower incomes face greater barriers to web access [60]. This inequality results in disparities in access to digital tools and hampers the implementation of digital interventions in health care [61]. To enhance accessibility, patients and health care professionals need to be involved in the development of these interventions, ensuring that they meet the needs of diverse patient populations. In addition, educational campaigns should aim to raise awareness and provide training on digital tools while also challenging stereotypes about older adults' technological capabilities and reinforcing patients' confidence in maintaining their privacy when using such interventions [61].

Strengths and Limitations

This review focuses on managing medication adherence at home for patients with cancer who are prescribed oral SACTs. All studies included are RCTs, considered the gold standard for measuring intervention efficacy [62]. We excluded single-group pre-post test designs to ensure randomization and aimed to cover various contemporary digital tools to assess their efficacy on medication adherence. One study had a 3-year follow-up, offering valuable insights into long-term impact [21]. The pooled meta-analysis results provide an integrated understanding of digital tools' efficacy in supporting medication adherence among patients with cancer.

While digital interventions hold promise, we acknowledge several limitations in this study, including various cancer types and oral SACT classes introducing disease uniqueness and drug response variability, potentially impacting medication adherence and intervention efficacy.

Despite including only RCTs, these studies exhibited considerable variability in research design, data collection methods, outcome measures, and the digital interventions used, as well as diversity in the cancer types investigated. The inability to conduct a patient-blinded experiment due to patient expectations of additional digital support is recognized [23,25]. Follow-up phone calls by different health care professionals may introduce bias [44,45]. Furthermore, reliance on subjective self-monitoring or self-reporting for medication adherence evaluation poses potential errors [24,33,46]. Small sample sizes

in some trials may limit statistical power and significance between intervention and control groups.

This heterogeneity is inherent to the subject matter [63]. Methodological heterogeneity was notable (I^2=73.1%), but it was accounted for by using a random-effects model in the meta-analysis, which assumes a normal distribution of underlying effects [40]. Also, due to the significant heterogeneity, the publication bias assessment test was not conducted to avoid presenting potentially misleading results. Acknowledging these limitations is crucial for interpreting the research results and allows readers to evaluate the significance and scope of the study more comprehensively. Another limitation of the study was that subgroup analyses were not conducted due to lack of data. This could have been used to investigate heterogeneous results or ask specific questions about a cancer type or intervention type.

This review included a variety of adherence and outcome measures due to the lack of consensus on these metrics. While self-reported adherence may be less robust due to recall bias and social desirability effects [64], only those studies using validated tools widely accepted in adherence research were included. Although these tools facilitate low-burden data collection, self-reported adherence may not always accurately reflect actual behavior, necessitating cautious interpretation of results. This diversity in outcome measures provides a comprehensive view of adherence-related consequences, which is crucial for understanding the broader context of digital interventions but may also complicate the ability to draw definitive conclusions.

Cancer populations encompass low-, middle-, and high-income regions globally, each with varying access to digital technologies and health care systems. Most studies have been conducted in high-income regions, which limits the generalizability of the results to low- and middle-income areas. In addition, the limited and diverse regional patient inclusion across these studies may further restrict the applicability of the findings to broader conditions [23-25,43].

Recommendations

Future interventions should be developed that focus on patient-centered, motivation-driven, and culturally adapted digital tools and be tailored for individuals with different types of cancer or oral SACTs. Efforts should focus on minimizing the threshold and difficulties associated with using digital tools and ensuring accessibility and ease of implementation for patients of all ages. Investigating patients' preferences for digital interventions could also increase usage rates. Monitoring health care professionals' responses and perspectives on digital interventions, alongside tracking patients' medication adherence, would provide valuable insights. To prevent alert fatigue [21], future research could explore optimal timing and frequency for implementing digital interventions. Qualitative studies could be conducted to delve deeper into the experiences of digital intervention users in real-world therapeutic settings, complementing quantitative findings.

Conclusions

Considering the growing use of oral SACTs and their higher patient acceptance over intravenous therapy, addressing medication adherence is vital in clinical oncology. Digital interventions offer effective support, enhancing adherence to oral SACTs and improving treatment outcomes while providing convenience for patients. This study highlights the significant benefits of digital technology in promoting adherence. Future research should focus on refining and personalizing digital tools to better meet individual patients' needs.

Acknowledgments

The authors thank Mr Tony Wei for data extraction and technical support and Dr Tristan P Martin for his guidance on conducting journal surveys. Dr Wan-Chuen Liao acknowledges the National Science and Technology Council, Taiwan, for supporting her Overseas Project for Postgraduate Research (112-2917-I-002-025) at The University of Manchester from 2023 to 2024. The authors attest that there was no use of generative artificial intelligence technology in the generation of text, figures, or other information content in this manuscript.

Authors' Contributions

The study was conceptualized by LCC and FA with data curated by WCL and FA. Formal analysis was conducted by WCL, FA, and JC. There was no funding acquisition for the study. The investigation was conducted by WCL, FA, and JC, and the methodology was developed by LCC, WCL, FA, and JC. Project administration was primarily by LCC and with support from WCL and FA. Resources and software were provided by The University of Manchester, and supervision was done by LCC. Validation was done by WCL and FA, and visualization was prepared by WCL and FA. The original draft was written by WCL and FA, and the review and editing of the writing were done by WCL, FA, and LCC. This statement has been written according to the CRediT taxonomy.

Abstract

Background: Artificial intelligence (AI) is a revolutionary tool yet to be fully integrated into several health care sectors, including medical imaging. AI can transform how medical imaging is conducted and interpreted, especially in cardio-oncology.

Objective: This study aims to systematically review the available literature on the use of AI in cardio-oncology imaging to predict cardiotoxicity and describe the possible improvement of different imaging modalities that can be achieved if AI is successfully deployed to routine practice.

Methods: We conducted a database search in PubMed, Ovid MEDLINE, Cochrane Library, CINAHL, and Google Scholar from inception to 2023 using the AI research assistant tool (Elicit) to search for original studies reporting AI outcomes in adult patients diagnosed with any cancer and undergoing cardiotoxicity assessment. Outcomes included incidence of cardiotoxicity, left ventricular ejection fraction, risk factors associated with cardiotoxicity, heart failure, myocardial dysfunction, signs of cancer therapy–related cardiovascular toxicity, echocardiography, and cardiac magnetic resonance imaging. Descriptive information about each study was recorded, including imaging technique, AI model, outcomes, and limitations.

Results: The systematic search resulted in 7 studies conducted between 2018 and 2023, which are included in this review. Most of these studies were conducted in the United States (71%), included patients with breast cancer (86%), and used magnetic resonance imaging as the imaging modality (57%). The quality assessment of the studies had an average of 86% compliance in all of the tool's sections. In conclusion, this systematic review demonstrates the potential of AI to enhance cardio-oncology imaging for predicting cardiotoxicity in patients with cancer.

Conclusions: Our findings suggest that AI can enhance the accuracy and efficiency of cardiotoxicity assessments. However, further research through larger, multicenter trials is needed to validate these applications and refine AI technologies for routine use, paving the way for improved patient outcomes in cancer survivors at risk of cardiotoxicity.

KEYWORDS

artificial intelligence; cardiology; oncology; cancer therapy–induced; cardiotoxicity; cardiovascular toxicity; machine learning; imaging; radiology

Introduction

The World Cancer Research Fund International reported 18.1 million cancer cases in the year 2020, with breast and lung cancer being at the top of the list, representing 12.5% and 12.2% of all cases, respectively [1]. Breast cancer is the most commonly diagnosed type of cancer globally [2]. In 2020, the International Agency for Research on Cancer reported 27,885 new cancer cases, with nearly 47% of these cases ending with death [3].

In the United States, there are currently 17 million cancer survivors; by 2030, that number is predicted to rise to 22 million. For many cancer survivors, cardiovascular disease (CVD) is the leading cause of noncancer morbidity and mortality. Studies show that compared to the general population, patients with cancer have a 2 - 6 times higher chance of dying from CVD. Considering the progress made in cancer therapies and the decrease in cancer-related fatalities, comprehensive cardiovascular care is essential to improving these patients' overall results [4].

In recent years, there has been a notable advancement in the fight against cancer. However, a new problem has come to light: the potential for lifesaving cancer treatments to cause unintended damage to the heart. This is where cardio-oncology, a rapidly developing field, comes into play. It focuses on the crucial relationship between cancer treatment and heart health, focusing on controlling and preventing cardiovascular toxicity [5].

Cardiovascular toxicity, commonly known as cardiotoxicity, defined by the 2022 European Society of Cardiology Cardio-Oncology guidelines, is the term used to describe the harm inflicted upon the heart muscle or cardiovascular system due to different cancer treatments. Although chemotherapy and radiation therapy are essential tools in the fight against cancer, they can have negative side effects on the heart. These adverse effects can include anything from mild alterations in cardiac function to potentially fatal issues, including heart failure [6].

According to the American Society of Clinical Oncology (ASCO), the survivorship of cancer in the United States is approximately 67% and 18% for 5 and 20 years or more after diagnosis, respectively [7], especially if diagnosed early [8]. However, patients receiving cancer treatments such as chemotherapy, radiotherapy, and targeted agents have a 20% chance of developing myocardial dysfunction, with up to 7% to 10% having cardiomyopathy or heart failure [9]—in other words, therapy-induced cardiotoxicity [10,11]. Therapy-induced cardiotoxicity depends on the type of treatment, such as mediastinal and left-sided radiotherapy, anthracycline-based chemotherapy, and trastuzumab (targeted therapy), and other risk factors such as age, stage of diagnosis, ethnicity, and pre-existing CVDs [12].

Trastuzumab is a targeted therapy that uses drugs and other substances to precisely identify and attack specific types of cancer cells [13]. It is a humanized immunoglobulin G1 monoclonal antibody that is used to treat HER2+ (human epidermal growth factor receptor 2) breast cancer. Recently, it has also been approved to treat HER2+ advanced gastric cancer. The use of trastuzumab on patients with HER2+ breast cancer, which constitutes 20% of breast cancer cases, has demonstrated a significant reduction in recurrence risk, morbidity, and mortality. However, not all patients with HER2+ breast cancer respond to trastuzumab treatment due to resistance [14]. Recently, targeted therapy has been increasingly used in treating cancer, which has resulted in a significant improvement in the overall survival of patients with cancer. However, it can cause systemic toxicity, particularly cardiovascular toxicity [15].

Moreover, one of the most effective chemotherapy agents for several cancer types is anthracycline-based chemotherapy [16]. The American National Cancer Institute defines anthracycline as a type of antibiotic extracted from certain types of *Streptomyces* bacteria; it kills cancer cells by causing damage to their DNA and interfering with their reproduction [17,18]. The anthracycline chemotherapy agents include doxorubicin, epirubicin, daunorubicin, idarubicin, mitoxantrone, and valrubicin [18]. Although anthracyclines have been proven effective in treating various types of cancer, they do not come without adverse effects, which can limit their therapeutic potential [16]. These adverse effects range from mild and short-term to severe and long-term side effects [19]. Thus, early detection of cardiac dysfunction or cardiotoxicity allows the administration of the appropriate cardiac care, improving the overall outcome [20].

Long-term, dose-dependent risks of cardiotoxicity with anthracyclines are well-established [19]. Therefore, the recommended current practice by ASCO is a comprehensive assessment before initiating the treatment that includes a history and physical examination, screening for CVD risk factors, and an echocardiogram [21]. ASCO also recommends that clinicians manage modifiable cardiovascular risk factors (smoking, hypertension, diabetes, and obesity); the clinicians may incorporate several strategies, such as the use of dexrazoxane for cardioprotection, continuous infusion, or liposomal formulation of doxorubicin during the administration of anthracycline therapy [21]. In addition to cardiac imaging during the routine clinical assessment before therapy initiation (echocardiogram and cardiac magnetic resonance imaging [MRI]), ASCO recommends routine surveillance for cardiac function in patients considered to be at increased risk of developing cardiac dysfunction or heart failure [21,22].

The current method for cardiac function surveillance is "echocardiography" [14] to assess the left ventricular ejection fraction (LVEF) and the global longitudinal strain (GLS) [23]. Echocardiography has many advantages, making it the first modality of choice to monitor cardiotoxicity. These advantages include its ability to provide real-time imaging; availability and accessibility; noninvasiveness; and low cost [23]. However, echocardiography has limitations that hinder the detection of early signs of cardiotoxicity. Some of these limitations include the fact that echocardiography is entirely user-dependent, subjectivity in results interpretation, and variability in the image quality [23]. These limitations can result in the inability to detect subclinical cardiotoxicity and the early signs of cardiac dysfunction, which are crucial for personalized treatment plans that aim to improve the patient's prognosis [23]. Moreover, other CVD manifestations, such as myocardial perfusion and mitochondrial dysfunction, may precede a myocardial injury detected by echocardiography; this can only be recognized by a higher level of imaging modalities, which use targeted radiotracers such as cardiac magnetic resonance imaging (CMR) and nuclear imaging to provide information on specific mechanisms of cardiotoxicity [24].

With the recent emergence of artificial intelligence (AI) and machine learning (ML), their applications have meritoriously contributed to many advancements, with a promising potential for more across different areas, including imaging in the medical field [23,25]. One of the potential advancements is the rise of

stable diffusion, a generative model; it is anticipated that it might fill the gap in low-quality medical images by generating data on the missing details of the pathology with pattern recognition [25,26]. AI can generate this data by processing large amounts of readily available imaging data through artificial neural networks inspired by the connectionism of the biological neural network in the brain [25]. Tasks executed by AI algorithms in medical image processing include image acquisition, analysis, segmentation, feature extraction, visualization, registration, and classification [25]. Using AI-augmented imaging in the assessment of cardiotoxicity can help in recognizing subclinical cardiotoxicity caused by anthracyclines in addition to being able to reproduce the images more accurately by enhancing the imaging quality produced by the echocardiograph, which eventually will allow better monitoring and earlier detection of cardiac dysfunction [27]. For more detailed definitions of cancer treatments, cardiovascular toxicity, imaging modalities, and the application of AI in healthcare, please refer to Multimedia Appendix 1.

Despite its potential, the evidence base of AI imaging solutions for cardiovascular care in general and predicting cardiotoxicity in particular has been limited to date. Therefore, further research about AI's usefulness and effectiveness in the routine practice of cardio-oncology care is necessary. This systematic review aims to review the available literature on the use of AI in cardio-oncology imaging to predict cardiotoxicity and describe the possible improvement of each modality for cardio-oncology imaging when deploying AI to routine practice.

Methods

This systematic review was conducted according to the PRISMA (Preferred Reporting Items for Reviews and Meta-Analyses) guidelines from July 1 to August 1, 2023. The review is registered in PROSPERO (International Prospective Register of Systematic Reviews; CRD42023446135).

Search Strategy

The literature search for this review was performed using PubMed, MEDLINE, Cochrane Library, CINAHL, and Google Scholar for relevant studies from inception until June 2023. An AI research assistant (Elicit) was also used to search for relevant papers using the same terminology. In addition, PROSPERO was searched for ongoing similar systematic reviews. The first and senior authors are experienced in systematically reviewing the literature and have published several reviews. In addition, the authors have consulted experts using Editage services to achieve a high level of reliability. Please see Multimedia Appendix 2 for a detailed search strategy.

Terminology

In order to achieve the objective of this review, the databases were searched using keywords and their Medical Subject Headings (MeSH) terms connected by the Boolean operators "AND," "OR," and "*."

The search used the following terms and their MeSH terms: artificial intelligence, AI, deep learning, machine learning, cardio-oncology, cardiotoxicity, cardiac toxicity, cancer treatment, cancer therapy, "artificial intelligence," "machine learning," "AI augmentation," "deep learning," OR "AI" AND "Cardio-oncology," "Cardiotoxicity," "Cardiovascular toxicity," OR "Cardiac toxicity" AND "chemotherapy," "anthracycline," "cytotoxic regimens," "immunotherapy," "Cancer treatment," OR "therapy-induced" AND "Imaging," "Echocardiogram," "Echo*," "Cardiac magnetic resonance imaging," "CMR," "Multigated acquisition," "MUGA," "Cardiac computed tomography," OR "CCT."

Eligibility Criteria and Study Selection

Original studies reporting AI outcomes in adult patients diagnosed with any type of cancer and undergoing cardiotoxicity assessment were included. Outcomes included incidence of cardiotoxicity, LVEF, risk factors associated with cardiotoxicity, heart failure, myocardial dysfunction, signs of cancer therapy–related cardiovascular toxicity (CTR-CVT), echocardiography, and CMR. Non-English studies, case reports, literature reviews, studies on children, and studies that did not include CTR-CVT were excluded from this review.

Quality Assessment

The first, second, and third authors (MR, HM, and AR) independently assessed the included articles according to the 42-item Checklist for Artificial Intelligence in Medical Imaging (CLAIM) [28]. CLAIM is modeled after the Standards for Reporting of Diagnostic Accuracy Studies guideline. It addresses the application of AI in medical imaging, including classification, image reconstruction, text analysis, and workflow optimization [28]. Subsequently, the first, second, and third authors cross-checked each other's articles, and conflicts were resolved through group discussion.

Risk of Bias

Finally, both HM and AO independently assessed the risk of bias for each study across ROBINS-I's (risk of bias in nonrandomized studies - of interventions) 7 domains: confounding, selection of participants, classification of exposures, deviation from intended exposure, missing data, measurement of outcomes, and selection of reported results. Each domain was rated as low, moderate, serious, or critical based on the each domain's algorithm, with the most severe rating across all domains determining the overall assessment for each study. Any disagreements in the assessments were discussed until a consensus was reached, with one reviewer (DJ) ensuring consistent application of judgments. Additionally, we engaged a fifth-year medical student experienced in systematic reviews and various research projects to independently evaluate the risk of bias for all included studies using the same tool.

Statistical Extraction and Analysis

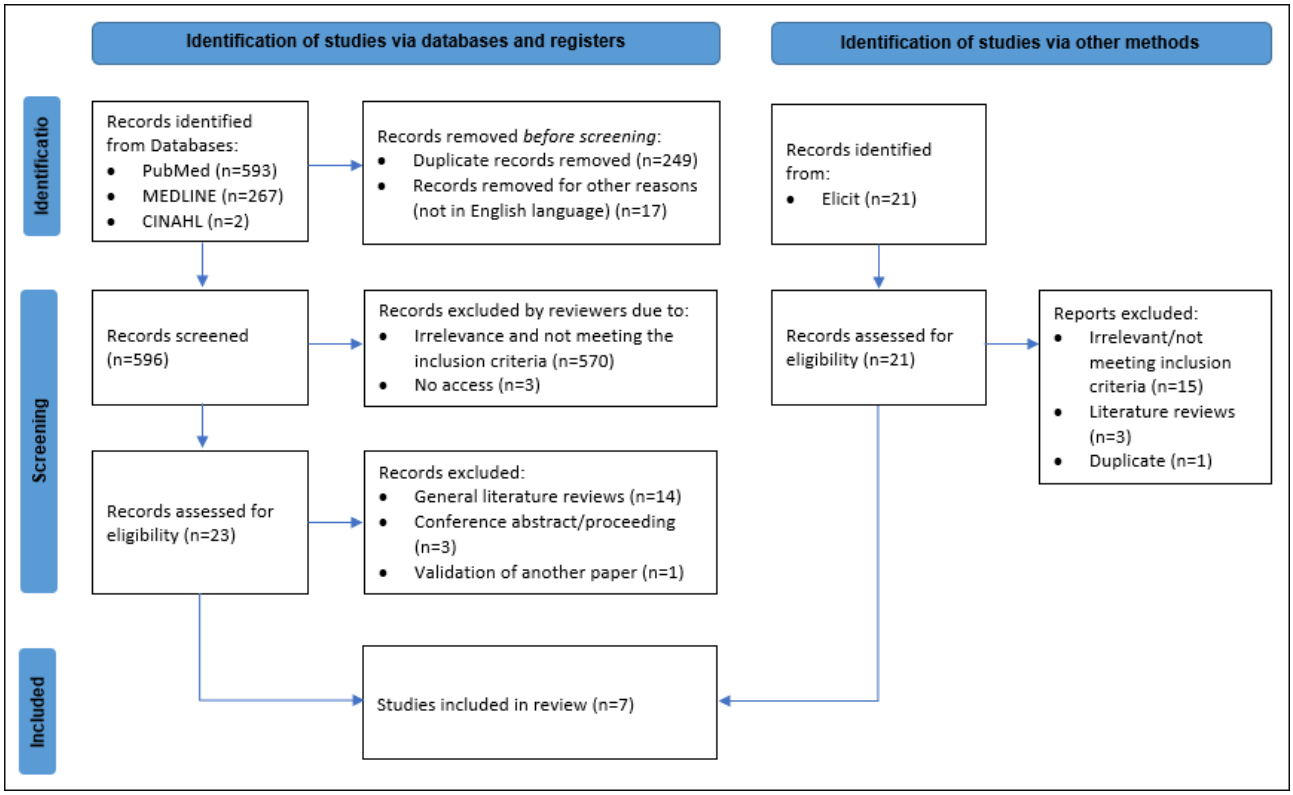
According to the CLAIM checklist, the first, second, and third authors (MR, HM, and AR) extracted data from the included studies. All discrepancies were resolved after a discussion, with HM acting as an arbitrator. Descriptive information about each study was recorded, including publication details (author, year, and country), sample size, cancer type, imaging technique, AI model, outcomes, and limitations. AO performed analysis, and figures were generated using RStudio (version 2023.06.0; Posit PBC).

Results

Study Selection

A total of 883 articles were identified in the database search, comprising 593 articles from PubMed, 267 from MEDLINE, 2 from CINAHL, and 21 from Elicit. After eliminating duplicate titles and articles in non-English languages, 617 articles remained. Then, the title and abstract of the 617 articles were screened independently by the first and second authors (MR and HM), and 44 remained. The authors reviewed full texts and 7 articles met the inclusion criteria (Figure 1).

Figure 1. PRISMA flow diagram of the systematic search of the databases for artificial intelligence in cardio-oncology imaging. PRISMA: Preferred Reporting Items for Reviews and Meta-Analyses.



Quality Assessment of Included Studies

The quality assessment used the 42-item CLAIM. The distribution and percentages of different sections and items of CLAIM compliance are depicted in Figures 2 and 3. These sections include title/abstract, introduction, methods, results, discussion, and other information. Each section is categorized into “No” and “Yes” groups, indicating whether it is reported in the selected articles.

Figure 2. CLAIM sections compliance. CLAIM: Checklist for Artificial Intelligence in Medical Imaging.

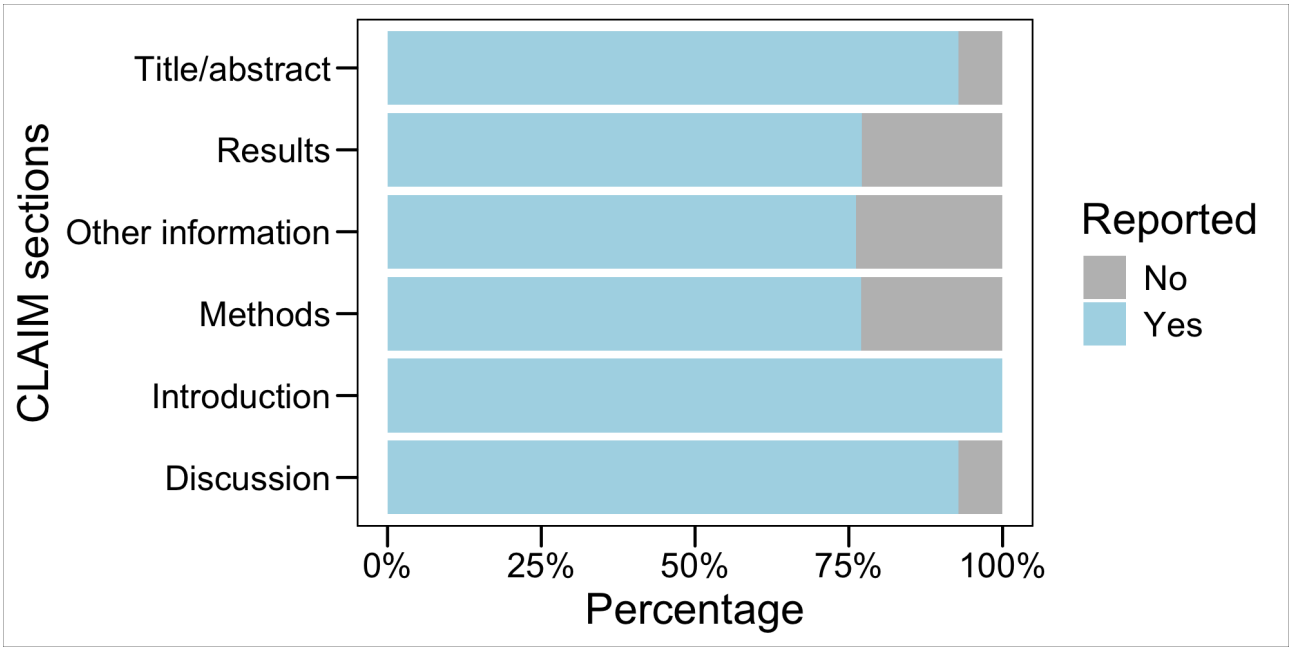


Figure 3. CLAIM items compliance. CLAIM: Checklist for Artificial Intelligence in Medical Imaging.

Based on the data, the title/abstract section was compliant in 93% of the articles (1 article was compliant with the title but not the abstract, which was considered as half compliant). An introduction section was included in all 7 articles, representing 100% compliance. Methods had 77% compliance, results represented 77% compliance, and there was a discussion in 93% of the articles, while other information was 76% compliant. Items 5 and 6 of the checklist—specific to the study methodology and design—were met as follows: 5 studies were conducted prospectively, while the remaining 2 were conducted retrospectively. Moreover, 4 studies were reported as feasibility studies, 2 were exploratory studies, and 1 was a model creation study. Finally, items 10 and 27 of the CLAIM criteria did not apply to the 7 studies.

Characteristics of the Included Studies

In total, 7 studies conducted between 2018 and 2023 were included, with 5 from the United States (Kar et al [29-31], Zhang et al [32], Edalati et al [33]), 1 from China (Shen et al [34]), and 1 from Taiwan (Chang et al [35]). Of these, 6 studies involved patients with breast cancer with additional cancers (eg, sarcoma, lymphoma, leukemia) in some cohorts. Imaging modalities included MRI (4 studies: 3 displacement encoding with stimulated echoes [DENSE] MRI, 1 CMR), echocardiography (n=2), and nongated, noncontrast chest computed tomography (CT) (n=1). AI approaches varied: 4 studies (57%) used convolutional neural networks (CNNs), 1 (14%) used ML, and 6 (86%) implemented image segmentation. Table 1 provides demographic and descriptive data and Table 2 provides details of the AI components of the included studies.

Table . Summary of the studies included in this review: demographic and descriptive data.

Author, year, country	Study design	Sample size	Gender	Age (years)	Treatment	Cancer type	Imaging technique
Shen et al, 2023, China [34]	Retrospective, multicenter	N=1468	Male: n=785, female: n=683	>60: n=617, <60: n=851	Anthracycline	Diffuse large B-cell lymphoma	Nongated and noncontrast chest computed tomography for coronary artery calcium scoring echocardiography for cancer therapy–related cardiac dysfunction and major adverse cardiovascular event

Table . Summary of the studies included in this review: details of the artificial intelligence components in the included studies.

Author, year, country	Artificial intelligence solution	Main outcomes	Limitation
Shen et al, 2023, China [34]	Artificial intelligence coronary artery calcium scoring: • Deep learning algorithm • Image segmentation • Bound the range of the heart area • Detect and segment the calcified lesions in coronary arteries • Calculate coronary artery calcium score	• Cancer therapy–related cardiac dysfunction • Major adverse cardiovascular events	• A larger sample is needed to validate the model's accuracy • The study was limited to Chinese patients
Chang et al, 2022, Taiwan [35]	Machine learning: • Multilayer perceptron • A tree-based estimator was used to compute essential features, and 15 features were included in our multilayer perceptron model based on experts' judgments.	• Cancer therapy–related cardiac dysfunction • Symptomatic heart failure with reduced ejection fraction	• A relatively small number of included patients
Kar et al, 2023, United States [31]	Validated advanced artificial intelligence methodologies (DeepLabV3+) with fully convolutional networks: • Segmenting the DENSE[a] magnitude images for chamber quantification • Segmenting the DENSE phase images for phase-unwrapping and 3D strain analysis	• Global longitudinal strain • Cancer therapy–related cardiac dysfunction • Adverse cardiac events	• Single-center study without external validation • No integration between cancer therapy–related cardiac dysfunction risk analysis by combining circulating troponin levels with global longitudinal strain measurements for a practical bivariable prognostic approach
Kar et al, 2022, United States [30]	An FCN[b]-based solution adapted from the DeepLabV3+ network: • Phase-unwrapping FCN. • Compared with conventional unwrapping techniques, validation via phantom setup with known displacements and 3D strain analysis in healthy patients. • Left ventricular volume was estimated with previously validated DeepLabV3+. • Computation of 3D myocardial strains with the meshfree Radial Point Interpolation Method	Global longitudinal strain	• Comparing the performance of phase unwrapping with DeepLabV3+ to another FCN such as PhaseNet. • The relationship between the wrapped phase and wrap count can be leveraged with more arbitrary shapes rather than round and ellipsoidal shapes only.
Kar et al, 2021, United States [29]	An automated left ventricular chamber quantification tool (deep learning): • DCNN[c] and DeepLabV3+ with ResNet-50 backbone • Some layers of the original ResNet-50 to tailor DCNN for cardiac image segmentation • DENSE-based results were validated by corresponding steady-state free precession data in the same patients who were trained using an identical DeepLabV3+ DCNN. • Chamber quantification and strain analysis were done after the image-based reconstruction of the full 3D left ventricle.	• Left ventricular end diastolic diameter • Left ventricular ejection fraction • Myocardial strains analyzed with the radial point interpolation method	• Backbone networks such as Xception, Inception, ResNet-101, U Net, and others were not tested for left ventricular segmentation.

Author, year, country	Artificial intelligence solution	Main outcomes	Limitation
Zhang et al, 2018, United States [32]	A computer vision pipeline for automated 2D echocardiogram interpretation: • Convolutional neural network for view classification • Image segmentation • Measurements of cardiac structure and function disease detection	• Automated identification of 23 viewpoints segmentation of cardiac chambers across 5 common views • Quantification of structure and function • Detection of hypertrophic cardiomyopathy • Detection of cardiac amyloid • Detection of pulmonary arterial hypertension	• Problems with segmentation • Forced normalization to the lower strain value because of the lack of electrocardiogram information, which can result in biases in measurements, estimate of strain • Lack of distinguished diagnosis of hypertrophy cardiomyopathy, amyloid, or any hypertrophic disease • Lack of comparison of deep learning models to onesbuilt using hand-selected features (left atrial mass or septal thickness)
Edalati et al, 2022, United States [33]	EasyScan: • Otsu method: segment heart region • Trained regression network: distance map calculation	• Scan time difference • Accuracy of cardiac plane prescriptions • Signal to noise ratio • Contrast to noise ratio • Overall image quality (sharpness and magnetic resonance image degradation) • Ejection fraction • Absolute wall thickening	N/A[d]

[a]DENSE: displacement encoding with stimulated echoes.

[b]FCN: fully convolutional network.

[c]DCNN: deep convolutional neural network.

[d]N/A: not applicable.

The included studies revealed significant clinical heterogeneity across the studies. Study designs ranged from retrospective (eg, Shen et al [34]: n=1468; Zhang et al [32]: n=260) to prospective (eg, Chang et al [35]: n=211; Kar et al [29-31]: n=32 - 42), impacting sample size and follow-up duration (eg, 3 years in Chang et al [35] vs 10 years in Zhang et al [32]). Imaging modalities differed in application: echocardiography (Chang et al [35], Zhang et al [32]) assessed LVEF and GLS; DENSE MRI (Kar et al [29-31]) focused on strain analysis; CT (Shen et al [34]) targeted coronary artery calcium scoring (CACS); and CMR (Edalati et al [33]) evaluated image quality and efficiency. AI techniques showed varied sophistication—CNNs (eg, DeepLabV3+ in Kar et al [29-31], CNN pipeline in Zhang et al [32]) and deep learning (Shen et al [34]) enhanced segmentation and classification, while ML with multilayer perceptron (Chang et al [35]) predicted outcomes like heart failure with reduced ejection fraction.

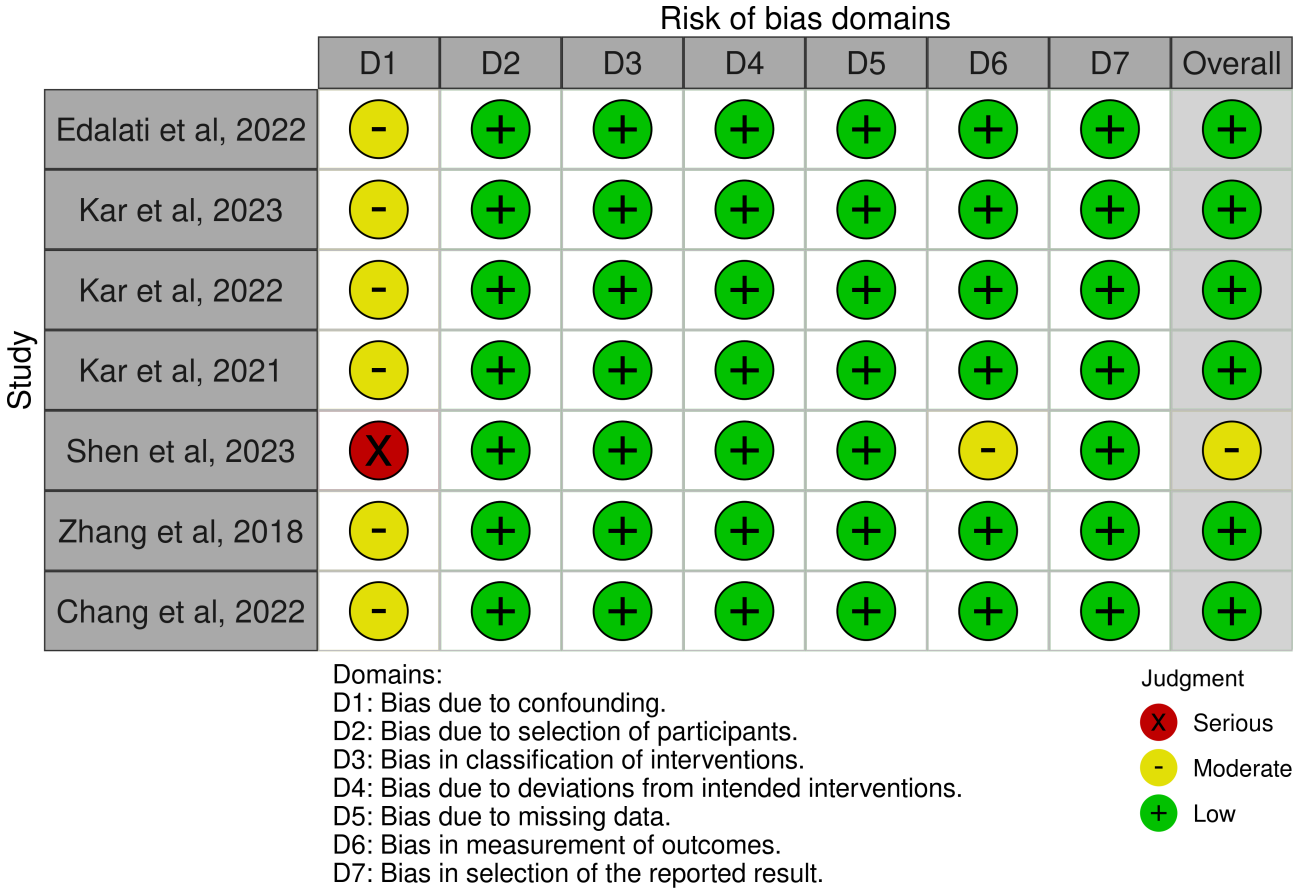
Outcomes centered on CTR-CVT, with cancer therapy–related cardiac dysfunction assessed in 5 studies (Shen et al [34], Chang et al [35], Kar et al [31], Zhang et al [32], Edalati et al [33]), GLS in 3 (Kar et al [29-31]), and LVEF in 3 (Kar et al [29], Edalati et al [33], Zhang et al [32]). Shen et al [34] uniquely linked CACS to major adverse cardiovascular events (MACE). At the same time, Edalati et al [33] emphasized scan time and signal-to-noise ratio. AI improved detection accuracy (eg, automated CACS in Shen et al [34], GLS computation in Kar et al [30,31]) and efficiency (eg, EasyScan in Edalati et al [33]) compared to manual methods. However, direct comparisons across studies were limited by outcome diversity.

Common limitations included small sample sizes (eg, Chang et al [35], Edalati et al [33]), single-center designs (eg, Kar et al [31], Chang et al [35]), and lack of external validation (eg, Kar et al [31]). Geographic restriction (Shen et al [34], Chinese patients) and technical challenges (eg, segmentation issues in Zhang et al [32]) further constrained generalizability.

Risk of Bias Assessment

The risk of bias assessment began with general considerations for all studies, which included establishing a minimal set of confounders identified by the reviewers as likely to introduce bias in the observed associations. Next, each study was described individually within the framework of an ideal target trial. The consensus results from the evaluations of the 7 nonrandomized studies are depicted in the “traffic light” plot shown in Figure 4.

Figure 4. Traffic light plot of risk of bias assessment.



Discussion

Summary of Included Studies

In 2018, Zhang et al [32] published their work on automating echocardiographic cardiac images using 14,035 echocardiograms collected retrospectively spanning 10 years. Their study included 152 patients diagnosed with CTR-CVT and other patients with other heart conditions such as hypertrophic cardiomyopathy (n=260), amyloidosis (n=81), and pulmonary arterial hypertension [32]. Zhang developed a model for view classification in just a few steps. First, they taught the machine to recognize individual echocardiographic views, where models were trained using manual labels assigned to individual images. Then, they used deep learning architecture for view classification, designed to mimic how the visual system works [32]. This process refers to multiple layers of neurons, processing nodes tuned to recognize features within an image. Afterward, they trained a 13-layer CNN and assessed the accuracy using 5-fold cross-validation. Finally, they used t-distributed stochastic neighbor embedding (an algorithm for visualizing high-dimensional data) to cluster the output of the top layer to visualize the output of their view classification network [32]. By training the CNNs, Zhang could perform image segmentation to locate cardiac chambers that derived cardiac structure and function measurements to develop disease classification models [32]. Zhang's approach is intended to enable data mining and knowledge extraction from the enormous number of archived echocardiograms, which will have a significant clinical impact by introducing relatively low-cost quantitative metrics into clinical practice and enabling causal insights that require systematic longitudinal tracking of patients [32]. The study results favored using AI-automated measurements over manual measurements across 11 internal consistency metrics. One of these is the correlation between left atrial and left ventricular volumes. This work is argued to have laid the basis for using automated interpretation to support serial patient tracking. Limitations to the study are the length of the analysis period and room for bias. Moreover, the study did not include the number of males or females involved, which may affect the results.

Using a different imaging modality, Edalati et al [33] developed EasyScan, which is automated cardiac planning, by developing, training, and validating 2 deep neural networks on preacquired cardiac MRI datasets (also known as cardiovascular magnetic resonance). EasyScan is implemented with the CMR scanner for automatic slice planning and shimming. The trial included 10 healthy individuals (5 males and 5 females) and 10 cardio-oncology patients (5 males and 5 females) undergoing 2 identical CMR protocols (manual cardiac planning versus AI-based EasyScan) to assess the time difference and accuracy of the cardiac plane. Moreover, Cine images were obtained for the study participants with standard cardiac volume shim and AI-shim to assess the signal-to-noise ratio, contrast-to-noise ratio, overall IQ (sharpness and magnetic resonance image degradation), LVEF, and absolute wall thickening [33]. EasyScan demonstrated accelerated cardiac exams compared to standard manual cardiac planning and achieved an improved and more uniform B0 magnetic field homogeneity using the

AI-shim technique compared to volume shimming [33]. Eldalati argued that his results suggest many potential positive outcomes of implementing AI, including a more straightforward and faster workflow chain by minimizing technique complexity. However, a significant limitation of this study is the cohort size, as it is considered small compared to other papers in this field.

Kar et al [29-31] used AI, deep learning, segmentation, and fully convolutional networks (FCN) on the DENSE MRI sequence imaging modality in their 3 studies. In the study published in 2021, Kar et al [29] investigated the automation of measuring left-ventricular strain with a quantification tool via segmentation with a supervised deep convolutional neural network (DCNN) before strain analysis with DENSE images [29]. Kar and her team were able to introduce a novel and automated DCNN architecture–based chamber quantification methodology for detecting the extent of left-ventricular myocardium in single-scan DENSE MRI for patients with breast cancer susceptible to cardiotoxicity. Kar et al identified accurate segmentation, chamber quantification, and subsequent strain analysis in the myocardium as the main critical requirements for engineering and developing this solution. After validation, Kar et al emphasized that their DCNN-based segmentation can provide accurate estimates of the left-ventricular chamber quantification required in strain analysis.

Kar et al argued that their model can perform fast and inexpensive automated measurements of cardiac strain as the model can detect altered material properties. However, the thresholds that define cardiac dysfunction caused by cancer therapy are still an area that needs to be further studied [29].

In 2022, Kar and her team continued their work using DENSE in developing another direct MRI-based, FCN-based, deep-learning semantic segmentation approach for computing GLS for patients with breast cancer [30]. This time, they computed myocardial strains directly from the unwrapped phases with the radial point interpolation method. They compared the results of 30 patients with 30 healthy individuals, and the difference in GLS results between the participants demonstrated that the FCN is sensitive to unwrapping left ventricular data in a heterogeneous cohort [30]. Moving forward with their work on GLS computation, Kar and her team investigated early alterations in prognostic factors such as GLS with standard Cox proportional hazards regression for estimating the risk of CTR-CVT incidents in patients with breast cancer undergoing cancer treatment using their previously developed AI-FCN.

Moving forward, Kar and her team carried out a trial using their tool to estimate the risk of developing cardiotoxicity in patients with breast cancer using data from their previous studies [31]. The trial proved their hypothesis that GLS computation can be used for early detection of CTR-CVT as an independent prognostic method of left ventricular dysfunction [31]. The advantage Kar et al had in their studies was that they were able to validate their solution internally within their center. However, their trials did not come without limitations. The solutions were not validated externally with other centers, and there was a greater sample for better accuracy measures [29-31]. In addition, the phase unwrapping approach for GLS measures was not compared to phase wrapping with another FCN, such as PhaseNet, which is considered a significant limitation in their conclusion [30].

Concurrently, in 2022, Chang et al [35] conducted another single-center prospective study and included a larger sample size of 211 patients diagnosed with breast cancer at different stages [35]. Chang et al [35] aimed to establish an AI-based predictive model for CTR-CVT using a cardio-oncology program. They prospectively collected clinical information and echocardiographic images from patients with breast cancer over 1 year. In their study, 2 echo technicians performed an echocardiogram independently to measure the LVEF at baseline, 3 months, 6 months, and 1 year after patients received their treatment. A cardiologist with a validated reliability and reproducibility interpreted the images. Moving forward with the AI solution, data were validated using a data mart for further analysis. Then, we compared the accuracy, precision, sensitivity, specificity, and area under the curve of the random forest, logistic regression, support vector clustering, LightGBM, K-nearest neighbour, and multilayer perceptron models. This process yielded the best accuracy in predicting CTR-CVT [35]. Moreover, the multilayer perceptron showed the best results in predicting heart failure with a reduced ejection fraction as an early sign of myocardial dysfunction after the occurrence of CTR-CVT [35].

Shen et al [34] conducted the most recent study in China in 2023. The study aimed to evaluate whether the pretreatment CACS can stratify the risk of CTR-CVT and MACEs in patients with diffuse large B-cell lymphoma (DLBCL). They retrospectively collected nongated and noncontrast chest CT scans of 1468 patients from 4 health centers in China, then used a deep-learning–based algorithm software (CACScoreDoc) to calculate the automatic CACS. CACScoreDoc automatically calculated the CACS and transmitted the results to the doctors after uploading the CT images to the software. The study showed that automating CACS derived from chest CT scans done before receiving the treatment is potentially helpful in identifying patients at risk of developing CTR-CVT and MACEs in patients with DLBCL receiving anthracycline chemotherapy, which can guide clinicians to implement cardiovascular protective strategies and minimize CTR-CVT in DLBCL patients [34].

Although cardiovascular events that are caused by cancer medications vary in prevalence from one type of cancer and its medication to another, they are still the second most common cause of mortality in cancer survivors. To accurately predict the risk of cardiotoxicity among individuals receiving cancer treatment is still a great challenge in the cardio-oncology field due to high cost, limited access to care, and inadequate compliance with screening protocols. Therefore, noninvasive, low-cost, accessible, innovative approaches to predict high-risk individuals and detect cardiotoxicity early among patients with cancer are critically needed to enable optimal screening, early diagnosis, and timely interventions [36].

Current Versus Future AI Practice

The current tool used to investigate signs of cardiotoxicity is medical imaging, with the 2 most used imaging modalities for this purpose being the echocardiograph and CMR. However, although these modalities have helped the medical field to

achieve significant improvement in prognosis in this area, some drawbacks hold them back from being optimal methods of investigation. The echocardiograph is entirely user-dependent in image reproducibility and results interpretation, leaving ample room for bias and inconsistency. On the other hand, the CMR is not always available due to its high cost. Therefore, more robust, cost-effective methods and imaging protocols are needed in this cardio-oncology area to optimize patient care [36].

Many health care disciplines have moved toward advancing artificial intelligence and developing better ML algorithms as they continue to improve patient care quality significantly. With the availability of enormous volumes of patient data and accessibility of proper hardware, AI and ML can accelerate the pace of change in health care. These technologies can sift through the data and analyze it much faster than humans, leading to increased efficiency. ML is used to predict clinical risk factors by feeding it with an enormous volume of data retrieved from patient medical records or national datasets and registries or detect cardiotoxicity via deep learning of patients' cardiovascular images. In this review, the authors focused their assessment on using AI and ML in cardiovascular imaging to increase the diagnostic strength and accuracy in detecting CTR-CVT.

This review included 7 studies that intended to assess the implementation of AI in cardiovascular imaging among patients with cancer. These studies examine the use of AI on MRI, echocardiogram, and CT imaging modalities with different AI technologies such as ML, CNNs, and image segmentation.

The future of imaging AI in cardio-oncology holds substantial promise. This convergence of cutting-edge technologies, encompassing molecular imaging, wearable devices, multiomics data, and predictive modeling, is poised to transform cardiotoxicity management in patients with cancer. These advancements enable early detection and personalized risk assessment and promise targeted interventions, ultimately enhancing patient outcomes and survivorship. This future trajectory in imaging AI aligns with the significant advancements witnessed from ML to deep learning in AI, revolutionizing robotics and autonomous systems' capabilities and enabling them to perceive, learn, and adapt with increased efficiency and accuracy in complex environments. These models, leveraging AI algorithms trained on diverse patient cohorts and multimodal imaging data, could assist clinicians in formulating proactive strategies for long-term cardiac care in cancer survivors, thereby enhancing overall cardiovascular health and quality of life.

Challenges of AI in Health Care

As promising as AI and ML sound to the advancement of imaging in health care and the prediction of the risk of developing cardiotoxicity among patients receiving cancer treatment specifically, there are methodological and practical limitations preventing these technologies from reaching their full potential. The evidence base needs more prospective validation of the technology and current workflow, including evidence on the length of analysis required for validation and the interoperator and interobserver variability to eliminate manufactured variations that limit reproducibility [23]. Moreover, their usefulness in health care depends on incorporating the AI tool in clinical decision-making as part of the clinical practice routine, and that concern needs further investigation [37]. Another inadequacy of AI applications in health care is the systematic biases affecting patient demographics, such as gender imbalance [38]. It is worth mentioning that AI requires training on all kinds of populations with different demographics to guarantee equal performance from one population to another. It is recommended that multiple massive datasets be combined either retrospectively or prospectively to improve the generalizability of the ML process and the training of AI models, which was not achieved by all the included studies in this review [39].

Review Limitations

The first limitation we had while conducting this review was the limited published evidence in the literature about the application of imaging AI in cardio-oncology to predict CTR-CVT. Therefore, we could not specify the cancer type or treatment under investigation. Second, even though there is significant literature on AI and imaging with different modalities, when we narrowed it down to our criteria, which was patients with cancer who are undergoing cardiotoxicity assessment, the literature search resulted in 3 different imaging modalities rather than studying AI with one specific imaging technique at a time. This resulted in different outcomes that prevented us from proceeding with a meta-analysis.

The use of AI in the medical field is a relatively new research area. This review could be used to stimulate further research. It can be used as groundwork for lab work to improve AI models or inspire new ones. In addition, this review highlights the positive outcomes of different studies in this area and their limitations. It may encourage experts to improve the AI and ML models and eventually implement them into medical imaging, possibly leading to the advancement of the field. However, given this field's rapidly evolving nature, additional studies may have been published since the initial search process for this paper.

Conclusions

In conclusion, this systematic review highlights the promising potential of AI in enhancing cardio-oncology imaging for predicting cardiotoxicity in patients with cancer. Through analyzing 7 studies conducted between 2018 and 2023, it became evident that AI methodologies, including ML and deep learning, can significantly improve the accuracy and efficiency of cardiotoxicity assessments across various imaging modalities, such as echocardiography and CMR.

The review underscores that AI-driven tools have demonstrated improved clinical outcomes by enabling earlier detection of cardiovascular complications associated with cancer therapies. However, while the findings are encouraging, the limited number of studies and their varying methodologies indicate a need for further research. This includes conducting larger, multicenter trials to validate AI applications in diverse patient populations and refine these technologies for routine clinical use.

In light of these insights, collaboration among data scientists, health care professionals, and researchers is essential to advancing AI's integration in cardio-oncology. This collaboration will pave the way for personalized medicine approaches, ultimately enhancing patient care and improving the quality of life for cancer survivors at risk of cardiotoxicity.

Acknowledgments

The authors would like to thank Ms Amnah Hazimi, a fifth-year medical student, for her time and effort in reviewing the articles for the risk of bias assessment. No funding was acquired for this review.

Data Availability

Data are available upon request.

Authors' Contributions

HM was responsible for the conception of the work, developing the search strategy, conducting a systematic database search, writing the manuscript, and supervising all coauthors throughout the project. MR contributed by performing a literature review, conducting a parallel systematic database search, writing sections of the manuscript, and conducting the CLAIM assessment. AR also engaged in the literature review and participated in the CLAIM assessment. As the toxicologist, RE critically reviewed the materials and contributed to manuscript revisions and edits. TS focused on reviewing material related to artificial intelligence and medicine, in addition to contributing to manuscript review and edits. AO, the biostatistician, conducted the analysis for the CLAIM assessment and created the traffic plot for risk of bias assessment. Medical students MO and RAH assisted with the literature review. Finally, DJ supported the development of the search strategy, contributed to the systematic database search, and contributed to reviewing and editing the manuscript. The only artificial intelligence tool used in writing this paper was Grammarly for proper language editing.

Abstract

Background: Cancer imposes significant physical and emotional distress not only on patients, but also on their caregivers. In recent years, there has been a growing focus on the mental and physical well-being of caregivers. Among various psychological interventions, cognitive behavioral therapy (CBT) is widely recognized as one of the most effective approaches. However, traditional CBT is often limited by time and geographical constraints, resulting in delayed or inefficient support for caregivers. Internet-based cognitive behavioral therapy (ICBT) presents a valuable alternative for alleviating the caregiving burden and the negative emotions experienced by caregivers.

Objectives: This study aimed to provide a scoping review of ICBT interventions for caregivers of patients with cancer, examining intervention content, outcome measures, and effectiveness and to offer insights and references for the development and clinical applications of ICBT programs tailored to caregivers of patients with cancer in China.

Methods: Relevant literature was systematically searched in PubMed, Web of Science, Cochrane Library, CINAHL, Embase, China National Knowledge Infrastructure (CNKI), Wanfang Data, and VIP Chinese Journal Database. The search timeframe was from database inception to June 6, 2024. Inclusion criteria encompassed intervention studies that implemented cognitive behavioral therapy for caregivers of patients with cancer via the internet, WeChat (Tencent), or mobile electronic devices. This category includes both randomized and nonrandomized controlled trials.

Results: A total of 12 studies met the criteria and were included in the review. The intervention content included the following components: treatment initiation and brief introduction (5/12, 41%), cognitive education and restructuring (7/12, 58%), emotional expression and coping (6/12, 50%), cognitive restructuring and reinforcement (4/12, 33%), behavioral training and activation (9/12, 75%), problem-solving techniques (4/12, 33%), communication (5/12, 41%), and completion of treatment with follow-up consolidation (3/12, 25%). The intervention duration typically ranged from 6 to 8 weeks. Outcome indicators encompassed feasibility and acceptability, anxiety, depression, caregiver burden, and quality of life. ICBT demonstrated positive effects for caregivers of patients with cancer. Most intervention programs were feasible and acceptable, with 2 out of 5 feasibility studies reporting recruitment rates below 50%. Attrition rates across studies ranged from 3% to 16%, and caregivers expressed satisfaction with the information, quality, and skills provided. ICBT exhibits a moderate effect in diminishing negative emotions among caregivers and alleviating caregiver stress. However, its impact on improving quality of life is not statistically significant, underscoring the need for long-term follow-up.

Conclusions: The implementation of ICBT for caregivers of patients with cancer has demonstrated beneficial outcomes, attributed to its practicality and flexibility, which contribute to its greater acceptance among caregivers. Nevertheless, there is significant heterogeneity in intervention format, duration, and outcome indicators. It is necessary to develop optimal intervention strategies and secure online platforms based on the cultural background in China to improve the quality of life of caregivers.

KEYWORDS

cancer; oncology; caregivers; informal caregivers; internet; scoping review; cognitive behavioral therapy

Introduction

The incidence and mortality rates of cancer are rapidly increasing globally. According to the International Agency for Research on Cancer, there were 19.29 million new cancer cases and 9.96 million cancer deaths worldwide in 2020, and the rise in cancer incidence and mortality rates has resulted in a significant disease burden on people [1]. The diagnosis and long-term treatment of cancer not only cause adversity for patients but also impose psychological stress and burdens on caregivers [2]. Caregivers of patients with cancer refer to informal caregivers, including family members, partners, or friends. They provide unpaid social, emotional, and economic support to a family member with cancer requiring care and are involved throughout the patient's symptom management and nursing [3,4]. Caregivers attend to the daily needs of patients and fulfill family responsibilities; they also serve as the patient's primary emotional support. Due to complex treatment environments, a lack of disease-related knowledge, and significant economic burdens, caregivers often experience negative emotions such as anxiety and depression [5]. Zhou et al [6] found that 60.7% of caregivers of patients with cancer experience sleep disturbances. Yang et al [7] conducted a survey involving 116 caregivers of terminally ill patients with cancer receiving home care, revealing that 83.62% of the caregivers reported experiencing moderate to severe fatigue, primarily characterized by physical fatigue. Geng et al [8] reported that the prevalence of anxiety and depression among caregivers of patients with cancer was 46.55% and 42.30%, respectively, with 62% of caregivers bearing a heavy burden that negatively affected their daily lives. Therefore, attention should be given to the physical and mental health of caregivers, along with the provision of appropriate supportive care.

Current interventions for caregivers of patients with cancer include psychosocial support, education, and informational support [9]. Cognitive behavioral therapy (CBT) has received considerable attention owing to its robust theoretical foundation, brief treatment duration, and well-defined structural approach. However, traditional CBT is often influenced by economics, time, and spatial factors, preventing some caregivers from accessing effective help and support [10]. In recent years, with the rise of the "Internet+Healthcare" service model, internet-based cognitive behavioral therapy (ICBT) has emerged. ICBT is an internet-based treatment approach that uses tools such as computers and mobile devices to deliver the core content and skills of CBT through text, video, images, and audio [11].

ICBT addresses the limitations of CBT in its application. Some caregivers concentrate on caregiving behaviors, frequently suppressing their own emotions, which may lead to distress stemming from a deficiency in caregiving skills. ICBT provides caregivers with a discreet online platform that allows them to access relevant information at any time through simple and user-friendly self-service methods, facilitating timely communication with health care professionals and enhancing their cognitive abilities. In addition, techniques such as emotional guidance and relaxation training are used to alleviate caregiver stress and improve their quality of life (QoL) [12,13]. Existing studies have shown that ICBT can mitigate the anticipatory grief experienced by caregivers of patients with cancer, decrease caregiving burden, and improve their self-efficacy [14].

Currently, research on the application of ICBT for caregivers of patients with cancer is steadily growing. However, there is significant heterogeneity in the forms of online interventions, intervention content, and outcome indicators. To gain a comprehensive understanding of the current research status of ICBT, this study uses a scoping review to systematically analyze pertinent studies from both domestic and international contexts. Our goal is to provide references to promote the use and dissemination of ICBT among caregivers of patients with cancer in China.

Methods

Study Design and Framework

This scoping review adhered to the methodological framework developed by the Joanna Briggs Institute (JBI; 2019) [15]. The reporting follows the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines (Checklist 1).

Research Questions

The review addressed three key questions: (1) what are the intervention components of ICBT for caregivers of patients with cancer?; (2) what are the intervention forms, duration, and evaluation time points for ICBT?; and (3) what are the outcome indicators and effects of ICBT interventions?

Search Strategy

A systematic search was conducted across 9 databases, including CNKI, Wanfang Database, China Biomedical Literature Database, VIP, PubMed, Web of Science, Embase, CINAHL, and Cochrane Library. The search timeframe extended from the establishment of the databases to June 6, 2024. A combination of subject headings and free-text terms was used. The search strategy was formulated with the guidance of a librarian. The English search terms were "neoplas*, carcinoma*, tumor, oncology, cancer*;" "Cognitive Behavio*, Behavio* Therap*, Cognitive Therap*, ICBT, cognitive behavioural therapy, CCBT;" "online, network, Internet, smartphone, telephone, computer;" and "caregiver*, spouse, family, informal caregiver, couple*." The search strategy for each database was documented in the Multimedia Appendix 1.

Study Selection

The eligibility criteria is presented in Textbox 1.

Textbox 1. Inclusion and exclusion criteria for article selection.

Inclusion criteria:

- Study participants: caregivers of confirmed (by pathology or imaging) patients with cancer, including offspring, parents, and spouses, aged 18 years or older.
- The intervention emphasizes the implementation of cognitive behavioral therapy via the internet, WeChat, mobile devices, or other applications.
- Literature type: original research, including randomized controlled trials or quasiexperimental studies.
- Published literature in both Chinese and English.

Exclusion criteria:

- Literature for which the full text could not be obtained.
- Duplicated publications.
- Conference abstracts.
- Research protocols, reviews, and case studies.

Data Extraction and Quality Assessment

The literature search results were imported into EndNote X9 for duplicate removal. Two independent reviewers (CTS) and (XML) screened titles, abstracts, and full texts against the predefined inclusion and exclusion criteria. Discrepancies were resolved through discussion with a third researcher to reach consensus. One reviewer (CTS) extracted study data using a standardized Microsoft Excel form, capturing authors, publication year, country, design, population characteristics, sample size, interventions, and outcomes, with a second reviewer (XML) independently verifying the accuracy and completeness of all extracted data. For included randomized controlled trials, we conducted quality assessments using the Cochrane Risk of Bias Tool (version 5.1.0) [16], categorizing studies as grade A (low risk), B (moderate risk), or C (high risk), with any discrepancies resolved through consultation with a third researcher to reach consensus.

Results

Study Selection and Characteristics

The systematic search identified 1005 records, with 12 studies meeting inclusion criteria after screening (Figure 1) [14,16-26]. The studies (2013 - 2023) represented diverse geographic regions, such as the United States (4/12, 33%), Australia (3/12, 25%), China (3/12, 25%), Lithuania (1/12, 8%), and Germany (1/12, 8%). Study designs included randomized controlled trials (9/12, 75%), quasi-experimental (1/12, 8%), mixed-methods (1/12, 8%), and feasibility studies (1/12, 8%). Quality assessment of randomized controlled trials (RCTs) indicated moderate methodological rigor (B-level). Table 1 details the basic characteristics of the included studies.

Figure 1. Literature screening process diagram.

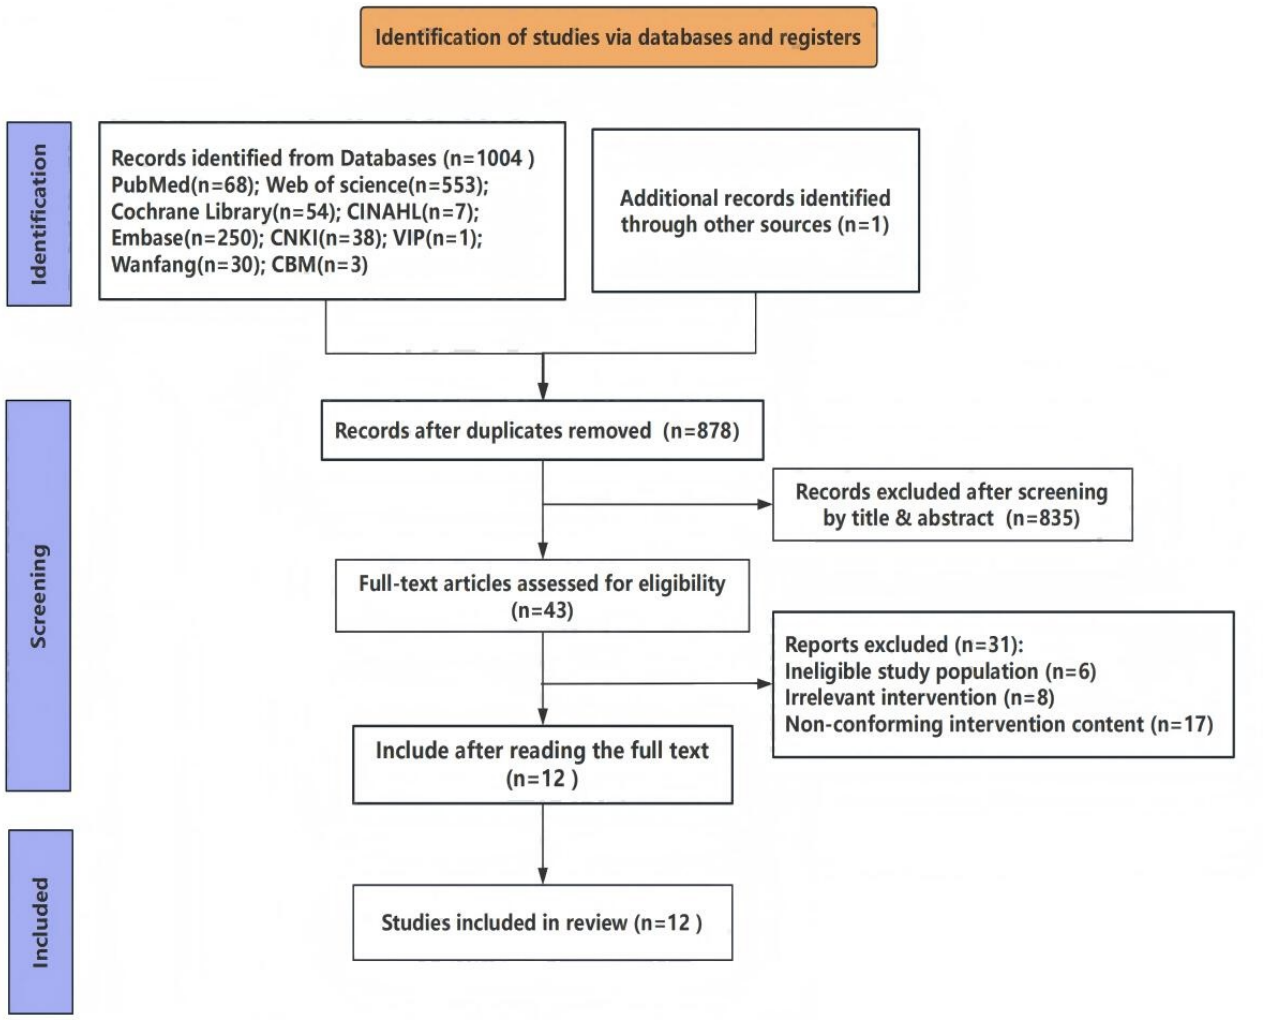

Table . Basic characteristics of included literature.

Reference	Study type	Interference objects	Sample (example, T/C)	Intervention and groups	Outcome indicators; evaluation time	Results
Scott et al [17]	Feasibility of the intervention	Carers of adult patients with cancer receiving curative treatment	13	• Therapist-administered 6-week ICBT[a] program via website and email. • CCO[b] components included: starting treatment; coping with physical symptoms and side effects; coping with emotional distress; body image, identity and sexuality; family and friends; completing treatment.	Primary outcomes: feasibility and acceptability; secondary outcomes: negative affect, distress, QoL; 2-time point evaluation (pre-post)	Engagement was modest; CCO resulted in large overall reductions in negative affect (Cohen *d*=0.88) and small reductions in cancer-specific distress (Cohen *d*=0.37), small to moderate increases in QoL.
Chambers et al [18]	RCT[d]	Patients with cancer and caregivers	345/345	• A 5-session psychologist cognitive-behavioral intervention delivered by telephone (psychoeducation; coping and stress management skills; problem solving; cognitive therapy; enhancing support networks). • A single session of nurse-led self-management intervention.	Primary outcomes: psychological; cancer-specific distress and posttraumatic growth; 4-time point evaluation (pre-3-6-12 months).	The psychologist-led intervention demonstrated reductions both psychological distress (Cohen *d*=0.2, *P*<.001) and cancer-specific distress (Cohen *d*=0.77, *P*<.001), while also enhancing positive adjustment (Cohen *d*=0.82, *P*<.001) from baseline to 12 months.

Reference	Study type	Interference objects	Sample (example, T/C)	Intervention and groups	Outcome indicators; evaluation time	Results
Mosher et al [19]	RCT	Patients with lung cancer and their family caregivers	51 pairs/55 pairs	• Psychologists and clinical social workers delivered the TSM[e] intervention to participants via telephone, with 4 weekly sessions. • TSM components included: relaxation; cognitive restructuring; problem-solving; self-soothing/emotion-focused approach; pleasant activities; activity pacing; communication; plan for continued skills practice. • Education or support	Primary outcomes: depression and anxiety; secondary outcomes: self-efficacy and caregiver burden; 3-time point evaluation (baseline-2 - 6 weeks postintervention).	Small effects in favor of TSM were found regarding caregiver self-efficacy for managing their own emotions and perceived social constraints from the patient.
Kubo et al [20]	2-arm RCT	Patients undergoing cancer chemotherapy and caregivers	Patients: 54/43; caregivers: 17/14	• Psychologists, psychosocial workers, and nurses implemented the 8-week Headspace program through website or mobile apps. • Headspace: encourage participants to first complete a 30-day mindfulness meditation foundation course; they can also choose 10 to 30 days of related symptom or meditation courses. • UC[f]	Primary outcomes: mindfulness and quality of life; secondary outcomes: distress; posttraumatic growth; fatigue; sleep quality; 2-time point evaluation (pre-post).	Headspace significantly improved mindfulness (P=.03) with borderline significant effects on PTGI[g] new possibilities (P=.06) versus controls
Biliunaite et al [21]	2-arm RCT	Caregivers of individuals with dementia, cancer, or other illnesses	31/32			

Reference	Study type	Interference objects	Sample (example, T/C)	Intervention and groups	Outcome indicators; evaluation time	Results
				• Therapists implemented an 8-week ICBT program through the Slaugau Artima website. • ICBT: introduction; thoughts; stress and relaxation; problem solving; communication; anxiety; behavioral activation; and maintenance. • UC	Primary outcome: CBI[h]; secondary outcomes: depression, anxiety, stress, and QoL; 2-time point evaluation (pre-post).	ICBT showed large effects on burden reduction (P<.001) and stress (P<.001), moderate effects on anxiety (P=.004) and depression (P=.01), and significant QoL enhancement (P=.001).
Luo et al [22]	RCT	Parents of children diagnosed with cancer	52/51	• Psychologists, doctors, and nurses implemented the 8-week a mobile device–based resilience training program. • Resilience training program: understanding the purpose of intervention, relaxation technique training, problem-solving skills, cognitive restructuring, promoting good relationships, and cultivating positive performance and beliefs, etc. • UC	Primary outcome: resilience; secondary outcomes: depressive symptoms and QoL; 3-time point evaluation (pretreatment, 2 and 6 months after the intervention began).	At the 6-month follow-up, the intervention demonstrated statistically significant improvements in resilience (P=.01) and depressive symptoms (P=.04), but failed to show significant QoL enhancement (P=.38), although the experimental group showed numerically higher QoL scores than controls.
Wakefield et al [23]	3-arm RCT	Parents or caregivers of children	19/18/19		Feasibility; acceptability; safety; efficacy (QoL; psychological outcomes); 4-time point evaluation (baseline, 2‐4 weeks post-intervention; 2‐4 weeks post-booster and 6 months postintervention).	Most Cascade parents were satisfied and reported experiencing benefits from the program. However, Cascade did not improve their main outcomes, including parents' quality of life, depression and anxiety.

Reference	Study type	Interference objects	Sample (example, T/C)	Intervention and groups	Outcome indicators; evaluation time	Results
				• Psychologist-delivered online intervention. • Cascade: introduction and behavioral activation; identifying and challenging unhelpful thoughts; mindfulness and disengagement; skills for fostering relationships and living a rich life after cancer; booster session. • Peer-support or waitlist.		
Trevino et al [24]	RCT	Older adults with cancer and their caregivers	14 pairs/14 pairs	• Social workers provide 7-session over the telephone. • MAC[i]: this includes providing information on treatment methods for the elderly, addressing the widespread shame associated with psychological services among the elderly, and integrating strategies to address cancer-specific stressors during the intervention process. • UC	Feasibility, acceptability, participant adherence, anxiety, depression, and QoL; 2-time point evaluation (pre-post).	85.7% participants completed all 7 sessions, over 80% of caregivers rated MAC as "moderately" to "very" helpful. MAC dyads experienced a greater reduction in anxiety than dyads in usual care with smaller changes in depression and quality of life.
Kaiser et al [25]	RCT	Caregivers of cancer bereavement	44/43			

Reference	Study type	Interference objects	Sample (example, T/C)	Intervention and groups	Outcome indicators; evaluation time	Results
				• Caregivers completed 2 self-scheduled 45-minute writing sessions weekly via a website. • ICBT: 10 structured writing tasks, 3 modules (self-confrontation; cognitive reappraisal; and social sharing). • Waitlist	Primary outcome: prolonged grief; secondary outcomes: depression, anxiety, posttraumatic stress, posttraumatic growth, somatization, sleep quality, and mental and physical health; 5-time point evaluation (baseline, posttreatment, and 3、6-12 months).	ICBT reduced symptoms of prolonged grief (Cohen *d*=0.80; *P*<.001) to a clinically significant extent. It had favorable effects on depression, anxiety, posttraumatic stress, posttraumatic growth, and overall mental health but not on somatization, sleep quality, or physical health.
Yang et al [26]	RCT	Patients undergoing cervical cancer chemotherapy and their spouses	53 pairs/53 pairs	• Psychological counselors and nurses delivered an 8-week ICBT program through WeChat (Tencent) public platform and offline group sessions. • ICBT: psychological diagnosis; cognitive education; behavior training; emotional expression; consolidate follow-up. • UC	The patients' distress and QoL; 2-time point evaluation (pre-1 month after intervention).	ICBT significantly reduced the detection rate of psychological distress (*P*<.05) and improved quality of life (*P*<.01) among patients.
Carr et al [27]	Mixed research	Caregivers of a phase 1 oncology trial patient	23 quantitative cases; 5 qualitative cases		Primary outcome: acceptability and feasibility; secondary outcomes: caregiver distress; caregiver burden; PAC[k]; caregiver grief; anxiety and depression; 2-time point evaluation (pre-post).	Although the P1CaLL[l] pilot achieved limited recruitment feasibility (45.3% enrollment), its high acceptability (84% completion) and preliminary efficacy signals across multiple caregiver outcomes (stress reduction, isolation mitigation, and self-control improvement) support further development.

Reference	Study type	Interference objects	Sample (example, T/C)	Intervention and groups	Outcome indicators; evaluation time	Results
				• Clinician-administered telephone intervention comprised 4 CBMS[j]+4 randomized CBT sessions across 9 weeks. • CBSM: mind-body connection; coping skills; communication; and social support; metta meditation. • CBT: intro to CBT-tracking automatic thoughts; identifying distorted thoughts; challenging distorted thoughts; core beliefs or relapse prevention		
Wang [14]	Quasiexperimental study	Caregivers of patients with cancer	38/38	• Physicians and nurses administered ICBT through a website and WeChat groups, including twice-weekly digital content and monthly peer support video sessions. • ICBT: basic knowledge; symptom education; common knowledge of home care; relaxation training; social support • UC	Care burden, anticipatory grief, and self-efficacy; 3-time point evaluation (pretreatment, posttreatment 6-12 weeks).	ICBT demonstrated significant efficacy in reducing caregivers' anticipatory grief levels (P<.001), alleviating caregiving burden (P<.001), and enhancing self-efficacy (P<.001).

[a]ICBT: internet-based cognitive behavioral therapy.

[b]CCO: cancer coping online.

[c]QoL: quality of life.

[d]RCT: randomized controlled trial.

[e]TSM: telephone-based symptom management.

[f]UC: usual care.

[g]PTGI: posttraumatic growth inventory.

[h]CBI: caregiver burden inventory.

[i]MAC: managing anxiety from cancer.

[j]CBSM: cognitive behavioral stress-management.

[k]PAC: positive aspects of caregiving.

[l]P1CaLL: Phase 1 Caregiver LifeLine.

Intervention Content

The included studies incorporated the following key components in their ICBT interventions for caregivers (Textbox 2).

Textbox 2. Key components of internet-based cognitive behavioral therapy interventions for caregivers.

- Treatment introduction: a total of 5 studies [14,17,21,23,26] initiated interventions with an introductory phase, wherein researchers presented the medical center and care team to establish caregiver-provider collaboration. Before intervention delivery, caregivers underwent baseline assessments, received psychoeducation on cognitive-behavioral therapy principles, and were guided on study protocols to optimize adherence. In addition, they were encouraged to set personalized goals to enhance engagement and motivation.
- Cognitive education and restructuring: a total of 7 studies [14,18,19,22,24-26] incorporated structured modules to help caregivers reframe maladaptive cognitions. Through perspective-taking exercises and peer-sharing sessions, participants were educated on disease-related knowledge to foster accurate perceptions of cancer. This component also emphasized symptom recognition training to improve timely and appropriate caregiving responses.
- Emotional expression and coping: a total of 6 studies [17-19,21,26,27] assessed caregivers' emotional states using standardized questionnaires or individual interviews, followed by discussions on psychosocial impacts. To mitigate distress, interventions introduced techniques such as cognitive restructuring diaries, mindfulness meditation, and progressive relaxation training.
- Cognitive restructuring and reinforcement: a total of 4 studies [22,23,25,27] focused on identifying and modifying maladaptive thought patterns. Caregivers were taught to recognize automatic thoughts and common cognitive distortions. Through guided exercises, they practiced challenging unhelpful beliefs to cultivate healthier cognitive frameworks.
- Behavioral training and activation: the most frequently implemented component (9 studies [14,17,19-24,26]) involved skill-building through evidence-based techniques such as progressive muscle relaxation, diaphragmatic breathing, music therapy, and guided imagery. Caregivers selected preferred modalities based on individual capacity and preferences. Protocols also emphasized self-care strategies, including scheduled personal time and reward systems.
- Problem-solving techniques: a total of 4 studies [18,19,21,22] trained caregivers in structured problem-solving. Participants learned to deconstruct challenges, identify barriers, evaluate coping strategies, and implement solutions. Postintervention, they monitored outcomes and adjusted approaches through reflective practice to enhance long-term adaptive skills.
- Communication: a total of 5 studies [17,19,21,23,27] addressed communication dynamics, exploring how caregiving roles influenced interpersonal interactions. Caregivers practiced maintaining or improving intimacy through verbal and nonverbal techniques, sustaining social connections, and fostering supportive relationships.
- Completion of treatment and consolidation follow-up: a total of 3 studies [17,21,26] concluded with a review phase, summarizing key concepts and reinforcing long-term skill retention. Caregivers were guided in self-directed practice, goal reflection, and future planning to sustain intervention benefits long-term skill retention. Caregivers were guided in self-directed practice, goal reflection, and future planning to sustain intervention benefits.

The included studies typically incorporated 3‐5 core intervention modules. Following each intervention session, participants were required to complete structured homework assignments, which included documenting caregiving-related emotional experiences, evaluating automatic thoughts using thought records, emotional expression through writing exercises [21], completion of structured writing tasks [25], and home practice of acquired skills [19,20].

The reviewed literature revealed 2 distinct ICBT delivery models for caregivers. Seven studies [14,17,21-23,25,27] implemented caregiver-specific interventions focusing on cognitive restructuring, emotional regulation training, and evidence-based relaxation techniques to enhance multidimensional wellbeing. Alternatively, 5 studies [18-20,24,26] used dyadic approaches that simultaneously engaged both patients and caregivers through adapted protocols delivered in either parallel or joint therapeutic sessions. Both models demonstrated effectiveness in addressing the psychological needs of caregivers while accounting for different caregiving contexts.

Intervention Elements

The ICBT interventions examined in this study comprised several key components, such as delivery modality, provider qualifications, intervention duration, and evaluation timelines. The primary delivery modalities included web-based platforms (4/7, 57%) studies with real-time psychologist support or email feedback [14,17,20-22,25,26], telephone sessions (45‐60 min) [18,19,24,27], and video conferencing [23]. Interventions were predominantly delivered by psychotherapists, with 1 study [22] using a multidisciplinary team (psychologists, physicians, and nurses). Intervention duration varied (most commonly 6‐8 weeks [17,20-22,26]) depending on content and format. Telephone sessions typically lasted 45‐60 minutes [19,24], though some flexible protocols permitted completion within 1 week [14,17,21,26]. Effectiveness was evaluated at 3 time

points: (1) baseline (preintervention, confirming group comparability [*P*>.05]), (2) postintervention, and (3) follow-up (1‐12 months) in 4 studies [18,22,23,25]. Qualitative components (semistructured interviews) were included in 2 studies [17,27] to assess participant experiences.

Outcome Indicators and Effectiveness Evaluation of Interventions

The ICBT interventions evaluated 7 primary outcome measures: feasibility (n=4 studies [17,23,24,27]), acceptability (n=4 studies [17,23,24,27]), QoL (n=8 studies [17,20-26]), caregiver burden (n=4 studies [14,19,21,27]), psychological distress (n=11 studies [14,17-25,27]), posttraumatic growth (n=3 studies [18,20,25]), and self-efficacy (n=3 studies [14,19,23]).

Feasibility

Feasibility was assessed based on recruitment, retention, and completion rates. In total, 2 studies [17,27] reported recruitment rates below 50%, primarily attributed to participants' aversion to online support, lack of interest, demanding work schedules, and substantial caregiving commitments. Although most participants completed all intervention modules, attrition occurred due to heightened psychological distress, time constraints, or deterioration of the care recipient's health [20]. Attrition rates generally ranged from 3% to 16%, with one exception reaching 31% [17]. Qualitative analysis suggests this discontinuation pattern may result from both the lack of personalized engagement in digital interventions and deliberate withdrawal after achieving therapeutic objectives.

Acceptability

Acceptability was assessed through participant-reported satisfaction with both intervention content and engagement modalities. Many caregivers expressed positive feedback regarding the intervention, stating that "the online intervention is convenient, time-saving, and practical," "they were satisfied with the information and quality provided," "the skills learned were relevant to cancer treatment," and "the intervention courses helped alleviate stress." However, 1 study [17] indicated that 33% of participants felt the intervention did not adequately address the needs of caregivers, while another study revealed disagreement about whether patients and caregivers should be treated together. Specifically, 45% of caregivers preferred individual interventions, 36.4% favored some combined treatment, and 18.2% preferred fully integrated interventions.

Psychological Outcomes of Caregiver Intervention

Cognitive-behavioral interventions demonstrated measurable benefits for caregiver mental health. The stress management program by Carr et al [27] significantly improved caregivers' stress coping abilities (effect size *r*=0.39), while 2 other trials [14,21] reported statistically significant reductions in caregiver burden (*P*<.05). Caregivers often experience negative emotions such as anxiety, depression, or sadness due to prolonged caregiving and stress [28]. ICBT interventions showed moderate efficacy in alleviating anxiety and depression [17,21], with the structured writing intervention ("Online-Trauertherapie") by Kaiser et al [25] producing effect sizes ranging from 0.29 to 0.84 across multiple psychological domains. Notably, Trevino et al [24] found patient-caregiver anxiety changes were positively correlated, though other psychological outcomes showed nonsignificant associations. Some studies [23,29] reported limited effects on anxiety or depression, potentially due to low baseline distress levels or requiring specific intervention components (eg, guided imagery) to achieve psychological benefits.

QoL

The included studies reported mixed effects on caregiver's QoL. A total of 4 trials [17,20,21,25] demonstrated statistically significant QoL improvements following intervention. Notably, one spouse-focused intervention [26] showed significant patient QoL benefits, suggesting potential secondary effects. However, 3 studies [22-24] found no significant QoL changes for caregivers, potentially due to shorter intervention durations or differing outcome measures.

Discussion

Principal Findings and Comparison With Previous Work

This study examines the existing research on ICBT interventions for caregivers of patients with cancer. A systematic review of 12 eligible studies revealed that ICBT is a feasible and acceptable approach for this population. The findings suggest that ICBT may alleviate anxiety and depressive symptoms among caregivers, with some studies additionally reporting reduced caregiver burden and enhanced self-efficacy.

These findings are consistent with previous studies, demonstrating the acceptability and feasibility of ICBT when applied to caregivers. For instance, Meichsner et al [30] observed high satisfaction and enhanced well-being among dementia caregivers following ICBT. Similarly, Tur et al [31] documented strong participant satisfaction in an ICBT program for prolonged grief disorder, with 75% of participants achieving clinically significant reductions in depressive symptoms and 50% demonstrating meaningful improvements in grief-related cognitions. Further corroborating these results, Titov et al [32] reported that 63% of individuals with generalized anxiety disorder experienced significant anxiety reduction after ICBT, with concurrent improvements in comorbid depression.

However, the effects of ICBT on caregivers' QoL were inconsistent across studies. While some improvement in QoL was observed, the overall effect was not statistically significant, possibly due to the relatively short intervention duration. Although follow-up assessments were conducted in some studies, no significant differences in QoL were detected. Li et al [33] suggested that improvements in QoL generally require a longer time to manifest compared with behavioral or mental health changes. In addition, multiple factors, such as caregivers' socioeconomic status, age, caregiving duration, coping strategies, the patient's clinical condition, and available social support may influence intervention outcomes [34]. Therefore, future studies should implement multidimensional assessments of caregiver well-being (addressing physical, psychological, emotional, and social domains) to inform personalized interventions, while extending intervention durations to better evaluate long-term QoL outcomes.

This scoping review synthesizes existing literature on ICBT interventions for caregivers of patients with cancer, offering key insights into the current evidence base. Our findings highlight the feasibility and acceptability of most programs; however, recruitment challenges were evident, with a substantial proportion of eligible caregivers declining participation. Furthermore, enrolled participants exhibited high attrition rates. To enhance intervention engagement and retention, future studies should focus on precise population targeting, refined inclusion criteria, and proactive baseline assessments to identify and support at-risk caregivers.

Population Specificity and Methodological Variability

Among the included studies, 3 investigations [21,24,25] specifically targeted subgroups with distinct characteristics, such as caregivers exhibiting elevated anxiety levels or heightened caregiving burdens. Another 3 studies [19,26,27] enhanced research specificity by focusing on particular cancer types. Several studies treated patient-caregiver dyads as intervention units [24,26], demonstrating that caregiver support could reduce patients' psychological distress and improve their QoL. This reciprocal relationship reflects how caregivers' comprehensive support impacts patients' recovery and emotional state, while patients' conditions similarly affect caregivers' wellbeing. Li et al [35] found dyadic collaboration improved both QoL and coping outcomes, though some caregivers preferred individual interventions. Future research should systematically compare the efficacy of caregiver-only interventions versus dyadic intervention approaches.

In total, 2 studies [17,27] included qualitative postintervention evaluations. Carr et al [27] reported that caregivers benefited from recognizing automatic thought patterns, which improved their awareness of irrational thinking and overall wellbeing. However, participants suggested improvements, including initial in-person contact with facilitators, more personalized resources, and better scheduling to accommodate caregiving duties. While ICBT applications for caregivers remain exploratory, mixed-methods approaches combining quantitative outcome measures with qualitative insights can strengthen the evidence base for optimizing interventions [36].

Exploring Intervention Content and Delivery Formats

Effective intervention design must prioritize both engagement and usability through personalized support programs that address caregivers' specific needs. A critical yet frequently overlooked component is the implementation of preparatory phases, as evidenced by our review finding that only 5 studies incorporated preintervention assessments. These preliminary modules should systematically collect caregiver characteristics to inform tailored recommendations, which could significantly improve both participation rates and intervention adherence. Establishing such foundational elements represents an important direction for future research development.

The caregiving role often generates substantial psychological burdens, stemming from challenging role transitions, difficulties adapting to medical environments, and the inherent stress of managing a loved one's illness. Compounding these issues, caregivers frequently suppress their emotions and neglect self-care, resulting in diminished QoL [37,38]. Research by Zhang et al [39] demonstrates that targeted interventions incorporating relaxation training can yield multiple benefits, such as regulating neuropsychological functions, alleviating chronic physical tension, improving physiological responses, and reducing illness-related stress, ultimately decreasing caregiver burden while promoting positive behavioral changes. Therefore, intervention content should integrate 3 key components: (1) cognitive restructuring to modify maladaptive thought patterns; (2) emotional support systems; and (3) practical strategies including context-appropriate health education and relaxation techniques. This comprehensive approach will better equip caregivers to manage their multifaceted challenges.

This study found that few interventions target caregivers' self-symptom management. While 2 studies assessed interventions for caregiver symptoms (eg, pain, fatigue, and sleep) [20,25], no significant improvements were observed, possibly due to differing intervention focuses. However, Shaffer et al [40] reported substantial reductions in insomnia among cancer caregivers through an internet-based program, even though it was not caregiver-specific. Similarly, Ye et al [41] demonstrated that ICBT improved sleep, anxiety, and depression in patients with insomnia . Future research should develop symptom-specific interventions tailored to caregivers to validate their efficacy.

Our study found that online caregiver interventions typically involve real-time psychologist support or email feedback. To optimize website- or WeChat-based interventions, integrating interactive features (eg, chat functions and message boards) is recommended. Caregivers should receive prompt module-specific feedback via email, with professionals addressing inquiries swiftly to build trust. Evidence confirms that therapist-guided ICBT outperforms unguided interventions [42], as therapist engagement sustains participant adherence. For caregivers with limited digital literacy, technical assistance and age-friendly design features (eg, larger subtitles and enhanced visibility) are essential [43]. While video or telephone interventions enable direct communication and emotional support, they risk inefficiency in handling repetitive queries and may compromise continuity. WeChat public platforms or online websites could serve as supplementary tools. Telemedicine and mobile health solutions should be leveraged to comprehensively address caregivers' diverse needs.

Limitations

This review acknowledges several limitations. First, the included studies exhibited significant variability in intervention measures, participant characteristics, sample sizes, and outcome indicators, potentially limiting the generalizability of ICBT efficacy findings. Second, the lack of long-term follow-up assessments in most studies necessitates future research with extended evaluation periods to better understand sustained intervention effects. Third, while we only assessed risk of bias in RCTs, more comprehensive bias evaluations using standardized tools would strengthen future findings. Finally, the included studies originated from various countries, highlighting certain cultural differences. Nonetheless, this diversity underscores the

feasibility and acceptability of ICBT among caregivers of patients with cancer.

Implications for Future Research

To optimize resource use and enhance support for caregivers seeking online assistance, it is imperative to establish a dedicated support team composed of oncologists, nurses, and psychotherapists. Oncologists can build trust with patients and caregivers, promoting engagement and addressing maladaptive cognitions, which has been shown to improve outcomes and reduce attrition [44]. Nurses can serve as interdisciplinary coordinators and health educators, identifying caregiver needs, delivering symptom management guidance, and providing holistic biopsychosocial support. By fostering collaboration among multidisciplinary professionals, caregivers can receive more comprehensive support, capitalizing on the diverse strengths of various specialists and enhancing overall caregiver satisfaction.

Conclusions

This study presents a scoping review of the application of ICBT among caregivers of patients with cancer. ICBT combines the advantages of CBT with the accessibility of smart devices. Preliminary evidence suggests that ICBT is effective in alleviating caregivers' negative emotions, reducing stress, and enhancing positive experiences. Nevertheless, significant shortcomings remain in the research concerning intervention content, sample size, adherence, evaluation criteria, software development, and intervention teams. Currently, internet-based cognitive-behavioral interventions for caregivers of patients with cancer in our country are still in the nascent stages. It is crucial to draw upon relevant international studies while considering the unique characteristics of domestic caregivers to develop tailored ICBT intervention programs. By leveraging artificial intelligence to create safe and effective online platforms and fostering multidisciplinary collaboration, we can provide comprehensive physical and mental health interventions for caregivers, thereby genuinely alleviating their caregiving burden, reducing negative emotions, and enhancing their QoL.

Abstract

Background: Home-based hospice care offers patients with terminal cancer the comfort of receiving care in a familiar environment while enabling family members to provide personalised support. Despite the critical role families play, the literature remains underexplored in terms of their experiences, needs, and perceptions. A robust qualitative synthesis is needed to inform improvements in palliative care services.

Objective: This meta-synthesis aims to systematically review and synthesize qualitative evidence regarding the experiences, needs, and perceptions of family caregivers in home-based hospice care for patients with terminal cancer. The goal is identifying key themes that can improve caregiver support and service delivery.

Methods: A systematic search was conducted across MEDLINE, Embase, Scopus, PsycINFO, CINAHL, Google Scholar, and relevant gray literature sources up to March 14, 2025. Studies were included if they focused on family caregivers' experiences in home-based hospice care settings, excluding those that addressed only patients or health care providers. Two independent reviewers performed study selection, data extraction, and quality assessment using the Critical Appraisal Skills Programme checklist. Data were synthesized using a 3-step thematic synthesis approach, and the confidence in the findings was assessed via the GRADE-CERQual (Grading of Recommendations Assessment, Development, and Evaluation–Confidence in the Evidence from Reviews of Qualitative Research) framework.

Results: Five studies published between 1989 and 2022 from diverse geographical regions (including Asia and Western settings) met the inclusion criteria. Two major themes emerged: (1) being physically and emotionally present, where caregivers expressed a strong commitment to remain with their loved ones, providing emotional support and maintaining a sense of control; and (2) sharing responsibilities, which underscored the importance of both formal support from palliative care teams and informal support from family and friends in mitigating caregiver burden. These findings directly address the study's aims by illustrating how caregivers balance emotional commitment with the practical challenges of providing home-based care.

Conclusions: Although family caregivers are dedicated to delivering high-quality, personalized care, they encounter significant emotional and logistical challenges. Variability in study settings, potential recall bias from retrospective interviews, and limited gray literature access may affect the generalizability of the findings. This meta-synthesis underscores the essential role of family involvement in home-based hospice care for patients with terminal cancer. The combined reliance on emotional commitment and shared responsibilities—with support from professional care teams—is vital for optimal care delivery. Future interventions should enhance formal and informal support systems to meet family caregivers' diverse needs better.

palliative; hospice; home care; cancer; meta-synthesis.

Introduction

Background

Palliative care is an active, holistic approach aimed at relieving severe or chronic suffering and enhancing the quality of life for individuals with life-threatening illnesses at any stage of the illness trajectory, from diagnosis onward, whether curative treatments continue or not [1-3]. Hospice care, however, refers explicitly to palliative care provided when patients no longer pursue curative treatments, typically with a prognosis of 6 months or less, focusing on comfort, dignity, and quality of life during the end-of-life stages [2].

Cancer remains the second leading cause of death globally, with continually rising incidence rates each year [4]. Advances in cancer treatment and early detection have contributed to prolonged survival, even for patients in advanced stages. Nevertheless, extended survival often results in protracted suffering, posing significant physical, emotional, social, and spiritual challenges for both patients and their families, especially during the end-of-life phase [5]. Terminal cancer typically refers to patients with cancer with a prognosis of 6 months or less to live, at which point curative treatments are usually ceased and care transitions toward symptom management and comfort measures [2].

Home-based hospice care allows patients with terminal cancer to spend their final days at home, as many of them prefer [6,7]. This care typically comprises scheduled visits by health care professionals and 24-hour on-call support rather than continuous, around-the-clock in-home care [8]. Such services often include symptom management, holistic nursing care, and psychosocial and spiritual support tailored to individual family needs [9,10]. The popularity of home-based hospice care is increasing due to multiple factors, such as overcrowded hospital environments [11], rising complexity of symptoms and treatments [12], improvements in living standards and education [13], and a growing emphasis on maintaining quality of life at the end of life [14]. The aging population and a shift toward value-based care models have also contributed to the rising demand for home-based hospice services [15].

Family caregivers are pivotal in home-based hospice care, often providing daily care and managing multifaceted emotional and logistical responsibilities. In many cultural contexts, caregiving is perceived as a moral or filial obligation, significantly influenced by cultural norms and values that shape caregiver expectations and decision-making processes [16]. For example, in many Asian cultures, caregiving at home is deeply rooted in filial piety, emphasizing familial responsibility and moral duty toward elders [16,17]. Understanding caregivers' culturally influenced experiences, attitudes, perceptions, and unique support needs is essential for effective and culturally competent interventions.

Given these considerations, home-based hospice care is experiencing increasing demand and attention, primarily due to its valuable support for family caregivers who assume multifaceted responsibilities involving intensive physical care, emotional support, and complex decision-making. These caregivers' experiences, perceptions, and needs vary significantly, influenced by personal, cultural, and contextual factors. Therefore, understanding caregivers' perspectives is essential for assessing the effectiveness of current hospice services and identifying opportunities for enhancing family support at home, ultimately leading to improved patient and caregiver experiences during this critical period.

Objectives

The overall aim of this study was to update and synthesize qualitative research on home-based hospice care based on the experiences of family caregivers of patients with cancer.

The three specific objectives for this review were as follows:

1. To explore the experiences of families of patients with terminal cancer receiving home-based hospice care.
2. To examine attitudes and perceptions of families toward home-based hospice care.
3. To identify key needs within the context of home-based hospice care services.

This meta-synthesis seeks to address a significant gap in the current literature by conducting a comprehensive review of the experiences of family caregivers supporting patients with terminal cancer in home-based hospice care settings. By examining the caregiver experience, this study aims to assess whether existing palliative care provisions sufficiently meet their needs and provide insights for future improvements. Ultimately, this research will ensure that caregivers receive holistic and compassionate support during this critical phase of the illness trajectory.

Methods

Overview

The qualitative evidence from primary qualitative studies and mixed-methods studies were synthesized and integrated using the thematic synthesis method. The meta-synthesis protocol was reported following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 checklist [18] (Checklist 1). The meta-synthesis was guided by the 6 steps of qualitative research synthesis developed by Major and Savin-Baden [19], including formulating the questions, identifying studies, selecting studies and extracting data, appraising studies, synthesizing and finalizing data, and reflecting upon the process, which was based on the step-by-step qualitative research synthesis approaches by Noblit and Hare [20] and Sandelowski and Barroso [21]. The study protocol has been registered in PROSPERO (Prospective Register of Systematic Reviews) under registration number CRD42023486012.

Eligibility Criteria

Identifying appropriate studies is crucial in alignment with step 2 of the Major and Savin-Baden [19] approach. Essential components in this identification process include (1) the scope of included studies, (2) inclusion and exclusion criteria, (3) quality assessment, (4) data synthesis method, and (5) criteria for reporting findings [22,23].

The criteria for considering studies for this review were based on the PICo (Population, Interest, Context) framework [24]. The inclusion criteria were as follows: (1) population: the studies involving adults who are family members of patients with terminal cancer; (2) interest: the experiences, attitudes, and needs regarding home-based hospice care services; (3) context: under the care of home-based hospice care service, particularly those with a physical home visit; and (4) the research design was qualitative or mixed methods. The exclusion criteria were as follows: (1) studies focusing on patients themselves, health care providers, or non–home-based hospice services (such as inpatient hospice or nursing home care), and studies involving only telemedicine visits, and (2) language is not English. The eligibility criteria are outlined in Multimedia Appendix 1.

Information Sources

We searched 5 electronic databases—Scopus, Embase, MEDLINE, CINAHL, and PsycINFO—from inception until March 14, 2025. These databases were chosen for their relevance to qualitative research in various health care settings [25]. To maximize the range of articles retrieved, we searched Google Scholar and gray literature sources, including ProQuest, for unpublished dissertations. The complete search strategy can be found in Multimedia Appendix 2.

Search Strategy

The search began by defining the scope of the study and addressing the research questions focusing on terminal cancer, home-based care, and palliative care. Broad search terms and synonyms were used to create a comprehensive search string encompassing all relevant keywords. The PICo framework [24] was used to guide search term generation. The full search strategies included an initial search of MEDLINE, Embase, Scopus, PsycINFO, and ProQuest up to September 13, 2023. Following our initial database search, we conducted an additional search in CINAHL on March 13, 2025, and Google Scholar on March 14, 2025, to ensure comprehensive coverage of relevant literature.

Controlled vocabulary terms were used for each database: Medical Subject Headings (MeSH) for PubMed and Emtree terms for Embase. Boolean operators and truncation symbols combined the terms according to each database's specifications. This initial step helped us develop effective search strategies, become familiar with the terminology, and conduct preliminary searches. We then consulted a subject librarian to further refine these search terms and strategy. Subsequently, a formal literature search was conducted to identify and compile eligible studies, with language limited to English only.

Selection Process

Adhering to the third step of the Major and Savin-Baden [19] meta-synthesis method, we used EndNote 21 (version 21.2.0.19537; Clarivate Plc) [26] to import articles and find duplicates. Subsequently, the titles and abstracts of the imported articles were screened for relevance using RAYYAN [27], using the blinding function to mitigate bias. This initial screening, followed by full-text screening, was independently conducted by 2 reviewers (XMD and KH), with discrepancies resolved through discussion to reach a consensus.

Data Extraction

As the third step of Major and Savin-Baden's [19] meta-synthesis approach, we meticulously extracted the qualitative data from the included articles. This process was conducted in 2 stages. First, a pilot test of the data-extraction form was performed by 2 reviewers (XMD and KH) and validated by the third reviewer (WWST) before extracting relevant information. Subsequently, the data-extraction form was applied, which included author, year of publication, study setting, aim, sample characteristics, methodology (population characteristics, sampling method, data collection, and data analysis), and key findings.

Quality Assessment

For the quality appraisal, 2 investigators (XMD and KH) independently assessed each included study using the Critical Appraisal Skills Programme (CASP) checklist (2019) [28]. All discrepancies between the 2 investigators were resolved through discussion. The third reviewer (WWST) counterchecked the results to ensure accuracy and consistency. This assessment included statements of research aims, appropriate qualitative methodology, research designs, recruitment strategies, data collection, adequate relationship between researcher and participants, ethical issues consideration, the rigor of data analysis, statement of findings, and value of the study.

Synthesis Methods

The data analysis used the 3-step thematic synthesis method [25] as the fifth step in the Major and Savin-Baden [19] approach. This method, based on Braun and Clarke's thematic analysis techniques [29], was extensively used in nursing and medical research to identify intervention needs, appropriateness, acceptability, and factors influencing implementation. Thematic synthesis integrates findings from primary studies to identify prominent or recurrent themes within the relevant literature.

In the initial step of thematic synthesis, findings were extracted and coded line-by-line using Excel (Microsoft Corp). Reviewer XMD conducted the line-by-line coding, maintaining fidelity to the data and preserving the original concepts. Reviewer KH subsequently verified the codes to ensure alignment and completeness, facilitating identifying and categorizing key elements within the data.

The primary codes were then grouped based on conceptual similarities upon mutual agreement by reviewers (XMD and KH), resulting in a structured interpretation of the findings through the development of descriptive themes. These descriptive themes were subsequently synthesized into higher-level analytical themes. These analytical themes represented the key outcomes relevant to our meta-synthesis topic, achieved by merging and summarizing similar descriptive themes to highlight core insights and conclusions drawn from the data. The final process and results were screened thoroughly and confirmed by all reviewers (XMD, KH, WWST, and VL), with any disagreements resolved through consensus.

Third, the use of the approach by Major and Savin-Baden [19] involved 5 steps; the last was adopting the 3-step thematic synthesis method [25]. This nursing and medical method was

used massively using Braun and Clarke's thematic analysis methods [29] to determine intervention needs, appropriateness, acceptability, and factors regarding implementation.

Confidence Measurement

After generating the analytical themes, a further quality appraisal stage using the GRADE-CERQual (Grading of Recommendations Assessment, Development, and Evaluation–Confidence in the Evidence from Reviews of Qualitative Research) approach [30] was used to evaluate the confidence level of our findings (Table 1). This aligned with the final step of Major and Savin-Baden's [19] approach of "reflecting upon the process."

Table . Evidence profile table.

Major theme and summarized review finding	Methodological limitations	Coherence	Adequacy	Relevance	GRADE-CERQual[a] assessment of confidence	References
Being physically and emotionally present						
• Belief that home palliative care provides better care than hospitals • Commitment to care at home • Cultural and moral obligations • Personal reflections and challenges	No or very minor concerns	No or very minor concerns	Minor concern	Minor concerns	High confidence	[16,31-34]
Sharing responsibilities						
• Challenges in caregiving • Formal support needs • Informal support needs	No or very minor concerns	No or very minor concerns	No or very minor concerns	Minor concerns	High confidence	[16,31-34]

[a]GRADE-CERQual: Grading of Recommendations Assessment, Development, and Evaluation–Confidence in the Evidence from Reviews of Qualitative Research.

Two reviewers (XD and KH) conducted independent reviews and discussed discrepancies to reach a consensus. The GRADE-CERQual approach evaluates confidence based on 4 components: methodological limitations, coherence, adequacy of data, and relevance of included studies. Each element was categorized as having "no or very minor concerns," "minor concerns," "moderate concerns," or "serious concerns," leading to varying grades of confidence [35].

The assessment of methodological limitations aligns with the CASP appraisal, evaluating the trustworthiness of study findings by examining the appropriateness of the research methodology, which is closely related to the quality of the results [36]. Our assessment indicated that the findings were supported by articles with no to very minor concerns regarding methodological limitations.

The coherence assessment measures the relevance of the data from the included studies to the review findings [37]. Based on key findings extracted from the included studies, we confirmed that the data were relevant to the review findings (Table 2).

To assess the adequacy of the data, we evaluated both the quantity and richness of the data in relation to the review findings, in line with the GRADE-CERQual approach [38]. Studies with limited data, particularly those with findings supported by only 1 or 2 participant voices, were noted as having insufficient depth and quantity to robustly support specific review findings [31,39].

Lastly, we assessed relevance by evaluating the extent to which the data from the primary studies apply to the context outlined in the synthesis results [32].

Table . Characteristics of included studies.

Study	Albert et al [33]	Milberg and Strang [34]	Hull [32]	Lee et al [16]	Barlund et al [31]
Setting	Malaysia, palliative care center, Kota Kinabalu, Sabah	Sweden, hospital-based home care	United States, combined hospice program, home care	Taiwan, hospice home care, northern Taiwan	Norway, municipalities, Førde Central Hospital, Sogn og Fjordane
Aim	To explore the suffering experienced by Malaysian family members caring for patients with advanced cancer nearing end-of-life.	To describe and interpret comprehensibility and manageability experiences of informal caregivers of advanced patients with cancer in palliative home care.	To explore hospice home care experiences and perceptions of family caregivers of dying relatives.	To examine family experiences and needs when providing hospice home care to older adults with terminal cancer.	To explore factors influencing caregivers' sense of security and facilitators for home deaths among dying patients with cancer.
Sample	First-degree relatives living with patients; primary caregivers for ≥8 hours/day	Primary caregivers at home of patients with cancer receiving hospital-based home-based palliative care	Primary home caregivers; adults living at home (with/without patient responsibilities); adults living outside home with regular care duties	Caregivers of patients with advanced cancer receiving home hospice care	Parents, children, or spouses of deceased patients with cancer
Method	Purposive sampling; semistructured in-depth interviews; thematic analysis	Maximum variation sampling; semistructured interviews; qualitative hermeneutic approach	Convenience sampling; semistructured interviews and field observation; thematic analysis	Consecutive sampling; in-depth semistructured interviews; qualitative inductive content analysis	Purposive sampling; semistructured in-depth interviews; thematic analysis
Key findings	• Empathic suffering: Witnessing functional decline; fear of discomfort; receiving bad news; duties. • Powerless and hopeless suffering • Predictive suffering • Compliance suffering: Burden of caregiving and social • Barriers' wrath: Patient-related barriers; family-related barriers; health care–related hurdles.	• Comprehensibility: Congruent inner reality through open information, symbols, basic life assumptions, previous knowledge • Manageability: Togetherness/isolation involving power, competence, accessibility, and support.	• Confronting reality: Acute health changes, physician prognosis, treatment refusal. • Surveying options: Gathering and reviewing alternatives, clarifying values, learning about hospice. • Immersion: Disengaging from other tasks, shifting priorities, acquiring patient care skills. • Refocusing	• Hoping for cure: Concealing diagnoses from patients; expectations for prolonged life. • Fluctuating emotions: Positive, negative, and difficult emotions. • Accepting death: Fulfilled duties, acceptance. • Perceptions of a good death: Smooth, painless, peaceful. • Needs: Emotional support, information.	• Personal factors • Health care professionals • Organizational factors

Ethical Considerations

This meta-synthesis did not involve primary data collection, and thus ethical approval was not required. However, ethical rigor was maintained by ensuring that all included studies adhered to standard ethical guidelines, such as obtaining informed consent from participants and safeguarding participant confidentiality. Additionally, no unpublished or personally identifiable information was included in the synthesis. All sources were appropriately cited, and transparency regarding any potential conflicts of interest or funding has been maintained throughout the study.

Positionality Statement

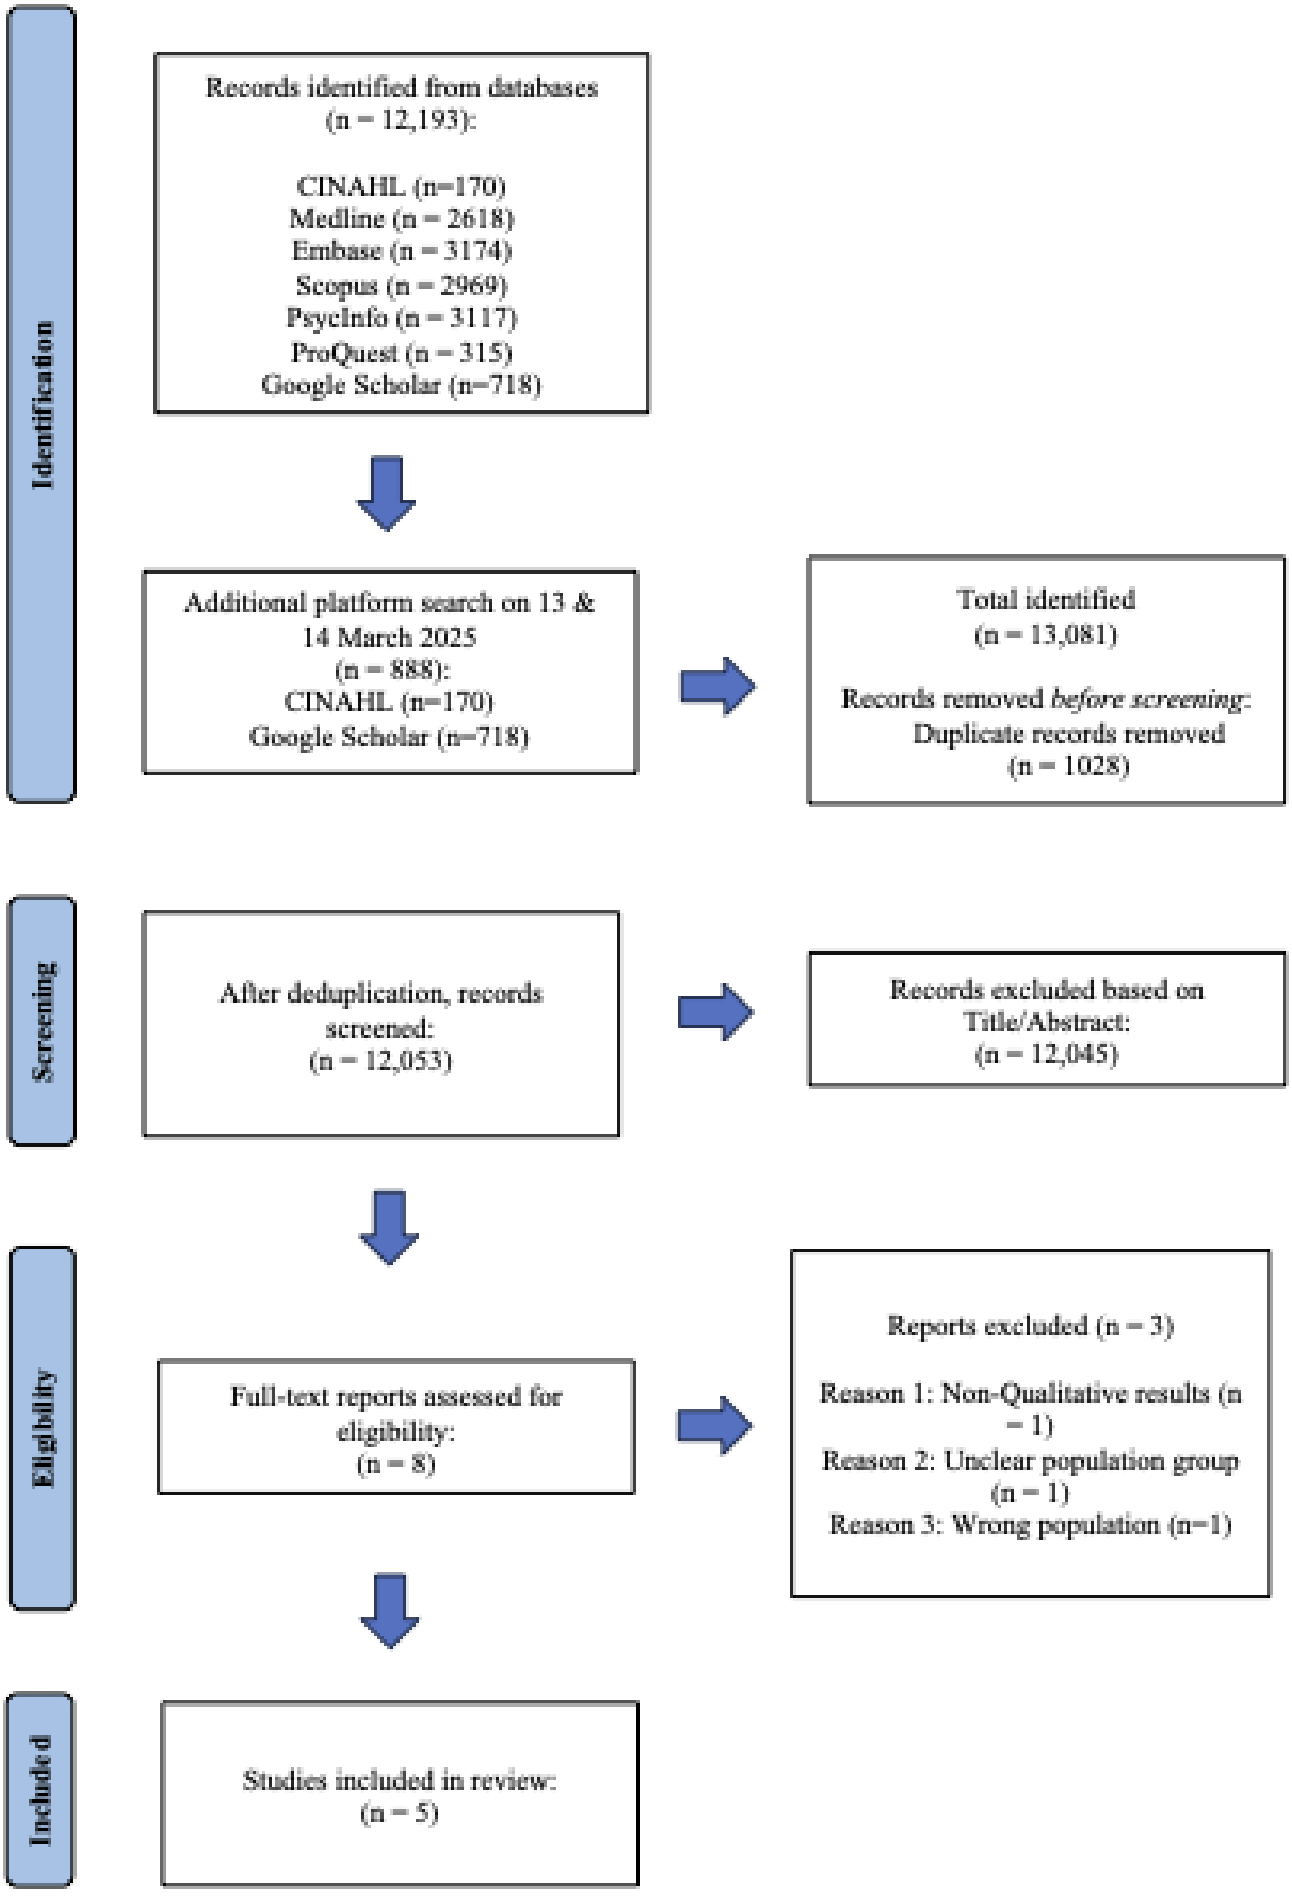
The reviewers overseeing the analysis and synthesis process (VL and WWST) are experienced qualitative researchers. The initial drafting, coding, and synthesis were primarily conducted by 2 researchers (XMD and KH) who have clinical backgrounds relevant to the review topic. All reviewers acknowledged that their personal characteristics, values, and beliefs, shaped by their clinical and academic experiences, could influence the synthesis process. Thus, regular discussions were held among the team to examine assumptions, challenge interpretations, and ensure a balanced and rigorous analysis of the findings to enhance reflexivity and reduce potential bias.

Results

Study Selection

A total of 13,081 articles were identified through our comprehensive search. This included 12,193 articles from the initial search and an additional 888 articles from the supplementary search. A total of 1028 duplicates were removed. Then, 12,053 titles and abstracts were reviewed, and 12,045 were excluded according to the eligibility criteria. Subsequently, 8 articles were read in full text, and 3 studies were excluded. Two articles were excluded due to the inability to confirm the cancer stage or to separate qualitative findings within mixed method studies, and attempts to contact the authors for verification were unsuccessful. An additional article was excluded after discussion because it predominantly contained patients' findings, which could not be distinctly separated to focus solely on caregivers' perspectives. Finally, 5 full-text articles met the eligibility criteria. The result of the selection process is presented in Figure 1.

Figure 1. PRISMA (2020) flowchart of search results and study selection. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.



Study Characteristics

The 5 studies included in this meta-synthesis were published between 1989 and 2022, with 2 studies [31,33] published in the last 5 years. The research was conducted across diverse geographical settings: Malaysia (n=1), Sweden (n=1), the United States (n=1), Taiwan (n=1), and Norway (n=1). Study settings varied, including a palliative care center, hospital-based home care, hospice programs, and municipal or hospice-affiliated home care services.

Sample sizes across the studies ranged from small, focused groups of 12 to larger caregiver cohorts of up to 44 participants. Most studies involved between 12 and 19 participants, while one study included a substantially larger sample. One study did not report the exact number of participants. These variations reflect the diversity in study aims and sampling strategies, as well as the depth of qualitative inquiry. All participants were family caregivers of individuals with advanced cancer receiving home-based palliative care.

Sampling strategies included purposive sampling (n=3), maximum variation sampling (n=1), and consecutive or convenience sampling (n=2). Data were primarily collected through semistructured, in-depth interviews (n=5), with one study also incorporating field observation. Thematic analysis was the predominant analytical approach, although one study used a qualitative hermeneutic method and another used inductive content analysis.

Although the articles had slightly different objectives, all contributed to our understanding of the experiences, needs, and perceptions of families of patients with terminal cancer in home-based hospice care. Sampling and data collection methods varied across the studies due to population and setting differences. Four of the 5 studies were qualitative, with Hull [32] being the exception, including a quantitative portion as part of the dissertation. However, this quantitative aspect did not influence our findings, as the qualitative portion was clearly differentiated and extracted.

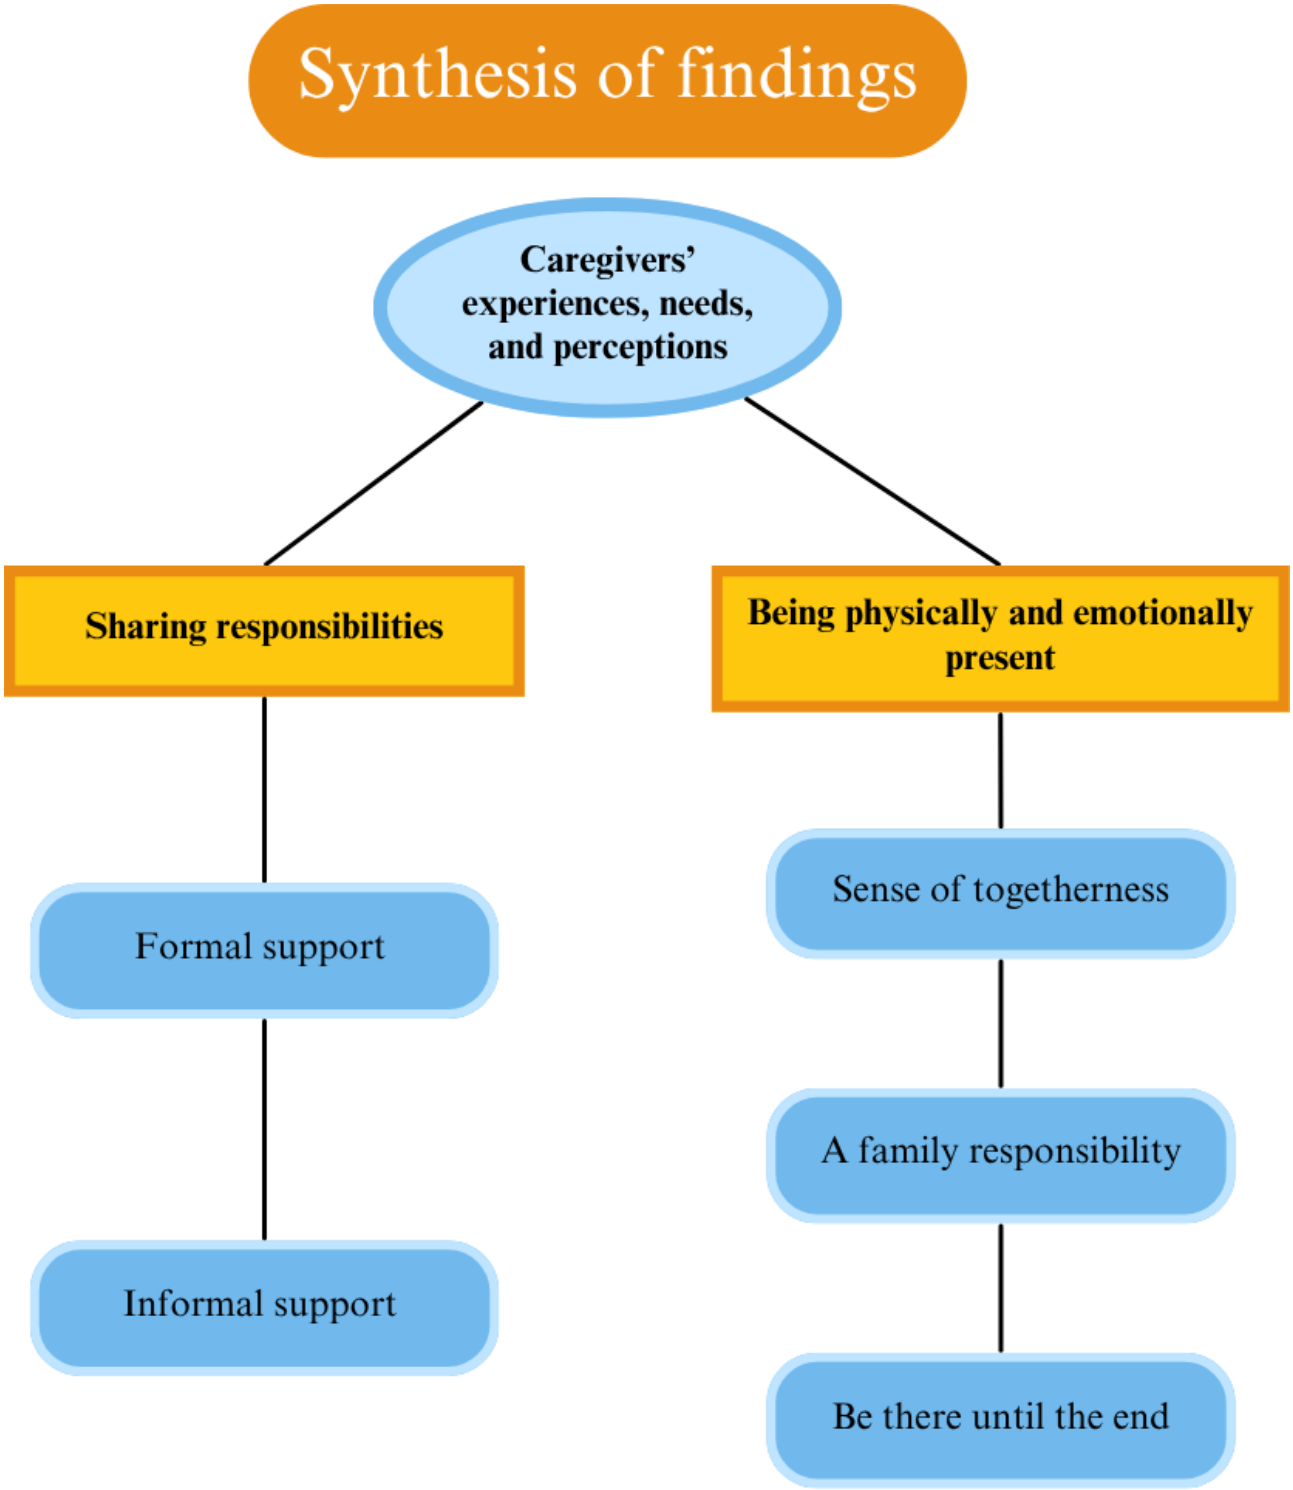
We noticed that one significant contributing study was notably outdated. After thorough discussion between 2 reviewers (XMD and KH), it was decided to include this study because it provided findings that remain relevant and fit well within the overall research context. Despite being published over 30 years ago in 1989 [32], the foundational concepts and findings still offer valuable insights into home-based hospice care and address aspects that are not sufficiently covered by more recent studies. The inclusion of this study ensured a comprehensive understanding of the evolution and continuity of caregiving practices. The characteristics of the included studies are presented in Table 2.

Synthesis Findings

Overview

A total of 17 groups of primary codes and corresponding descriptive themes were identified. These were further synthesized into 5 overarching analytical themes, culminating in 2 central themes that represent the final synthesis. These include (1) being physically and emotionally present and (2) sharing responsibilities. The 3 subthemes that support the main theme of “being physically and emotionally present” were a sense of togetherness, family responsibility, and being there until the end. Similarly, for the main theme of “sharing responsibilities”, we synthesized the findings based on 2 subthemes: formal support and informal support (Figure 2).

Figure 2. Synthesis of findings, including subthemes and main themes.



Family caregivers of patients with terminal cancer made a deliberate commitment to be physically and emotionally present to care for their loved ones at home. They were motivated by the belief that they could provide a higher standard of care than what was offered in the hospital, where they observed their dying relatives being treated more as objects than as individuals with dignity. One participant expressed this sentiment: "When my dad was in the

hospital, they bathed him, fed him, and gave him his meals, and he just lay there. After these, nobody bothered him, nobody did anything more. He was nothing" [32]. At home, caregivers felt they could better meet their loved ones' needs, taking comfort in the familiar environment and the reduced stress for both patient and caregiver. This approach offered a sense of control and personal involvement. For example, a 64-year-old daughter noted: "It didn't take long to learn how to care for Mum. Being a mother and a wife, it was easy enough to pick up those skills, so there were no problems. I could go into nursing now (laughs); I've had practical experience" [32]. Similarly, a 75-year-old wife reflected on her experience: "There was no issue for me in knowing how to care for my husband. I kept him clean, the

bed clean, and his pyjamas were fresh every day. It was really no problem for me" [32]. In another instance, a 35-year-old son demonstrated his capability by innovatively managing bedsores using a combination of a water mattress and an alternating mattress [32].

The 3 subthemes supported this theme: a sense of togetherness, a family responsibility, and being there until the end.

Sense of Togetherness

A sense of togetherness is a crucial emotional factor in home-based hospice care. Being at home made caregivers and patients feel safe and secure, knowing they were close and always within reach. One participant shared: "It was important for me to be with him... to be there all the time. And it wasn't difficult; it felt natural. It was safe for me to be there with him" [31]. Another participant described the comfort of staying connected through a monitor: "I always had the monitor with me, even when I was out front talking to a neighbour. I kept my little walkie-talkie with me so I could always keep tabs on him" [32]. Being at home symbolized the caregivers' commitment to staying close to the patient in the home they had built together and filled with memories, despite the good or bad times. One participant poignantly remarked:

> *This is our home, and this is where she should be as long as she lives. She's receiving better care here than she would anywhere else, and as long as I'm here, she'll have that care as long as it's needed. This is where she belongs. This is her life's work. We raised our family here for 38 years. I lived through the good years; now I want to live through the bad. What's one bad year out of 47? [32].*

A Family Responsibility

From a cultural perspective, caregiving is a natural extension of one's commitment to loved ones and a moral obligation. For many children caregivers, taking on the responsibility of caring for their parents with terminal illness at home is deeply rooted in cultural and ethical values, often viewed as a way to repay their parents. In this cultural context, there is a strong belief in managing care independently rather than relying on nursing homes to express filial duty. This sentiment is reflected in the words of a daughter from Taiwan: "Because my father's condition was so bad, it made my heart ache to watch him suffering from pain...I wanted to care for my father on my own and did not need anyone else to bear my responsibility" [16]. Another participant echoed this sense of responsibility: "The most important thing for me to learn is that you have to give yourself an opportunity to take care of your sick parents who have taken care of you since you were a child...I was really proud of becoming familiar with the skills of care" [16]. This highlights the emotional significance of caregiving, which carries a deep sense of responsibility. Many caregivers, particularly those who were the sons or daughters of patients with cancer, believed they had fulfilled their filial duties and wanted their loved ones to have a natural death and a proper funeral. As one son expressed: "We will not have regrets if our father dies tomorrow...We believe we demonstrated the value of filial piety as much as we could by taking good care of him at home without sending him to a nursing home...we knew he wanted to die at home" [16].

Be There Until the End

However, families often face significant emotional challenges when discussing topics related to death or illness while striving to be emotionally present for their loved ones. In Sweden, being present was crucial, even when it was difficult to discuss such matters. One participant shared: "She [mother] is talking a bit too much about the funeral and such things. I find it quite burdensome. But it is good for her, so we talk" [34]. Some family members chose to hide terminal diagnoses from their loved ones in an attempt to protect them from losing hope, believing that revealing the full extent of the illness might cause them to give up on life [16]. In Malaysia, caregivers also expressed a strong desire to remain with their loved ones and provide care until the end, keeping them happy and shielding them from their emotions. One caregiver shared: "I do not want him to see me crying. I want him to be happy. I know that I am the only one next to him. If I were there with a sad feeling...I think it might make him sad" [33]. The complexity of providing compassionate care while managing one's emotional burdens is evident in these experiences, underscoring families' challenges in navigating the end-of-life journey.

Sharing Responsibilities

Sharing responsibilities in caregiving can involve the patient, family, friends, home palliative care teams, and other community organizations. This collaborative approach helped family caregivers feel less isolated when managing challenging situations. Throughout the caregiving process, these groups play a vital role in supporting family caregivers of patients with terminal cancer. It is essential to recognize that family caregivers often require various types of support. This theme was further supported by 2 subthemes: support from a palliative home-based care team and support from others.

Formal Support

The involvement of a palliative home care team can help caregivers perceive caregiving as more manageable [34], boosting their confidence in providing care for their loved ones at home [16]. A Swedish participant shared a poignant experience:

> *My husband was going to be discharged from the hospital [with a percutaneous endoscopic gastrostomy], but I said I can't take care of such things. But they said it was very easy to learn how to use it. 'No,' I said. 'I can't take that responsibility'...Then the dietician came and said, 'It is so easy.' I felt I was going to be ill because I could not do this. (Sighs) And later on that afternoon, I had diarrhoea. I was not feeling well and was terribly worried...Then the palliative doctor came, and he was almost like an angel. He presented all the things the palliative home care team could offer. And then I felt that this was a support for us [34].*

The need for qualified health care professionals is often emphasized, as they are the support personnel to whom caregivers can express their concerns, thoughts, and worries.

This interaction gave caregivers confidence and security, reassuring them that they appropriately fulfilled their caregiving role. Caregivers welcome palliative care nurses or coordinators, as one participant reported:

> *"It felt safe and secure for us to know that they were visiting us (ie, home nursing care)" [31].*

Some caregivers acknowledged that having palliative home care made it easier to fulfill their wish to care for patients at home during the final stage of life, facilitating a dignified end-of-life experience. As one son reflected:

> *"I thought my mother's death was a good death because she passed away without pain or any distressing symptoms from cancer. It was really important for us, and we appreciated what the hospice home-based care team did for us" [16].*

Informal Support

Other family members, relatives, and friends play a crucial role in supporting family caregivers who provide care for patients with terminal cancer. In families with children, caregivers were glad to share their responsibility with their offspring, viewing it as an expression of filial piety. One participant said:

> *"I was glad to see my son helping me care for his dad...I thought that if I'm sick someday he would care for me like now and our relationship gave me the energy to care for my husband" [16].*

Managing the financial responsibilities of caregiving often necessitates sharing the burden with other family members or government organizations. The emotional and physical toll of caregiving can be overwhelming, as one participant poignantly expressed:

> *"I declined the offer of attendance allowance; I wanted another sister to do this. I didn't want to be alone in this [ie, follow the patient in the last phase]. I wanted more people to be involved because I had... (Sighs) I had been doing this alone for so long" [31].*

This highlights the deep need for collective involvement, especially in the final stages of care, which can be particularly draining when borne alone.

Quality Appraisal of Included Studies

The methodological quality of the included studies was assessed using the CASP Qualitative Checklist. All 5 included studies demonstrated generally high methodological quality, with scores ranging from 29 to 30 points out of a possible maximum score of 30 points (Table 3). All studies clearly stated their research aims, adopted appropriate qualitative methodologies, applied suitable research designs, and used adequate recruitment strategies and data collection methods. Four studies clearly considered ethical issues, while 2 lacked explicit discussion regarding the relationship between researchers and participants, introducing minor ambiguity. Nevertheless, all included studies clearly articulated their findings and demonstrated valuable contributions to the topic. A detailed summary of the quality appraisal results is presented in Table 3.

Table . Quality appraisal of the included studies using the Critical Appraisal Skills Programme (2019).

	Albert et al, 2022 [33]	Milberg and Strang, 2004 [34]	Hull, 1989 [32]	Lee et al, 2014 [16]	Barlund et al, 2021 [31]

Confidence of Evidence

Two major themes emerged from the thematic synthesis: (1) being physically and emotionally present and (2) sharing responsibilities. Both themes were assessed with high confidence according to the GRADE-CERQual framework (Table 1). The theme “being physically and emotionally present” had no or very minor concerns regarding methodological limitations and coherence, minor concerns related to data adequacy, and minor concerns regarding relevance due to the partial inclusion of studies addressing home- and hospital-based settings. Similarly, the theme “sharing responsibilities” had no or minor problems related to methodological limitations, coherence, and adequacy, with minor concerns regarding relevance, given the partial relevance of 2 included studies that covered broader contexts beyond home-based care. These results demonstrate robust qualitative evidence reflecting the experiences, perceptions, and needs of family caregivers in home-based hospice care for patients with terminal cancer.

Discussion

Principal Findings

This review synthesized findings from 5 qualitative studies exploring family caregiver experiences, perceptions, and needs in home-based hospice care for patients with terminal cancer. Two prominent themes emerged: (1) being physically and emotionally present, highlighting caregivers’ dedication and the emotional complexities involved in caregiving, and (2) sharing responsibilities, demonstrating the importance of formal and informal support systems. These themes reflect the complex emotional and practical challenges caregivers encounter while striving to provide high-quality care aligned with their loved ones’ wishes.

Comparison to Prior Work

Our findings align with previous research highlighting family caregivers’ essential role in delivering compassionate and dignified end-of-life care [40]. The emotional dedication caregivers demonstrate, often deeply embedded in cultural expectations such as filial piety, confirms existing literature emphasizing the profoundly personal nature of caregiving.

However, this synthesis also underscores specific challenges faced by caregivers, including managing difficult conversations about death, balancing caregiving responsibilities, and navigating cultural norms, consistent with prior research identifying caregiver stress and potential burnout risks.

These findings align with established social support theories, confirming that emotional, informational, and instrumental support from formal (health care professionals) and informal networks (family and friends) substantially alleviates caregiving stress [41]. Nonetheless, our analysis revealed a significant gap in integrating these support systems, leaving caregivers vulnerable to isolation and overwhelm.

Strengths and Limitations

The strength of this review includes the rigorous methodological approach followed, adherence to PRISMA guidelines, quality appraisal using the CASP checklist, and confidence assessment using GRADE-CERQual. Including diverse cultural contexts from Asian and Western countries further enhances the generalizability and applicability of our findings.

However, this review has several limitations. First, limiting the search to studies published in English may have restricted the inclusion of research conducted in non–English-speaking regions, thereby reducing the diversity in cultural contexts and settings across the included studies and potentially affecting the generalizability of the findings [42]. Second, despite the growing global reliance on family caregivers in home-based hospice care [43], this review identified only 5 eligible studies, with just 2 published in the past 5 years. This limited number may reflect the specificity of our inclusion criteria, which focused solely on caregivers of patients with terminal cancer receiving home-based palliative care. Many existing end-of-life care studies include a broader population with varied diagnoses and may not isolate the unique caregiving experience related to cancer. This scarcity highlights a critical gap and the need for more focused, culturally diverse qualitative research in this area [44]. Third, the retrospective nature of some studies introduced a potential recall bias, affecting the accuracy of reported experiences. This could be addressed in future research through prospective study designs. Fourth, our review's reliance on specific databases potentially limited the comprehensiveness of identified literature, mainly gray literature. Future studies should broaden database searches and proactively include unpublished literature to enhance comprehensiveness. Lastly, including older literature (more than 5 years old) may limit the review's alignment with the most current evidence. However, older studies were included due to their foundational insights, which remain relevant to the current practice context. Future research should emphasize more recent publications to align closely with contemporary practices and emerging evidence.

Future Directions

The findings indicate several avenues for future research and practice. There is a clear need to develop and evaluate culturally sensitive interventions tailored to both formal and informal caregiver support needs. Initiatives should aim to bridge existing gaps in caregiver support through integrated services that alleviate isolation and promote emotional and practical caregiving capacities. Structured educational programs and support groups designed to improve communication around end-of-life topics could also substantially enhance caregiver experiences.

Conclusion

Home-based hospice care has a significant impact on patients, but the experience of family members who support them remains neglected in literature and daily practices. The results highlight both the emotional rewards and daunting challenges caregivers encounter and point to the need for systemic, culturally competent strategies to support this population. By bridging the gaps within formal and informal support systems and encouraging open communication, these health care providers can enable caregivers to maneuver their roles effectively. These findings present critical implications for the delivery of hospice care as the world learns to provide holistic, compassionate care, without fail, for patients and their families. Future research should investigate diverse caregiver experiences and further inform the refinement of focused interventions to improve home-based hospice care.

In conclusion, this review highlights the critical role of caregivers in home-based hospice care for patients with terminal cancer, emphasizing the need for culturally competent, comprehensive caregiver support strategies. Addressing identified gaps can significantly improve caregivers' experiences and ultimately enhance the quality of hospice care services delivered at home.

Acknowledgments

We sincerely thank VL from the School of Nursing, Midwifery & Social Sciences, Central Queensland University, Australia, for her invaluable guidance. We also wish to thank KH for her contributions to data curation and formal synthesis and WWST for contributing to conceptualization, methodology, supervision, and validation.

Authors' Contributions

Abstract

Background: Blood tests used to identify patients at increased risk of undiagnosed cancer are commonly used in isolation, primarily by monitoring whether results fall outside the normal range. Some prediction models incorporate changes over repeated blood tests (or trends) to improve individualized cancer risk identification, as relevant trends may be confined within the normal range.

Objective: Our aim was to critically appraise existing diagnostic prediction models incorporating blood test trends for the risk of cancer.

Methods: MEDLINE and EMBASE were searched until April 3, 2025 for diagnostic prediction model studies using blood test trends for cancer risk. Screening was performed by 4 reviewers. Data extraction for each article was performed by 2 reviewers independently. To critically appraise models, we narratively synthesized studies, including model building and validation strategies, model reporting, and the added value of blood test trends. We also reviewed the performance measures of each model, including discrimination and calibration. We performed a random-effects meta-analysis of the c-statistic for a trends-based prediction model if there were at least 3 studies validating the model. The risk of bias was assessed using the PROBAST (prediction model risk of bias assessment tool).

Results: We included 16 articles, with a total of 7 models developed and 14 external validation studies. In the 7 models derived, full blood count (FBC) trends were most commonly used (86%, n=7 models). Cancers modeled were colorectal (43%, n=3), gastro-intestinal (29%, n=2), nonsmall cell lung (14%, n=1), and pancreatic (14%, n=1). In total, 2 models used statistical logistic regression, 2 used joint modeling, and 1 each used XGBoost, decision trees, and random forests. The number of blood test trends included in the models ranged from 1 to 26. A total of 2 of 4 models were reported with the full set of coefficients needed to predict risk, with the remaining excluding at least one coefficient from their article or were not publicly accessible. The c-statistic ranged 0.69 - 0.87 among validation studies. The ColonFlag model using trends in the FBC was commonly externally validated, with a pooled c-statistic=0.81 (95% CI 0.77-0.85; n=4 studies) for 6-month colorectal cancer risk. Models were often inadequately tested, with only one external validation study assessing model calibration. All 16 studies scored a low risk of bias regarding predictor and outcome details. All but one study scored a high risk of bias in the analysis domain, with most studies often removing patients with missing data from analysis or not adjusting the derived model for overfitting.

Conclusions: Our review highlights that blood test trends may inform further investigation for cancer. However, models were not available for most cancer sites, were rarely externally validated, and rarely assessed calibration when they were externally validated.

Introduction

Cancer incidence trends are projected to increase globally: 18 million new cases diagnosed in 2020 versus 28 million projected in 2040 [1]. The likelihood of survival improves by cancer detection at earlier stages [2-7]. Earlier detection is crucial to improve patient outcomes and reduce cancer-related mortality [8]. Screening programs may contribute to early detection but have been implemented for a minority of countries and cancers [9]. Risk prediction models for cancer could improve early detection rates. These models combine patient data, such as patient demographics, medical history, or cancer symptoms, to identify patients with an increased risk of undiagnosed cancer.

Blood tests commonly performed in clinical practice, including full blood count (FBC) and liver function tests, are often included in cancer risk prediction models, as they have an important role in risk-stratifying symptomatic patients for cancer investigation [10,11]. Blood tests are commonly requested by clinicians, with rates of testing increasing yearly. Despite panels of blood tests being taken together, blood tests are almost entirely interpreted in isolation in current clinical guidance [11,12]. In the United Kingdom, the National Institute for Health and Care Excellence (NICE) suspected cancer guidelines recommend referral for urgent investigation if low albumin, low hemoglobin, raised platelets, raised bilirubin, raised calcium, or raised inflammatory markers are observed, as these increase risk of cancer [11]. Monitoring temporal trends (ie, changes over time) in repeated blood tests may improve risk stratification, by incorporating an individual's trajectory from which to identify change. For example, declining hemoglobin confined within the normal range would be a relevant cancer-related trend, but missed in practice as the results appear normal. Our recent systematic review on the association between blood test trends and cancer diagnosis identified many trends that have the potential to improve cancer risk stratification [13]. However, the potential benefits and challenges and methodological considerations of incorporating combinations of trends into cancer risk prediction models remain unrealized.

Recent methodological advancements in both traditional statistical and machine-learning methods allow for the development of dynamic prediction models, which incorporate repeated measures data for clinical risk prediction and may hold greater potential to rule-in and rule-out referral for cancer investigation. We aimed to conduct a systematic review to critically appraise diagnostic clinical prediction models using trends in blood tests commonly used in primary care for the risk of undiagnosed cancer.

Methods

Overview

We followed the PRISMA (Preferred Reporting Items for Systematic review and Meta-Analysis) guidelines (Checklist 1) for reporting the findings of this review [14]. Ethical approval was not required, as there were no direct patient investigations in this study and only published articles were systematically reviewed. The review protocol was registered with the International PROSPERO (Prospective Register of Systematic Reviews) database on July 25, 2022 (CRD42022348907). There were no deviations to the protocol.

Participants

We included studies of participants aged 18 years or older reporting prediction models incorporating trends in blood tests commonly available in primary care and cancer diagnosis in any clinical setting. We excluded blood tests taken after cancer diagnosis, such as to predict prognosis or monitor treatment.

Outcome

The main outcome was a first diagnosis of cancer across all cancer sites, including composite cancer sub-groupings and all cancers combined. Cancer diagnosis was defined as per the individual studies, such as confirmed cancer via laboratory tests/radiology in clinical/prospective studies or the use of ICD10 (*International Statistical Classification of Diseases and Related Health Problems 10th Revision)* codes [15] in studies of eHealth records.

Search Strategy

We worked with our review specialist (NR) to derive a comprehensive search strategy. The MEDLINE (OVID) (1946-present) and EMBASE (OVID) (1974-present) databases were searched from inception to April 3, 2025 to identify articles that report on the association between trends in blood tests commonly available in clinical practice and a cancer diagnosis. The initial search was conducted in June 2022, with a full update in February and May 2023 and April 2025. Search terms included MeSH headings and title, abstract, and author keywords for blood tests, cancer diagnosis, and prediction or risk. Cancer-related terms included "tumor" and "cancer". However, some cancers are not usually paired with these terms, such as "leukaemia" or "lymphoma", so it was important to include such cancer types explicitly to ensure they were captured. No language or other limits were applied to the search. The full search strategy for each database is provided in Table S1 (MEDLINE) and Table S2 (EMBASE) in Multimedia Appendix 1. In the eligible studies, we actively searched through each article's reference list to find eligible studies that were not identified by the search strategy.

Study Selection

All references initially underwent de-duplication in Endnote 20 [16] (by NR). Abstract and title screening was performed in Endnote 20 and Rayyan [17] (by PSV, KKC, CFS, and XY). The retrieved articles were initially split among the reviewers for screening, with a sample of 1000 from each of the three reviewers (KKC, CFS, and XY) independently screened by a second reviewer (PSV) to assess agreement, with discrepancies discussed until an agreement was reached. The full-text screening was subsequently performed independently by two reviewers (by PSV and SZ) to identify eligible articles for data extraction and analysis, with discrepancies discussed until agreement was reached. We included any in-human primary research article reporting the development or validation of a diagnostic clinical risk prediction model using a prediagnostic trend over repeat measurements of at least one blood test parameter (Table 1) for subsequent diagnosis of cancer. A prediction model was defined as any multivariable model

designed to predict the presence of undiagnosed cancer (outcome), where at least one predictor in the model was a blood test trend. A model was considered to include "trend" if it included temporal changes in the quantitative blood test result over repeatedly measured tests per patient as a predictor. The blood tests in Table 1 are nonspecific (ie, not cancer-specific) blood tests that are commonly available in primary care settings. Recent evidence highlighted trends in many of these common tests as risk factors for cancer diagnosis [13]. Using these blood tests provides an opportunity to use commonly available data to support cancer detection.

Table . Blood tests included in this review.

Blood test	Blood level
Full blood count	Red blood cell count, hemoglobin, hematocrit, mean cell volume, mean cell hemoglobin, mean cell hemoglobin concentration, red blood cell distribution width, platelet count, mean platelet volume, white blood cell count, basophil count, eosinophil count, lymphocyte count, monocyte count, neutrophil count, basophil %, eosinophil %, lymphocyte %, monocyte %, neutrophil %
Liver function tests	Alanine aminotransaminase, albumin, alkaline phosphatase, aspartate transaminase, bilirubin
Renal function	Sodium, potassium, creatinine, urea
Inflammatory markers	C-reactive protein, erythrocyte sedimentation rate, plasma viscosity
Other tests	Amylase, HbA_{1c}[a], calcium, calcium adjusted, total protein, blood glucose, fasting glucose, thyroid stimulating hormone

[a]HbA_{1c}: hemoglobin A1c.

We excluded abstracts and conference proceedings, as they produce incomplete data for a thorough review. Studies using a cross-sectional design were excluded, as the data reflects a "snapshot" at a certain time so cannot assess risk over time. Clinical trials of treatment intervention were excluded to reduce the influence of treatments on blood test data. Existing systematic reviews, correspondence, and case studies pertaining to<5 individuals were excluded. Non-English full-texts without English versions available or nontranslatable were excluded.

Data Extraction

Data was extracted using an extraction form designed in Microsoft Excel and piloted on 3 randomly selected eligible articles. Data items included study design and population, blood test trends studied, analytic methods, cancer site, and predictive performance measures. Data extraction from each eligible article was performed by 2 reviewers independently (PSV, KKC, CFS, XY, and SZ), with disagreements discussed until agreement was reached.

Data Analysis and Synthesis

Quantitative data were summarized using means with SD for continuous data and counts with proportions for categorical data. We narratively described and critically appraised prediction models incorporating prediagnostic blood test trend. We performed a random-effects meta-analysis of the c-statistic (or area under the curve) for prediction models externally validated by at least 3 studies. The τ^2 statistic was used to describe heterogeneity and I^2 statistic to assess the proportion of heterogeneity explained by between-study differences. We also conducted a post hoc analysis, repeating the meta-analysis by including only studies using primary care data and again using only other studies, to assess if findings differed between underlying populations of care. Analyses were performed in Stata/SE 17.0.

Risk of Bias Assessment

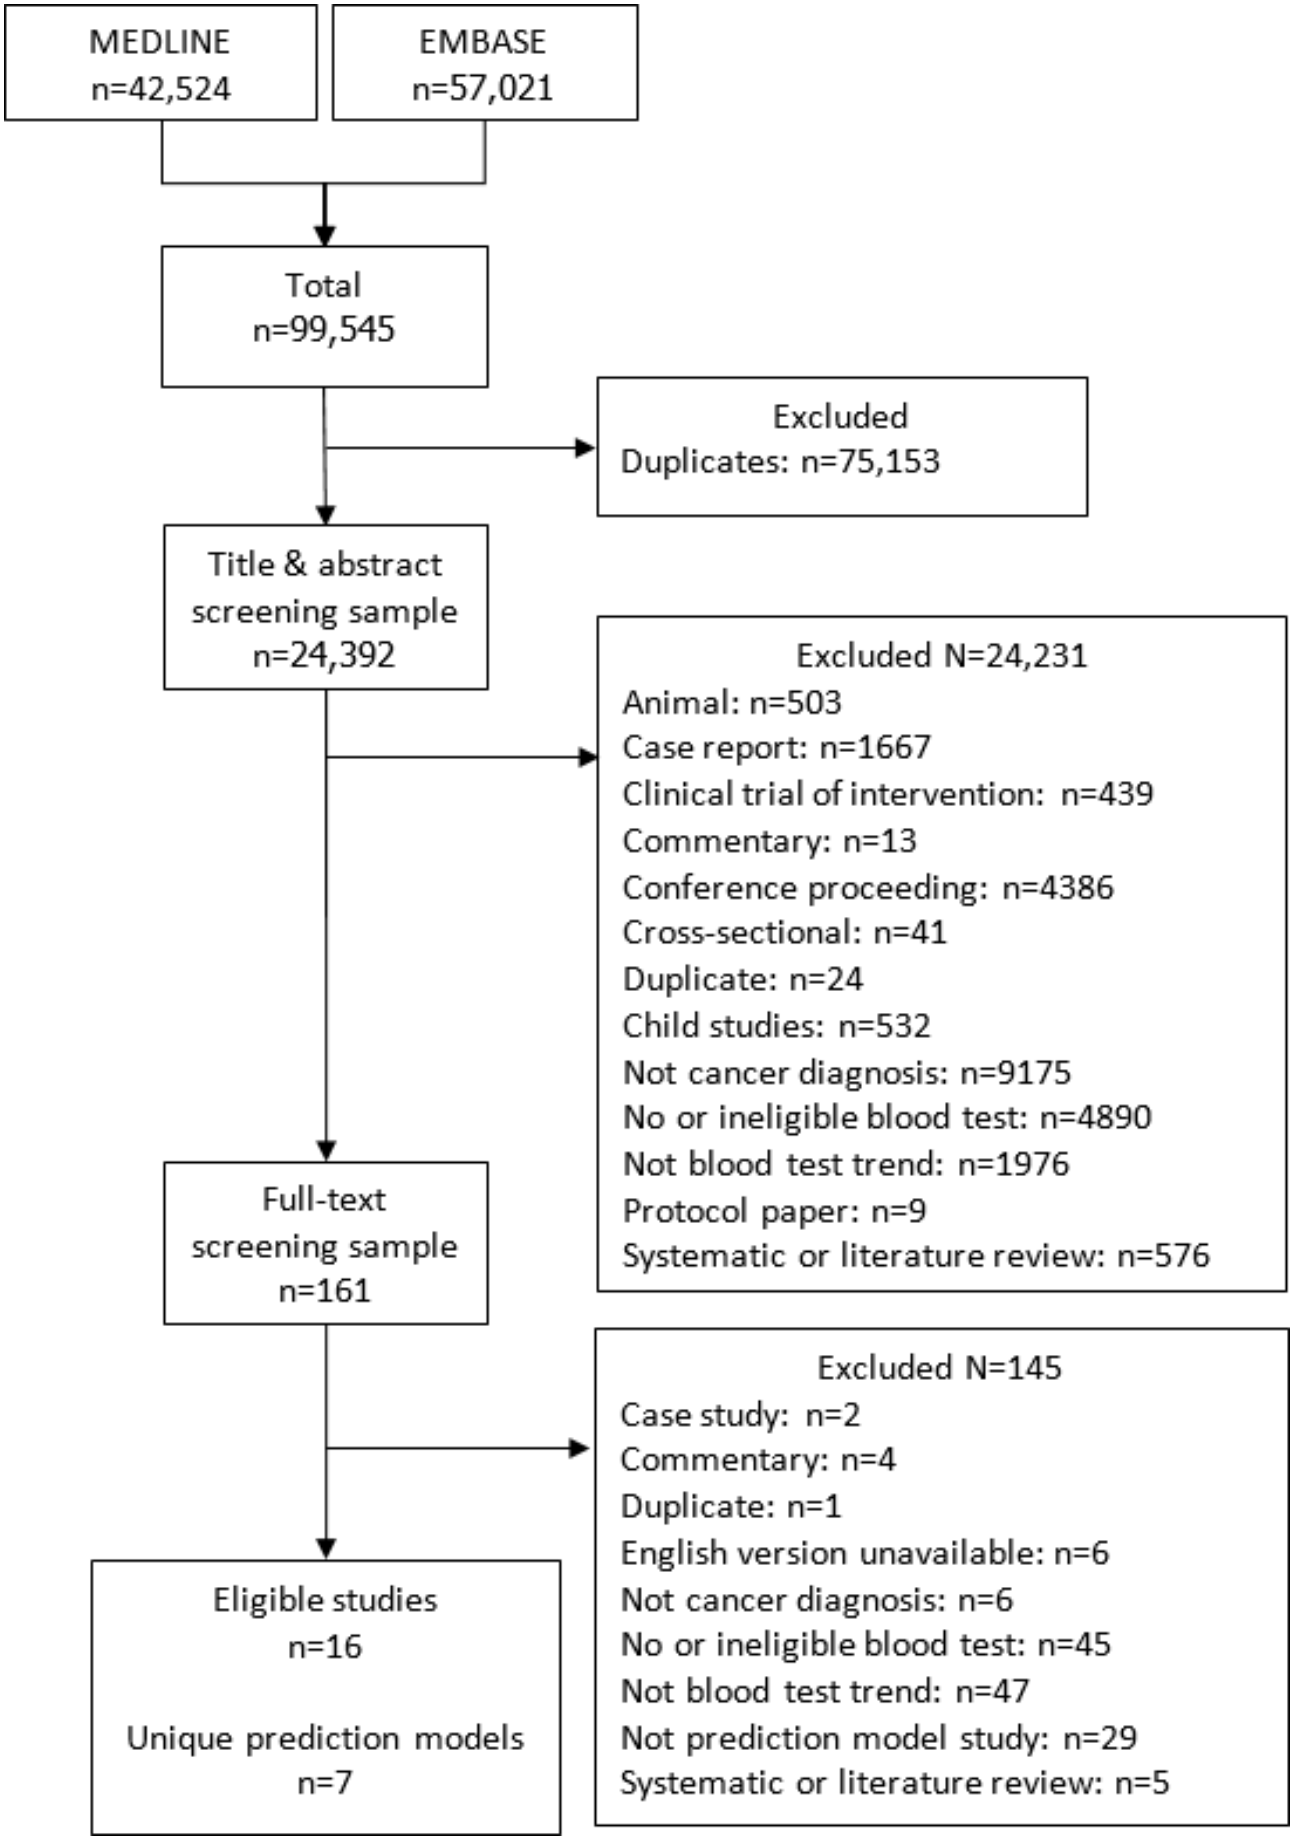
Risk of bias in each study was assessed using the Cochrane Prediction model Risk Of Bias Assessment Tool (PROBAST) [18]. Each study was assessed by two reviewers independently (PSV, KKC, CFS, XY, and SZ), with disagreements discussed until agreement was reached. Articles coauthored by a reviewer were assessed by other reviewers.

Results

Overall Summary

In total, 99,545 references were identified, of which 24,392 were unique after deduplication (Figure 1). A total of 16 studies met the eligibility criteria and were included in the review [19-34]. A total of 7 blood test trend-based prediction models were developed in total among 5 studies [23,27,28,30,31] and the remaining 11 studies [19-22,24-26,29,32-34] externally validated existing prediction models. In total, there were 14 external validations of 2 models (ColonFlag by Kinar et al [27] and ENDPAC (Enriching New-Onset Diabetes for Pancreatic Cancer) by Sharma et al [30]).

Figure 1. PRISMA (preferred reporting items for systematic review and meta-analysis) diagram.



Description of Studies

Study Design

A description of each study is provided in Table S3 in Multimedia Appendix 1. Of the 16 studies, a case-control design was used by 19% (n=3) [23,25,29] and cohort design by 81% (n=13) [19-22,24,26-28,30-34]. In addition, 25% (n=4) [19,20,22,24] used prospectively-collected data and 75% (n=12) [21,23,25-34] used retrospective data. Furthermore, 19% (n=3) [19,20,28] collected data at clinical centers, 75% (n=12) [21-23,25-27,29-34] used eHealth record databases, and 6% (n=1) [24] used both. All studies used opportunistic tests (ie, performed for any reason excluding screening for cancer, such as to monitor symptoms or comorbidity).

Participants

The mean number of participants recruited was 23,896 among prospective studies and 502,730 among retrospective studies, ranging from 617 to 2,914,589 participants over all the studies. The 16 articles spanned 4 different countries: the United States of America (44%, n=7) [23,25,28-30,33,34], the United Kingdom (25%, n=4) [19-21,31], Israel (25%, n=4) [22,26,27,32], and Canada (6%, n=1) [24]. The period of recruitment ranged from 1996 to 2020 in all studies. There were 38% (n=6) [21,26-28,31,32] studies conducted in primary care, 12% (n=2) [19,20] in secondary care, and 31% (n=5) in other settings: community-based insured adults (n=1) [25], endoscopy unit (n=1) [24], and insured individuals (n=3) [23,29,33]. It was unclear in 18% (n=3) [22,30,34]. One study [24] (6%) was limited to asymptomatic patients, including only patients without symptoms, and the remaining 94% (n=15) [19-23,25-34] included participants regardless of whether they experienced symptoms or not. A total of 6 studies [20,21,24,26,28,31] reported age, with a mean age 58.1 years (SD 5.2) among them. A total of 7 studies [21,25,27-29,31,32] reported sex, with mean 54.9% (SD 3.9) of females among them.

Model Building Strategy

Characteristics of the 7 models are in Table 2. A total of 4 models (57%) were developed in the USA population [23,28,30], 2 (29%) in United Kingdom [31], and 1 (14%) in Israel [27]. A total of 3 models (43%) were developed for risk of colorectal cancer [27,31], 2 (29%) for gastro-intestinal cancer (defined by Read as cancer of the esophagus, stomach, small intestine, colon, rectum, or anus) [28], 1 (14%) for nonsmall cell lung cancer [23], and 1 (14%) for pancreatic cancer [30]. A total of 6 models assessed cancer risk from the time of the latest blood test included and it was unclear in one study [23].

Table . Characteristics of 7 trend-based prediction models for cancer diagnosis.

Article	Country	Model (name, if assigned)	Outcome	Outcome risk window	Patient setting	Blood level(s) trend	Number of cases/total	Predictors in the final model
Gould et al [23]	United States of America	MES	Nonsmall cell lung cancer	Diagnosis	Other – insured individuals	ALT[a], creatinine, blood glucose, MCHC[b], platelets, RDW[c], WBC[d]	3942/117669	Age, sex, education, race, marital status, smoking status, smoking pack year, smoking years, smoking intensity, days since quitting, Hospitalization due to COPD and allied conditions, Diagnosis of COPD and allied conditions, Hospitalization due to Cancer, Diagnosis of Cancer, ALT, Creatinine, Glucose, MCHC, Platelets, RDW, WBC
Kinar et al [27]	Israel	ColonFlag	Colorectal cancer	3 - 6 months	Primary care	RBC[e], hemoglobin, hematocrit, MCV[f], MCH[g], MCHC, RDW, platelets, MPV[h], WBC, basophil#, basophil%, eosinophil#, eosinophil%, lymphocyte#, lymphocyte %, monocyte#, monocyte %, neutrophil#, neutrophil %	2437/466107	RBC, hemoglobin, hematocrit, MCV, MCH, MCHC, RDW, platelets, MPV, WBC, basophil#, basophil%, eosinophil#, eosinophil%, lymphocyte#, lymphocyte %, monocyte#, monocyte %, neutrophil#, neutrophil %, age, sex

Article	Country	Model (name, if assigned)	Outcome	Outcome risk window	Patient setting	Blood level(s) trend	Number of cases/total	Predictors in the final model
Read et al [28]	United States of America	Logistic model	Gastrointestinal cancer (esophagus, stomach, small intestine, colon, rectum, or anus)	6 months	Primary care	RBC, hemoglobin, hematocrit, MCV, MCH, MCHC, RDW, platelets, MPV, WBC, basophil#, basophil%, eosinophil#, eosinophil%, lymphocyte#, lymphocyte %, monocyte#, monocyte %, neutrophil#, neutrophil %	1025/148158	Age, sex, race, BMI, RBC, hemoglobin, hematocrit, MCV, MCH, MCHC, RDW, platelets, MPV, WBC, basophil#, basophil%, eosinophil#, eosinophil%, lymphocyte#, lymphocyte %, monocyte#, monocyte %, neutrophil#, neutrophil %, most recent BMP (8 components)
Read et al [28]	United States of America	Machine learning model	Gastrointestinal cancer (esophagus, stomach, small intestine, colon, rectum, or anus)	6 months	Primary care	RBC, hemoglobin, hematocrit, MCV, MCH, MCHC, RDW, platelets, MPV, WBC, basophil#, basophil%, eosinophil#, eosinophil%, lymphocyte#, lymphocyte %, monocyte#, monocyte %, neutrophil#, neutrophil %	1025/148158	Age, sex, race, BMI, RBC, hemoglobin, hematocrit, MCV, MCH, MCHC, RDW, platelets, MPV, WBC, basophil#, basophil%, eosinophil#, eosinophil%, lymphocyte#, lymphocyte %, monocyte#, monocyte %, neutrophil#, neutrophil %, most recent BMP (8 components)
Sharma et al [30]	United States of America	ENDPAC[i]	Pancreatic cancer	3 years	Unclear	Blood glucose	16/256	Change in weight, change in blood glucose category, age, change in blood glucose
Virdee et al [31]	United Kingdom	BLOOD-TRACC[j] Colorectal (females)	Colorectal cancer	2 years	Primary care	Hemoglobin, MCV, platelets	677/246695	Age, hemoglobin trend, MCV trend, platelets trend

Article	Country	Model (name, if assigned)	Outcome	Outcome risk window	Patient setting	Blood level(s) trend	Number of cases/total	Predictors in the final model
Virdee [31]	United Kingdom	BLOOD-TRACC Colorectal (males)	Colorectal cancer	2 years	Primary care	Hemoglobin, MCV, platelets	865/250716	Age, hemoglobin trend, MCV trend, platelets trend

[a]ALT: alanine aminotransaminase.

[b]MCHC: mean cell hemoglobin concentration.

[c]RDW: red blood cell distribution width.

[d]WBC: white blood cell count.

[e]RBC: red blood cell count.

[f]MCV: mean cell volume.

[g]MCH: mean cell hemoglobin.

[h]MPV: mean platelet volume.

[i]ENDPAC: enriching new-onset diabetes for pancreatic cancer.

[j]BLOODTRACC: full blood count trends for colorectal cancer detection.

In total, 2 models were developed using multivariate joint modeling [31], 2 using logistic regression [28,30], and 1 using each of XGBoost [23], decision trees [27], and random forests [28]. A total of 3 models (43%) were built by including all candidate predictors [27,28], 2 (29%) included clinically relevant predictors that were commonly available in practice [31], 1 (14%) included statistically significant variables in univariable analysis [30], and the model building process was unclear for 1 (14%) model [23]. To address missing blood test data, 2 (29%) models derived missing blood levels from other available blood levels using known mathematical relationships (eg mean cell hemoglobin=hemoglobin/red blood cell count) [31], 2 (29%) used imputation methods [28], 1 (14%) analyzed the blood test data as-is (without altering missing data) [23], and 1 (14%) used other methods (linear models to replace missing values using historical blood tests or mean value across all blood tests if no historic blood tests were present) [27]. Methods for handling missing blood test data were not discussed in 1 (14%) study [30].

Modeling Blood Test Trends

A total of 3 models (43%) assessed trends over repeated quantitative blood test results; Kinar et al [27] used ensembles of decision trees for the ColonFlag model, modeling changes over tests measured at 3 - 6 months before diagnosis and 18 and 36 months before that for each patient in the ensemble model, and Virdee et al [31] used multivariate joint modeling, which uses mixed-effects modeling to account for differing numbers of tests and the time between them in sporadically available repeated measures data between patients, for both BLOODTRACC models. One model (14%), by Sharma et al[30], calculated the difference between tests and included this as a single continuous variable in a logistic regression model to determine risk. It was unclear how trends were included in 3 (43%) models to predict risk [23,28].

The number of repeat blood tests used to define trend varies between models. Read et al [28] calculated the change in slope (reflecting the trend/trajectory) over at least 2 repeated tests sporadically measured over 3 years, Sharma et al [30] calculated the difference between blood tests measured at 18-3 months before new-onset diabetes and included this in their model, and Virdee et al[35] included the change in slope across all available blood tests (median=3 per patient) sporadically measured over 5 years to predict risk. The number of repeated blood tests used to derive trends was not reported for 3 models (43%) but the period of repeated testing among them ranged between 18 months and 5 years [23,27,30]. See Table S4 in Multimedia Appendix 1 for further details.

A total of 6 models (86%) used combinations of blood test trends and 1 model (14%) used trend in a single blood test (plus with other patient data) to predict cancer risk. The logistic model and random forests model by Read et al [28] combined trends in 28 blood tests Kinar et al [27]. combined trends in 20 blood tests (that make up the FBC) using decision trees, and Gould et al [23] combined trends in 7 blood tests using XGBoost. Virdee et al [35] combined 3 blood test trends (hemoglobin, mean corpuscular volume, and platelets) using multivariate joint modeing.

Model Reporting

Total 3 (43%) models were reported using appropriate reporting guidelines to report model findings (TRIPOD [Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis] guidelines [28,31,36]). For 3 (43%) models, justification for their choice of outcome risk window was provided [23,31]. In addition, 2 (29%) models were reported to be sufficiently powered, having provided a sample size calculation to show the number of patients and events needed to ensure reliable predictions and minimize optimistic performance [31].

Read et al [28] did not report the coefficients from their logistic model and Sharma et al [30] did not report the intercept from their logistic model. The full risk equation needed to derive an individual's risk of diagnosis was only reported for 2 models [31]. The models developed using XGBoost, decision trees, and random forests were not reported, due to the nature of machine

learning, and a reference to publicly available models was not provided [23,27,28].

Internal Validation

A total of 6 (86%) models underwent internal validation and one (14%) (by Sharma [30]) did not (Table 3). The internal validation sample was obtained using random data splitting for 4 (57%) models [23,27,31] and cross-validation for 2 (29%) models [23,,2828]. On average, there were 214,883 participants in the validation samples, ranging from 78,433 to 462,900. A total of 4 (57%) models were adjusted for overestimated performance [27,28,31] and it was unclear for 2 (29%) models [23,28].

Table . Performance statistics from internal and external validations of the final models, which include trends and other patient data.

Article	Model name/description	Outcome risk window	Overall performance		Discrimination		Calibration	
			Method	Result	Method	Result (95% CI)	Method	Result
Internal validation								
Gould et al [23]	MES	3 - 6 months	No		AUC/C-statistic	0.870 (0.856 - 0.886)	Isotonic regression

[a]BLOODTRACC: Full blood count trends for colorectal cancer detection.

[b]ENDPAC: enriching new-onset diabetes for pancreatic cancer.

Only 4 (57%) models assessed overall performance. Virdee et al [31], derived Brier scores of 0.0028 (men) and 0.0033 (women) for 2-year risk of colorectal cancer and Read et al [28] derived Brier scores of 0.008 (logistic regression) and 0.092 (random forests) for 6-month risk of GI cancer28.

A total of 6 (86%) models (100% of those internally validated) assessed discrimination, each using the c-statistic. Gould 2021 [23] and Kinar 2016 [27] reported c-statistic=0.87 and 0.82 for 3 - 6-month risk of nonsmall cell lung cancer in the United States of America and Israel based on various blood test trends measured over 5 years combined with other patient data and colorectal cancer based on all FBC parameters over 3 years combined with other patient data, respectively. Read 2023 [28] reported c-statistic=0.711 (logistic regression) and 0.713 (random forests) for 6-month risk of GI cancer based on FBC trends combined with other patient data. Virdee et al [31] reported c-statistic=0.75 (men) and 0.76 (women) for 2-year risk of colorectal cancer following trends in hemoglobin, mean cell volume, and platelets, together with age, measured over 5 years in UK primary care patients.

A total of 4 (57%) models were assessed for calibration. Gould 2021 [23] used isotonic regression to assess calibration, but did not report the corresponding results. Kinar 2016 [27] used the Hosmer-Lemeshow test and reported *P*=.47 for 3 - 6 month risk of colorectal cancer. Virdee et al [31] derived calibration slopes of 1.06 (men) and 1.05 (women) for 2-year risk of colorectal cancer and presented calibration plots.

External Validation

Fourteen external validation studies were performed in total for 2 models (Table 3): the ColonFlag by [27] was externally validated by 10 studies and the ENDPAC model by [30] by 4 studies. There were on average 244,580 participants included in the external validation studies, ranging from 532 to 2,225,249. Overall performance, discrimination, and calibration are all essential assessments to assess external validity of prediction models [37]. Overall performance of the ColonFlag or ENDPAC model was not assessed during external validation.

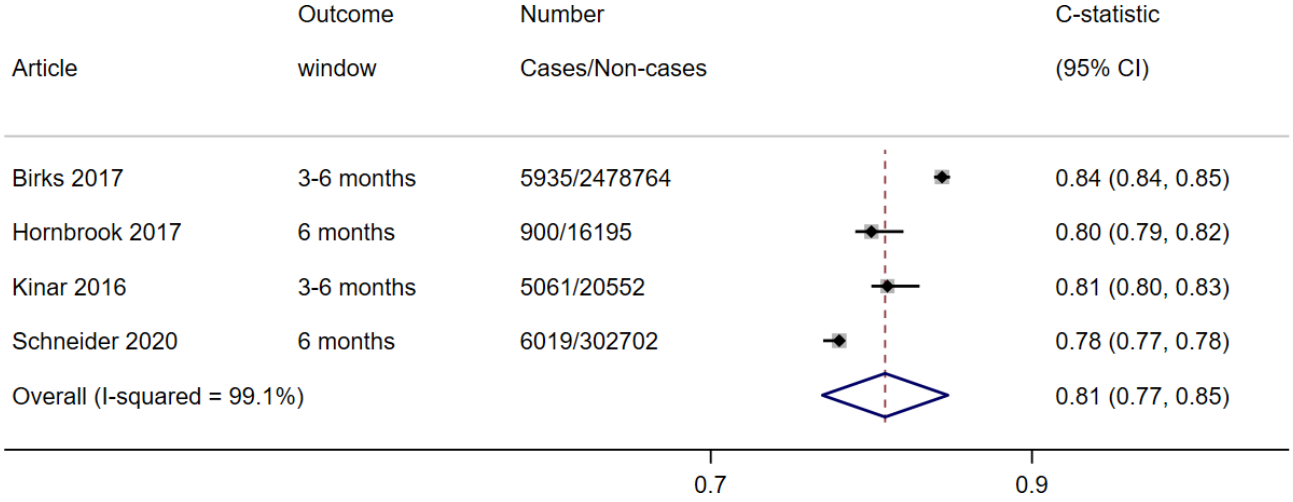
A total of 6 (29%) of the 14 external validations assessed discrimination, with all using the c-statistic. Birks et al [21] externally validated ColonFlag at multiple time intervals between the most recent blood test and diagnosis in a UK sample, reporting c-statistic=0.844 at 3 - 6 months, which reduced to 0.751 at 23 - 36 months [21]. Kinar et al [27] also externally validated the ColonFlag using UK data and reported a similar c-statistic (0.81) at 3 - 6 months before colorectal cancer diagnosis [27]. However, Kinar et al [27] removed the red blood cell distribution width blood level from the model and assessed predictive performance of the resulting model.

This was because the UK dataset did not include red blood cell distribution width, but the removal of a predictor from the model consequently means the external validation is incomplete.

A total of 4 studies with available data assessed <6-month risk of colorectal from ColonFlag and were included in a random-effects meta-analysis [21,25,27,29]. The pooled estimate indicated c-statistic=0.81 (95% CI 0.77 - 0.85) (τ^2=0.0016), with 99.1% (I^2) of the heterogeneity attributable to between-study differences (Figure 2). Our post hoc meta-analyses including only primary care populations and nonprimary care populations separately reduced heterogeneity, but this remained high (Figure S1 in Multimedia Appendix 1).

Calibration was assessed by Kinar et al [27]2016 only, using the Hosmer-Lemeshow test for the ColonFlag. They reported weak calibration at 3 - 6 months in the UK dataset (P<.001).

Figure 2. Forest plot of c-statistic for risk of colorectal cancer from ColonFlag external validations [21,25,27,29].



Added Value of Trend

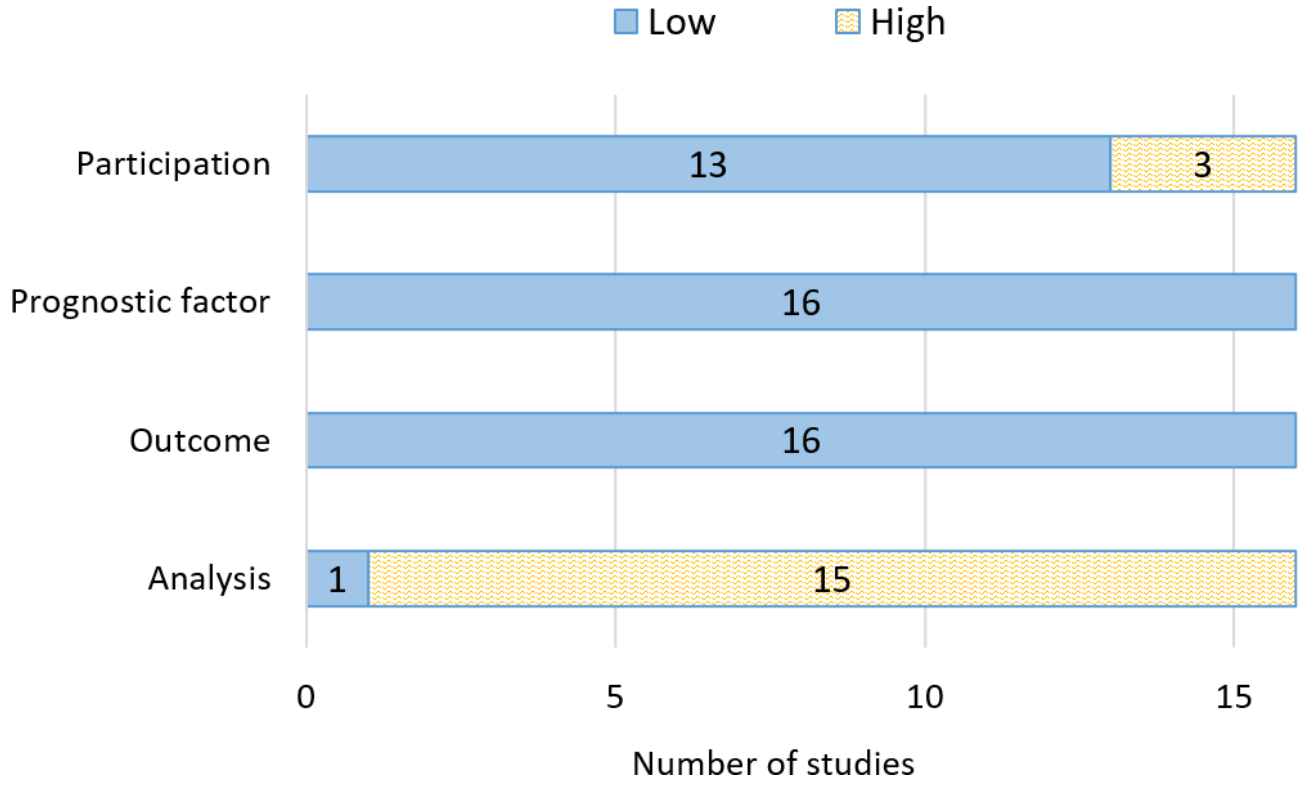
Kinar et al [27] assessed which blood test trends contributed most to the c-statistic of their prediction model for 3 - 6 month risk of colorectal cancer. Their model included trend in 20 FBC parameters, age, and sex. Red blood cell-related parameters contributed the most to the c-statistic, with trend in hemoglobin contributing the most (around 0.11) when added to age and sex. White blood cell-related parameters added the least to the c-statistic when combined with age and sex, such as adding around 0.03 AUC with the inclusion of monocyte count trend.

Read et al [28] used logistic regression to develop prediction models for the 6-month risk of gastro-intestinal cancer, including age, sex, BMI, blood test trends, and further covariates. They compared the c-statistic of their final model to one including blood tests measured at a single time point (the last test prior to the prediction interval). They report a higher c-statistic for their model including blood test trends (0.711, 95% CI 0.691 - 0.731) compared with the model including blood tests from a single time point (0.697, 95% CI 0.679 - 0.715). As secondary analyses, they assessed the c-statistic for one-, three-, and five-year risk, reporting higher c-statistics for models including blood test trends compared to models including single blood tests for one- (0.705, 95% CI 0.689 - 0.722 trend and 0.693, 95% CI 0.675 - 0.710 single) and three-year (0.735, 95% CI 0.713 - 0.757 trend and 0.683, 95% CI 0.665 - 0.701 single) risk but a lower c-statistic for their model including trends for five-year risk (0.672, 95% CI 0.653 - 0.691 trend and 0.703, 95% CI 0.686 - 0.720 single). No other study reported the added benefit of blood test trend to the prediction models.

Risk of Bias

Risk of bias for each domain is summarised in Figure 3 and per study in Table S5 in Multimedia Appendix 1. All 16 studies scored a low risk of bias in the predictors and outcome domains. All but 3 studies in the participant domain scored low risk of bias, with (Gould et al, Hornbrook et al, and, Schneider et al [23,25,29]) scoring high risk of bias for not including all eligible patients in their analyses. All but one study scored a high risk of bias in the analysis domain, commonly due to studies removing patients with missing data from all their analyses, not adjusting the developed model for under or overfitting, or not accounting for complexities in the data, such as censoring.

Figure 3. Summary of risk of bias scores, assessed using the prediction model risk of bias assessment tool.



Discussion

Principal Findings

This systematic review builds on our recent review on the association between blood test trend and cancer diagnosis [13] by highlighting the potential for risk stratification and methodological considerations of incorporating combinations of trends into cancer risk prediction models for use in practice. Our review identified logistic regression (incorporating the difference between 2 blood tests as a single variable) and multivariate joint modeling as the most commonly used modeling techniques. Models were often developed using poor methods. For example, although all but one model underwent internal validation during model development, model performance was not adequately assessed, with calibration often ignored and recalibration rarely performed for overfitting [37-41]. Where calibration was assessed, the Hosmer-Lemeshow test was sometimes used, which is known to have limited power and poor interpretability [37]. Many models were inadequately reported, with only one study providing the full risk-equation needed to derive an individual's risk of diagnosis. Without the full risk equation being available, models are unlikely to be independently externally validated or easily embedded into practice. Although our primary focus was to critically appraise trend-based prediction models, it is important to also highlight caution in the interpretation of performance measures from the models, as these may be subject to publication bias. For example, a prediction model with a poorer c-statistic is less likely to be published.

The ColonFlag model was most commonly externally validated, although this model is commercially developed so not publicly available. This model uses trends in FBC parameters to predict a monotonic score confined between 0 - 100, where higher scores reflect a higher likelihood of colorectal cancer diagnosis [27]. A pooled c-statistic of 0.81 from 4 studies indicates that trends in the FBC could be generalizable to other clinical settings and geographical locations, with good predictive ability to distinguish between patients with and without colorectal cancer. Heterogeneity was however high. This was anticipated due to the variation between studies included in the meta-analysis, such as differing geographical settings, health care systems, and eHealth records used. Therefore, caution should be given in the interpretation of these results when making generalisations between different clinical settings. There were few studies demonstrating the external validity of other models including blood test trend. Predictive ability of models was not assessed by cancer characteristics, such as by cancer stage, in any study.

Comparison of Models

A total of 3 models were identified for colorectal cancer: the ColonFlag and sex-specific BLOODTRACC models. Both models include age and sex, with the ColonFlag also including trend in all 20 FBC parameters and the BLOODTRACC models including trend in only three FBC parameters (hemoglobin, mean cell volume, and platelets). The ColonFlag uses changes over tests measured at 36 and 18 months up to the current test, with all patients requiring a test at each time point, whereas the BLOODTRACC models use all available tests over a five-year period before the current test and takes into consideration the timing of tests, as blood tests are not performed routinely in the United Kingdom. Although the ColonFlag was developed for 3 - 6 month risk in Israeli primary care, external validation studies of this model for two-year risk found it performed similarly to the BLOODTRACC models for 2-year risk in UK

primary care. This suggests that the 17 additional blood test trends in the ColonFlag may not add further diagnostic benefit to the combination of hemoglobin, mean corpuscular volume, and platelet trends for colorectal cancer. This may suggest that the underlying methodology used to develop the models (decision trees for the ColonFlag and joint modeling for the BLOODTRACC models) does not affect discriminative performance, but this would need assessing on the same patient dataset and multiple study designs employed to reduce heterogeneity. This assessment was performed in the BLOODTRACC model derivation study, where both models derived comparable c-statistics in the same cohort, both overall and in subgroups of age, by number of blood tests used to derive trends, and by longitudinal period used to derive trends [31].

Read et al[28] developed two models for gastro-intestinal cancer, one using random forests and one using logistic regression. Both models were designed to be as similar as possible, such as using the same study sample, outcome window, longitudinal period to derive trends, and similar covariates, with the methodological approach used to derive the methods being the biggest difference. Both models achieved an AUC of 0.71, suggesting that the underlying methodological approach may not affect discriminative performance, although the logistic model had better overall performance (lower Brier score). Neither model was assessed for calibration so further testing is required.

The remaining 2 models were for lung and pancreatic cancer. These were not compared with other models, as no further models for lung or pancreatic cancer were identified.

Strengths and Limitations

To our knowledge, this is the first review of cancer prediction models that incorporate blood test trend. We performed a comprehensive search, developed with an information specialist, including full-length articles retrieved from MEDLINE and EMBASE. It is possible that additional relevant studies may be found exclusively in other databases and were missed by our review. However, it is likely that most relevant manuscripts were found, as MEDLINE and EMBASE had 97.5% coverage of articles in previous systematic reviews and we conducted citation searching of all included manuscripts [42]. Our review identified prediction models for only four cancer types, with two externally validated (colorectal and pancreatic). We were therefore unable to draw conclusions regarding external validity for many cancer types. One further limitation is that we were unable to draw conclusions regarding publication bias, assessing whether prediction models were more likely to be published if they had good predictive performance. Only five models had c-statistics with corresponding confidence intervals at internal validation, making it difficult to assess symmetry in a funnel plot and deduce any publication bias.

Comparison With Previous Work

To date, prediction models for cancer risk are most commonly developed using single blood test results (plus other predictors). These include the QCancer models for the 2-year risk of cancer [43,44] and unexpected weight loss models for the 6-month risk of cancer [45], which combine patient demographics, symptoms, and single blood test values for cancer risk in symptomatic patients in UK primary care practices. Collectively, these models have c-statistics ranging 0.79 - 0.92, comparable to 0.71 - 0.87 reported for the models included in this review, which often included only blood test trends, age, and sex and different outcome risk windows. Existing systematic reviews have identified prediction models for individual cancer sites, including lung, breast, colorectal, and prostate, but the focus of these reviews was not on the role of blood test trend [46-49]. Lung cancer prediction models in those reviews often included patient demographics, pneumonia, exposure to smoking, and single blood tests for one-year risk, with c-statistic ranging 0.66 - 0.91. In this review, Gould et al [23] reported 0.87 for six-month risk of lung cancer using similar predictors combined with trend in seven blood tests. Colorectal cancer prediction models in those reviews often included patient demographics and single blood tests, with c-statistic ranging from 0.82 - 0.84 for 6-month risk and 0.72 - 0.92 for 2-year risk. In this review, Kinar et al [27] and Birks et al [21] reported 0.82 - 0.84 for 6-month risk and Virdee et al [31] reported 0.75 - 0.76 for 2-year risk of colorectal cancer using trend in 20 and three blood tests, respectively, age, and sex. Although those reviews identified prediction models using single blood test results for breast and prostate cancer [46,49], we found no prediction models incorporating trends for these cancers in this systematic review.

Clinical and Research Implications

Thorough testing of prediction models is required before clinical guidelines for cancer investigation can incorporate blood test trends. This includes assessment for the predictive ability of blood test trend compared to single blood tests and symptoms and the potential for early detection of cancer. For example, in the cancer field, the NICE guidelines recommend primary care to refer for cancer investigation if a patient's risk is above 3%, which is often used to support referral of symptomatic patients, whose risk is likely higher than nonsymptomatic patients. For models derived for more general populations, such as the trend-based models included in this review, there is no clear cut-off. To assess the potential added benefit of trend, studies would need to compare the diagnostic accuracy of trend-based and static/single-test models. No study in our review performed such comparisons, so this potential remains unknown. Patient- and clinician-acceptability of blood test trend approaches for cancer detection also requires investigation to optimize uptake of such models in practice. As some clinicians order blood tests more than others, methods to standardize blood testing across practices may be warranted and could reduce practice-level variability through clinical guidelines on repeat blood testing. This additional testing may add burden to health care, but the balance of patient benefit and outcomes to health care burden would need investigation. In terms of reporting, prediction models were often not reported in full, which is required for implementation into clinical systems and use in practice. Future models should follow appropriate reporting guidelines to ensure they are appropriately reported, such as the TRIPOD [36] or TRIPOD-AI [50] guidelines.

Sub-optimal methods to analyse trends were often identified, such as logistic regression incorporating change between tests.

Recent technological advancements have allowed for dynamic models, which are designed for repeated measures data by appropriately accounting for nonindependent data sporadically recorded in routine clinical practice [51], to be incorporated into analysis software packages. These include models such as landmarking and joint modeling of longitudinal and time-to-event data [52-54]. Research is required to assess the implementation considerations of different methodological techniques. For example, the feasibility of incorporating computationally intensive approaches, such as joint modeling, or approaches that require larger datasets or are nontransparent, such as machine learning. Our ongoing research aims to develop and validate trend-based prediction models for cancer, with eventual integration of trend into risk stratification in clinical practice [55]. Future prediction model studies should employ appropriate validation metrics, as we found that most studies did not assess overall performance or calibration. Further sub-optimal analysis methods commonly used included removing patients with missing data from all their analyses, not adjusting the developed model for under or overfitting, or not accounting for complexities in the data, such as censoring. Future models should consider such points to reduce bias.

Conclusion

We highlight the cancers for which there is a reported prediction model incorporating changes in repeated blood tests over time and the cancers and blood tests with no published literature. We provide an overview of the predictive performance of prediction models incorporating blood test trends and highlight that further testing is needed for all models identified. This review lays the foundation for further research.

Acknowledgments

PSV and BDN are funded for this work by a Cancer Research UK Clinical Careers Committee Postdoctoral Fellowship (RCCPDF\100005). The authors would also like to thank patient and public involvement representatives Alton Sutton, Bernard Gudgin, Clara Martins de Barros, Emily Lam, Ian Blelloch, Julian Ashton, Margaret Ogden, Shannon Draisey, and Susan Lynne for applying a patient perspective on the relevance of blood test trends for cancer detection.

Abstract

Background: Many cancer survivors experience a wide range of symptoms closely linked to psychological problems, highlighting the need for psychological treatment, one of the most popular being mindfulness. The use of the internet has greatly increased in the last decade, and has encouraged the use of remote-based interventions to help people living with cancer access treatment remotely via devices.

Objective: The primary aim of this study was to explore the efficacy of internet-based mindfulness interventions on the physical symptoms of people living with cancer, where physical symptoms are defined as distressing somatic experiences (eg fatigue, insomnia, and pain) regardless of the underlying cause. The secondary aim was to investigate interventions for the quality of life (QoL).

Methods: This study followed the Preferred Reporting Items for Systematic Review and Meta-analysis (PRISMA) guidelines. Relevant articles were systematically searched using electronic databases, namely Scopus, Medline through PubMed, Cumulated Index in Nursing and Allied Health Literature (CINAHL) through EBSCOhost, and Cochrane Central Database. Randomized controlled and pilot trials involving adults and/or older adults with cancer and using remote-based mindfulness interventions compared to usual care were included. The quality of the trials included in this study was assessed using the revised Cochrane risk of bias, version 2.0. This study estimated the standardized mean difference (SMD) and mean difference (MD) with 95% CI. The I^2 test was used to identify potential causes of heterogeneity. Publication bias was assessed using contour-enhanced funnel plots and the Egger linear regression test to reveal a small study effect.

Results: The initial search yielded 1985 records, of which 13 studies were ultimately included. After treatment, remote-based mindfulness significantly reduced fatigue (SMD −0.94; 95% CI: −1.56 to −0.33; *P*=.002), sleep disturbance (SMD −0.36; 95% CI: −0.60 to −0.12; *P*=.004), and improved physical function (SMD .25; 95% CI: 0.09 to 0.41; *P*=.002) compared to that observed before treatment. However, compared with usual care, remote-based mindfulness showed a statistically significant reduction only in sleep disturbance (SMD: −0.37; 95% CI: −0.58 to −0.16; *P*=.0006) after treatment. Moreover, remote-based mindfulness was not statistically significant in reducing pain both within and between groups.

Conclusions: Remote-based mindfulness shows promise in reducing sleep disturbances; however, its impact on fatigue, pain, and physical function may be limited.

KEYWORDS

cancer; physical symptoms; mindfulness; remote-based intervention; quality of life

Introduction

Advancements in cancer medication have extended the life expectancy of cancer patients in recent years [1]. However, more cancer survivors undergo cancer treatment for a longer period. Chronic treatment has been shown to increase symptom burden and reduce the quality of life (QoL) of cancer survivors [2-7]. More than two-thirds of cancer survivors with advanced disease are symptomatic [8]. Cancer survivors receive supportive care focused on relieving symptoms at all stages of their illness [9-11].

Most cancer survivors frequently experience physical symptoms such as pain and fatigue. Physical symptoms are defined as the subjective experiences of distressing somatic symptoms (eg fatigue, insomnia, pain, and nausea), regardless of the cause [12]. In most cancer survivors, pain may be managed with relatively standard treatment [13]. Recent suggestions include a multimodal approach with tailored therapy, including perceptual, homeostatic, and behavioral reactions to chronic illness. This approach allows healthcare professionals to dynamically manage pain by integrating pharmacological and nonpharmacological strategies (eg, acupuncture and psychotherapy) based on pain pathophysiology and characteristics. Following pain symptoms, 50 - 90% of patients experience fatigue, which negatively affects their daily activities and QoL [14]. Insomnia is also a common symptom in cancer survivors and can have a systematic effect on psychological burdens, such as stress, fatigue, and depression [15,16].

The symptoms experienced by cancer survivors and their relationship with psychological problems often benefit from psychotherapy. The benefits of psychotherapy can be explained by the body-mind-spirit model [17], which highlights the interconnectedness of physical, mental, and spiritual health [18]. Commonly used psychotherapies include mindfulness-based stress reduction-based interventions and cognitive behavioral therapy (CBT). These therapies are effective in reducing symptoms in cancer survivors, particularly chronic pain and stress [19-21]. CBT is considered beneficial for alleviating pain and other symptoms by reducing catastrophic thinking and enhancing self-efficacy in coping with symptoms such as pain [22]. Similarly, mindfulness-based interventions are considered beneficial for chronic pain by promoting mindfulness and promoting greater acceptance of pain or other symptoms [22]. Unlike traditional psychotherapies, such as CBT, which primarily focus on cognitive restructuring, mindfulness interventions offer the unique benefit of directly enhancing patients' capacity for present-moment awareness and acceptance of their experiences.

Advancements in healthcare information technology along with the broader accessibility of healthcare services have driven the rapid growth of remote-based interventions. The intervention spans a wide array of practices and specialties, facilitating interactions through various modalities such as telephone, email, video conferencing, online platforms, and remote monitoring devices. The rapid growth of remote-based methods has led to the delivery of mindfulness through the internet. Remote-based interventions have been integrated into cancer care and treatment, which suggests a benefit in treatment outcomes [23]. Remote-based mindfulness is defined as a psychotherapy program that uses a technological device that ensures interactive and immediate communication and does not require the patient to be present with the therapist [24].

Recent evidence suggests the benefits of remote-based interventions using a website on psychological well-being, such as reducing distress, depression, and anxiety [25-27]. Remote-based interventions may be more suitable for patients who experience weakness and fatigue due to physical limitations, such as cancer survivors. A study conducted by Schellekens et al suggested the benefit of web-based mindfulness-based cognitive therapy programs for improving care outcomes in patients with chronic cancer-related fatigue [28]. While a previous meta-analysis has evaluated the benefit of remote-based mindfulness for cancer survivors [29,30], its focus on physical symptom outcomes remains limited. Therefore, this study aimed to explore the benefit of remote-based mindfulness interventions on physical symptom outcomes as a primary and/or secondary outcome of trial studies in cancer survivors.

Methods

Study Design

This study was a systematic review and meta-analysis. This study was presented in accordance with the preferred reporting items for systematic reviews and meta-analyses (PRISMA; Checklist 1) [31]. The protocol was not prospectively registered in any database such as PROSPERO (Prospective Register of Systematic Reviews).

Eligibility Criteria

The inclusion criteria were defined according to the Population, Intervention, Comparison, Outcome (PICO) framework. The population of the included studies was diagnosed with cancer through imaging, laboratory tests (including tumor marker tests), tumor biopsies, endoscopic examinations, surgeries, and genetic testing. Interventions were remote-based mindfulness interventions defined as mindfulness interventions that integrated information and communication technology, such as mobile phones, websites, mobile apps, and asynchronous instruction with text-based reminder messages. Comparisons were defined as standard or usual care with face-to-face mindfulness interventions, or standard cancer care. The outcomes of this study included the physical symptoms related to cancer outcomes. Physical symptoms were defined as the subjective experiences of distressing somatic symptoms (eg, fatigue, insomnia, and pain). The outcomes were measured using self-reports or standard questionnaires. The exclusion criteria were the types of articles, such as case reports, editorials, invited commentary, reviews, non-research letters, and

abstract-only articles. To prevent bias, articles published before 2012 and those written in a language other than English as an international language were excluded from this study. This review focused on studies published after 2012 to ensure that the findings represented the most recent advancements in technology, healthcare practices, and guidelines that have progressed markedly over the past decade.

Study Search Strategy and Selection Process

The selection process for this study followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses protocol. This review systematically searched electronic databases, namely Scopus, Medline, PubMed, Cumulated Index in Nursing and Allied Health Literature (CINAHL), EBSCOhost, and the Cochrane Central Database. The search was conducted until December 2022. The following keywords were used. (All Fields] OR Internet-based intervention "web-based"[All Fields] OR "internet-based intervention"[All Fields] OR "online based"[All Fields]) AND ("mind s"[All Fields] OR "minded"[All Fields] OR "mindful"[All Fields] OR "mindfulness"[MeSH Terms] OR "mindfulness"[All Fields] OR "mindfulness intervention"[All Fields] OR "mindfulness-based stress reduction"[All Fields] OR "mindfulness- based cognitive therapy"[All Fields]) AND ("cancer s"[All Fields] OR "cancer"[All Fields] OR "cancers"[All Fields] OR "oncology patients"[All Fields] OR "Patients with cancer" [All Fields]). The detailed search strategy can be found in Multimedia Appendix 1. In addition, we used a hand-searched reference list of the included studies to expand the number of additional studies.

The reference manager automatically removed duplicate articles using Mendeley (Mendeley Ltd.). Two independent authors (SM and SA) initially screened the text (eg, title and abstract). The full text of the articles that met the eligibility criteria were independently assessed by two independent authors. At this stage, the articles were meticulously evaluated based on predetermined inclusion and exclusion criteria, and irrelevant studies were excluded. Discrepancies were resolved by a third reviewer (MK).

Data Extraction

Two authors (MK and SM) independently extracted data using standard tabulation tables (spreadsheets). The following data were included: study characteristics (ie, author, year, study design, country, model intervention, and follow-up duration); participant characteristics (ie, average age, education level, number of participants, and cancer site); and physical symptoms (eg pain, fatigue, and insomnia). Data extraction was performed independently and disagreements were resolved through discussion and consensus among the authors.

This study assessed the quality of this randomized-controlled trial (RCT) using the Cochrane risk of bias, version 2.0. Three authors (MK, SM, and HP) evaluated the enrolled studies separately. The following factors were considered in the assessment: bias arising from random processes, bias due to deviation from the intended intervention, bias due to missing outcome data, bias in outcome measures, and bias in selection of reported outcomes. This discourse resolved the differences in perceptions regarding the quality of the research.

Statistical Analysis

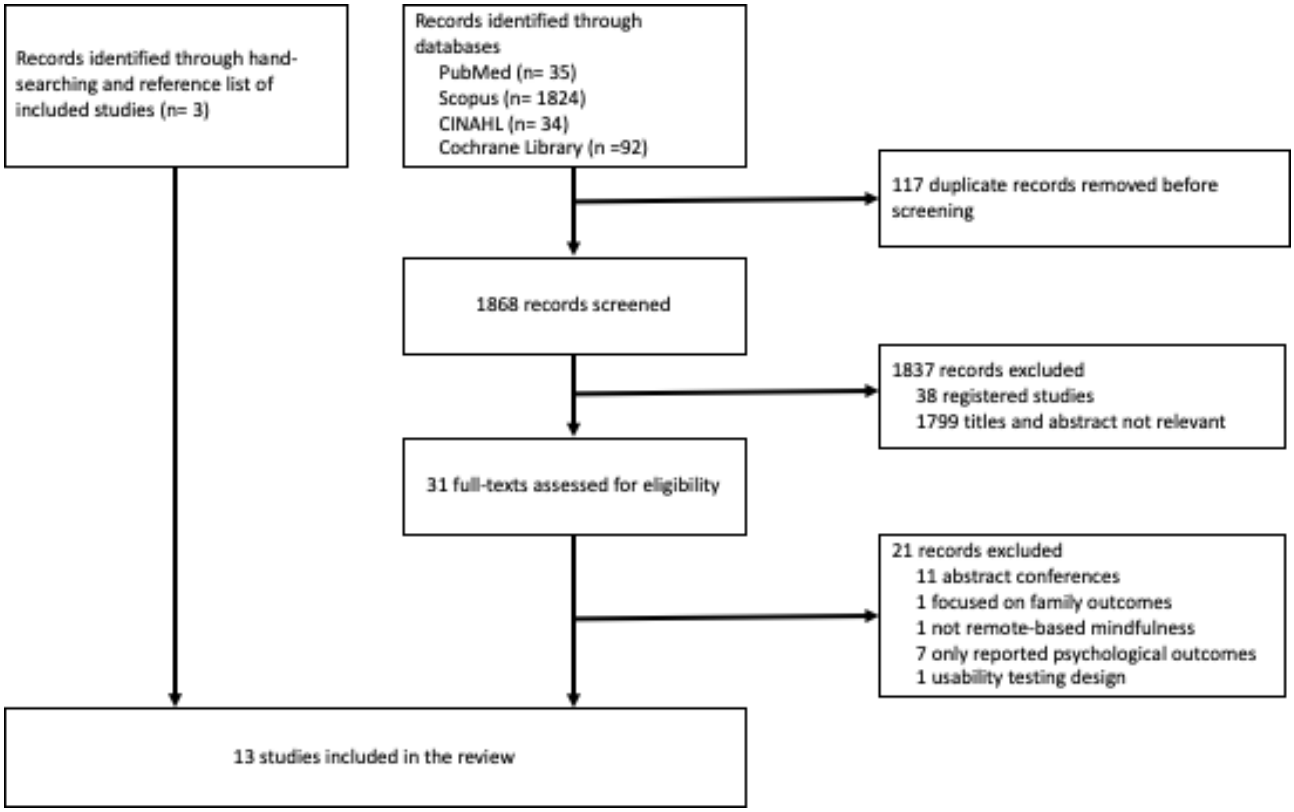
All statistical analyses were performed using Review Manager version 5.4.1 (RevMan) [32]. This study estimated the effect size in the form of the standardized mean difference (SMD) for the outcome and the mean difference (MD), with the 95% CI. The SMD was used when the outcomes were measured in different units across studies. The MD was used when the outcomes were measured in the same unit across studies. The SMD criteria were divided into three categories: low, medium, and large effects, with values of <0.5, ≥05, and ≥0.8, respectively [33]. This review conducted posttreatment analysis that reported pre- and post–remote-based intervention. We also conducted a comparison between remote-based intervention and usual care after treatment. The inconsistency index (I^2) and subgroup analysis using the I^2 test were used to identify potential causes of heterogeneity. An I^2 value of >50% and a P-value of <.05 were considered statistically significant for heterogeneity [34]. A random-effects model was applied despite the study heterogeneity to account for interstudy variability [35]. In this study, a two-tailed P value of .05 was considered statistically significant. Publication bias was analyzed qualitatively using a contour-enhanced funnel plot and quantitatively using the Egger linear regression test.

Results

Study Selection

The process of selecting the studies for inclusion in the review is presented in Figure 1. An initial search across PubMed, CINAHL, Scopus, and Cochrane Library databases yielded 1985 articles. A total of 177 duplicate articles were removed before screening, resulting in 1868 articles. After screening, 1837 studies were excluded because of 38 preregistered studies (eg ClinicalTrials.gov), and 1799 titles and abstracts were not relevant. After assessing 31 full-text articles for eligibility, 21 studies were conference abstracts, focused on family outcomes, not remote-based mindfulness or usability testing, and did not report the physical outcomes. Ten studies met the criteria identified through the database, and 3 studies were identified through manual searches and reference lists of the included studies. Hence, 13 studies were included in the systematic review and meta-analysis [26,36-47].

Figure 1. Study selection process.



Characteristics of the Included Studies

The mean age of the participants was <60 years in 10 of the included studies and ≥60 years in 2 studies. Most participants were female, with 74.38% (572/894) in the remote-based intervention group and 70.61% (322/894) in the usual care group. The studies were conducted across several countries, with most studies conducted in the United States (n=4) and the Netherlands (n=4), followed by China (n=2), and 1 each in Ireland, Denmark, and Iran. Regarding the study design, 11 studies were RCTs and 2 were pilot RCTs. The mindfulness type included web-based interventions, mobile apps, and virtual meetings, whereas the control groups included treatment as usual, wait-list controls, face-to-face mindfulness, and interventions without a control group. The outcome measurements included assessments of fatigue, sleep disturbances, and physical function. Fatigue was measured in 5 studies by using different instruments, such as the checklist of individual strength (CIS)-fatigue, BFI-9, fatigue symptom inventory, and cancer quality of life questionnaire (QLQ)-C30. Sleep disturbance was evaluated in 6 studies using tools such as the patient-reported outcomes measurement information system (PROMIS), Pittsburgh sleep quality index (PSQI), and insomnia severity index (ISI). Physical function was measured in 7 studies, most frequently using the short form (SF)-12, functional assessment of chronic illness therapy (FACIT), and QLQ-C30. The details of these characteristics are presented in Table 1 and Multimedia Appendix 2.

Study Outcomes

A meta-analysis of remote-based mindfulness revealed 4 physical outcomes. The outcomes included fatigue (n=5), sleep disturbance (n=6), pain (n=3), and physical function (n=6). The outcome measurements varied, as shown in Table 1. The effect sizes for each outcome are listed in Table 2.

Table . Effect size of mobile-based mindfulness on physical symptoms in cancer survivors.

Outcome	Number of studies	Effect size	95% CI	*P* value	Heterogeneity	Reference
Pre- and postintervention						
Fatigue	5	SMD[a] −0.94	−1.56 to −0.33	.002*[b]	85%	[36,41,44,45,47]
Sleep disturbance	6	SMD −0.36	−0.60 to −0.12	.004*	31%	[26,41,43-45,47]
Pain	3	MD[c] −5.33	−10.90 to 0.25	.06	85%	[40,41,44]

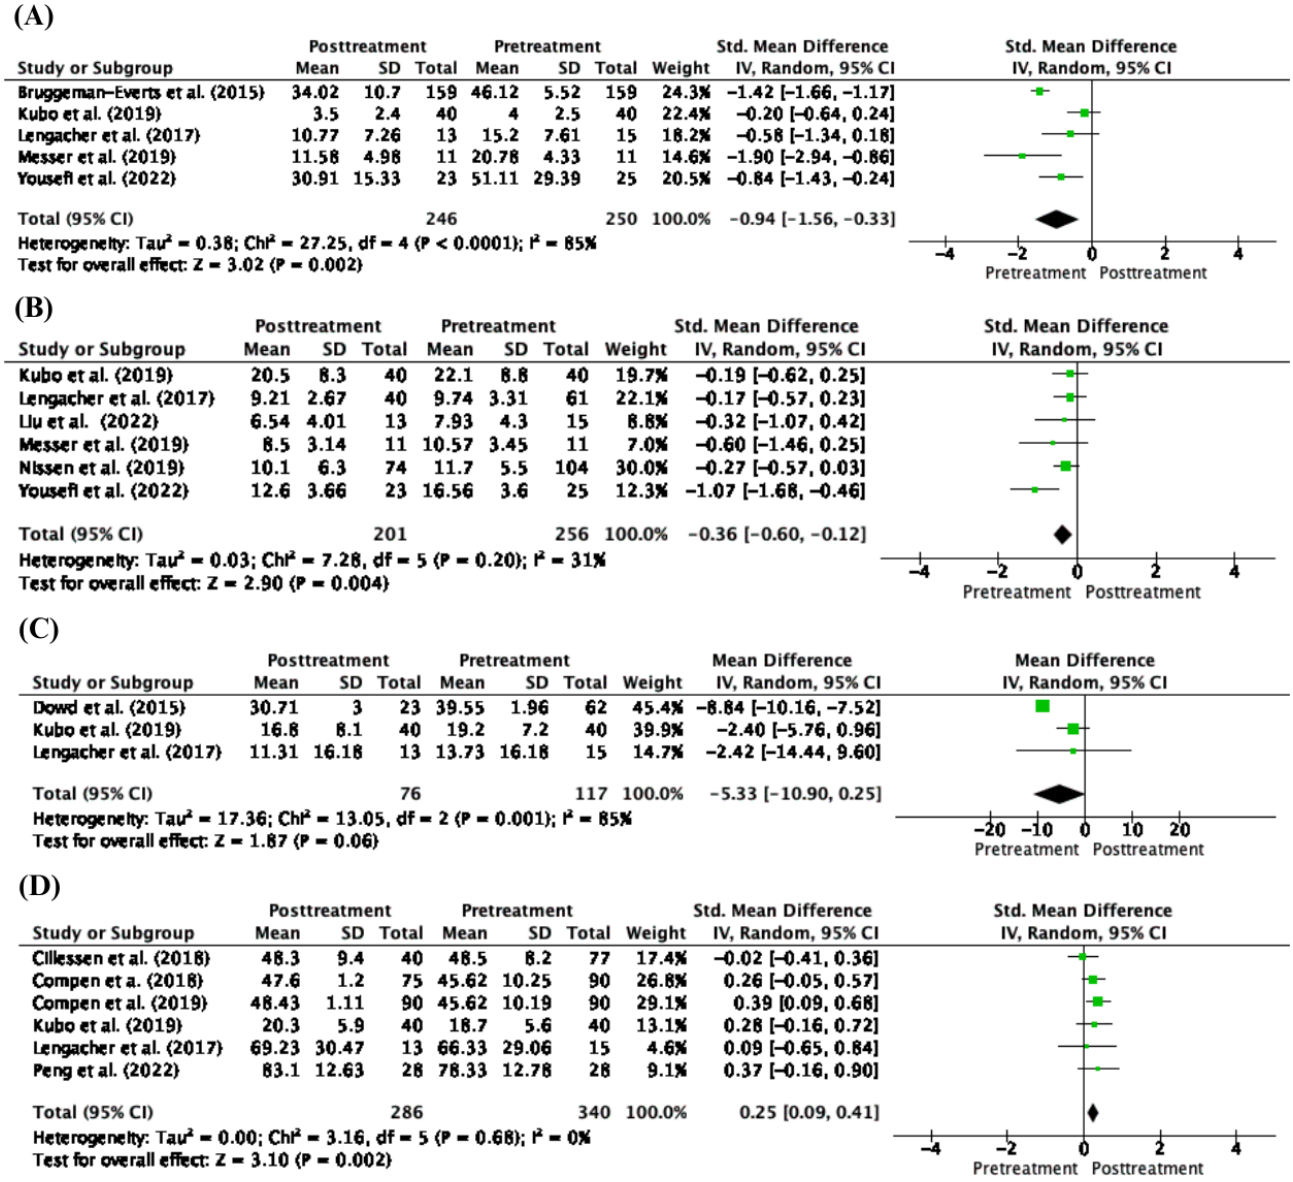
[b]The asterisk indicates statistical significance (P<.05)

[c]MD: Mean difference.

Pre- and Postanalysis of Remote-Based Mindfulness to Physical Outcomes After Treatment

After remote-based mindfulness treatment, cancer survivors showed a significant reduction in fatigue (SMD −0.94; 95% CI: −1.56 to −0.33; P=.002), sleep disturbance (SMD −0.36; 95% CI: −0.60 to −0.12; P=.004), and improvement in physical function (SMD 0.25; 95% CI: 0.009 to 0.41; P=.002) compared with baseline or pretreatment values. Although posttreatment outcomes were more favorable compared to baseline values, there was no statistically significant difference in pain reduction (MD −5.33; 95% CI: −10.90 to 0.25; P=.06; Table 2). A forest plot of the pre- and posttreatment meta-analyses conducted on the remote-based mindfulness group is shown in Figure 2. Among these 4 outcomes, fatigue and pain showed significant heterogeneity (I^2=85%).

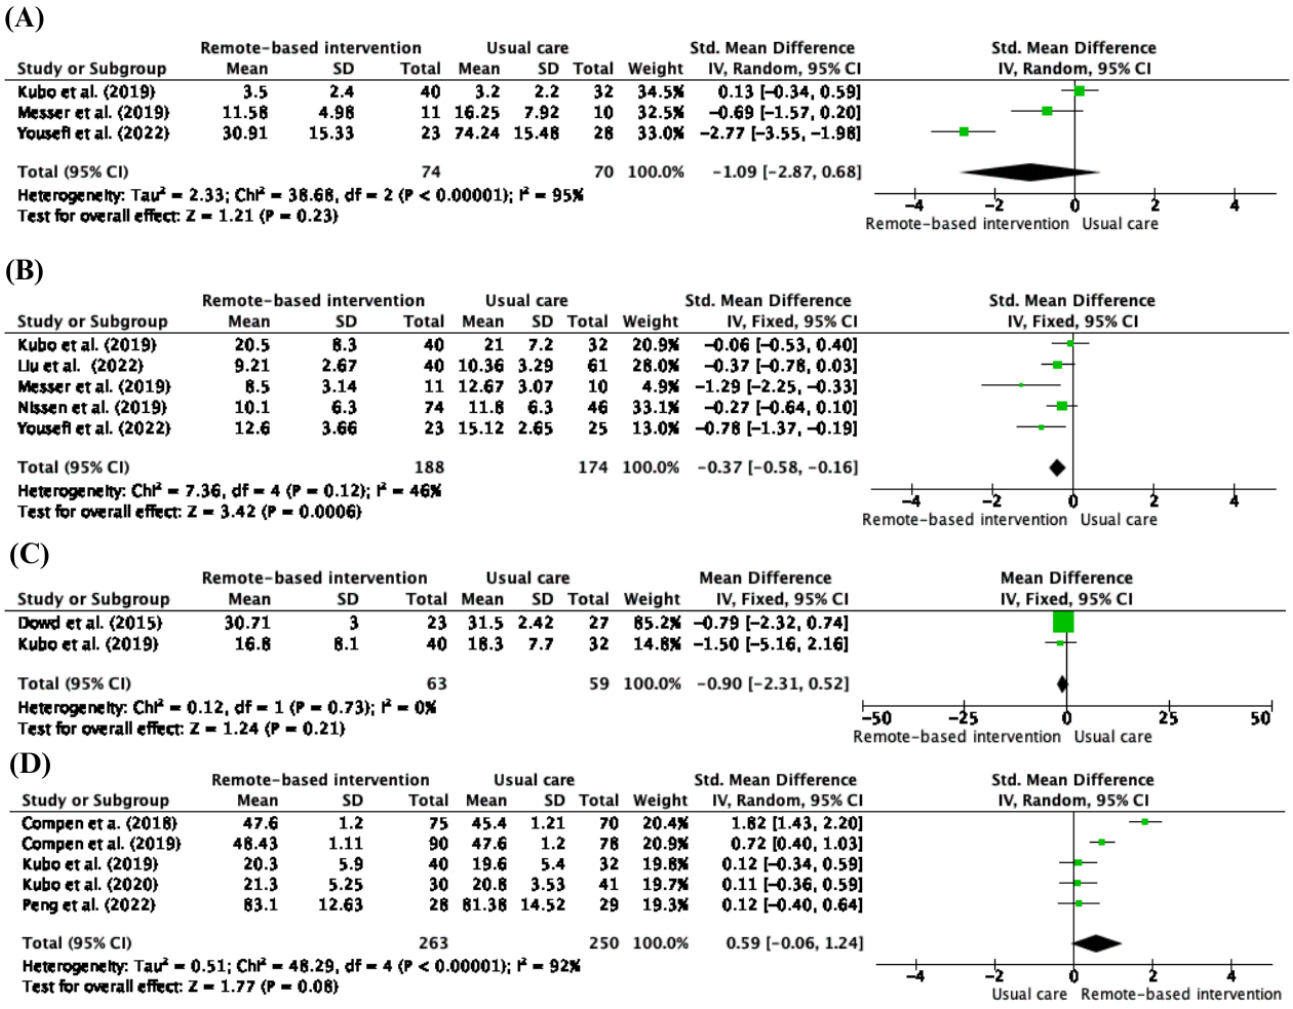
Figure 2. Meta-analysis of the benefits of remoted-based mindfulness intervention on physical symptoms after treatment. (**A**) Fatigue outcome. (**B**) Sleep disturbance outcome. (**C**) Pain outcome. (**D**) Physical function.



Benefits of Remote-Based Mindfulness on Physical Symptoms Compared to Usual Care After Treatment

Despite the small effect, the meta-analysis showed that remote-based mindfulness significantly reduced sleep disturbance (SMD −0.37; 95% CI: −0.58 to −0.16, *P*=.0006) compared with usual care after treatment. There were no statistically significant differences in the reduction of fatigue, pain, or improvement of physical function between the remote-based mindfulness and usual care groups (Table 2). Although not statistically significant, the remote-based mindfulness group had reduced fatigue, sleep disturbance, and pain compared with the usual care group after treatment. The forest plot of the meta-analysis of the benefits of remote-based mindfulness compared to usual care after treatment is shown in Figure 3.

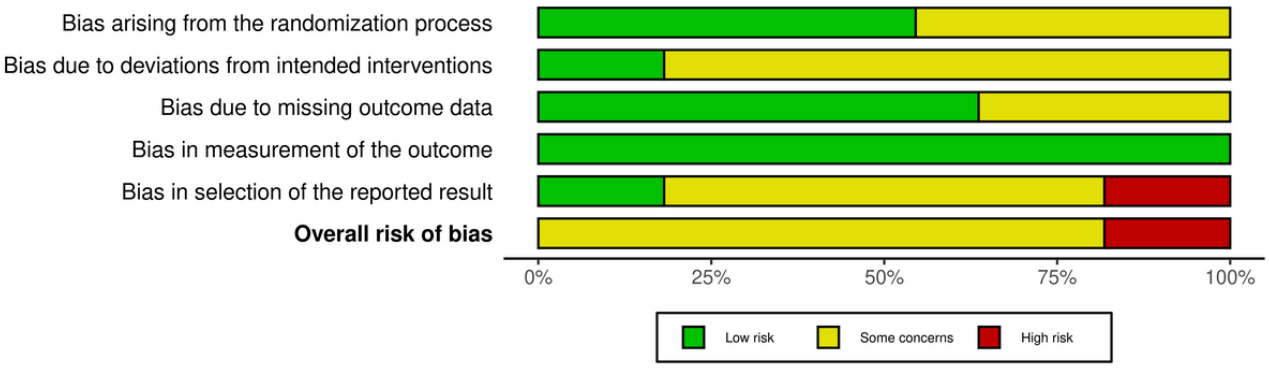
Figure 3. Meta-analysis of the benefits of remote-based mindfulness intervention on physical symptoms compared to usual care. (**A**) Fatigue outcome. (**B**) Sleep disturbance outcome. (**C**) Pain outcome. (**D**) Physical function.



Quality Assessment

Over 75% of the studies showed some concerns in at least 1 domain, but no study was rated as high risk considering the measurement of the outcomes (Figure 4). Most studies showed a low risk of bias across most domains, particularly for bias in the measurement of outcomes and missing outcome data. However, some concerns were found regarding the bias arising from the randomization process and deviations from intended interventions, with several studies lacking sufficient details on allocation concealment or participant adherence. Two studies, notably those by Cillessen et al (2018) and Nissen et al (2019), demonstrated a high risk of bias in the selection of the reported results. These studies may have selectively reported favorable outcomes, raising concerns about the validity of their findings. A detailed assessment of each included study can be found in the traffic-light plot provided in Multimedia Appendix 3.

Figure 4. Summary risk of bias.



Publication Bias

We evaluated the likelihood of publication bias by analyzing funnel plots and using the Egger test. We did not conduct statistical tests or create funnel plots for any outcome because each outcome had fewer than 10 studies, which is necessary to ensure sufficient power for detecting asymmetry [29,48].

Discussion

Study Findings and Comparison With Previous Works

To the best of our knowledge, this systematic review and meta-analysis is the first to assess the benefits of remote-based mindfulness interventions on physical outcomes in individuals living with cancer. This study has yielded several findings. First, the meta-analysis concluded that a significant effect was observed in reducing fatigue and sleep disturbance after treatment. Second, remote-based mindfulness was significantly more effective in reducing sleep disturbances compared to usual care. Third, remote-based mindfulness was not significantly effective at reducing pain. Finally, a significant improvement in physical function was observed after treatment.

The present meta-analysis suggests that remote-based mindfulness is beneficial for improving physical outcomes. The present study adds to the knowledge regarding the benefits of remote-based mindfulness in cancer survivors. A previous meta-analysis suggested that remote-based mindfulness reduces psychological symptoms in cancer survivors, such as depression, distress, and perceived stress [30,49]. Another meta-analysis observed a significant effect of remote-based mindfulness with a specific web-based platform in reducing anxiety, depression, and distress [29].

The biological mechanisms underlying the benefits of mindfulness treatments suggest additional pathways that may strengthen evidence-based understanding of their physical health effects. Preliminary supporting studies indicate that mindfulness interventions promote two pathways of stress resilience in the brain (the regulatory and reactivity pathways) and may enhance the regulation of the stress reactivity of the hypothalamic-pituitary-adrenal and sympathetic-adrenal-medullary axes, thereby elucidating the effects of mindfulness interventions on stress-related health and disease outcomes over time [50]. The effectiveness of remote-based mindfulness can be understood through the body-mind-spirit model, in which physical health is influenced by the interconnectedness of biological and psychological factors involving self-regulation [17,18]. This self-regulation encompasses the release of dopamine, endocannabinoids, endorphins, and stress hormones in addition to the signaling pathways of oxytocin and serotonin [51].

The present meta-analysis showed a significant effect in reducing sleep disturbance compared with usual care, which is consistent with the findings of a previous meta-analysis [29]. Mindfulness treatment has the potential to alleviate sleep disturbances because mindfulness practice enables individuals to observe their thoughts, emotions, and bodily sensations without emotional involvement or judgment [52]. It also seeks to increase an individual's awareness and acceptance of their thoughts, emotions, and physiological sensations. This treatment improves cognitive flexibility and cultivates a more comprehensive understanding of sleep, thereby alleviating anxiety or arousal, which may exacerbate sleep disturbances [30].

Despite the present meta-analysis showing that remote-based mindfulness significantly reduced fatigue after treatment, the results showed no significant difference when compared with usual care. Consistent with a previous meta-analysis of web-based mindfulness, there was no significant effect compared to usual care [30]. This may align with the different types of cancer and stages, types of technological intervention, treatment duration, and diverse measurement instruments within the studied population. Despite this, remote-based mindfulness showed high effectiveness after treatment, which aligns with a previous meta-analysis of face-to-face mindfulness [53]. A meta-analysis conducted by Johns et al showed a moderate effect after treatment and a small effect at the first-month follow-up [53]. Remote-based mindfulness is well-documented for its efficacy in reducing and managing stress, which may subsequently impact fatigue. Furthermore, fatigue may be alleviated by enhancing insomnia, as better sleep quality leads to increased freshness [47]. Peripheral inflammatory cytokines can communicate with the central nervous system to induce cancer-related fatigue [54]. Mindfulness, such as the body-mind-spirit technique, may reduce NF-kB signaling, a major regulator of inflammatory activity [55].

This meta-analysis showed no significant difference in pain reduction compared to usual care. This outcome may be attributed to the fact that both the remote-based and control groups were provided with standard care, which included adequate analgesic administration as part of their standard treatment protocol [56]. Mindfulness-based interventions may have been marked by the high efficacy of analgesics in alleviating chronic pain in cancer survivors. A previous meta-analysis of face-to-face mindfulness showed only a small effect in reducing chronic pain in various health conditions [57]. A psychotherapy form similar to online-based acceptance and commitment therapy showed moderately reduced chronic pain in various health conditions [58].

Evidence suggests that remote-based mindfulness improves QoL [29], with no exception to the present meta-analysis, which showed that remote-based mindfulness significantly improved the physical function of QoL after treatment. By reducing cancer-related symptoms, including physical symptoms, remote-based mindfulness can improve physical function. However, the present meta-analysis concluded that there was no significant improvement in physical function compared with usual care. This result may largely benefit psychological outcomes rather than physical health outcomes.

Future Direction

This evidence suggests a potential remote-based mindfulness intervention to alleviate physical symptoms (eg, sleep disturbance and fatigue) and improved physical function. The understanding of mindfulness interventions, including remote-based mindfulness, and their benefit on physical health remains insufficient considering the large RCT literature

associating mindfulness interventions with psychological outcomes [50,59]. Further research is needed to evaluate the efficacy of remote-based mindfulness in improving physical outcomes (eg, blood pressure, weight loss, and biomarkers of health). Integrating mindfulness practices into supportive care programs acknowledges the importance of addressing multidimensional aspects of a patient's experience. This personalized and holistic approach aligns with the principles of patient-centered care, recognizing the unique needs and challenges faced by individuals undergoing cancer treatment.

Despite the small number of included studies, the evidence of the pain outcomes suggests the limited benefit of remote-based mindfulness intervention due to the administration of standard analgesics in both groups [56]. Considering the analgesic effects induced within the central nervous system, the common adverse effects of opioids include nausea, vomiting, constipation, drowsiness, disorientation, hallucinations, and respiratory depression. Other adverse effects include endocrine alterations (eg, androgen insufficiency and bone demineralization) and the risk of depression due to long-term opioid prescriptions [51]. Owing to the growing "opioid crisis," the use of opioids as a psychotherapy option is now being recommended as a complementary treatment. Hence, further research and modification of mindfulness interventions with other psychotherapies is needed to enhance the benefits and evidence of remote-based mindfulness on pain.

Limitations

Despite this present study indicating the potential effects of remote-based mindfulness on physical health outcomes and physical status, our study has several limitations. This meta-analysis was not registered prospectively in any registered database such as PROSPERO. The transparency of this meta-analysis was limited because of the minimized risk of selective reporting. A few studies included in the meta-analysis had a high bias in the selection of the reported results that influenced the concern that positive results are more likely to be published. Meta-regression was not performed in the present meta-analysis to assess potential moderating factors such as participant characteristics, intervention components, or variations in study design. Moreover, this systematic review and meta-analysis assessed mindfulness as psychotherapy, and the included studies were unlikely to evaluate physical health outcomes as primary outcomes.

Conclusion

This meta-analysis provided evidence regarding remote-based mindfulness interventions to alleviate physical symptoms in cancer survivors. The findings of this study suggest that remote-based mindfulness interventions may be effective in reducing sleep disturbances in clinical practice. Despite limited evidence regarding its benefits compared with usual care, the effect of remote-based mindfulness on fatigue and physical function was observed after treatment. Due to the limited number of included studies and the heterogeneity of the included studies, the conclusions must be considered along with these limitations. Therefore, well-designed trials are required to obtain robust evidence.

Acknowledgments

We would like to express our heartfelt gratitude to Universitas Padjadjaran for providing a grant to conduct this systematic review and meta-analysis. We also thank you for the financial support provided by the article processing charges (APC).

Data Availability

The published article and its supplementary information files contain all study data.

Authors' Contributions

MK, SM, HP, and LR were involved in the conceptualization. SM and SA performed the formal investigation and analysis. All authors contributed to writing the review and editing. All authors contributed to and approved the final manuscript.

Abstract

Background: Limited access to nutrition support among populations with cancer is a major barrier to sustainable and quality cancer care. Increasing use of mobile health in health care has raised concerns about its validity and health impacts.

Objective: This systematic review aimed to determine the effectiveness of commercial or cancer-specific nutritional mobile apps among people living with cancer.

Methods: A systematic search of the CENTRAL, Embase, PubMed (MEDLINE), and Scopus databases was carried out in May 2024. All types of intervention studies were included, except observational studies, gray literature, and reference lists of key systematic reviews. Studies were eligible for inclusion if they involved (1) patients with or survivors of cancer and (2) nutrition-related mobile apps. Studies were excluded if the nutrition intervention was not delivered via mobile app or the app intervention was accompanied by dietary counseling. The review process was conducted based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The Risk of Bias 2 and Risk of Bias in Nonrandomized Studies tools were used to assess the study quality. The Cochrane Review Manager (version 5.4) software was used to synthesize the results of the bias assessment.

Results: A total of 13 interventions were included, comprising 783 adults or teenagers with cancer. Most studies focused on breast cancer (6/13, 46%), overweight (6/13, 46%), and survivors (9/13, 69%). Data on anthropometry and body composition (7/13, 54%; 387 participants), nutritional status (3/13, 23%; 249 participants), dietary intake (7/13, 54%; 352 participants), and quality of life (6/13, 46%; 384 participants) were gathered. Experimental groups were more likely to report significant improvements in body weight or composition, dietary compliance, nutritional status, and quality of life than control groups.

Conclusions: Although mobile app platforms are used to deliver nutrition interventions, the evidence for long-term efficacy, particularly in populations with cancer, remains elusive. More robust randomized controlled trials with larger sample sizes, as well as more homogeneous population characteristics and outcome measures, are warranted.

Introduction

Background

More than 50% of patients with cancer are likely to develop undernutrition upon diagnosis [1]. At least 5% of patients with cancer who are malnourished report drastic weight loss [2]. In total, 3 out of 5 patients report a significant weight reduction ranging from 1 to 10 kg 6 months after a cancer diagnosis [3]. Surprisingly, approximately 20% of patients with cancer die of undernutrition and its complications [4]. It is necessary to implement an early screening and detection of undernutrition based on the parameters of dietary intake, biochemical indexes, and body weight and composition. The overall nutritional status can be evaluated using cancer-specific assessment tools such as the Subjective Global Assessment, Patient-Generated Subjective Global Assessment (PG-SGA), and Mini Nutritional Assessment [5].

European Society of Parenteral and Enteral Nutrition guidelines have highlighted the importance of a multidisciplinary approach in managing undernutrition among patients with cancer [4]. However, this nutritional issue is not considered as equally important as the cancer disease itself [6,7]. If undernutrition is left untreated, this can result in poor immune response, increased treatment toxicities, impaired quality of life (QoL), increased risk of infection, increased admission rates and hospital stays, and increases in health care costs [4,7,8].

Overnutrition or excessive body fatness is another nutritional disorder that should be gaining greater attention in survivorship care [9,10]. Approximately 1 in 3 survivors of cancer report having obesity and not meeting the American Cancer Society's BMI guidelines of <30 kg/m^2 [10]. It is highly recommended that those living with or free of cancer eat a balanced diet to reduce the risk of recurrence and promote healthy survivorship [11].

To sustain a normal body weight, patients with cancer are advised to consume enough food to meet their daily requirement of energy and protein. In view of the differences in energy expenditure, the European Society of Parenteral and Enteral Nutrition recommends that the total energy requirement of patients with cancer be similar to that of survivors or healthy populations [4]. This elucidates that focusing on the basic principle of a balanced diet could be a nutrition guideline for patients with cancer, particularly those who are undernourished.

Studies have shown that approximately 90% of patients with cancer perceive nutrition support as an essential component in oncology care. However, less than half of patients with cancer are seen by dietitians [12]. According to the PG-SGA score, in a study by Pinho et al [1], 45% of patients with cancer required dietary intervention. In spite of that, dietetic support is not readily accessible to patients throughout their cancer journey. The high prevalence of undernutrition is commonly observed in people with upper digestive cancer, head and neck cancer, and lung cancer [1,2]. Still, in a study by Deftereos et al [7], approximately 40% of patients with upper digestive cancer did not receive any dietetic intervention before surgery.

Poor access to dietary services can be attributable to several factors, including lack of qualified dietitian staffing, lack of integration of nutrition services, lack of medical reimbursement for nutrition services, lack of awareness of cancer-related malnutrition, and inconsistent practice of nutritional risk screening in oncology [8]. Without a professional evidence-based dietary intervention, patients are likely to obtain information from the media or their peers. Conflicting information about nutrition makes them confused about what they should eat to optimize their well-being after a cancer diagnosis. Due to fear of cancer recurring, survivors can be desperate to modify their dietary habits [13,14]. This results in the adoption of unproven dietary strategies, including fad diets, juicing, and herbs and supplements, as well as avoiding certain food groups that are essential to their health [12].

The World Health Organization has called for a global initiative to leverage the use of digital health in areas of clinical medicine and public health [15]. During the COVID-19 pandemic, the application of digital technology targeting from planning and tracking, medical supplying, and screening for infection to clinical management was successful [16]. The pandemic has brought about an accelerated growth of digital health use to deliver continuous health care services while reducing virus transmission. For instance, telemedicine allowed for appointment scheduling and enhanced feasible health care delivery during the pandemic [17]. In addition, the use of digital health encourages engagement between practitioners and patients, as well as ensuring a sustainable health care system [18,19].

Objectives

To date, the implications of mobile app use in cancer screening, prevention, and management have been greatly highlighted [20,21]. However, there is a lack of empirical evidence that focuses on populations with cancer [22-24] and mobile app platforms [22], particularly for healthy eating and nutritional management. This systematic review aimed to determine the effectiveness of commercial or cancer-specific nutritional apps in improving nutrition-related health outcomes for people receiving treatment for or living with cancer.

Methods

Study Protocol and Guidance

The protocol for this review was registered with PROSPERO (registration number: CRD42023330575) [25]. This review was reported based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines (Multimedia Appendix 1) [26].

Databases and Search Strategy

Systematic searches were conducted across 4 databases—CENTRAL, Embase, PubMed, and Scopus—in May 2024. The search strategy incorporated Medical Subject Headings (MeSH), keywords, and free-text searches that related to the 3 main concepts: mobile apps, cancer, and nutrition. The search string used in the literature search was as follows: "Mobile Applications"[Mesh] OR "mobile application*"[tw] OR "mobile apps"[tw] OR "mobile app"[tw] OR "mobile

technolog*"[tw] OR "mobile health"[tw] OR mHealth[tw] OR smartphone[tw] OR "smart phone"[tw] OR telemedicine[tw] AND "Neoplasms"[Mesh] OR cancer*[tw], neoplasm*[tw] OR oncology[tw] OR tumour*[tw] OR tumor*[tw] OR malignant[tw] OR malignanc*[tw] AND "Diet, Food, and Nutrition"[Mesh] OR nutrition[tw] OR diet[tw] OR eat[tw] OR food[tw] (Multimedia Appendix 2). It included original articles published between January 2013 and December 2023 and in the English language. This is a change from the registered protocol [25].

Study Selection

First, EndNote (version 20.3; Clarivate Analytics) was used to identify and remove duplicates from the list. The titles and abstracts of articles were screened independently by 2 reviewers (KLSN and MA) to identify potential eligible studies. The references retrieved from the search were categorized as excluded or included based on the population, intervention, comparator, outcome, and study design criteria [27]:

- Population—this included individuals who had a cancer diagnosis or a history of cancer.
- Intervention—the studies included commercial or cancer-specific mobile apps and nutrition-related key functions, including recording or monitoring food intake and providing feedback, recommendations, or coaching. Due to limited studies that included stand-alone use of mobile apps, studies on multicomponent interventions, such as targeting sleep, physical activity, or psychosocial care, were included.
- Outcome—the measures included changes in nutritional-related health outcomes. Due to a lack of feasibility studies, data on the evaluation of the quality of the mobile apps were not included. This is a change from the registered protocol [25].
- Study design—all types of intervention studies were considered, such as pretest-posttest studies, pilot studies, quasi-experimental studies, and randomized controlled trials (RCTs). Observational studies, gray literature, expert recommendations, or references in articles were not included.

A full-text screening was carried out by reviewing in detail the studies that were not excluded at the first screening based on the inclusion criteria. Each full text was retrieved and assessed independently by the same authors before inclusion in the review. Non–English-language articles were excluded. Any disagreements during the selection process were resolved through consensus.

Data Extraction and Synthesis

The data were extracted systematically from each article by KLSN and then checked by MA. The data included were authors, publication date (year), country, study design, sample size, participant characteristics, and details on the mobile app intervention. Next, data were extracted based on the type of population (survivors or patients receiving treatment), components of the app (eg, diet alone or diet plus physical activity), duration of the intervention and follow-up, and outcome measures (body weight, body composition, QoL, and dietary factors). A comparison of the descriptive findings was made across the studies. The outcome data between groups and before and after the intervention within groups were compared using mean differences and significance values (*P* value). The heterogeneity of the interventions and measures precluded a statistical combination of the quantitative findings; therefore, a meta-analysis was not conducted.

Risk-of-Bias Assessment

Analysis of the risk of bias was conducted using the Review Manager (version 5.4; The Cochrane Collaboration) software. The Risk of Bias 2 (RoB 2) and Risk of Bias in Nonrandomized Studies (ROBINS) tools were used for RCTs and non-RCTs, respectively. The risk of bias assessment was carried out by 2 reviewers independently (KLSN and MA). All discrepancies were resolved through consensus.

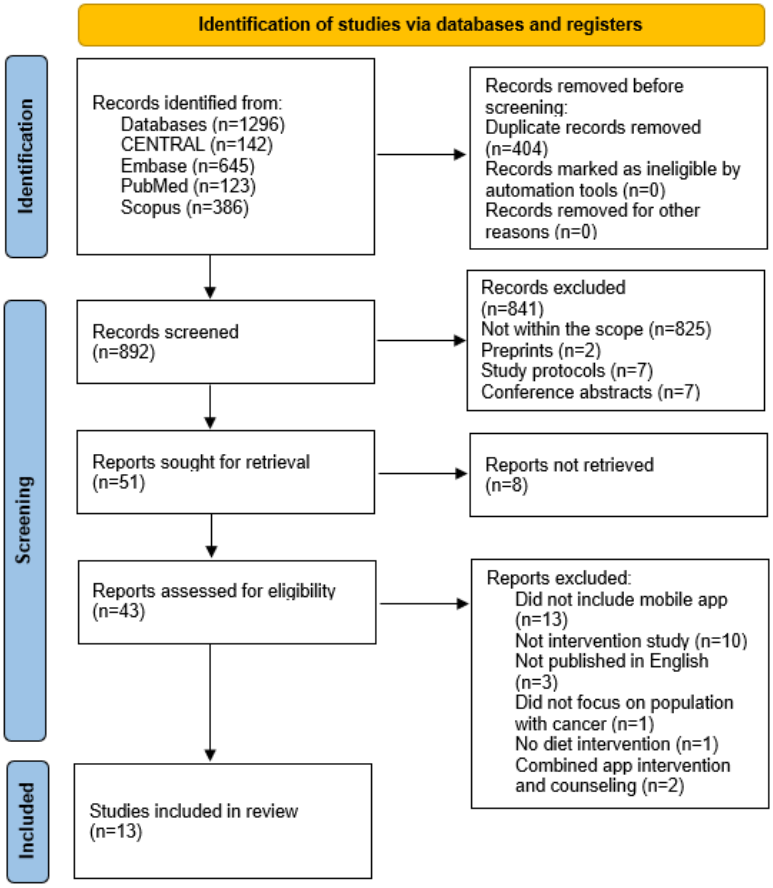
The seven areas included in the RoB 2 tool were (1) random sequence generation, (2) allocation concealment, (3) blinding of participants and personnel, (4) blinding of outcome assessment, (5) incomplete outcome data, (6) selective reporting, and (7) other bias. For the ROBINS tool, the seven areas included were (1) bias due to confounding, (2) bias in selection of participants for the study, (3) bias in classification of interventions, (4) bias due to deviations from the intended intervention, (5) bias due to missing data, (6) bias in measurement of outcomes, and (7) bias in selection of the reported results. According to the Cochrane Handbook for Systematic Reviews of Interventions, each area was assigned a classification of low, unclear, or high risk of bias [28].

Results

Overview

A total of 1296 articles were identified from all database searches. After 31.17% (404/1296) of duplicates were removed, the abstracts and titles of 68.83% (892/1296) of relevant articles were screened. The full texts of 5.7% (51/892) of these studies were retrieved and assessed for eligibility based on the population, intervention, comparator, outcome, and study design criteria. Finally, 13 articles were eligible to be included in this review. The procedure for article selection is shown in Figure 1 [26].

Figure 1. Study flowchart adapted from the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement.



Study Characteristics

Participants

Of the 13 included studies, there were 7 (54%) that were RCTs [29-35]; 4 (31%) that were single-arm, pretest-posttest studies [36-39]; and 2 (15%) that were quasi-experimental studies [40,41]. In total, 62% (8/13) of the included studies were conducted in the United States [29-31,35-38,40]; 15% (2/13) were conducted in South Korea [33,39]; and the remaining 23% (3/13) were conducted in Germany [41], Turkey [32], and Australia [34]. Most studies (9/13, 69%) were published within the past 5 years [29,30,32-35,38-40].

Among the 13 studies, a total of 783 participants with cancer aged 12 to 75 years was included. The sample sizes ranged from 22 to 127. In total, 15% (2/13) of the studies had no comparison groups [36,37]. A total of 8% (1/13) of the studies were conducted on teenagers [38], whereas the remaining 92% (12/13) of the studies were conducted on adults aged between 18 and 75 years. The most prevalent condition targeted in the studies was breast cancer (6/13, 46%) [29-32,37,40], followed by gastrointestinal cancer (2/13, 15%) [33,34], hematologic cancer (2/13, 15%) [35,38], mixed cancer (2/13, 15%) [36,41], and esophageal cancer (1/13, 8%) [39]. A total of 46% (6/13) of the studies were conducted among participants with overweight or obesity [29,35-38,40]. In total, 15% (2/13) of the studies were conducted among participants with body weight within the normal range [33,39], whereas 38% (5/13) of the studies did not state the weight status of the population [30-32,34,41]. Of the 13 studies, 9 (69%) recruited survivors [29-32,35-38,40], and the remaining 4 (31%) recruited patients with newly diagnosed cancer or receiving treatment [33,34,39,41]. Table 1 shows the summary of the study details, participant characteristics, and intervention types.

Table 1. Study characteristics.

Study and country	Study design	Sample size, N	Population characteristics	Cancer type	Intervention	Control	App features
Chow et al [35], 2020, United States	Pilot RCT[a]	Experimental group: 24; control group: 17	Adults diagnosed for ≥5 years; mean age 44 (range 20.9-54.0) years in the experimental group and 46.0 (range 20.2-54.8) years in the control group; mean BMI 28.6 (SD 6.5) kg/m^2 in the experimental group and 29.6 (SD 6.3) kg/m^2 in the control group	Hematologic	Had access to HealthWatch 360 (GB HealthWatch) and Fitbit Flex wristband (Google) with goal setting and peer support	Had access to Fitbit Flex wristband and HealthWatch 360 without goal setting and peer support	Commercial app; tracking of food intake
McCarroll et al [36], 2015, United States	Pretest-posttest study	50	Women with OW[b] or obesity diagnosed over the previous 3 years; mean age 58.4 (SD 10.3) years	Endometrium or breast cancer	Had access to LoseIt!	—[c]	Commercial app; logging of food, exercise, and BW[d] and provision of personalized feedback
Orlemann et al [41], 2018, Germany	Pilot; QED[e]	Experimental group: 12; control group: 12	Adults receiving treatment; mean age 58.4 (range 27-90) years	Mixed (GI[f] tumor; n=16)	Had access to OncoFood (Huawei Technologies Co Ltd)	Received nutrition counseling and therapy without app	Custom-developed app; recording of food intake and monitoring of nutritional goals and BW
Stubbins et al [37], 2018, United States	Prospective, single arm, and open label	33	Survivors with OW; mean age 57 (SD 9) years; mean BMI 32.7 (SD 5.7) kg/m^2	Breast cancer	Used MOCHA[g] for ≥5 days	—	Custom-developed app; access to sleep and mood data, provision of a list of cardiovascular and strength activities with amount of calories burned, logging of food, and monitoring of progress
Baik et al [30], 2020, United States	Pilot RCT	Experimental group: 39; control group: 39	Latina survivors; mean age 52.54 (SD 11.36) years	Breast cancer	Access to My Guide	Access to My Health	Custom-developed app; My Guide: focus on ways to cope with side effects of treatment, stress management, social support, and breast cancer–related knowledge; My Health: provides recommendations regarding nutrition, exercise, and prevention of chronic illnesses
Buscemi et al [31], 2019, United States	Pilot RCT	Experimental group: 40; control group: 40	Latina survivors; mean age 52.54 (SD 11.36) years	Breast cancer	Access to My Guide	Access to My Health	Custom-developed app; My Guide: focus on ways to cope with side effects of treatment, stress management, social support, and breast cancer–related knowledge; My Health: provides recommendations regarding nutrition, exercise, and prevention of chronic illnesses

Study and country	Study design	Sample size, N	Population characteristics	Cancer type	Intervention	Control	App features
Cairo et al [40], 2020, United States	Non-RCT	Experimental group: 66; control group: 61	Female survivors; mean age 51.4 (SD 8.1) years in the experimental group and 56.7 (SD 9.8) years in the control group; mean BMI 29.4 (SD 6.0) kg/m^2 in the experimental group and 30.2 (SD 7.3) kg/m^2 in the control group	Breast cancer	Access to Vida	Received self-guided nutrition "toolkit," exercise stretch band, pedometer, and self-guided walking DVD	Commercial app; tracking of medication, diet, exercise, sleep, and BW and pairing with a certified coach
Fuemmeler et al [38], 2020, United States	Single-group pretest-posttest design	15	Teenage survivors; mean age 14.8 (SD 1.97) years; mean BMI 22.6 (SD 4.1) kg/m^2 in the experimental group and 22.7 (SD 2.7) kg/m^2 in the control group (data from post hoc analysis)	Acute lymphoblastic leukemia or lymphoma	Used Mila Blooms for ≥4 weeks	Used Mila Blooms for <4 weeks	Custom-developed app; monitors progress, allows for autonomic feedback, and uses game mechanics to promote healthy eating and PA[h]
Allicock et al [29], 2021, United States	Pilot RCT	Experimental group: 13; control group: 9	African American women after treatment (except Herceptin therapy and endocrine pills); mean age 52.8 (SD 9.57) years in the experimental group and 51.44 (SD 9.18) years in the control group; mean BMI 33.26 (SD 5.42) kg/m^2 in the experimental group and 38.35 (SD 7.08) kg/m^2 in the control group	Breast cancer	Access to CHAT[i] and ActiGraph wGT3X-BT accelerometer plus tailored health messages	Access to CHAT and ActiGraph wGT3X-BT accelerometer	Custom-developed app; provision of suggestions about PA and healthy diet
Çınar et al [32], 2021, Turkey	Single-blinded, single-center, randomized pretest-posttest design	Experimental group: 31; control group: 33	Women receiving hormonal therapy; mean age 45.7 (SD 9.0) years	Breast cancer	Received routine care plus mobile app–based training	Received routine care	The nature of the app was not mentioned; provision of information about breast cancer, symptom diary, balanced diet, regular PA, and stress management
Keum et al [33], 2021, South Korea	Prospective, single-center, nonblinded RCT	Experimental group: 20; control group: 20	Patients scheduled for chemotherapy; median age 62 (range 45-70) years in the experimental group and 61 (range 34-78) years in the control group; mean BMI 21.91 (SD 1.57) kg/m^2 in the experimental group and 23.5 (SD 2.72) kg/m^2 in the control group	Pancreatic cancer	Access to Noom mobile app (Noom Inc)	Did not have access to the Noom app and received none of the nutrition intervention	Commercial app; logging of food, step count, and BW; provided coaching and allowed for messaging for tracking caloric intake and muscle gain

Study and country	Study design	Sample size, N	Population characteristics	Cancer type	Intervention	Control	App features
Yang et al [39], 2021, South Korea	Prospective, single-arm pilot study	Experimental group: 38; control group: 60	Men scheduled for neoadjuvant chemoradiotherapy; median age 59.2 (SD 6.5) years in the experimental group and 58.5 (SD 7.8) years in the control group; mean BMI 21.8 (SD 2.6) kg/m^2 in the experimental group and 22 (SD 6) kg/m^2 in the control group	Esophageal cancer	Access to Noom mobile app	Previous cohort: received usual care	Commercial app; recording, monitoring, and provision of recommendations about diet, exercise, and BW changes
Huggins et al [34], 2022, Australia	3-arm RCT	Mobile app group: 36; telephone group: 38; control group: 37	Adults newly diagnosed with cancer; mean age 63.2 (SD 9.9) years in the control group, 67.5 (SD 10.3) years in the telephone group, and 66.6 (SD 9.7) years in the mobile app group; mean BW 75.0 (SD 20.0) kg in the control group, 71.9 (SD 12.7) kg in the telephone group, and 76.4 (SD 14.7) kg in the mobile app group	Upper GI cancer	Mobile app group: received symptom-directed nutrition intervention via the internet-enabled mobile app “myPace”; telephone group: received symptom-directed nutrition intervention via telephone	Received usual care	Commercial app; self-monitoring of goal attainment and BW

[a]RCT: randomized controlled trial.

[b]OW: overweight.

[c]Not applicable.

[d]BW: body weight.

[e]QED: quasi-experimental design.

[f]GI: gastrointestinal.

[g]MOCHA: Methodist Hospital Cancer Health Application.

[h]PA: physical activity.

[i]CHAT: Creating Healthy Actions Through Technology.

Mobile Apps

Types

Most studies (10/13, 77%) included a multicomponent intervention that combined diet with physical activity, psychosocial support, sleep, or behavior modification. Specifically, 50% (5/10) of these studies involved a combination of diet and physical activity [29,35,36,38,39], with additional components in the other 50% (5/10) of the studies [30-32,37,40]. The remaining 23% (3/13) of the studies included a dietary intervention as a single component [33,34,41].

Duration

The duration of the interventions ranged from 4 weeks to 6 months. A total of 62% (8/13) of the studies lasted up to 8 weeks [29-31,36-39,41], with 75% (6/8) of these studies including anthropometry or body composition as outcome measures. A total of 23% (3/13) of the studies lasted between 12 and 16 weeks [32,33,35], with one of the studies mainly evaluating QoL. The remaining 15% (2/13) of the studies lasted up to 6 months [34,40] and included both anthropometry and QoL measures. A total of 38% (5/13) of the studies continued to evaluate the participants’ progress after the intervention by investigating changes in QoL or dietary intake [29-31,34,35].

Features

A total of 46% (6/13) of the studies included the common features of logging, tracking, or monitoring in the mobile apps [33-35,37,38,41]. In total, 31% (4/13) of the studies focused on the provision of dietary information [29-32], whereas the remaining 23% (3/13) of the studies allowed for logging and provision of guidance or coaching [36,39,40]. Table 1 provides a more detailed description.

Retention Rate

Of the 13 studies, 9 (69%) reported the percentage of participants who remained in the study over the intervention or follow-up periods. A total of 44% (4/9) of these studies reported a retention rate of >90% [29,31,35,40], 44% (4/9) reported retention rates of 70% to 90% [33,36,37,39], and 11% (1/9) reported a retention rate of <70% [34]. Table 2 provides a more detailed description.

Table 2. Key findings of the included studies.

Study	App intervention duration	Follow-up	Retention rate (%)	Outcome measures	Main findings
Diagnosis					
Huggins et al [34], 2022	18 weeks	30 weeks	49.5	• QALYs[a] (EQ-5D-5L tool) • QoL[b] (EORTC QLQ-C30[c] scale) • Nutritional status (PG-SGA[d]–Short Form) • Self-reported BW[e]	• Mean weight 75.6 (SD 20.3) kg at 3 months, 75.6 (SD 17.5) kg at 6 months, and 73.2 (SD 18.4) kg at 12 months in the control group; 71.7 (SD 11.8) kg at 3 months, 70.2 (SD 11.7) kg at 6 months, and 68.6 (SD 13.3) kg at 12 months in the telephone group; and 71.7 (SD 15.6) kg at 3 months, 68.7 (SD 14.1) kg at 6 months, and 68.5 (SD 14.1) kg at 12 months in the mobile app group; *P*=.08 for control group vs telephone group; *P*=.03 for mobile app group vs telephone group; *P*=.48 for mobile app group vs control group • Mean QoL score 54.3 (SD 25.1) at 3 months, 69.8 (SD 12.2) at 6 months, and 72.2 (SD 15.9) at 12 months in the control group; 66.4 (SD 19.7) at 3 months, 68.0 (SD 28.13) at 6 months, and 74.8 (SD 23.8) at 12 months in the telephone group; and 62.3 (SD 24.5) at 3 months, 59.25 (SD 21.1) at 6 months, and 73.5 (SD 20.5) at 12 months in the mobile app group; *P*=.22 for control group vs telephone group; *P*=.08 for mobile app group vs telephone group; *P*=.85 for mobile app group vs control group • Mean QALY score 0.55 (SD 0.28) at 12 months in the control group, 0.57 (SD 0.28) at 12 months in the telephone group, and 0.59 (SD 0.23) at 12 months in the mobile app group; *P*>.99 for control group vs telephone group; *P*=.71 for mobile app group vs telephone group; *P*=.14 for mobile app group vs control group • Mean PG-SGA score 7.5 (SD 5.0) at 3 months, 4.6 (SD 3.6) at 6 months, and 4.1 (SD 4.1) at 12 months in the control group; 7.8 (SD 5.7) at 3 months, 6.2 (SD 5.1) at 6 months, and 4.3 (SD 4.7) at 12 months in the telephone group; and 8.4 (SD 6.1) at 3 months, 7.2 (SD 4.0) at 6 months, and 4.9 (SD 3.6) at 12 months in the mobile app group; *P*=.35 for control group vs telephone group; *P*=.58 for mobile app group vs telephone group; *P*=.19 for mobile app group vs control group
Treatment					
Orlemann et al [41], 2018	4 weeks	—[f]	NR[g]	• BW, BMI, SMM[h], and FFM[i] (BIA[j]) • Nutritional goals (intake of protein, fibers, energy, carbohydrates, and fats)	• Mean change in BW 1.03 kg in the experimental group and –1.46 kg in the control group (*P*=.045) • Mean change in SMM 0.58 kg in the experimental group and –0.61 kg in the control group (*P*=.009); mean change in FFM after the intervention (*P*=.03) • *P*=.91 for difference in mean changes in the intake of protein and fats, *P*=.34 for difference in mean changes in the intake of fiber, *P*=.27 for difference in mean changes in the intake of carbohydrates, and *P*=.42 for difference in mean changes in the intake of energy in the control group after the intervention; mean values NR

Study	App intervention duration	Follow-up	Retention rate (%)	Outcome measures	Main findings
Çınar et al [32], 2021	12 weeks	—	NR	• QoL (FACT-ES[k]) • Symptom distress (NCCN[l] Distress Thermometer)	• QoL: t_{30}=–5.13 and *P*<.001 in the experimental group and t_{32}=3.25 and *P*=.003 in the control group; physical well-being: t_{30}=–4.60 and *P*<.001 in the experimental group and t_{32}=1.13 and *P*=.27 in the control group; emotional well-being: t_{30}=–2.58 and *P*=.02 in the experimental group and t_{32}=2.88 and *P*=.007 in the control group; functional well-being: t_{30}=–1.01 and *P*=.32 in the experimental group and t_{32}=2.67 and *P*=.01 in the control group; endocrine symptoms: t_{30}=–6.49 and *P*<.001 in the experimental group and t_{32}=3.08 and *P*=.004 in the control group; pretest distress score: 1003 (*P*=.32); posttest distress score: –2265 (*P*=.03)
Keum et al [33], 2021	12 weeks	—	82.5	• QoL (EORTC QLQ-C30) • Nutritional status (PG-SGA) • SMI[m] (CT[n]) • Total protein and energy intake	• Reduced SMI: –3.27 in the experimental group and –13.96 in the control group (*P*=.11) • Improved GHS[o] and QoL in experimental group compared to control group (*P*=.004) • Mean protein intake after the intervention: 1.3 g per kg per day in the experimental group and 1 g per kg per day in the control group (*P*=.02); mean energy intake after the intervention: 25.2 kcal per kg per day in the experimental group and 17.7 kcal per kg per day in the control group (*P*=.04) • Improved PG-SGA score in both groups (*P*<.001)
Yang et al [39], 2021	8 weeks	—	78.9	• SMI (CT) • NLR[p], PLR[q], and PNI[r]	• Mean change in SMI after the intervention –7.4% (SD 6.5%) in the experimental group and –8.1% (SD 5.3%) in the control group (*P*=.57) • PNI: mean change –9.8 (SD 6) in the experimental group and –6.7 (SD 7.5) in the control group (*P*=.04); NLR: mean change 0.4 (SD 3.9) in the experimental group and 0.6 (SD 5.1) in the control group (*P*=.82); PLR: mean change 84.1 (SD 157.6) in the experimental group and 62.4 (SD 173.4) in the control group (*P*=.55)
Survivorship					

Study	App intervention duration	Follow-up	Retention rate (%)	Outcome measures	Main findings
Chow et al [35], 2020	16 weeks	8 weeks	90.2	• PA[s] • Daily percentage of added sugar, saturated fat, and sodium (HEI[t]-2015) • Physical health and mental health (PROMIS[u] Global Health–10) • Health-related self-efficacy score	• Physical health: mean 2.7 (95% CI 0.7-4.6) in the experimental group and 1.8 (95% CI –0.3 to 3.8) in the control group (between-group *P*=.52); mental health: mean 4.2 (95% CI 1.5-6.9) in the experimental group and 1.8 (95% CI –1.1 to 4.8) in the control group (between-group *P*=.24) • HEI-2015 score: mean 1.6 (95% CI –1.5 to 4.6) in the experimental group and 0.6 (95% CI –2.8 to 4.0) in the control group (between-group *P*=.67); daily percentage of added sugar: mean –0.8 (95% CI –2.2 to 0.5) in the experimental group and 0.1 (95% CI –1.5 to 1.6) in the control group (between-group *P*=.39); daily percentage of saturated fat: mean –0.3 (95% CI –1.5 to 0.9) in the experimental group and –0.8 (95% CI –2.2 to 0.6) in the control group (between-group *P*=.60); sodium intake: mean –832 (95% CI –1421 to –243) mg per day in the experimental group and –279 (95% CI –937 to 379) mg per day in the control group (between-group *P*=.22)
McCarroll et al [36], 2015	4 weeks	—	70	• BW, BMI, and WC[v] • QoL and self-efficacy (FACT-G[w] and Weight Efficacy Lifestyle Questionnaire) • Minutes spent in PA • Weekly intake of carbohydrates, fats, protein, fiber, and calories	• Mean pretest BW 97.3 (SD 22.5) kg and mean posttest BW 95.0 (SD 22.1) kg (*P*<.001); mean pretest BMI 36.4 (SD 8.1) kg/m^2 and mean posttest BMI 35.6 (SD 8.0) kg/m^2 (*P*<.001); mean pretest WC 106.6 (SD 16.8) cm and mean posttest WC 103.4 (SD 17.4; *P*<.001) cm • Mean pretest FACT-G score 50.47 (SD 13.3) and mean posttest FACT-G score 44.35 (SD 19.9; *P*=.15) • Carbohydrates: mean pretest intake 120.6 (SD 69.3) g and mean posttest intake 124.0 (SD 120.3) g (*P*=.73); fat: mean pretest intake 44.1 (SD 23.4) g and mean posttest intake 58.2 (SD 60.0) g (*P*=.18); protein: mean pretest intake 55.2 (SD 26.6) g and mean posttest intake 65.4 (SD 62.3) g (*P*=.23); fiber: mean pretest intake 11.0 (SD 6.3) g and mean posttest intake 13.3 (SD 13.6) g (*P*=.28); calories: mean pretest intake 1022.6 (SD 494.4) kcal and mean posttest intake 1281.1 (SD 1130.6) kcal (*P*=.26)
Stubbins et al [37], 2018	4 weeks	—	75.8	• Adherence to the MOCHA[x] app • System Usability Scale score • Weight loss • Dietitian-participant interaction	• Mean reduced BW 2 (range +4 to –10.6) lbs after the intervention; *P* value NR
Baik et al [30], 2020	6 weeks	2 weeks	NR	• QoL (FACT-B[y]) • Symptom burden (25-item Breast Cancer Prevention Trial questionnaire) • Cancer-specific distress (15-item Impact of Event Scale) • Cancer-relevant self-efficacy (CASE-Cancer[z]) • Breast cancer knowledge (16-item Knowledge About Breast Cancer questionnaire)	• Experimental group—breast cancer well-being score for low app users: mean pretest score 23.47 (range 12-36) and mean posttest score 26.13 (range 14-35); control group—social well-being, score: mean pretest score 20.74 (range 5-28) and mean posttest score 22.52 (range 11-28); *P* value NR

Study	App intervention duration	Follow-up	Retention rate (%)	Outcome measures	Main findings
Buscemi et al [31], 2019	6 weeks	2 weeks	>90	• Daily intake of fat and FV[aa] • PA level	• Fat sources: EMM[ab] 2.38 (SE 0.21) in the experimental group and 2.86 (SE 0.21) in the control group at baseline, 2.42 (SE 0.22) in the experimental group and 2.38 (SE 0.21) in the control group at 6 weeks, and 2.36 (SE 0.22) in the experimental group and 2.20 (SE 0.22) in the control group at 8 weeks (P=.03)
Cairo et al [40], 2020	6 months	—	100	• BW and BMI • PA level • Adherence to a healthy diet (27-item "Rate Your Plate" survey) • Presence and severity of fatigue (VAS[ac]-Fatigue) • Depression and anhedonia (PHQ[ad] tool)	• Mean reduced BW 1.8 (SD 4.9) kg in the experimental group (P<.01) and –0.2 (SD 3.7) kg in the control group (P=.70); mean reduced BMI 0.7 (SD 1.8) kg/m^2 in the experimental group (P<.01) and –0.7 (SD 1.4) kg/m^2 in the control group (P=.68) • Mean reduced fatigue score 1.2 (SD 2.4) in the experimental group (P<.001) and 0.65 (SD 2.3) in the control group (P=.03); P=.36 for depression between experimental and control groups • Improved adherence to a plant-based diet: mean change in score –6.2 (SD 5.8) in the experimental group (P<.001) and –2.0 (SD 6.5) in the control group (P=.02)
Fuemmeler et al [38], 2020	8 weeks	—	NR	• Height, BW, BMI, z score, and percentile • Intake of calories and nutrients • PA level • Diet and PA self-efficacy (PACE[ae]) • User satisfaction and narrative engagement	• Mean pretest BMI 22.6 (SD 4.1) kg/m^2 and mean posttest BMI 22.8 (SD 4.1) kg/m^2 in the experimental group (P=.41); mean pretest BMI 22.7 (SD 2.7) kg/m^2 and mean posttest BMI 23.1 (SD 2.6) kg/m^2 in the control group (P=.24) • Mean pretest sweet food intake 8.4% (SD 3.6%) of kcal and mean posttest sweet food intake 13.5% (SD 9%) of kcal in the experimental group (P=.12) and mean pretest sweet food intake 8.8% (SD 6.3%) of kcal and mean posttest sweet food intake 7.5% (SD 4.8%) of kcal in the control group (P=.35; between-group P=.049); mean pretest sugary beverage intake 206.5 (SD 202.1) g and mean posttest sugary beverage intake 156.6 (SD 145.0) g in the experimental group (P=.08) and mean pretest sugary beverage intake 336.8 (SD 367.7) g and mean posttest sugary beverage intake 370.4 (SD 410.9) g in the control group (P=.04; between-group P=.04); mean pretest FV self-efficacy score 4.2 (SD 0.8) and mean posttest FV self-efficacy score 4.3 (SD 0.6) in the experimental group (P=.35) and mean pretest FV self-efficacy score 4.0 (SD 0.8) and mean posttest FV self-efficacy score 4.0 (SD 0.6) in the control group (P=.24; between-group P=.80)
Allicock et al [29], 2021	4 weeks	4 weeks	100	• BMI and WC • FV intake and percentage of energy from fat and fiber • PA level	• Mean change in BMI –0.19 (SD 0.35) kg/m^2 in the experimental group (P=.10) and –0.24 (SD 0.76) kg/m^2 in the control group (P=.76); mean WC change –1.04 (SD 0.95) cm in the experimental group (P=.003) and –0.47 (SD 1.57) cm in the control group (P=.39) • Mean FV change 0.67 (SD 2.35) servings in the experimental group (P=.34) and 0.78 (SD 2.48) servings in the control group (P=.38); mean fast food intake change –1.5 (SD 1.98) servings in the experimental group (P=.008) and –1.11 (SD 1.45) servings in the control group (P=.09)

[a]QALY: quality-adjusted life year.

[b]QoL: quality of life.

[ac]VAS: Visual Analog Scale.
[ad]PHQ: Patient Health Questionnaire.
[ae]PACE: Patient-Centered Assessment and Counseling for Exercise.

Risk-of-Bias Assessment

The assessment of risk of bias was conducted for each study. The RoB 2 assessment is shown in Figure 2 [29-35]. In total, 8% (1/13) of the studies had a low risk of bias in all aspects [35]. A total of 15% (2/13) of the studies were reported as double blind [34,35]. Due to uncertainty or unblinded treatment allocation, the quality of 38% (5/13) of the trials was considered low with regard to performance and detection bias [29-33]. There was an unclear risk of selection bias in these 5 trials due to limited information about allocation concealment [29-33] and generation of a randomized sequence [30-32]. Huggins et al [34] reported a low retention rate (<50%), with the use of the multiple imputation approach for handling missing data. The suboutcomes resulting from a web-based intervention were not reported in a breast cancer study investigating the effect of mobile app–based training on QoL [32]. One study did not report the *P* value for the difference in breast cancer well-being after the intervention [30].

The ROBINS assessment is shown in Figure 3 [36-41]. A total of 17% (1/6) of the studies mentioned the frequency of mobile app use (at least 5 days) during the intervention [37], whereas the remaining 83% (5/6) of the studies did not report the intervention status. In total, 67% (4/6) of the studies reported a low retention rate or uncertainty about missing data management [36,37,39,41]. A total of 50% (3/6) of the studies had a high risk of bias in the selection of study participants, which could affect the quality of the intervention and outcomes [36,38,39]. In total, 33% (2/6) of the studies did not provide information on whether there was a deviation from the intended intervention [37,41]. Fuemmeler et al [38] failed to show the changes in weight and height measurements after the intervention. A total of 17% (1/6) of the studies did not provide information about *P* values of weight loss data [37]. In total, 33% (2/6) of the studies reported no information on whether any confounding factors were present [38,41]. A total of 17% (1/6) of the studies had a high risk of bias in outcome measurements that resulted from inappropriate methods of delivering the intervention [37] and measuring outcomes [42].

Figure 2. Risk-of-bias assessment of randomized controlled trials (n=7) using the Risk of Bias 2 tool, with a quality rating of low risk (–), high risk (+), or unclear risk (?).

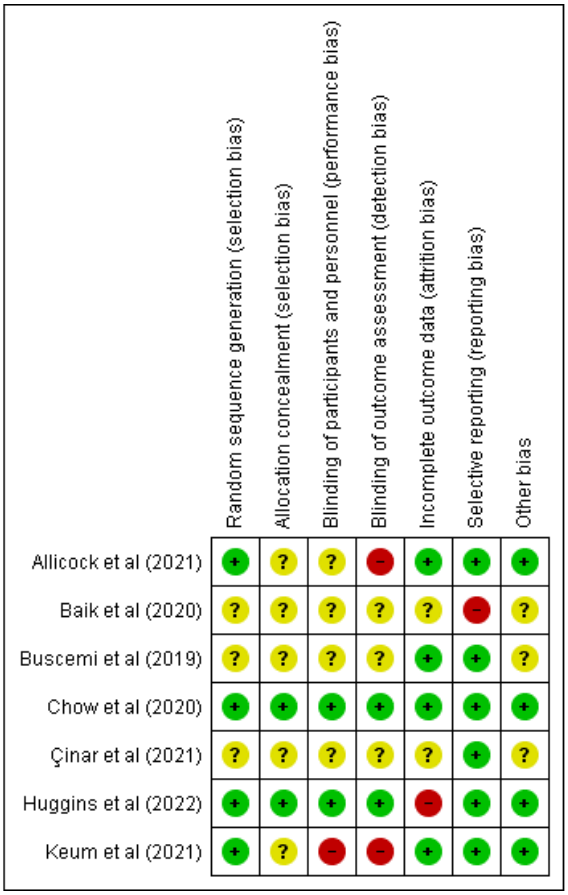

Figure 3. Risk-of-bias assessment using the Risk of Bias in Nonrandomized Studies tool in 6 studies, with a quality rating of low risk (–), high risk (+), or unclear risk (?).

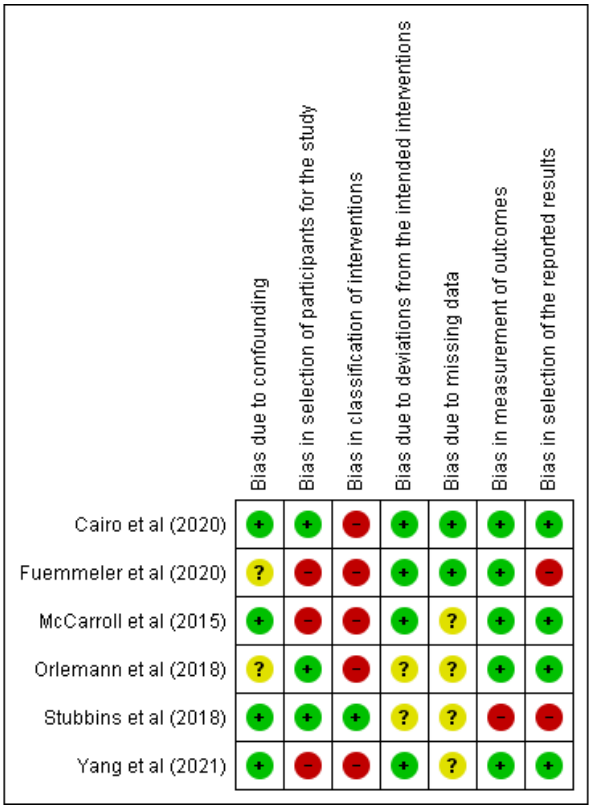

Outcome Measures

A summary of outcome measures and study findings can be found in Table 2.

Anthropometry and Body Composition

Of the 13 studies, 7 (54%) analyzed anthropometry measures, including body weight, BMI [29,34,36-38,40,41], and waist circumference [29,36]. Of these 7 studies, 5 (71%) intended to support weight reduction [29,36-38,40], and 2 (29%) supported weight retention [34,41]. Of the 5 studies supporting weight reduction, 2 (40%) reported significant improvement in weight after the intervention [36,40]. On the other hand, only 50% (1/2) of the studies that supported weight retention reported significant weight gain in patients with cancer who were at risk of malnutrition [41]. Huggins et al [34] reported attenuation of weight loss in patients with upper gastrointestinal cancer who received a symptom-directed nutrition intervention via telephone compared to a mobile app. A total of 29% (2/7) of the studies did not find significant changes in BMI between groups [29,38]. A study showed a decrease in weight among survivors of breast cancer with overweight; however, neither the *P* value nor the significance of the change was stated [37]. A total of 29% (2/7) of the studies reported a significant reduction in waist circumference after the intervention [29,36].

In total, 23% (3/13) of studies aiming to combat cancer-induced malnutrition assessed body composition, namely, skeletal muscle mass, fat-free mass, fat mass, and bone mineral density [33,39,41]. Significant increases in skeletal muscle mass and fat-free mass were reported in app users based on the results of bioimpedance analysis [41]. However, the studies by Keum et al [33] and Yang et al [39] did not show significant results of the skeletal muscle index using computed tomography.

Nutritional Status or Index

Nutritional status was evaluated in 23% (3/13) of studies aiming at weight gain [33,34,39]. According to the Scored PG-SGA, Keum et al [33] reported significant improvements in nutritional status in both the experimental and control groups but with no statistically significant difference between groups. Similarly, a nonsignificant difference in PG-SGA scores in the intervention groups (delivered via telephone or mobile app) compared with the control group was reported by Huggins et al [34]. The PG-SGA score is derived from 7 domains, namely, weight, food intake, nutrition impact symptoms, functional capabilities, presence of catabolic condition, metabolic demand, and physical examination. The scores range from 0 to 53, with higher scores indicating poorer nutritional status [43].

Another study measured the prognostic nutritional index (PNI), neutrophil-to-lymphocyte ratio, and platelet-to-lymphocyte ratio for nutritional status assessment. Only the PNI showed a significant reduction in the experimental group compared to the control group [39]. These 3 indexes were derived from laboratory parameters (PNI: 10 × albumin + 0.005 × absolute lymphocyte count; neutrophil-to-lymphocyte ratio: absolute neutrophil count/absolute lymphocyte count; platelet-to-lymphocyte ratio: platelet/absolute lymphocyte count). Higher readings indicate higher level of inflammation or severity of malnutrition.

Dietary Factors

A total of 62% (8/13) of the studies examined the effect of nutritional mobile apps on dietary outcomes in cancer [29,31,33,35,36,38,40,41]. The common outcome measures were daily nutrient intakes [29,31,33,36,38,41] and level of adherence to dietary recommendations [35,40]. App users reported reduced consumption of high-fat food, including fast food, after the intervention [29,31]. A higher consumption of sugary beverages was observed in non–app users compared to app users, but no significant results were reported for the intake of fruits and vegetables [38]. Keum et al [33] reported higher intake of protein and energy in app users, whereas 33% (2/6) of the studies that measured daily nutrient intake did not report any significant findings [36,41].

The level of adherence to a healthy diet was analyzed in 25% (2/8) of these studies. On the basis of a Rate Your Plate survey, app users reported a significantly improved adherence to a plant-based diet [40]. However, no significant results were reported using the Healthy Eating Index score [35].

QoL and Symptom Burden

The impact of nutritional mobile apps on QoL was evaluated in 46% (6/13) of the studies. In total, 33% (2/6) of these studies measured QoL using the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire (EORTC QLQ-C30) [33,34]. A total of 50% (3/6) of the studies used the Functional Assessment of Cancer Therapy–General (FACT-G) [36], the Functional Assessment of Cancer Therapy–Breast (FACT-B) [30], and Functional Assessment of Cancer Therapy–Endocrine Symptoms (FACT-ES) [32]. In total, 17% (1/6) of the studies used the Patient-Reported Outcomes Measurement Information System Global Health–10 to assess QoL [35]. In total, 33% (2/6) of the studies reported significant improvements in QoL based on the EORTC QLQ-C30 [33] and FACT-ES [32] tools. Higher scores were reported for overall perception of QoL and physical, emotional, and functional well-being, whereas lower scores were reported for endocrine symptoms and psychosocial distress. The remaining studies did not report any significant QoL results [34-36,40].

The EORTC QLQ-C30 covers 5 functional domains (physical, emotional, social, role, and cognitive), 9 symptoms (fatigue, nausea and vomiting, pain, dyspnea, insomnia, appetite loss, constipation, diarrhea, and financial difficulties), and a general health perception. The total score ranges from 0 to 100, with higher scores indicating greater symptoms or better functional status [44]. The FACT-G comprises 27 items and 5 Likert rating scales (0-4), similar to the FACT-B and FACT-ES. The FACT-G measures the domains of physical, social, emotional, and functional well-being, whereas the FACT-B and FACT-ES have 11 additional breast cancer–related items and 9 additional endocrine-related items, respectively. The total score of these QoL tools can be >100, with higher scores indicating greater symptoms or better functional status [45].

The Visual Analog Scale–Fatigue and 2-item Patient Health Questionnaire were used in the study by Cairo et al [40]. Although the experimental group reported improved levels of fatigue and depression after the intervention, these changes were

not statistically significant. The Visual Analog Scale–Fatigue comprises 18 items answered on a Likert scale from 0 to 10, with higher scores indicating higher levels of pain or fatigue. On the other hand, the 2-item Patient Health Questionnaire comprises 2 items pertaining to anhedonia and depression ranging from 0 to 6, with higher scores indicating more depressive symptoms [46].

No significant results were found using quality-adjusted life years (QALYs) in the study by Huggins et al [34].

Discussion

Principal Findings

Nutritional mobile apps for populations with cancer have the potential to improve body weight or composition, nutritional status, dietary adherence, and QoL across the continuum of cancer care. The apps offered the basic functions of recording and tracking users' food intake and weight in general. It was unclear whether custom-developed mobile apps were efficacious for nutrition-related health outcomes and QoL in cancer care. However, incorporating commercial mobile apps seemed to be beneficial for improving nutritional care in populations with cancer. This could be due to the implementation of self-monitoring of their progress, a necessary step in delivering quality nutrition care [5]. This review observed that the beneficial effect of stand-alone interventions was comparable with that of multicomponent interventions. However, the results may not be able to discern the magnitude of the difference due to limited data. Overall, the studies included in this review were of low to moderate quality. For RCTs, lack of blinding and biased treatment allocation were the major concerns. Failure to define the intervention status in terms of types, frequency, and timing reported by non-RCTs made the evaluation of nutritional mobile apps challenging.

Comparison to Prior Work

Among the interventions that aimed to support weight loss, almost half (2/5, 40%) reported successful weight control among patients with cancer and overweight. In public health research, the common measures are BMI, waist circumference, waist-to-hip ratio, and body fat percentage [47]. Waist-to-height ratio has also been known to be a good surrogate in predicting the risk of noncommunicable diseases [48,49]. Implementing effective dietary strategies for successful weight loss is highly recommended to reduce the risk of cancer recurrence in long-term survivorship [4]. A review underpinned the beneficial effects of eHealth interventions on weight management in survivors of cancer, with a greater impact if combined with dietary counseling [50].

Our review found reduced intake of fast food [29] and sugary food [38] in app users. When aiming at weight loss, adhering to healthy eating guidelines should be the goal to sustain good health and well-being. A bariatric study highlighted the need to change eating behaviors for sustainable weight management [51]. Self-monitoring weight changes and dietary behavior is a common feature in app-based weight loss programs. The use of mobile app interventions for improved eating behavior and diet quality seems to be promising [52]. There are multiple factors influencing eating habits among school-aged children, particularly role modeling and parenting styles [53]. In addition to app gamification, creating a conducive learning environment in schools and at home could be a way to promote healthy eating habits among children.

The primary concern regarding undernutrition is the lack of energy that the body needs to undergo cancer treatment, which could result in treatment toxicities, longer hospital stays, or reduced QoL [4]. Among interventions that aim to support weight gain in patients with cancer who were malnourished, delivering nutrition support via mobile app platforms may help prevent drastic weight loss and improve skeletal muscle mass and overall nutritional status. However, the findings of this review do not reflect the long-term beneficial effects due to lack of data. Despite the growing development of nutrition apps, tailoring dietary interventions to individuals' needs, nutritional status, cancer type, treatment plan, and comorbid conditions is still an unmet need [54].

Of the 6 studies that focused on QoL, only 2 (33%) showed significant changes in QoL at the treatment phase based on the EORTC QLQ-C30 and FACT-ES [32,33]. A review that focused on app-based interventions to improve nutrition or lifestyle behaviors in patients with breast cancer showed a similar finding during chemotherapy [55]. This could be due to enhanced user engagement by improving self-motivation, health information, social support, and goal setting [56]. The 2 cancer-specific tools used in our review were the EORTC QLQ-C30 [44] and FACT-G [45], which allow for a multidimensional assessments of QoL. These tools yield a comprehensive evaluation of individuals' progress. QALYs, which account for both QoL and survival, have been increasingly used as a standard measure to evaluate disease burden at the population or regional level [57,58]. However, Huggins et al [34] reported no significant results for QALYs in groups that received the intervention via mobile app or telephone compared to controls. Failure to obtain significant results could be due to less participants who continued to use the mobile app after the intervention period.

Strengths and Limitations

This is the first review that has evaluated the impact of app-based dietary interventions in cancer care. The review was based on a systematic search strategy that focused on nutrition interventions delivered via mobile app platforms and on populations with cancer. However, this review has certain limitations. First, only English-language articles were included in the search for this review. Second, the heterogeneity of study designs, interventions, app features, and cancer types was substantial, requiring the results to be interpreted cautiously. Third, the inconsistent measurement and reporting of incomplete data made comparisons difficult across the studies. Finally, this review included pilot studies that comprised small sample sizes (11/13, 85% of the interventions enrolled <70 participants per group), resulting in limited generalizability of the study findings.

Conclusions

Mobile app–based nutrition interventions have a favorable effect on nutritional status and QoL in patients with cancer. In addition, mobile apps that incorporate nutrition interventions could also

be beneficial for survivors after cancer treatment. However, it was unclear whether custom-developed apps were efficacious for improved nutrition-related outcomes and QoL. The continuity of nutritional care in patients with cancer via mobile app platforms could help in achieving a healthy weight by improving their adherence to dietary guidelines. Although most studies yielded favorable outcomes, they were rated as being of low to moderate quality.

Future studies should emphasize randomized controlled designs, larger sample sizes, diet-only mobile apps, greater homogeneity of outcome measures and population characteristics, and high participant engagement and retention within the study.

Abstract

Background: Advances in therapies have significantly improved the outcomes of patients with cancer. However, multidimensional symptoms negatively impact patients' quality of life. Traditional symptom analysis methods fail to capture the dynamic and interactive nature of these symptoms, limiting progress in supportive care. Network analysis (NA) is a promising method to evaluate complex medical situations.

Objective: We performed a systematic review to explore NA's contribution to understanding the complexity of symptom experiences in patients with cancer.

Methods: The research question was as follows: "In patients with cancer (population), what is the contribution of NA (intervention) to understanding the complexity of multidimensional symptom experiences (outcome)?" The keywords "network analysis" AND "symptoms" AND "cancer survivors" OR "cancer patients" were searched in MEDLINE, Embase, Google Scholar, and Scopus between 2010 and 2024. Citations were extracted using Covidence software. Two reviewers independently screened the articles and resolved inclusion disagreements through consensus. Data were synthetized, and results have been narratively described. Bias analysis was performed using the Methodological Index for Non-Randomized Studies tool.

Results: Among 764 articles initially identified, 22 were included. Studies evaluated mixed solid tumors (n=10), digestive tract cancers (n=4), breast cancer (n=3), head and neck cancer (n=2), gliomas (n=2), and mixed solid and hematological cancers (n=1). Twelve studies used general symptom assessment tools, whereas 10 focused on neuropsychological symptoms. Moreover, 1 study evaluated symptoms at diagnosis, 1 evaluated them during curative radiotherapy, 4 evaluated them during the perioperative period, 5 evaluated them during chemotherapy, 4 evaluated them during ongoing cancer therapies, and 7 evaluated them after acute treatments. Among these, 3 evaluated the longitudinal changes in symptom networks across chemotherapy cycles, and 1 evaluated changes during radiotherapy. Three studies investigated the associations between symptoms and biological parameters. Several NA approaches were used: network visualization (n=1), Bayesian network (n=1), pairwise Markov random field and IsingFit method (n=1), unregularized Gaussian graphical model (n=2), regularized partial correlation network (n=6), network visualization and community NA (n=1), network visualization and Walktrap algorithm (n=1), undirected network model with the Fruchterman-Reingold and edge-betweenness approaches (n=4), biased correlation and concise pattern diagram (n=1), extended Bayesian information criterion graphical LASSO method (n=3), cross-lagged panel network (n=1), and unspecified NA (n=3). Psychological symptoms, particularly anxiety, depression, and distress, were frequently identified as central and stably interconnected. Fatigue consistently emerged as a core symptom, closely linked to sleep disturbances, cognitive impairment, and emotional distress. Associations between symptoms and inflammatory biomarkers (eg, interleukin-6, C-reactive protein, and tumor necrosis factor-α) suggest a biological basis for symptom interconnectivity.

Conclusions: NA consistently identified core symptoms, particularly psychological symptoms and fatigue, and associations with inflammatory biomarkers. NA may deepen the understanding of symptom interconnectivity and guide more effective interventions. However, further longitudinal homogeneous studies using standardized methodologies are needed.

KEYWORDS

network analysis; symptoms; cancer patients; systematic review; cancer treatment; symptom management

Introduction

The global burden of cancer is continuously increasing, with Europe accounting for one-fifth of the total cancer cases and cancer deaths [1]. Over the past 2 decades, advances in multidisciplinary management and tailored drug therapies have significantly improved treatment outcomes, offering potential cures or long-term remission and leading to the concept of cancer survivorship [2,3]. However, despite these medical advancements, many patients with cancer continue to experience persistent and complex symptoms resulting from both the disease and its treatments, negatively affecting their quality of life (QoL) for years after diagnosis [4,5]. New treatment opportunities provided by cancer research are often paired with unpleasant side effects, such as those observed with recent advances in immunotherapy, highlighting the need for a deeper understanding of symptom interactions to improve symptom management strategies [6,7].

Traditional approaches to symptom analysis, such as the symptom cluster approach [8,9], have sought to identify groups of co-occurring symptoms that share common mechanisms and clinical outcomes [10-12]. However, the symptom cluster approach has faced criticism due to its reliance on statistical grouping techniques that do not fully capture the dynamic relationships between symptoms and clusters [11,13-15]. Specifically, it lacks the ability to assess direct interactions within or between symptom clusters and does not account for causal relationships between symptoms [13,14]. These limitations have prompted researchers to explore network analysis (NA) as a novel methodological framework for studying symptom complexity [16,17]. NA, originally developed in mathematics and graph theory, has gained traction in psychological and medical research for its ability to estimate complex patterns of relationships and to reveal core features of mental disorders [18,19]. This approach grants a new ontological view on mental diseases, conceiving them as complex systems of components, which are maintained by mutual relationships between them, without the need to identify causal latent variables [17,19,20].

This network-based approach differs fundamentally from traditional models by conceptualizing diseases as interconnected systems rather than relying on predefined diagnostic categories [18].

In cancer research, NA offers a powerful framework for understanding symptom interactions, identifying core symptoms, and refining symptom management strategies. This approach could enable clinicians to develop targeted interventions, prioritizing symptoms that have the highest impact on patients' QoL, which can ultimately enhance patient care [21]. In the study by Kossakowski et al [21], NA was used to analyze data related to health-related QoL in both a healthy population and patients with cancer, showing that maintaining daily routines and work activities could prevent symptom-related vicious cycles. Their findings emphasized the importance of psychosocial interventions in cancer treatment strategies [21].

Beyond symptom management, NA also holds promise for uncovering the underlying biological mechanisms driving symptom progression [22]. By integrating biological markers into symptom networks, this approach could provide new insights into pathophysiological pathways, offering opportunities for more biologically informed therapeutic strategies.

Kosvyra et al [22] explored the application of NA in the study of the biological data of patients with cancer, highlighting a significant gap in multiomics and predictive analyses, which limits the integration of biological mechanisms into symptom network research [22].

Despite promising findings, the application of NA in cancer symptom research remains fragmented, with existing studies often limited by sample heterogeneity, varied methodologies, and a lack of integration with biological data and therapeutic interventions. In this systematic review, we propose to investigate this complex and heterogeneous literature with a precise research question focusing on the contribution of NA in understanding the symptom experience of patients with cancer. The results will be detailed, and we will discuss methodological approaches used in existing studies, including differences in network construction and analysis; identify knowledge gaps; and propose future research directions.

By critically evaluating the existing literature, this review provides the first comprehensive assessment of the role of NA in understanding cancer symptomatology, emphasizing its potential to refine symptom management and enhance patient outcomes.

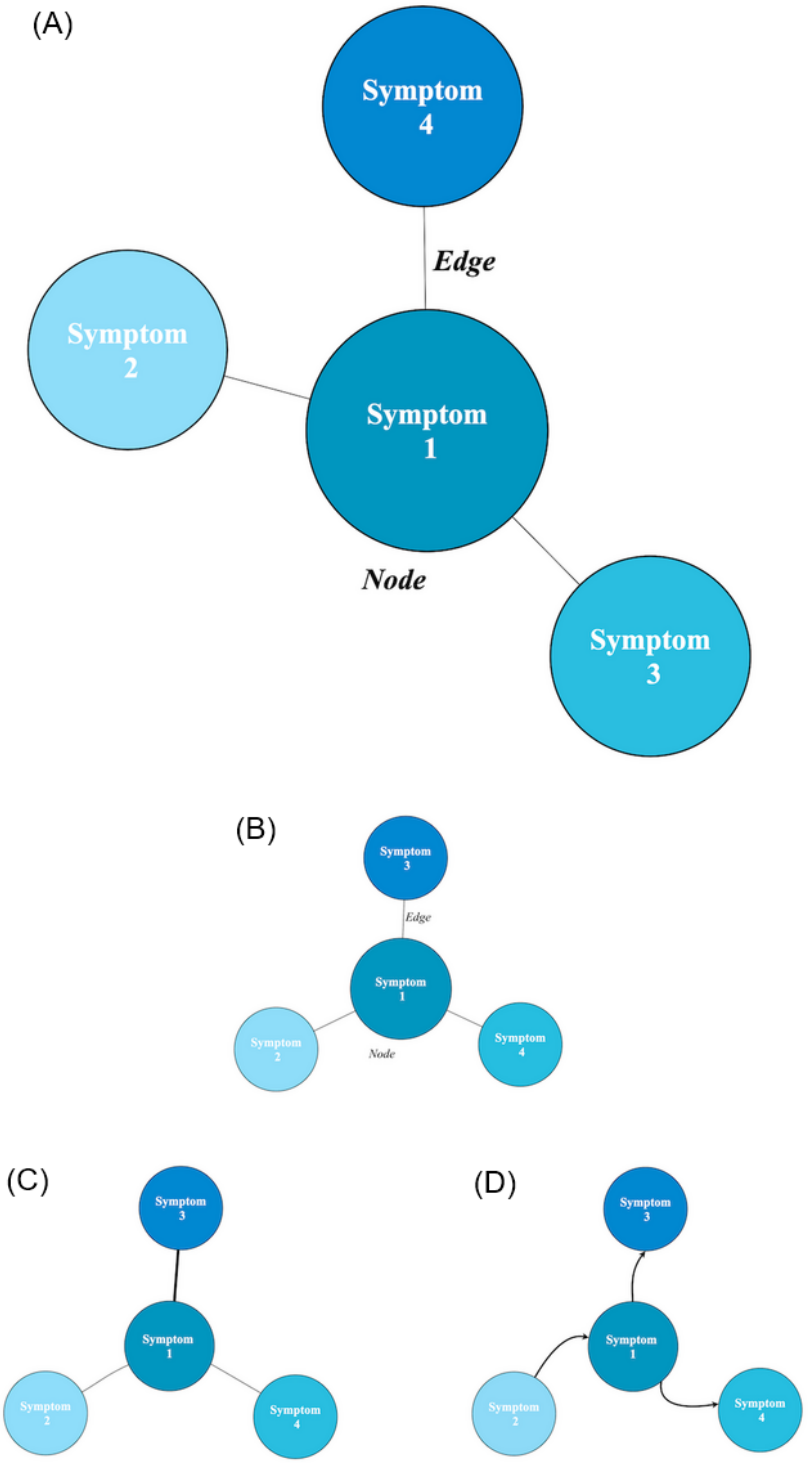
Methods

NA Approach

A network is a set of nodes (variables) and a set of edges (statistical relationships) connecting the nodes [19]. In the medicine field, nodes are symptoms, and a network is a graphic representation of the complex association observable between symptoms. Several types of networks have been developed: *directed networks* (cyclic or acyclic), in which the direction of the edges is determined; *undirected networks*, in which the direction of the edges is unknown [19]; *weighted networks*, in which the weight of the edges is represented by their thickness

and can represent a positive association or negative association; and *unweighted networks*, in which the edges either exist or not, and if they exist, they all have the same importance [18]. The classical structures of networks are represented in Figure 1.

Figure 1. (A) Representation of 3 nodes (symptoms) with their relationships (edges). Networks: (B) unweighted, undirected network; (C) weighted network; and (D) cyclic or acyclic directed network.



NA has to follow a precise methodology: collect the data of interest (from cross-sectional, longitudinal, or panel data studies), construct the network, describe it, and analyze its stability [18,19]. The choice of the NA method influences network structure, the relationships captured, and the assumptions imposed on the data [20].

Once constructed, the structures of the network have to be analyzed in terms of its properties: what is the importance of nodes, is the global structure dense, and are the nodes isolated? These properties are described in terms of centrality (degree, node strength, closeness, betweenness, and clustering) [18]. Finally, the network accuracy has to be evaluated [19].

Pairwise Markov random fields and directed acyclic graphs are the most used methods in the psychopathological sciences [18]. Pairwise Markov random fields (Ising model and Gaussian graphical model) involve undirected models used to represent conditional dependence or independence between pairs of variables and are constructed using local conditional probability distributions [18]. The presence of an edge between 2 nodes indicates that they are conditionally dependent, and the absence of an edge indicates that they are conditionally independent. However, they do not explain model causal relationships. In contrast, directed acyclic graphs represent causal relationships, mapping directed interactions between symptoms without relying on probability distributions [18]. A comparative summary of these models is provided in Table 1.

Table 1. Comparison between pairwise Markov random fields and directed acyclic graphs.

Variable	Pairwise Markov random field	Directed acyclic graph
Graph type	Undirected graph	Directed acyclic graph
Edge interpretation	Encodes conditional dependencies between variables	Represents causal relationships between variables
Edge direction	No direction (edges are bidirectional)	Directed edges (A → B means A influences B)
Conditional independence	An edge's presence or absence represents conditional dependence or independence	Uses d-separation to determine conditional independence
Causality	Does not assume causal relationships	Explicitly models cause-and-effect relationships
Loops/cycles	Can contain cycles	Acyclic (no feedback loops allowed)
Factorization of probability	Factorizes the joint distribution using local conditional distributions	Uses the chain rule to express joint probability based on parent-child relationships
Mathematical representation	Typically modeled using local Markov properties	Follows Bayes' theorem to express probabilities
Common models	Ising model, Gaussian graphical model, and mixed graphical model	Bayesian network and structural equation model (SEM)
Handling of latent variables	Typically does not incorporate latent variables directly	Can explicitly include latent variables
Parameter estimation	Uses maximum likelihood estimation (MLE) or regularization techniques (eg, LASSO)	Parameters estimated using MLE, Bayesian inference, or SEM methods

Research Question and Design

The research question was structured using the specialized PICO (population, intervention, comparator, outcome) framework. The final research question was as follows: "Considering patients with cancer (population), what is the contribution of the NA approach (intervention) to the understanding of the complexity of multidimensional symptom experiences (outcome)?" The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist was used to structure the report (Multimedia Appendix 1).

Search Strategy

We systematically searched the following databases: PubMed (MEDLINE), Embase, Scopus, and Google Scholar. The search strategy was developed by the authors using a combination of medical subject headings, EMTREE thesaurus terms, and free-text keywords informed by an initial scoping review of the literature. No librarian or information specialist was consulted.

The search combined the terms "network analysis," "symptoms," and ("cancer patients" or "cancer survivors") using Boolean operators. For multiword terms, quotation marks were used where appropriate (eg, "network analysis"). Filters were applied to limit results to studies on human adults published in English between 2010 and February 2024. A full description of the search strings and filters applied in each database is available in Multimedia Appendix 2.

References retrieved from the databases were imported into Covidence systematic review software, which automatically identified and removed duplicates. Additional references were identified through manual handsearching of Google Scholar.

Selection Criteria

To be included in the review, the articles had to evaluate symptoms or symptom clusters in adult patients with cancer via an NA approach, either at diagnosis or during acute cancer treatment, long-lasting adjuvant therapy, and follow-up alone. To maintain some disease homogeneity, studies focusing on hematological patients alone were excluded, although those with mixed patient populations, solid tumors, or hematological cancers were admissible. Given that this review focuses on symptoms, articles evaluating QoL, coping strategies, or symptom-targeted interventions alone were excluded. Reviews or meta-analyses were also excluded. Eligible articles had to be written in English. This systematic review was not registered.

Study Selection

The reference management software Covidence was used to export citations from database searches. Two reviewers (VR and AG) independently screened the titles and abstracts, and full-text screening was performed by both reviewers. Disagreements on inclusion were resolved through consensus.

Data Extraction

A predefined extraction form was developed for data extraction. The process was performed by one reviewer (VR) and verified by a second reviewer (AG). Data were synthesized regarding different parameters: design of the study, main purpose of the study, sample size, cancer type, time of symptom assessment,

tools used for symptom assessment and measures, NA methods, and main findings of the NA. The results are narratively described.

Bias Analysis

The methodological quality and risk of bias of the included studies were assessed using the Methodological Index for Non-Randomized Studies (MINORS) tool. This validated instrument was chosen as it is specifically designed to assess the methodological quality of nonrandomized surgical studies, whether comparative or noncomparative, and has been adapted for use in systematic reviews across various medical fields [23].

The MINORS tool evaluates studies across 12 items: 8 items for noncomparative studies and an additional 4 items for comparative studies. Each item is scored as 0 (not reported), 1 (reported but inadequate), or 2 (reported and adequate). For noncomparative studies, the global ideal score is 16, while for comparative studies, it is 24. Two reviewers (EP and GB) independently conducted the bias assessment, with disagreements resolved through discussion until consensus was reached.

The evaluation criteria included clearly stated aims, consecutive patient inclusion, prospective data collection, appropriate endpoints, unbiased outcome assessment, appropriate follow-up period, loss to follow-up analysis, and prospective calculation of study size. For comparative studies, additional criteria included adequate control group selection, contemporary groups, baseline equivalence, and adequate statistical analysis.

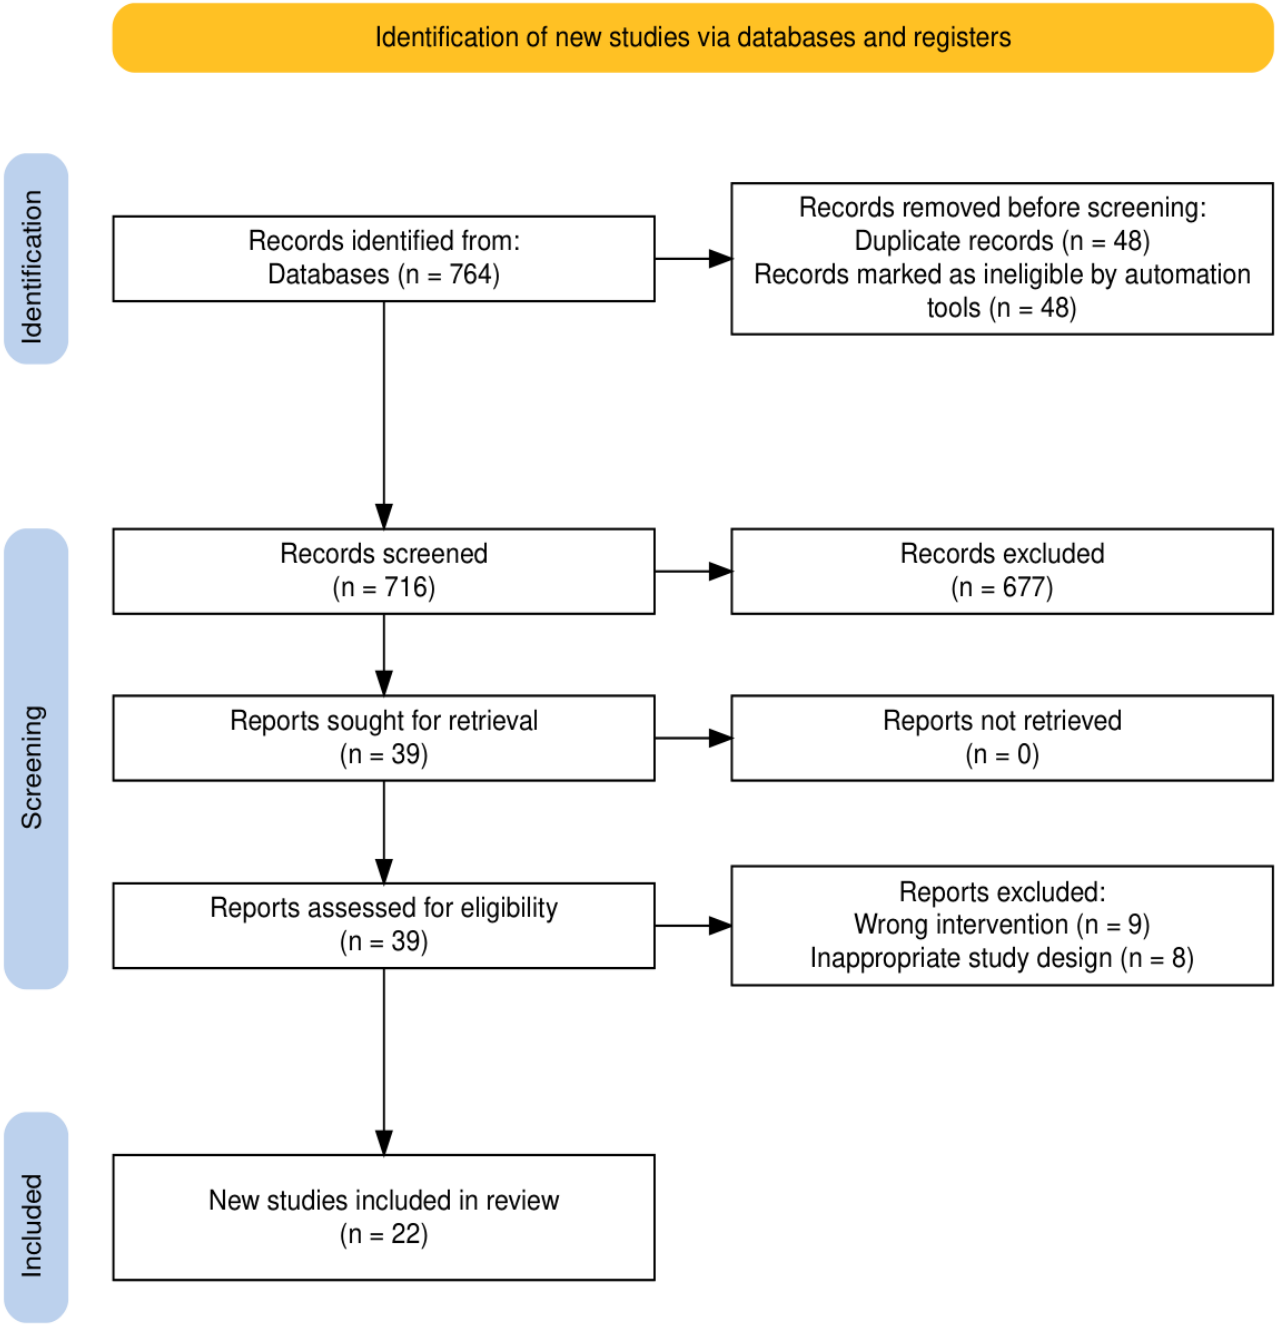
Results

Search Results

A total of 764 articles were initially identified through searches across 4 literature databases. After title and abstract screening, 677 articles were excluded. Of the 39 full-text articles assessed for eligibility, 17 were excluded (9 due to the use of the wrong intervention and 8 due to an inappropriate study design). Ultimately, 22 studies were included in this review, comprising a cumulative total of 20,393 participants.

The complete PRISMA flow diagram is presented in Figure 2. The diagram was generated using the PRISMA Flow Diagram Tool [24].

Figure 2. PRISMA 2020 flow diagram depicting the identification, screening, and inclusion process for studies in the systematic review.



Characteristics of the Included Studies

All characteristics of the selected studies are summarized in the subsections below and detailed in Table 2.

Table 2. Selected studies for the review.

Study and country	Study design	Main purposes	Sample description (including cancer type[a]) and assessment period	Symptom assessment: tools[b] and biomarkers[c]
Bhavnani et al [25], 2010; United States	Secondary analysis of a randomized trial (2007); Longitudinal	Explore symptom co-occurrence and overlap patterns using network analysis. Explore quantitative measures to analyze symptom co-occurrence and overlap (observed patterns).	• N=665 (463 female); Age: 21 years or older; Cancer type: solid tumors 94%, NHK 6%; Period: during CT[d]	Tools: MDASI (18 symptoms)
Xu et al [26], 2018; United States	Secondary analysis of a NIH[e]-funded study (2004-2010); Longitudinal	Investigate how depression, fatigue, and sleep interactions affect cognition and QoL[f] during CT.	• N=74 (74 female); Age: 51.8 (SD 9.5) years; Cancer type: BC; Period: pre-CT, post-CT, and 1 year after	Tools: PSQI (sleep quality), MFSI-SF (fatigue), CES-D (mood), FACT-B (quality of life), FOSQ (functional outcomes of sleepiness), and NP (cognition)
Papachristou et al [27], 2019; United States	Secondary analysis part of a longitudinal study	Evaluate the occurrence, severity, and distress of 38 cancer symptoms. Compare symptom networks based on occurrence, severity, and distress.	• N=1328 (1032 female); Age: 57.2 (SD 12.4) years; Cancer type: BC 40.2%, GI 30.7%, GYN 17.3%, LC 13.2%; Period: during CT	Tools: mMSAS (38 symptoms)
Hartung et al [28], 2019; Germany	Cross-sectional from 2 studies: cross-sectional prospective patients with cancer; survey control general population	Compare depressive symptom severity, frequency, and networks between patients with cancer and the general population.	• Study 1: N=4020 patients with cancer (2050 female); Age: 58 (SD 11) years • Study 2: N=4020 individuals from the general population (2050 female); Age: 55 (SD 15) years • Cancer type: BC 22.54%, PC 15.85%, CR 12.69%, and others 15.47%; Period: 14 months after diagnosis (mean)	Tools: PHQ-9 (depressive symptoms)
Schellekens et al [29], 2020; The Netherlands	Cross-sectional	Examine relationships among symptoms and psychosocial risk or protective factors.	• N=342 (264 female); Age: 51.35 (SD 10.62) years; Cancer type: BC 45.6%, metastatic 36.8%; Period: ongoing treatments.	Tools: CIS-FS (fatigue), CES-D (depressive and anxiety symptoms), HDI (well-being), RSCL (physical symptoms), GSBQ (social withdrawal), ICQ (illness cognition), GAS (goal engagement), and WGS (partner support)
de Rooij et al [30], 2021; The Netherlands	Secondary analysis from the PROFILES registry and NCR[g]; Cross-sectional survey data	Identify symptom clustering across cancer types using network modeling.	• N=1330 (835 female); Age: 61 (SD 15) years; Cancer type: BC 14.29%, CR 14.29%, Ov 14.29%, Thy 14.29%, HK 14.29%, NHK 14.29%, and CLL 14.29%; Period: years after diagnosis	Tools: EORTC-QLQ-C30 (30 symptoms; emotional and cognitive functioning scales)
Rha and Lee [31], 2021; Korea	Secondary data analysis from the SMILE RCT[h]; Longitudinal	Identify stable symptom clusters and their interrelationships across treatment cycles.	• N=249 (184 female); Age: 51.89 (SD 9.75) years; Cancer type: BC 60.3%, GC 33.3%, and LC 6.4%; Period: across CT cycles	Tools: assessment of 20 symptoms, including 12 core symptoms, with a numerical rating scale (0-10)
Shim et al [32], 2021; Korea	Longitudinal	Study physical or psychological symptoms and QoL changes before or after gastric surgery.	• N=256 (92 female); Age: 62.41 (SD 10.72) years; Cancer type: GC; Period: before and 1 week and 3-6 months after surgery	Tools: K-MDASI (Korean version; 13 symptoms), K-HADS (Korean version; depressive and anxiety symptoms), and FACT-Ga (QoL)

Study and country	Study design	Main purposes	Sample description (including cancer type[a]) and assessment period	Symptom assessment: tools[b] and biomarkers[c]
Henneghan et al [33], 2021; United States	Cross-sectional	Visualize symptom-cytokine networks and evaluate centrality in BC survivors.	• N=66 (66 female); Age: 48.44 (SD 8.73) years; Cancer type: BC; Period: after adjuvant CT (6 months-10 years)	Tools: PCI-total (cognition), UCLA Loneliness Scale (loneliness), Perceived Stress Scale (stress), PROMIS (fatigue, anxiety, depression), PSQI (sleep quality), and Epworth Sleepiness Scale (daytime sleepiness); Biomarkers: 13 cytokines (TNF-α, GM-CSF, INF-γ, IL-2, IL-1b, IL-5, IL-7, IL-8, IL-10, IL-13, IL-6, IL-2, and IL-4)
Kalantari et al [34], 2022; United Kingdom	Longitudinal	Analyze changes in symptom clusters across treatment time points.	• N=987 (779 female); Age: 56.9 (SD 12) years; Cancer type: BC 41.3%, GI 29.8%, GYN 17.7%, and LC 11.2%; Period: across 2 CT cycles, 6 time points	Tools: mMSAS (38 symptoms)
Lin et al [35], 2022; United States	Longitudinal	Examine temporal networks of psychoneurological symptoms.	• N=172 (45 female); Age: 59.8 (SD 9.9) years; Cancer type: HNC; Period: 4 times across radiotherapy	Tools: PHQ-8 (depressive symptoms), MFI (fatigue), PSQI (sleep quality), and PRO-CTCAE (cognitive dysfunction and pain)
Santoso et al [36], 2022; The Netherlands	Cross-sectional	Link 5 psychoneurological symptoms with stress biomarkers in newly diagnosed HNC.	• Cohort 1 (complete data): N=264 (55 female); Age: 65 (SD 8.2) years • Cohort 2 (incomplete data): N=475 (135 female); Age: 62 (SD 10.4) years • Cancer type: HNC; Period: at diagnosis and before treatment	Tools: PSQI (sleep quality), HADS (depressive and anxiety symptoms), EORTC-QLQ-H&N35 (EORTC-oral pain-related symptoms), and MFI (fatigue); Biomarkers: cortisol saliva, serum CRP, IL-6, IL-10, and TNF-α
Zhu et al [37], 2022; China	Cross-sectional	Explore network structure and symptom centrality in cancer survivors.	• N=1065 (712 female); Age: 65.00 (SD 11.42) years; Cancer type: BC 29.3%, GI 22.6%, HNK 14.74%, and LC 14.46%; Period: cancer treatments completed (years)	Tools: MDASI (18 symptoms)
Ji et al [38], 2023; China	Cross-sectional	Identify clusters and core symptoms after esophageal cancer surgery.	• N=286 (114 female); Age: 55.5% 65 years or older; Cancer type: early esophageal; Period: early postoperative	Tools: MDASI-GI
Röttgering et al [39], 2023; The Netherlands	Retrospective; Secondary analysis of merged studies	Compare global strength between symptom networks to understand if symptoms are more tightly connected in different subgroups of patients.	• N=256 (95 female); Age: mean 47 years; Cancer type: glioma; Period: pre- and postoperative	Tools: CIS-FS (fatigue), CES-D (depressive symptoms), MOS-cog (cognitive functioning), EORTC-BN-20 (EORTC brain-tumor-related symptoms), and SF-36 (HRQoL[i])
Jing et al [40], 2023; China	Secondary data analysis from a cross-sectional study	Explore symptom networks in patients with BC under endocrine therapy.	• N=613 (613 female); Age: 49.5 (SD 9.4) years; Cancer type: BC; Period: endocrine therapy after acute care	Tools: FACT-ES (19 items)
Li et al [41], 2023; China	Cross-sectional	Study links between symptoms and inflammatory biomarkers in glioma.	• N=203 (102 female); Age: 54.10 (SD 14.1) years; Cancer type: glioma; Period: during treatments	Tools: HAMA-14 (anxiety), HAMD-24 (depressive symptoms), PSQI (sleep quality), MFI (fatigue), and numerical rating scale 0-10 (pain); Biomarkers: IL-1β, IL-6, IL-4, IL-10, CRP, and TNF-α
Wang et al [42], 2023; China	Cross-sectional	Identify core symptom clusters in patients with DC.	• N=202 (58 female); Age: 66.01 (SD 8.97) years; Cancer type: DC; Period: ongoing therapies.	Tools: MDASI-GI

Study and country	Study design	Main purposes	Sample description (including cancer type[a]) and assessment period	Symptom assessment: tools[b] and biomarkers[c]
Teng et al [43], 2024; China	Cross-sectional	Map symptom clusters and central symptoms after CT in patients with LC.	• N=512 (139 female); Age: 65.21 (SD 8.94) years; Cancer type: LC (advanced 68%).; Period: post-CT	Tools: mMSAS (32 symptoms)
Kuang et al [44], 2024; China	Secondary analysis; Cross-sectional	Compare symptom networks by survivorship groups in elderly patients with cancer.	• N=485 (295 female); Age: 72.54 (SD 6.44) years; Cancer type: elderly patients with cancer; Period: after acute treatments	Tools: MDASI (18 symptoms)
Shang et al [45], 2024; China	Prospective	Track predictive interactions between symptoms over time.	• N=230 (94 female); Age: 66.13 (SD 10.80) years; Cancer type: operable CR; Period: pre- and postsurgery	Tools: MDASI-GI
Gong et al [46], 2024; China	Cross-sectional survey	Explore demoralization symptom networks in female patients with cancer.	• N=413 (413 female); Age: 54.01 (SD 10.35) years; Cancer type: BC 63.2%, GC 18.4%, DC 10.7%, and others 7.7%; Period: ongoing therapies	Tools: DS-MV

[a]The following cancer types were identified in the included studies: breast cancer (BC), chronic lymphocytic leukemia (CLL), colorectal cancer (CR), digestive cancer (DC), gastric cancer (GC), gastrointestinal cancer (GI), gynecological cancer (GYN), Hodgkin lymphoma (HK), head and neck cancer (HNC), lung cancer (LC), non-Hodgkin lymphoma (NHK), ovarian cancer (Ov), prostate cancer (PC), and thyroid cancer (Thy).

[b]The following assessment tools were used in the included studies: Center for Epidemiologic Studies Depression Scale (CES-D), Checklist Individual Strength–Fatigue Severity (CIS-FS), Demoralization Scale Mandarin version (DS-MV), European Organization for Research and Treatment of Cancer Quality of Life Core Questionnaire (EORTC-QLQ-C30), Functional Assessment of Cancer Therapy–Breast Cancer (FACT-B), Functional Assessment of Cancer Therapy–Endocrine Subscale (FACT-ES), Functional Assessment of Cancer Therapy–Gastric Cancer (FACT-Ga), Functional Outcomes of Sleepiness Questionnaire (FOSQ), Goal Adjustment Scale (GAS), Groningen Social Behavior Questionnaire (GSBQ), Hospital Anxiety and Depression Scale (HADS), Hamilton Anxiety Scale–14 items (HAMA-14), Hamilton Depression Scale–24 items (HAMD-24), health and disease inventory (HDI), illness cognitions questionnaire (ICQ), MD Anderson Symptom Inventory (MDASI), MDASI–gastrointestinal cancer version (MDASI-GI), Multidimensional Fatigue Symptom Inventory–Short Form (MFSI-SF), Modified Memorial Symptom Assessment Scale (mMSAS), Medical Outcomes Study Cognitive Functioning Scale (MOS-cog), neuropsychological test battery composite score (NP), Perceived Cognitive Impairment scale (PCI), Patient Health Questionnaire–8 items (PHQ-8), Patient Health Questionnaire–9 items (PHQ-9), Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE), Patient-Reported Outcomes Measurement Information System (PROMIS), Pittsburgh Sleep Quality Index (PSQI), Rotterdam Symptom Checklist (RSCL), 36-item short-form survey (SF-36), and ways of giving support (WGS).

[c]The following biomarkers were evaluated in the included studies: C-reactive protein (CRP), granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin (IL), interferon gamma (INF-γ), and tumor necrosis factor alpha (TNF-α).

[d]CT: chemotherapy.

[e]NIH: National Institutes of Health.

[f]QoL: quality of life.

[g]NCR: Netherlands Cancer Registry.

[h]RCT: randomized controlled trial.

[i]HRQoL: health-related quality of life.

Time of Publication

The included studies were published between 2010 and 2024, with 18 out of the 22 studies published between 2021 and February 2024.

Sample Sizes

The sample sizes ranged from 66 patients [33] to 4020 patients [28].

Design of the Study

Of the 22 studies, 7 were based on secondary data analyses and 15 were based on primary data (5 longitudinal and 10 cross-sectional studies).

Types of Cancer

Among the studies, mixed solid tumor populations were evaluated in 10 studies, digestive tract cohorts were assessed in 4 studies, breast cancer was evaluated in 3 studies, and head and neck cancers and gliomas were assessed in 2 studies. One study investigated a mixed cohort of solid and hematological cancers.

Tools for Symptom Assessment and Measures

Symptoms were assessed via 2 classes of validated tools. Twelve studies used general symptom assessment tools, such as the MD Anderson Symptoms Inventory and cancer type versions (n=6), the Modified Memorial Symptom Assessment Scale (n=3), the European Organization for the Research and Treatment of

Cancer Quality of Life Questionnaire (n=1), the Twenty Symptoms List (n=1), and the Functional Assessment of Cancer Therapy-Endocrine Subscale (n=1), whereas 10 studies focused on neuropsychological symptoms via tools such as the Patient Health Questionnaire-9 (n=1), the Perceived Cognitive Impairment scale (n=1), the Hospital Anxiety and Depression Scale (n=1), and 7 other tools.

Time of Symptom Assessment

Considering the timing of symptom assessments, only 1 study evaluated symptoms at diagnosis before any treatment [36], 1 evaluated symptoms during curative radiotherapy [28], 4 evaluated symptoms during the perioperative period [32,38,39,45], 5 evaluated symptoms during chemotherapy [25-27,31,34], 4 evaluated symptoms during ongoing cancer therapies [29,41,42,46], and 7 evaluated symptoms after acute treatments [28,30,33,37,40,43,44]. Among these, 3 studies evaluated the longitudinal changes in symptom networks across chemotherapy cycles [26,31,34] and 1 evaluated changes during radiotherapy sessions [35]. Three studies investigated the associations between symptoms and biological parameters [33,41,43].

NA Approach

Several NA approaches and models were used to perform the studies included in this review. Some studies used different models: network visualization (n=1), Bayesian network (n=1), pairwise Markov random field and IsingFit method (n=1), unregularized Gaussian graphical model (n=2), regularized partial correlation network (n=6), network visualization and community NA (n=1), network visualization and Walktrap algorithm (n=1), undirected network model with the Fruchterman-Reingold approach and edge-betweenness approach (n=4), biased correlation network and concise pattern network diagram (n=1), extended Bayesian information criterion graphical LASSO method (n=3), cross-lagged panel network (n=1), and unspecified NA (n=3).

Main Findings

In the following sections, we delve into the 22 included studies on the basis of the time of symptom assessment: at diagnosis and during or after acute cancer treatment.

Symptom Networks at Diagnosis

Only 1 study [36] evaluated symptom networks at cancer diagnosis (head and neck tumor). The connections between neuropsychological symptom networks and serum cytokines were also investigated. Four nodes had the most important position in the network: fatigue, poor sleep quality, C-reactive protein (CRP), and interleukin (IL)-6.

Symptom Networks During Acute Cancer Treatments

Chemotherapy

Five studies identified and evaluated symptom networks during chemotherapy.

Bhavnani et al [25] used NA to evaluate symptom co-occurrence in oncology, with a cohort of 665 patients with mixed tumors. Inspired by the results of symptom cluster research and its limitations, they used networks to visually analyze how 18 symptoms co-occurred across patients. They described a strongly nested structure of symptom co-occurrence, offering a new approach to the complexity of symptoms in patients with cancer.

Papachristou et al [27] investigated the relationships among 38 common symptoms in a cohort of 1328 patients with cancer, at 1 evaluation time point. They reported that the connections between and among symptoms may differ depending on the symptom dimension used to create the network (occurrence, severity, and distress). They identified a psychological symptom cluster that was stable across all 3 dimensions. They offered perspectives on the use of the network theory to develop new models aiming at improving therapeutic interventions for patients with cancer.

Other authors have reported the need for new interventions in patients with cancer. Rha and Lee [31] investigated clusters and the evolution of symptom networks across chemotherapy cycles in mixed solid tumor populations. They reported stable symptom clusters and evolving networks depending on the evaluation time point and the type of cancer, and the most central symptom identified was fatigue. The authors argued for the development of interventions focusing on central symptoms.

Kalantari et al [34] investigated 38 symptoms in 987 patients with cancer and assessed 4 different cancer types across 2 cycles of chemotherapy. They identified 8 relatively stable symptom clusters.

Xu et al [26] evaluated neuropsychological symptoms and QoL in a newly diagnosed breast cancer population across several chemotherapy cycles. They applied Bayesian network methods to investigate the role of sleep, fatigue, and mood on cognition and QoL across and after chemotherapy. They revealed strong direct and indirect links among symptoms, cognitive performance, and QoL. Sleep quality was directly linked to cognitive performance with late chemotherapy cycles. The authors concluded that a better understanding of the interrelationships among those symptoms, QoL, and cognition could guide the design of further effective interventions [26].

Radiotherapy

Lin et al [35] evaluated psychoneurological symptoms during radiotherapy (4 times) in 172 patients with newly diagnosed head and neck cancer. Depression and fatigue were the 2 core symptoms identified. The network structure was relatively stable over the treatment time. As previously suggested by other authors, Lin et al [35] argued that identifying core symptoms represents an opportunity to decrease other co-occurring symptoms.

Perioperative Period

Four studies evaluated symptom networks during the perioperative period (3 digestive tract tumor populations and 1 glioma population).

Röttgering et al [39] evaluated patterns of associations among depression, cognition, brain tumor–related symptoms, and QoL in a population of 256 diffuse gliomas. They constructed 6 networks based on the presence or absence of 3 disease statuses (surgical, tumor grade, and fatigue). Fatigue severity, depression, and social functioning were nodes highly correlated across the

6 networks. The number of nodes in the nonfatigued network was lower than that in the fatigued network. They suggested the need for integrative symptom management and targeted fatigue as a priority.

Other authors have reported the need to target specific psychological symptoms to reduce other interconnected symptoms [32]. Indeed, Shim et al [32] evaluated associations between cancer-related physical and psychological symptoms and QoL, before and after intent-to-cure surgery in 256 patients with gastric cancer. Distress and sadness were the most central symptoms across all time points. They identified connections between emotional and physical well-being.

Ji et al [38] reported that multiple symptom clusters occurred in a cohort of 286 patients with early esophageal cancer who were surgically treated. Sadness and fatigue were the core symptoms.

Shang et al [45] conducted a prospective study among 230 patients with operable colorectal cancer and evaluated 18 symptoms before and after surgery. They described a stable network with disturbed sleep and distress, which are the most prevalent symptoms to be targeted.

Ongoing Treatments

Several cross-sectional studies have evaluated networks in mixed cancer patient cohorts or mixed treatments (surgery, radiotherapy, chemotherapy, and hormonal treatment).

Among the objectives of NA research, identifying risk and protective factors has been discussed as an interesting approach to help further treatment strategies in patients with cancer. In 342 treated patients with cancer seeking psychological care, Schellekens et al [29] investigated the interconnectedness of fatigue, depression, anxiety, and potential risk and protective factors (physical symptoms, social withdrawal, illness cognition, goal adjustment, and partner support). Depressed mood, loss of enjoyment, and worthlessness were central nodes. Fatigue, anxiety, and depression appear strongly interconnected. Acceptance of illness was centrally embedded in the networks.

Wang et al [42] conducted a study among 202 treated patients with digestive cancer and identified distress, disturbed sleep, poor appetite, and sadness as the most common symptoms. The psychoemotional symptom cluster was the core symptom cluster.

Gong et al [46] explored the core and bridge symptoms of demoralization in 420 treated female patients with cancer. Discouragement, a lack of self-worth, hopelessness, and vulnerability were identified as the core and bridge symptoms.

Symptom Networks After Acute Cancer Treatments

Seven studies investigated symptom networks after acute cancer treatments, ranging from 1 week to several years.

Teng et al [43] identified 4 symptom clusters with a high stability network in 512 patients with advanced lung cancer 1 week after chemotherapy cycles.

Jing et al [40] explored the relationship of endocrine therapy–related symptoms to identify the core symptoms in a population of 613 patients with breast cancer receiving adjuvant hormonal treatment (average duration: 3.6 years). Mood swings and irritability were the most prevalent symptoms, and loss of interest in sex and joint pains were the most severe symptoms. There were no significant differences in network structure or global strength across treatment types (aromatase inhibitors vs selective estrogen receptor modulators) [40].

Concerning depressive symptoms in patients with cancer, Hartung et al [28] compared the frequency and relationships of depressive symptoms between patients with cancer and those in the general population. Depressive symptoms were much more common in patients with cancer but were less closely related to each other. Individual depressive symptom patterns should be considered in individuals rather than in group analyses.

de Rooij et al [30] aimed to explore the full complexity of symptoms. In a study evaluating symptom clusters in 1330 survivors of 7 cancer types, they reported that fatigue was consistently the most central symptom in an identified cluster and should be targeted. They concluded that interrelated symptoms may share the same underlying pathophysiological mechanisms, offering opportunities for new reflections on treatment strategies [30].

Henneghan et al [33] explored symptom networks in 66 patients with breast cancer after adjuvant chemotherapy (6 months to 10 years) and reported that stress, loneliness, depressive symptoms, and fatigue co-occur rather than occur as individual symptoms.

Zhu et al [37] investigated the symptom network of multidimensional symptom experiences and explored centrality indices and density networks in a cohort of 1065 patients with cancer who survived. They demonstrated that fatigue was the most severe symptom and that the density of the “less than 5 years” network was significantly different from that of the longest survivorship network. Distress, sadness, and lack of appetite were the core symptoms.

Kuang et al [44] explored symptom networks in 483 elderly patients with cancer who survived. The most common and severe symptoms were fatigue, disturbed sleep, and difficulty remembering. The density network showed differences between “less than 5 years” and “more than 5 years” survival.

Symptom Networks and Biological Parameters

A study by Santoso et al [36] examined potential connections between psychoneurological symptoms (poor sleep, anxiety, and fatigue) and biomarkers of stress (cortisol slope, CRP, IL-6, IL-10, and tumor necrosis factor-α) in more than 264 patients with newly diagnosed head and neck cancer before treatment. Four nodes had the most important position in the network (fatigue, poor sleep quality, CRP, and IL-6) and may play a role in the interconnections between symptoms and inflammatory conditions.

Henneghan et al [33] investigated different symptoms and 13 cytokines in 66 patients with breast cancer at least 6 months and up to 10 years after adjuvant chemotherapy. Node betweenness was the highest for perceived cognitive impairment and the IL-2 level. Two separate communities of nodes

(symptoms and cytokines) within the network were revealed and connected by several edges. They concluded that perceived cognitive impairment, stress, loneliness, depressive symptoms, and fatigue co-occur and that cytokines may be involved in these biological pathways.

A study by Li et al [41] evaluated the interrelations between neuropsychological symptoms and inflammatory biomarkers in a cohort of 203 patients with glioma. Depression, anxiety, fatigue, IL-6, and tumor necrosis factor-α had higher strength centrality indices and were identified as the most central nodes within the symptom-biomarker networks.

Methodological Quality and Risk of Bias

The methodological quality of the 22 included studies was evaluated using the MINORS tool, and the results are summarized in Table 3. Overall, studies demonstrated moderate to high methodological rigor. Many studies, including the studies by Bhavnani et al [25], Xu et al [26], and Shim et al [32], reported clear aims and appropriate statistical analyses. Several studies, such as the studies by Rha and Lee [31], Kalantari et al [34], and Lin et al [35], employed longitudinal designs, enhancing their capacity to assess symptom dynamics over time. Other studies, such as the studies by Papachristou et al [27] and de Rooij et al [30], used large, heterogeneous samples with comprehensive network models, though some lacked follow-up or sample size reporting. Comparative studies scored well across all 12 MINORS criteria (eg, [28,40,42]). In contrast, noncomparative studies were assessed on the first 8 criteria and showed greater variability (eg, [33,36,46]). No studies were excluded based on their MINORS scores, but rather, the risk of bias assessment informed our interpretation of the findings and provided essential context for understanding methodological strengths and limitations across the reviewed literature.

Table 3. Quality assessment of the included studies.

Study	Category														Key commentary
	CA[a]	CP[b]	PD[c]	AE[d]	UA[e]	FP[f]	Loss <5%[g]	SSC[h]	CG[i]	CoG[j]	GE[k]	SA[l]	NCS[m]	CS[n]	
Bhavnani et al [25], 2010	2	2	1	2	2	0	0	0	2	0	0	2	13	13	Innovative study using network analysis to show symptoms that follow a nested structure rather than distinct clusters; the main limitation was secondary data analysis.
Xu et al [26], 2018	2	1	2	2	2	2	0	0	0	0	0	2	11	11	Sophisticated Bayesian network modeling study; found that sleep quality during chemotherapy was directly linked to cognitive performance in patients with breast cancer.
Papachristou et al [27], 2019	2	1	2	2	2	0	0	1	0	2	2	2	10	14	Large sample study showing that symptom networks differ by the dimension assessed (occurrence).
Hartung et al [28], 2019	2	1	1	2	2	0	0	2	2	2	2	2	10	16	Rigorous study with large matched samples showing that depressive symptoms were more frequent but less interconnected in patients with cancer; suggested that external factors drive symptoms.
Schellekens et al [29], 2020	2	2	2	2	2	0	0	1	0	0	0	2	11	11	Robust preregistered analysis of distressed patients with cancer; identified depressed mood.
de Rooij et al [30], 2021	2	1	0	2	2	0	0	2	1	2	1	2	10	15	Strong methodological study examining symptom clusters across 7 cancer types; identified fatigue as a consistently central symptom; limited by cross-sectional design.
Rha and Lee [31], 2021	2	1	2	2	2	2	0	1	0	0	0	2	12	12	Strong longitudinal analysis identified 3 stable symptom clusters across chemotherapy cycles, with fatigue as the most central symptom across all time points.
Shim et al [32], 2021	2	2	2	2	2	2	0	0	0	0	0	2	12	12	Prospective study highlighting the central role of distress and sadness across perioperative time points; psychological symptoms served as bridges connecting symptoms to quality of life.
Henneghan et al [33], 2021	2	0	2	2	2	0	0	0	0	0	0	2	8	8	Innovative exploratory study examining symptom-cytokine networks in breast cancer survivors; identified IL-2 and cognitive impairment as central; limited by a small sample size.
Kalantari et al [34], 2022	2	1	2	2	2	2	0	0	0	2	1	2	11	14	Rigorous longitudinal study identifying 8 symptom clusters across chemotherapy cycles; demonstrated the stability of core symptoms over time despite changing severity.
Lin et al [35], 2022	2	1	2	2	2	2	0	1	0	2	1	2	12	15	Strong longitudinal study examining symptom networks in patients with head and neck cancer; identified depression and fatigue as core symptoms across time points.
Santoso et al [36], 2022	2	2	2	2	2	0	0	0	0	0	0	2	10	10	Large sample study found poor sleep.
Zhu et al [37], 2023	2	1	2	2	2	0	0	0	0	0	0	2	9	9	Large sample study found distress, sadness, and lack of appetite as core symptoms in cancer survivors; network density was higher in survivors <5 years vs >5 years.

Discussion

NA and Current Knowledge

Patients with cancer experience a highly interconnected network of co-occurring symptoms, which arise from both the disease itself and its treatment, significantly affecting QoL [4,5]. Traditional symptom analysis methods have primarily relied on symptom clustering approaches that fail to capture the dynamic interplay and mutual reinforcement between symptoms [13,14,16]. This review highlights the growing application of NA in oncology, demonstrating its potential to redefine symptom

management by shifting the focus from treating individual symptoms or clusters of symptoms to identifying core symptoms that exert a broader influence on the overall network. As Papachristou et al [27] suggested, the network theory could offer interesting perspectives for understanding and focusing on specific symptoms to implement new therapeutic interventions, subsequently improving the management of patients with cancer.

Across the 22 included studies, NA was applied at different cancer treatment stages to identify key symptom interconnections and potential intervention targets. One of the most consistent findings was the prominent role of psychological symptoms, particularly anxiety, depression, and distress, which formed stable and interconnected networks, especially during chemotherapy and long-term survivorship [27,37,40]. For instance, Papachristou et al [27] found that psychological symptoms, such as anxiety, depression, and distress, tend to form stable networks during chemotherapy, influencing overall symptom burden. The stability of these networks suggests that psychological symptoms play a central role in shaping cancer symptomatology, potentially exacerbating physical symptoms through stress-related mechanisms. In support of this assumption, previous studies that did not apply NA have suggested that psychological disorders can substantially worsen physical symptoms in patients with cancer [47,48]. A clear example is the study by Renna et al [47] showing that breast cancer survivors with a distress disorder may be particularly at risk for more physical symptoms and treatment, reducing their QoL and increasing the recurrence risk.

Another recurrent finding in our work was the identification of fatigue as a central symptom across all treatment phases, with strong interconnections to sleep disturbance, cognitive impairment, and emotional distress [30,31,35]. Prominent studies, such as those by Rha and Lee [31] and Lin et al [35], reported that fatigue and depression consistently emerge as core symptoms, suggesting that targeting these symptoms may alleviate multiple co-occurring symptoms. The widespread influence of fatigue highlights the importance of psychophysiological symptoms in cancer symptom monitoring, reinforcing the need for targeted interventions that address not only fatigue itself but also its cascading effects on other symptoms.

In addition, while most studies were purely descriptive, a subset integrated biological markers into NA models, revealing significant associations among fatigue, depression, sleep disturbances, and inflammatory biomarkers such as IL-6, CRP, and tumor necrosis factor-α [33,36,41]. These findings suggest a possible biological underpinning of symptom clustering, aligning with existing evidence that inflammatory pathways may contribute to cancer-related fatigue and neuropsychological symptoms [49,50]. However, the mechanistic links between inflammation and symptom networks remain unclear, warranting further investigation.

Collectively, these findings support the hypothesis that targeting core symptoms, particularly fatigue and psychological distress, may provide a more effective therapeutic approach than treating symptoms in isolation. Despite the promising insights provided by NA, the studies reviewed were primarily descriptive, limiting their immediate clinical applicability. Further studies, particularly longitudinal studies and interventional trials, are necessary to determine whether NA-informed symptom management strategies can improve patient outcomes and facilitate the integration of network-based approaches into clinical practice.

Implications for Clinical Practice

From the clinician's point of view, we strongly believe that the NA approach could lead to innovations in interventions for patients with cancer. We thus argue for more longitudinal design studies investigating homogeneous patient cohorts. Consensus is required on tools to measure symptoms, with preference for polyvalent assessment (somatic and psychological symptoms).

With respect to network types, we suggest the use of Bayesian networks as the primary approach, considering the potential implementation of their outcomes in artificial intelligence datasets and consequently their use in clinical settings, especially in health-risk prediction and the evaluation of specific therapeutic interventions.

Finally, we believe that more clinician involvement (medical oncology, radiotherapy, oncological surgery, supportive care, and palliative care) in this area of research is highly necessary.

Limitations and Perspectives for This Research Area

While this review offers a comprehensive synthesis of the current literature on the use of NA in cancer symptomatology, with most articles published during the last 3 years [30-46], some limitations must be acknowledged. First, there was considerable heterogeneity among the included studies in terms of cancer types, patient populations, sample sizes, symptom assessment tools, and network modeling techniques. This variability limited the ability to make direct comparisons across studies and precluded meta-analytic synthesis. Additionally, the majority of studies employed cross-sectional and exploratory designs, which, although valuable for hypothesis generation, limit the capacity to infer causality or observe symptom network evolution over time. Only a small number of studies incorporated biological markers [33,36,41], and none examined the impact of NA-informed therapeutic interventions, which constrains the applicability of the current findings to clinical practice.

In addition, although many included studies examined psychological symptoms, such as anxiety and depression, relatively few explicitly assessed neurocognitive functioning, despite its well-documented vulnerability to cancer treatments [51]. For example, while some studies incorporated cognitive performance indicators (eg, [26,39]), a more systematic and targeted exploration of cancer-related cognitive impairment within network models remains lacking. This represents an important research gap, as cancer-related cognitive impairment is increasingly recognized as a major component of cancer survivorship [51].

These limitations reflect broader gaps in the field and point to important directions for future research. First, there is a pressing need for longitudinal studies that can track changes in symptom

networks across different treatment phases and survivorship. Such designs would enable researchers to identify critical time points at which symptom interconnectivity shifts, potentially informing more precise and timely interventions. Moreover, future research should move beyond descriptive modeling to include interventional studies, particularly randomized controlled trials designed to test whether targeting core symptoms identified through NA leads to measurable improvements in symptom burden and QoL. For example, evidence from non-NA–based trials has shown beneficial effects of physical activity and mind-body interventions (eg, yoga and mindfulness) on neuropsychological symptoms in cancer populations [52,53]. Incorporating such interventions into future network-informed studies could provide valuable insights into how these therapies affect symptom interconnectivity.

Another key area for development is the integration of biological and physiological data into NA frameworks. The limited but promising evidence linking symptom networks with inflammatory markers (eg, IL-6, CRP, and tumor necrosis factor-α) suggests that incorporating physiological data, including genomic, proteomic, and metabolomic variables, could shed light on the underlying mechanisms driving symptom interactions [33,36,41]. This could, in turn, support the development of biologically informed, personalized treatment strategies.

Furthermore, to ensure greater consistency and comparability across future studies, standardization of methodological approaches is essential. This includes the use of validated and comprehensive symptom assessment tools, consistent time points for symptom evaluation, and transparent reporting of network construction and statistical parameters. The development of consensus guidelines for conducting and reporting NA in oncology would represent a valuable step toward building a more cohesive and interpretable body of research.

In addition to study design variability, methodological considerations inherent to NA approaches must also be acknowledged. Several included studies used different NA techniques, such as Gaussian graphical models or Bayesian networks, with varying assumptions, sparsity constraints, and estimation procedures. The sensitivity and specificity of these models in capturing symptom interconnections depend heavily on data quality, sample size, and statistical regularization methods [20]. Furthermore, the stability of centrality measures and the reproducibility of network structures were not systematically evaluated across studies, limiting conclusions about the robustness and generalizability of findings [54]. Greater methodological standardization and reporting transparency are needed to ensure the validity of symptom networks in oncology.

In summary, while current studies provide compelling evidence for the potential of NA to enhance symptom understanding in cancer care, addressing methodological limitations and expanding the scope of research are essential next steps.

Conclusions

Cancer is a complex disease that causes significant disruption to both biological systems and overall health, leading to complex, interrelated symptom experiences in patients with cancer. This review highlights the growing application of NA as a valuable tool for understanding the complexity of cancer-related symptoms.

Across the included studies, NA consistently identified core symptoms, particularly psychological symptoms and fatigue, that appear central to patients' experiences across treatment stages. These findings suggest that focusing on core symptom interconnectivity may offer more effective avenues for symptom management than traditional approaches targeting isolated symptoms.

While current research offers compelling evidence for the application of NA in cancer symptomatology, several methodological limitations persist. Future studies should focus on longitudinal designs that track symptom networks across different phases of cancer treatment and survivorship. Further research should also explore interventional approaches to determine whether NA-informed strategies can improve symptom management and enhance QoL. Integrating biological and physiological data into NA frameworks holds promise for developing personalized, biologically informed treatment strategies.

Standardization of methodological approaches, including validated symptom assessment tools, and transparent reporting of network construction are essential to strengthen the consistency and comparability of findings across studies. Ultimately, network-informed research can contribute to a deeper understanding of cancer symptom interconnectivity and lead to more effective and targeted interventions, improving outcomes for patients with cancer.

Acknowledgments

The authors would like to thank the staff and colleagues at the Department of Computational Medicine and Neuropsychiatry, Faculty of Medicine, University of Mons, for their support and collaboration throughout the development of this study. We also acknowledge the contributions of all researchers whose work formed the basis of this systematic review. Generative OpenAI (ChatGPT) was used under the authors' supervision for language editing and grammatical improvement only, without any intellectual contribution. This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Authors' Contributions

VR contributed to conceptualization, data curation, formal analysis, writing–original draft, and writing–review and editing. AG contributed to conceptualization, data curation, formal analysis, methodology, writing–original draft, and writing–review and editing. EP contributed to visualization and writing–review and editing. GB contributed to supervision, writing–review and editing, and validation.

Abstract

The increasing demand for population-wide genomic screening and the limited availability of genetic counseling resources have created a pressing need for innovative service delivery models. Chatbots powered by large language models (LLMs) have shown potential in genomic services, particularly in pretest counseling, but their application in returning positive population-wide genomic screening results remains underexplored. Leveraging advanced LLMs like GPT-4 offers an opportunity to address this gap by delivering accurate, contextual, and user-centered communication to individuals receiving positive genetic test results. This project aimed to design, implement, and evaluate a chatbot integrated with GPT-4, tailored to support the return of positive genomic screening results in the context of South Carolina's In Our DNA SC program. This initiative offers free genetic screening to 100,000 individuals, with over 33,000 results returned and numerous positive findings for conditions such as Lynch syndrome, hereditary breast and ovarian cancer syndrome, and familial hypercholesterolemia. A 3-step prompt engineering process using retrieval-augmented generation and few-shot techniques was used to create the chatbot. Training materials included patient frequently asked questions, genetic counseling scripts, and patient-derived queries. The chatbot underwent iterative refinement based on 13 training questions, while performance was evaluated through expert ratings on responses to 2 hypothetical patient scenarios. The 2 scenarios were intended to represent common but distinct patient profiles in terms of gender, race, ethnicity, age, and background knowledge. Domain experts rated the chatbot using a 5-point Likert scale across 8 predefined criteria: tone, clarity, program accuracy, domain accuracy, robustness, efficiency, boundaries, and usability. The chatbot achieved an average score of 3.86 (SD 0.89) across all evaluation metrics. The highest-rated criteria were tone (mean 4.25, SD 0.71) and usability (mean 4.25, SD 0.58), reflecting the chatbot's ability to communicate effectively and provide a seamless user experience. Boundary management (mean 4.0, SD 0.76) and efficiency (mean 3.88, SD 1.08) also scored well, while clarity and robustness received ratings of 3.81 (SD 1.05) and 3.81 (SD 0.66), respectively. Domain accuracy was rated 3.63 (SD 0.96), indicating satisfactory performance in delivering genetic information, whereas program accuracy received the lowest score of 3.25 (SD 1.39), highlighting the need for improvements in delivering program-specific details. This project demonstrates the feasibility of using LLM-powered chatbots to support the return of positive genomic screening results. The chatbot effectively handled open-ended patient queries, maintained conversational boundaries, and delivered user-friendly responses. However, enhancements in program-specific accuracy are essential to maximize its utility. Future research will explore hybrid chatbot designs that combine the strengths of LLMs with rule-based components to improve scalability, accuracy, and accessibility in genomic service delivery. The findings underscore the potential of generative artificial intelligence tools to address resource limitations and improve the accessibility of genomic health care services.

Introduction

The increased demand for genomic testing, resulting growth in patient volume, and limited access to providers with genomic expertise has necessitated new, innovative genetic service delivery models [1-6]. Prior research has demonstrated the feasibility and acceptability of incorporating technologies such as chatbots to support common communication that occurs throughout the genomic service delivery process [7-10]. Chatbots are a highly accessible and scalable platform that allows for simulated conversations. Accessible via the web through a hyperlink or downloadable app, chatbots can be used on a smartphone, tablet, or computer. The use of chatbots has also been shown to improve access to services and support health equity by providing personalized health education, being available in multiple languages, and offering continuous access to information [11-15].

The integration of chatbots into routine and ancillary tasks such as pretest counseling education, informed consent, delivery of negative results, and cascade testing have been shown to be feasible and effective in supporting genomic service delivery [8,16]. For example, chatbots have been used to collect family health history, provide pretest support, communicate with family members about results, and obtain consent for genomic research [8,17-19]. Prior results from the BRIDGE (Broadening the Reach, Impact, and Delivery of Genetic Services) trial showed equivalence between a technology-based chatbot approach and standard of care in the completion of pretest genetics education and completion of genetic testing among unaffected primary care patients meeting criteria for cancer genetic evaluation [20]. Additional research in other health service delivery contexts has found that patients using chatbots reported a better understanding of their condition or procedure, being more prepared for upcoming appointments, and feeling more informed when making health care decisions [21-29].

To date, the integration of chatbot technology into genomic service delivery has yet to focus on the return of positive genetic test results directly to patients. Currently, the return of positive results has been carried out largely through direct communication, due to the complex and sensitive nature of the information, the potential psychological impact of learning about genetic predisposition, and the need to ensure understanding of the results and their implications. However, nonchatbot technology-based solutions, such as digital patient portals, are available to communicate with patients about these results and have been shown to be highly acceptable and preferred in genomics research [8,10,16,30-35]. Furthermore, a large-scale study across 3 academic medical centers found that individuals preferred laboratory test results to be delivered immediately digitally [30].

Prior qualitative data have indicated that patients are favorable toward receiving results via chatbots, as they are convenient and allow for the opportunity to contemplate information and ask questions [8]. Digital health communication approaches, such as chatbots, may be especially appropriate for the disclosure of population-wide genomic screening (PGS) results. PGS is often conducted on a large scale, targeting asymptomatic individuals as part of public health initiatives. As a result, the communication typically emphasizes general risk awareness, with initial results disclosure indicating increased risk rather than confirming a diagnosis. The Consent and Disclosure of Recommendations workgroup funded by the National Cancer Institute's Clinical Genome Resource (ClinGen) recommends considering factors such as test complexity, testing situation complexity, implications of genetic diagnosis to the patient and family, evidence of potential adverse psychological impact, and availability of high-quality and patient-friendly materials when deciding on the level of interaction with the patient [36,37]. Since PGS is typically completed through research and consent from participants and individuals are receiving results for well-defined hereditary conditions, the necessary level of initial communication about positive PGS results is lower than more complex, clinical results.

While high levels of acceptability, usability, and understanding of chatbots have been found in prior research, the majority of chatbots developed to date are rule-based, meaning that they operate on a set of predefined navigation paths with predefined scripted options and responses [8,9,19]. This approach allows for reliability and consistency in managing response options. However, user testing of rule-based chatbots has also revealed a need for chatbots that allow users to ask open-ended questions and receive responses in real time [8,9,19]. More recently, the release of large language models (LLMs) such as ChatGPT offers an opportunity to direct open-ended questions to LLMs to better support the return of positive genetic testing results, as open-ended questions allow for more nuanced and personalized responses. However, it is critical to test such systems to ensure that patients would receive accurate and clear information. Indeed, creating a hybrid chatbot with both rule-based and LLM components can offer a versatile and streamlined user experience by ensuring that key information is covered in the rule-based components of the chatbot and allowing for the LLM component to support complex, open-ended queries that are not covered in the scripted content. The objectives of the present project were to (1) prompt engineer an LLM-based chatbot focused on answering questions about the return of positive PGS results, and (2) conduct an intrinsic evaluation of the prompt engineering approach based on hypothetical cases and expert raters. This viewpoint paper offers insight into the application of specific prompt engineering methods to create patient-facing chatbots in the hereditary cancer diagnostic process.

Methods

Project Setting

We trained this chatbot using prompt engineering for the context of answering questions about the return of PGS results for an ongoing PGS program being delivered at the Medical University of South Carolina (MUSC). The PGS program was established in November 2021 with a focus on providing free genetic screening to 100,000 individuals in South Carolina. At the time of analysis, the program has recruited 59,352 individuals, returned 33,142 results, and identified 132 individuals with Lynch syndrome, 265 individuals with hereditary breast and

ovarian cancer syndrome, and 191 individuals with familial hypercholesterolemia.

Prompt Engineering Approach for Open-Ended Content

Overview

LLM models have been applied to improve accuracy and standardization for a variety of biomedical tasks including medical guidelines retrieval, diagnostics, medical reporting, and medical education [38-40]. The LLM selected depends on the task at hand, with a variety of LLMs developed for specific medical tasks and specialties [41]. Commonly used LLMs include ChatGPT, Perplexity AI, Claude AI, and Google Bard [42]. Developing generative artificial intelligence (AI) standards emphasizes the need to design generative AI tools responsibly for user mental models and build trust while allowing for generative variability, cocreation, and imperfection [43]. Meeting these standards requires effective prompt engineering, which includes the process of developing the text that instructs the LLM to complete a given task [44].

We used a 3-step prompt using the retrieval-augmented generation (RAG) technique which integrates retrieval-based methods with generative models, enabling the generation of contextually informed responses by retrieving relevant knowledge from a large corpus and incorporating it into the output generation process. RAG has been shown to improve LLM model performances by incorporating external information as a domain-specific knowledge base [45,46]. This project used OpenAI's GPT Version 4-Turbo-Preview model, as new research has indicated GPT version 4 performs significantly better at answering genetics questions than version 3.5 [43,44,47]. OpenAI's Playground was used for prompt engineering and testing. GPT4 was trained to respond about a variety of topics including providing examples of the impact of positive results, screening recommendations, and family history and cascade testing resources, and providing details regarding genetic counseling and specific PGS programs. Boundaries were also provided to ensure GPT4 responses remained within the intended scope of the chatbot.

Step 1: Provide Content and Context to GPT4

We used the RAG technique for prompt development. The RAG approach consisted of providing supplementary materials that were uploaded through OpenAI's Playground "File Search" function which allows GPT4 to access the additional information in real time when responding to users' questions. The additional files uploaded were: (1) detailed descriptions and frequently asked questions from the MUSC's PGS website; (2) MUSC Genetic Counseling Scripts: standard scripts used by genetic counselors at MUSC, providing insights into professional communication and common queries; and (3) Genome Medical Genetic Counseling Scripts: scripts from Genome Medical to offer additional perspectives. These documents expanded the model's knowledge base to increase the detail, consistency, and accuracy of responses. The team observed an improvement in the chatbot's replies after including these documents based on the established evaluation criteria.

Step 2: Establish a Bank of Commonly Asked Questions

To train and test the LLM, a bank of commonly asked questions was developed. This bank of questions was derived from patient quality improvement interviews and expert input. This step ensures that the model is trained on a wide array of realistic and relevant scenarios, enabling it to provide accurate and helpful responses. The list of 27 questions was randomly divided into 13 training questions and 14 evaluation questions (Multimedia Appendix 1).

Step 3: Develop and Refine Prompts

The core of prompt engineering involves creating and refining prompts that train the AI model to elicit the most accurate and appropriate responses. The prompt development process used OpenAI GPT assistants to develop an initial draft prompt. The prompt aimed to not only inform the chatbot about the situational context and content to be discussed but also about the writing style and limitations it should adhere to. We completed iterative testing by inputting the prompt as the instructions for the AI assistant and running the 13 training questions through the messaging feature. Adjustments were made to the initial prompt until the chatbot answers were deemed accurate, clear, and appropriate by our internal team. This process is subject to the bias of the team. However, the team was careful to evaluate the chatbot responses strictly based on the evaluation criteria and quality of responses to the test questions. The prompt indicated to the LLM that patient cases would be provided as input.

Prompt Engineering Evaluation

Overview

After completing the prompt engineering of our LLM chatbot, we conducted an intrinsic evaluation based on 2 hypothetical cases that were presented to domain experts in clinical genomics. The evaluation consisted of 2 steps described below.

Step 1: Establish the Prompt Evaluation Criteria

Previous literature has indicated relevant criteria to consider for chatbots in health communication [48]. Considering this previous work, we established relevant evaluation criteria tailored to this project through discussion and consensus among the team (Table 1). Based on 8 criteria, an evaluation instrument was developed in REDCap (Research Electronic Data Capture; Vanderbilt University) consisting of the 8 criteria, their definitions, and the ability to rate each criterion using a 5-point Likert scale from 1=Very Poor to 5=Excellent. Because prompt engineering in this context is a relatively new field, these criteria were optimized as much as possible with limited precedent.

Table . Evaluation criteria.

Criteria	Quality definition
Tone	The ability of the chatbot to express information in a way that is appropriate for the type of information being delivered
Clarity	The ability of the chatbot to communicate information clearly and in a way that avoids ambiguity or confusion
Program accuracy	The ability of the chatbot to provide correct information about the PGS[a] program
Domain accuracy	The ability of the chatbot to provide correct information about the genetic test results and care implications
Robustness	Ability to handle ambiguous queries or incomplete information
Efficiency	Ability to provide answers that are direct, concise, and complete
Boundaries	Ability to avoid answering questions that are unrelated to the topic
Usability	Ease of interfacing with the chatbot

[a]PGS: population-wide genomic screening.

Step 2: Development of Case Scenarios and Expert Ratings

We developed 2 hypothetical scenarios focused on returning results to individuals who participated in PGS. We used scenarios to allow the expert raters to view the chatbot from the perspective of a specific hypothetical patient (Textbox 1).

Textbox 1. Case scenarios.

Case 1: Anna

- A 34-year-old White woman named Anna participated in the In Our DNA SC population-wide genomic screening program in November. She had no personal or family history of cancer. She saw a digital advertisement and decided to participate in the program out of curiosity about her health. She had previously completed a direct-to-consumer genetic screen through 23andMe but did not receive any concerning results. A few months passed after she provided her sample. Her results showed that she has a BRCA1 mutation. Anna was shocked to find this news about her BRCA1 mutation and is concerned about the next steps in her care.

Case 2: Josh

- A 56-year-old Black man named Josh previously had colorectal cancer. His sister participated in In Our DNA SC based on a recommendation from her doctor. Josh's sister convinced him that it would be beneficial for him to participate. He reluctantly agreed to participate but did not see much of a point since he had already been treated for colorectal cancer. Josh received results showing that he was positive for the MLH1 gene, which means he has Lynch syndrome. Josh was confused by these results. He did not understand how these results would be important to him since he already had cancer.

Results

Final Prompt and Example Responses

The final prompt used for the LLM is included in Multimedia Appendix 2. Instructions for the prompt included a description of the type of patients the chatbot would be interfacing with (eg, patients who have done genetic testing as part of MUSC's population genomics program and are receiving their results digitally), the types of questions the chatbot may receive (eg, patient questions may range from understanding their specific probability of developing cancer to inquiries about insurance coverage), and boundaries (eg, do not provide any kind of medical advice […] if the patient asks questions outside of your boundaries, reply with "I am unable to answer questions unrelated to genetic testing or helping you get to your first appointment with a genetic counselor."). Other elements of the prompt included the style of the response and literacy level (eg, you will be replying to adults, but use a fifth-grade level vocabulary. Provide a clear, direct, concise response, preferably in bullet point format). Examples of responses provided by the chatbot are included in Table 2.

Table . Sample questions and LLM[a] responses.

Question	LLM response
What is the cost of genetic counseling visits and the screening?	I'm here to help, but remember, I can't give you specific costs because they can vary a lot depending on several factors. Here's what you should know about the costs of genetic counseling visits and screenings: • Insurance coverage: Many health insurance plans cover genetic counseling and screening, especially if you have a higher risk for certain conditions. However, coverage can vary, so it's important to check with your insurance provider. • Genetic counseling costs: The cost of a genetic counseling session can vary based on the location, the facility, and whether the counselor is part of a hospital or a private clinic. Some genetic counselors may work with you on payment options if you are paying out of pocket. • Screening costs: Like counseling, the cost for genetic screenings can vary widely. It depends on the type of screening and whether it's covered by insurance. • Financial assistance programs: Some hospitals, clinics, and organizations offer financial assistance or programs that might help cover the cost of genetic testing and counseling for those who qualify. It's a good idea to: • Contact your insurance company to find out what they cover and if you need a referral. • Ask the genetic counseling service about costs and payment options when you schedule your appointment.

What is the recommended treatment or preventative care?	For individuals with an MLH1 mutation, recommended treatment and preventive care focus on lowering the risk of cancer and catching any signs of cancer early. While I can't give personal medical advice, here are some general recommendations:
	• Regular screenings:
	  • Colonoscopy: Starting at a younger age and happening more often than for the general population, usually every 1 to 2 years.
	  • Physical exams: Including checking for changes in your body that might indicate cancer.
	• Lifestyle changes: Eating a healthy diet.
	  • Staying active.
	  • Avoiding smoking.
	• Family planning discussions: Since this mutation can be passed to your children, talking with a genetic counselor about family planning options is helpful.
	• Consider surgery: In some cases, to prevent cancer, doctors might suggest surgery to remove certain parts of the body that are at high risk of developing cancer. This is a personal decision and requires a detailed discussion with your health care team.
	• Stay informed: New recommendations and treatments can become available. Keep in regular contact with your health care team.
	
	A genetic counselor can provide personalized information based on your specific situation and help you understand your options for prevention and early detection. It's important to discuss the best plan for you with your health care provider or genetic counselor.
	
	Remember, these are general recommendations, and the best approach for you should be discussed with your health care provider. If you need help scheduling an appointment with a genetic counselor at the MUSC[b] Hollings Cancer Center Hereditary Cancer Clinic, you can visit their website or call 843-792-0745 for more personalized support.

Question	LLM response
How can I stay up to date on the latest treatments and science about my pathogenic variant?	Staying informed about the latest treatments and science related to your MLH1 mutation is a great way to actively participate in your health care. Here are some ways to keep updated: • Follow reputable sources: Websites of major cancer centers, genetic organizations, and health institutions often share updates about new research and treatments. Some reliable sources include the National Cancer Institute, American Cancer Society, and the Genetic Alliance. • Attend appointments: Regular check-ins with your health care team, including your genetic counselor, can keep you informed on any new recommendations or treatments relevant to your situation. • Join support groups: There are support groups and communities for individuals with hereditary cancer risk. These can be great places to share information and experiences. • Subscribe to newsletters: Many organizations offer newsletters that summarize the latest research and developments in cancer treatment and genetics. • Educational events: Workshops, webinars, and conferences designed for patients and families can provide valuable information and updates. • Ask questions: Whenever you have an appointment with your health care provider or genetic counselor, ask if there are any new findings or treatments relevant to your mutation. Remember, while it's great to stay informed, always discuss any information or potential treatments you come across with your health care provider before making any changes to your health care plan. They can help interpret how new information may apply to your specific situation. If you're looking for specific resources or have more questions, feel free to ask.

[a]LLM: large language model.

[b]MUSC: Medical University of South Carolina.

Prompt Engineering Evaluation

The expert ratings of chatbot responses are provided in Table 3. Overall, the chatbot received an average score of 3.86 (SD 0.89) across all criteria and cases. The ability to express information (tone) and ease of interface (usability) received the highest scores (4.25, SD 0.68 and 4.25, SD 0.58, respectively). Boundary was rated as 4.0 (SD 0.73) followed by efficiency (3.88, SD 1.09). Clarity and robustness received scores of 3.81 (SD 1.05) and 3.81 (SD 0.66), respectively, followed by domain accuracy (3.63, SD 0.96). The lowest-rated domain was program accuracy (3.25, SD 1.39).

Table . Expert ratings for each case and combined.

Quality	Quality definition	Case 1: Anna			Case 2: Josh			Combined		
		Median (IQR)	Mean (SD)	Range	Median (IQR)	Mean (SD)	Range	Median (IQR)	Mean (SD)	Range
Tone	Ability of chatbot to express information in a way that is appropriate for the type of information being delivered	4 (4-5)	4.25 (0.71)	3 - 5	4 (4-5)	4.25 (0.71)	3 - 5	4 (4-5)	4.25 (0.68)	3 - 5
Clarity	Ability of chatbot to communicate information clearly and in a way that avoids ambiguity or confusion	4 (3-5)	3.88 (1.1)	2 - 5	4 (3-4.5)	3.75 (1.0)	2 - 5	4 (3-5)	3.81 (1.05)	2 - 5
Program accuracy	Ability of chatbot to provide correct information about the In Our DNA SC program	3.5 (2-4.5)	3.25 (1.58)	1 - 5	3.5 (2.5-4)	3.25 (1.28)	1 - 5	3.5 (2.5-4)	3.25 (1.39)	1 - 5
Domain accuracy	Ability of chatbot to provide correct information about the genetic test results and care implications	4 (4-4)	3.88 (0.83)	2 - 5	4 (3-4)	3.38 (1.06)	1 - 4	4 (3.5-4)	3.63 (0.96)	1 - 5
Robustness	Ability to handle ambiguous queries or incomplete information	4 (3-4)	3.75 (0.71)	3 - 5	4 (3.5-4)	3.88 (0.64)	3 - 5	4 (3-4)	3.81 (0.66)	3 - 5
Efficiency	Ability to provide answers that are direct, concise, and complete	4 (3-5)	4 (1.07)	3 - 5	3.5 (3-5)	3.75 (1.16)	2 - 5	3.5 (3-5)	3.88 (1.09)	2 - 5

Quality	Quality definition	Case 1: Anna			Case 2: Josh			Combined		
		Median (IQR)	Mean (SD)	Range	Median (IQR)	Mean (SD)	Range	Median (IQR)	Mean (SD)	Range
Boundaries	Ability to avoid answering questions that are unrelated to the topic	4 (3.5-4.5)	4 (0.76)	3 - 5	4 (3.5-4.5)	4 (0.76)	3 - 5	4 (3.5-4.5)	4 (0.73)	3 - 5
Usability	Ease of interfacing with the chatbot	4 (4-5)	4.38 (0.52)	4 - 5	4 (4-4.5)	4.13 (0.64)	3 - 5	4 (4-5)	4.25 (0.58)	3 - 5
Average scores	—[a]	3.92 (3-5)	3.94 (0.92)	1 - 5	3.80 (3-4)	3.88 (0.91)	1 - 5	3.88 (3-5)	3.86 (0.89)	1 - 5

[a]Not applicable.

We provided the 2 case scenarios, the test questions, and answers the chatbot had provided to those questions and were asked to rate the quality of the chatbot responses based on the designated criteria listed in Table 1. The experts independently evaluated, scored, and submitted their scores to the team. The 2 scenarios were selected to represent 2 common patient profiles that differed in age, race, gender, and background. The evaluators were aware that the responses were generated by an LLM. Eight experts completed the evaluation of the LLM output for the 2 hypothetical scenarios (Konstantinos N. Lazaridis, Libby Malphrus, Samantha Norman, Ravi Sharaf, JS, HS, Sarah English, and Anne Madeo). Experts included: 2 clinician-researchers with expertise in genomics, one genetic counselor, 3 program managers working with genomic screening programs, and 2 PhD-trained researchers with expertise in genomics. Experts were recruited based on their domain-specific knowledge and experience to provide a comprehensive evaluation of the chatbot. Descriptive statistics were calculated, including median and mean scores for each evaluation criterion.

Discussion

Principal Findings

We completed prompt engineering and intrinsic evaluation of the LLM component of a chatbot designed to facilitate the return of positive PGS results. Through the RAG technique, we successfully developed a prompt tailored for this application. Eight experts performed an intrinsic evaluation, which assessed the chatbot's responses to 14 questions across 8 distinct domains in 2 hypothetical case scenarios. The chatbot achieved an overall average score of 3.88 across all domains, with the highest ratings in the tone domain and the lowest in program accuracy. These findings will inform further refinement of the prompt and integration of the LLM with the existing rule-based system, ultimately leading to the development of a hybrid chatbot to support the return of genomic screening results. As indicated by the range of scores, there was some disagreement among raters regarding the chatbot's performance.

Comparison to Prior Work

Prior studies have indicated that individuals are favorable toward the use of chatbots for patient follow-up and genetic test results disclosure, with a preference to include open-ended response options [8]. However, to date, few chatbots have incorporated LLMs to answer open-ended responses to questions about genetic testing in real time [8,19]. LLM responses must be carefully engineered to ensure confidence in the accuracy and reliability of responses, as well as the ability to handle ambiguous questions [49]. Our prompt engineering process resulted in a chatbot that performed well in the criteria of boundaries (ability to avoid answering questions that are unrelated to the topic), domain accuracy (ability of chatbot to provide correct information about the genetic test result and care implications), and robustness (ability to handle ambiguous queries or incomplete information). Another project focused on generative AI solutions for personalized pharmacogenomics recently identified similar trends. Prior research indicated found that the accuracy (the degree to which the responses align with guidelines) of their chatbot was rated at the 75th percentile and relevance (similar to our criteria of boundaries) was rated at the 78th percentile for patient-facing responses delivered by their chatbot [50]. These significant differences in performance metrics for these domains across responses provided by ChatGPT 3.5 and their pharmacogenomics-specific AI assistant (71st percentile vs 75th percentile for accuracy and 68th percentile vs 78th percentile for relevancy) indicate the value in prompt engineering for specific use cases. Challenges exist in ensuring domain accuracy and boundaries, such as limitations in LLM's context retrieval and ability to process specialized biomedical and genomic data [51,52].

The combination of high domain accuracy and boundaries is essential for managing sensitive health information and mitigates concerns about chatbots offering misinformation and medical advice beyond the scope of the chatbot. As the LLM is further refined, it will be important to document all steps of the prompt engineering and be clear and transparent about the prompt engineering process used to develop the model in order to instill trust in the quality of responses and reduce the risk of

misinformation [49]. It will also be critical to involve patient stakeholders in the future evaluation process. Other approaches to prompt development and evaluation include the involvement of experts (genetic counselors, oncologists) to help identify unintentional sources of bias and decide on high-quality data sources that can be used to train the model [53]. Furthermore, given that the evaluation process included only a limited set of test questions, the inclusion of a more comprehensive question set could provide additional insight into the chatbot's performance and ensure its ability to manage a greater set of user interactions. For example, our testing included 14 questions, whereas other projects have included over 30 questions [50]. In particular, future studies should incorporate adversarial examples in both engineering and testing, especially to more comprehensively test the model accuracy and boundaries [53].

In addition to domain accuracy and boundaries, it is critical to ensure open-ended, LLM-generated responses are delivered in a tone that instills trust and engagement with the individual. Expert ratings indicated that the chatbot had good quality tone (ability to express information in a way that is appropriate for the type of information being delivered), usability (ease of interfacing with the chatbot), efficiency (ability to answer in a way that is direct, concise, and complete), and clarity (ability to communicate information clearly and in a way that avoids confusion) in both case scenarios. Prior research assessed a similar domain of language and bias (clarity and neutrality of responses, ensuring the context is understandable and devoid of bias), which was rated highly (87th percentile) [50].

Lessons Learned

Our prompt engineering approach incorporated multiple techniques to develop an LLM chatbot that was well-rated across several quality domains. Several valuable lessons were learned. We used RAG as our approach to prompt development, but other techniques such as few-shot, supervised fine-tuning, and reinforcement learning from human feedback could be used to further adjust the model's responses [45]. In addition, we focus on a use case of returning positive results for PGS, as PGS results return is among the least complex types of results being disclosed and could benefit from incorporating automation. Limitations of the project include our small sample size for the intrinsic evaluation of the chatbot responses and the lack of patients reviewing the responses. The reviewers are subject to bias when considering the perspective of the hypothetical scenarios which does limit the reliability of their scores.

Future Directions

At this phase of the project, our goal was to develop the initial prompt and assess the feasibility of the prompt to respond to questions about the return of results. Thus, we did not include patients but will include patient perspectives and ratings of the quality of responses in future refinement of the LLM. Patients may identify areas for improvement that are not apparent to expert reviewers. Further, we only evaluate the script produced by the LLM component of the chatbot across 2 use cases. Additional use cases should be assessed (eg, other genes) to identify whether one prompt can be used or whether multiple prompts need to be developed for specific open-ended components of a hybrid chatbot. Finally, our assessment is only focused on the LLM component of the chatbot. Our future work will integrate the LLM component with the rule-based script, allowing us to assess different hybrid approaches. For example, we could address whether open-response options should be available as part of each component of the chatbot, which may require specific prompts for each component, or whether the open-response LLM component is generic.

While the final prompt delivered relatively high-quality responses in an appropriate tone, it is important to note that we did not assess perceptions of the quality of delivery among patients. Many chatbots have been designed to support mental health and behavior change modifications and are explicitly focused on building relationships and natural language experience for genomics-focused chatbots, and this is an important aspect of communication that will need to be evaluated before implementing a similar chatbot [54,55]. Furthermore, we tested the responses for hypothetical scenarios returning Lynch syndrome pathogenic variant (MLH1) and hereditary breast and ovarian cancer syndrome (BRCA) results. There may be a need to further refine and test response quality and tone across specific genes, as each has unique implications and may require distinct prompts. User testing among patients will also help address potential adaptations needed to ensure culturally appropriate responses [56].

Our long-term goal is to incorporate the LLM component of the chatbot described here with an existing rule-based chatbot called Genetic Risk Assessment for Cancer Education. This hybrid approach could be ideal for the return of positive PGS results, as it integrates scripted content that is critical for results disclosure with patient preference for open-ended response options. The combined approach can address the limitations of purely rule-based or purely LLM-driven systems to combine consistency and accuracy with conversational fluidity and content comprehensiveness. Some information may be more suitable for rule-based or scripted content. For example, in our intrinsic evaluation, the LLM chatbot received poor scores for program accuracy (ability of chatbot to provide correct information about the genomic screening program). The program accuracy referred to the ability of the chatbot to provide factually correct information about the specific program that patients were engaged in through this testing process. Although provided materials about the specific program were included as part of prompt engineering, experts rated this lowest among the domains they evaluated. This may indicate that additional contextual knowledge is required to sufficiently explain the complexities of individual programs. This type of information does not require personalization and may be most suited for prescripted, educational content, whereas the LLM components are most suitable for complex and open-ended questions and more nuanced interactions [49]. This additional personalization may make education more accessible and streamlined for patients seeking genetic care, potentially increasing their participation. As a result, improving the program accuracy score is an important future research topic.

One hybrid approach could incorporate a scripted component that provides a predetermined set of information, followed by an LLM component that is engineered specifically to support open-ended questions about a certain domain (Multimedia

Appendix 3). This may include key domains of: overview of the PGS program, returning positive results, screening recommendations, impact on family, and next steps.

Another hybrid approach could vary when the LLM or rule-based components are used throughout the chatbot. For example, the return of results process involves 3 main stages: engagement, activation, and addressing information needs. In the engagement stage, the rule-based component of the chatbot would provide an overview of the PGS program, inform the individual of their positive results, and educate the individual about what this means for their long-term care. The activation phase could also use rule-based content and guide individuals through a core set of scripted information to encourage the next steps. In the subsequent open-ended content, participants' information needs could be addressed by allowing them to ask additional questions about topics they choose, which could be answered through the LLM. This hybrid approach has benefits and drawbacks [57]. While the increased efficiency of resources and centralized communication are benefits of implementing the technology, the technology can introduce new types of errors, have biases of their own, and be perceived as less personable.

Conclusions

This project demonstrated the initial feasibility of prompt engineering for the LLM component of a chatbot designed to return positive genomic screening results, with high expert ratings across most of the evaluation criteria. These preliminary findings will be used to further develop a hybrid chatbot that integrates the rule-based and LLM components to enhance the delivery of results by providing essential information with the flexibility of managing a range of patient queries. This increased efficiency has the potential to save health care systems financial and time resources. Additionally, hybrid AI tools such as these offer the potential to support patients' decision-making and improve their education and health behaviors. Further refinements of the prompt are needed, as well as broad user-testing that involves individuals with various genomic conditions and cultural preferences, and testing of the best integration of LLM and rule-based components of the chatbot. This new approach to conveying positive genetic screening results has promise and can help address the limitations of the current genomic workforce that would be needed for the return of all positive results in a population genomic screening context.

Abstract

Digital health interventions offer promise for scalable and accessible health care, but access is still limited by some participatory challenges, especially for disadvantaged families facing limited health literacy, language barriers, low income, or living in marginalized areas. These issues are particularly pronounced for patients with colorectal cancer (CRC), who often experience distressing symptoms and struggle with educational materials due to complex jargon, fatigue, or reading level mismatches. To address these issues, we developed and assessed the feasibility of a digital health platform, CRCWeb, to improve the accessibility of educational resources on symptom management for disadvantaged patients with CRC and their caregivers facing limited health literacy or low income. CRCWeb was developed through a stakeholder-centered participatory design approach. Two-phase semistructured interviews with patients, caregivers, and oncology experts informed the iterative design process. From the interviews, we developed the following 5 key design principles: user-friendly navigation, multimedia integration, concise and clear content, enhanced accessibility for individuals with vision and reading disabilities, and scalability for future content expansion. Initial feedback from iterative stakeholder engagements confirmed high user satisfaction, with participants rating CRCWeb an average of 3.98 out of 5 on the postintervention survey. Additionally, using generative artificial intelligence tools, including large language models like ChatGPT and multimedia generation tools such as Pictory, complex health care guidelines were transformed into concise, easily comprehensible multimedia content, and made accessible through CRCWeb. User engagement was notably higher among disadvantaged participants with limited health literacy or low income, who logged into the platform 2.52 times more frequently than nondisadvantaged participants. The structured development approach of CRCWeb demonstrates that generative artificial intelligence–powered multimedia interventions can effectively address health care accessibility barriers faced by disadvantaged patients with CRC and caregivers with limited health literacy or low income. This structured approach highlights how digital innovations can enhance health care.

Introduction

Colorectal cancer (CRC) is the third most common cancer and the second leading cause of cancer-related deaths in the United States [1]. For patients with CRC, educational materials play a critical role in understanding their diagnosis, exploring treatment options, self-managing their side effects and symptoms, and navigating posttreatment care, ultimately empowering them to make informed decisions about their health [2-4]. However, most of these materials are primarily text-based, which poses significant accessibility challenges for disadvantaged populations, such as individuals with low income or limited health literacy [5].

Caregivers, typically family members who provide emotional and physical support, frequently experience similar distressing symptoms, making it equally challenging for them to engage with complex medical content [6,7]. For disadvantaged populations with limited health literacy or low income, these barriers are even more pronounced, which reduces their ability to access and understand crucial health information [8]. Many educational materials are only available in English, further excluding non-English-speaking individuals from receiving critical guidance on symptom management and supportive care [9]. These factors combine to create a critical gap in the ability of patients with CRC and their caregivers to effectively manage symptoms and make informed decisions about their treatment, highlighting the urgent need for more accessible solutions.

Recent advancements in generative artificial intelligence (GenAI) offer a transformative solution to these challenges. GenAI can convert traditional text-based educational materials into multimedia formats at a fraction of the cost and time, making it an efficient and scalable option [10,11]. In this work, we introduce CRCWeb, a novel GenAI-driven digital health mobile platform designed to provide accessible, tailored symptom management resources to patients with CRC and their caregivers. Powered by state-of-the-art GenAI models like ChatGPT [12], CRCWeb transforms dense health care texts into digestible multimedia formats, including videos and audio, concise and easy-to-understand health knowledge, practical activity prompts, and quizzes. This approach makes essential health knowledge on symptom management and cancer care more accessible to individuals with CRC facing low literacy and other accessibility challenges [13]. By reducing the cognitive load required to process health information, CRCWeb empowers patients and caregivers with easy-to-understand materials, improving their abilities to manage symptoms and adhere to treatment plans and guidelines. Therefore, the purpose of this viewpoint is to describe the development of CRCWeb, which leverages GenAI for digital symptom management in patients with CRC and their caregivers, and present preliminary data to support its feasibility and potential to reduce barriers to accessing health information and improve user engagement, satisfaction, and symptom management.

Contextual Background

We used a stakeholder-centered participatory design approach to develop CRCWeb at the Nell Hodgson Woodruff School of Nursing, Emory University, Atlanta, Georgia, United States. The motivation for this project was to develop and test a symptom management tool tailored to the needs of disadvantaged patients with cancer, particularly those with limited health literacy or low income. The project was led by a multidisciplinary research team with expertise in oncology, nursing, AI, technology, psychology, behavioral science, and clinical trial design. The development and evaluation of CRCWeb took place between November 2022 and May 2025.

Designing CRCWeb

Overview

CRCWeb was developed through an iterative stakeholder-centered participatory design approach [14,15]. We conducted 2-phase, semistructured interviews using an interview guide developed from the existing literature that included open-ended questions and probes to elicit their specific needs, challenges, and expectations for a technology-based intervention tool for symptom management during chemotherapy treatment. Each interview lasted between 30 and 45 minutes and was conducted in either a private conference room at the clinic or virtually via Zoom (Zoom Video Communications, Inc), depending on the participant's preference. All interviews were audio-recorded and transcribed, and field notes were taken to document nonverbal cues. Content analysis was used to analyze the qualitative data through Dedoose (SocioCultural Research Consultants) and was completed in 4 steps: data preparation, writing memos, coding, and categorizing and connecting [16].

Semistructured Interviews: Phase 1

In Phase I, 11 patients with CRC, 8 caregivers, and 4 oncologists were asked about their perspectives and suggestions for a technology-based intervention to manage symptoms. We gathered their feedback before the platform's development. This early involvement of key users allowed us to ensure that the platform would be designed to address their specific needs, challenges, and expectations from the outset. During the interview, the participants were guided by the questions in Table 1. We started by discussing their needs for a technology-based intervention tool during chemotherapy (Question 1) and their experiences with existing technological tools for symptom management (Question 2), allowing us to identify key gaps in current digital solutions. Providers were also asked to offer suggestions for the development of this tool (Question 3).

Table . Two-phase semistructured interview questions designed for iterative stakeholder-centered participatory design[a].

Phase	Examples of interview questions
I	1. Can you describe your need for a technology-based intervention tool to manage symptoms during chemotherapy?
	2. Have you used any technological tools for symptom management? If so, which ones have you used, and what is your experience with them?
	3. Do you have any suggestions on developing a technology-based intervention program for patients and caregivers? What are they?
II	4. What are your likes and dislikes regarding the CRCWeb intervention components (eg, family involvement, symptom management, and coping strategies), delivery methods (eg, doses and intervals), and formats (eg, video, audio, and evaluations)?
	5. How easy or difficult was it for you to navigate and understand this technology tool?
	6. What challenges or barriers have you encountered when accessing cancer care and symptom management?
	7. In your opinion, how can we achieve health equity in cancer care?
	8. What are the facilitators and challenges related to implementing a technology-based intervention for patients and caregivers?

[a]Questions 1 to 3 were used in phase I to collect participants' needs for CRCWeb prior to development, while questions 4 to 8 were used in phase II to iteratively gather feedback from participants to propose new designs and functionalities.

Semistructured Interviews: Phase 2

In Phase II, we expanded the participant pool beyond the original 23 from Phase I to include a more diverse group: 5 additional patients and 5 caregivers, as well as a palliative care physician, a nurse practitioner, and a clinical leader. These participants were iteratively asked to provide feedback on CRCWeb's proposed content, including family involvement, symptom management, and coping strategies, as well as the delivery methods and formats (Question 4) and their user experiences (Question 5). Additionally, the interviews addressed topics such as barriers to accessing cancer care and symptom management (Question 6), participants' perspectives on achieving health equity (Question 7), and the facilitators and challenges associated with implementing the intervention (Question 8). After each iteration, we proposed new designs and functionalities based on participants' feedback. Given that over half of the participants that we interviewed came from disadvantaged backgrounds with limited health literacy or low income and were unfamiliar with technology, the iterative design process allowed them to actively engage with CRCWeb during its early development stages, ensuring that the approach aligned with their needs and preferences. These participants provided valuable insights into the specific needs that CRCWeb aimed to address, particularly the need for improved accessibility to health care resources and information.

Ethical Considerations

The study protocol (STUDY00004750) was approved by the institutional review board at Emory University. Written consent was obtained from participants. All participants were informed of the voluntary nature of their participation and their right to withdraw at any time without consequence. All research data were anonymized to maintain confidentiality. Study materials were securely stored and accessible only to authorized research team members. Participants received up to $60 compensation for their involvement. The study was conducted in accordance with the US Common Rule (45 CFR 46).

Design Principles

The design principles outlined in Table 2 were identified from our 2-phase semistructured interview transcripts using content analysis. To reduce the learning curve of using a new app, particularly for disadvantaged populations with limited health literacy or low income, we applied design principle 1, ensuring that CRCWeb includes intuitive and user-friendly navigation features. To increase participant engagement, we implemented design principle 2 to include multimedia components to enrich the content [17,18]. Design principle 3 ensures that the learning modules are concise, containing only essential information. This design principle minimizes learning time and makes the content easier for disadvantaged individuals with limited health literacy to comprehend. To assist individuals with vision impairments and reading disabilities, we designed the vision principle, optimizing CRCWeb to enhance accessibility for these users. Design principle 5 was implemented to ensure that the system is scalable, allowing for the inclusion of additional educational materials in various formats in the future without requiring changes to the system architecture. These qualitative data are invaluable in identifying key features that would drive the development of CRCWeb.

Table . Five design principles were outlined from the 2-phase semistructured interviews with patients and caregivers[a].

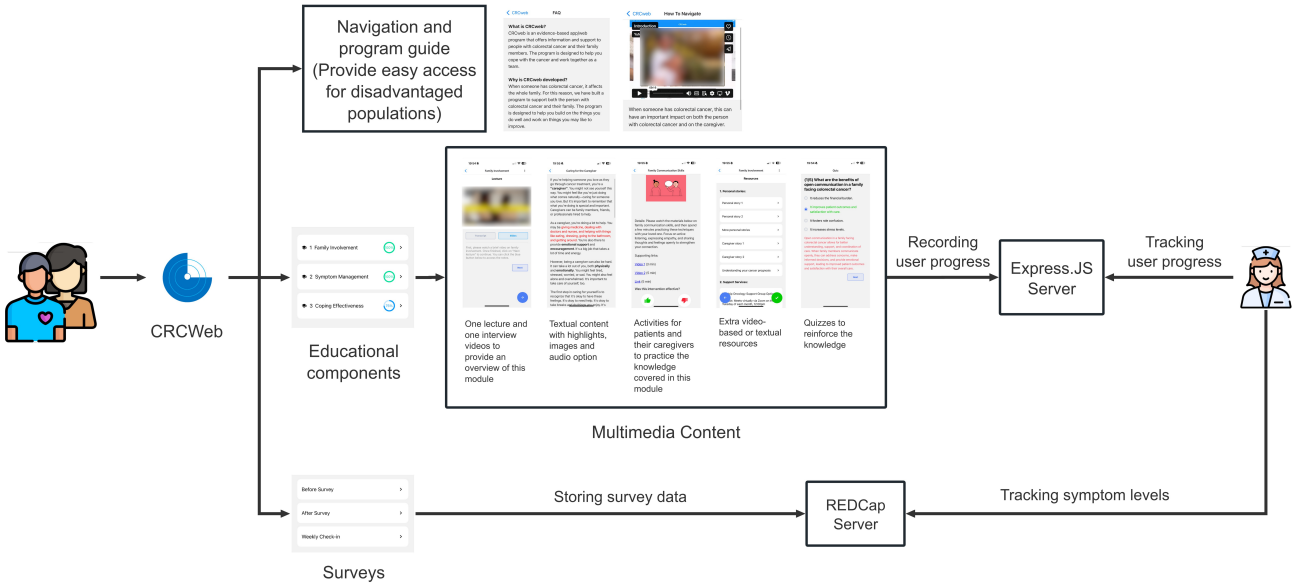
Design principle	Explanation
User-friendly principle	Our platform should feature intuitive and user-friendly navigation.
Multimedia principle	Our platform should feature multimedia components.
Concise principle	Extraneous material should be excluded to keep the content short and easy to understand.
Vision principle	Our app should feature functions that help people with limited vision to access educational content.
Scalability principle	Our platform should be scalable to include more topics and content formats in the future.

[a]These open-ended questions aim to address accessibility challenges for disadvantaged populations facing limited health literacy or low income by incorporating intuitive navigation, multimedia components, concise and easy-to-understand content, and functionalities designed to assist individuals with limited vision.

Development of CRCWeb

The development of CRCWeb strictly followed the design principles outlined in the previous section. As shown in Figure 1, CRCWeb contains 3 main components: navigation and program guide, educational materials, and surveys. The navigation and program guide simplify access while the educational components offer engaging, multimedia content tailored to different learning needs. The survey feature tracks symptom levels and user progress, with data securely stored on the REDCap (Research Electronic Data Capture; Vanderbilt University) server. Then, we discussed in detail how CRCWeb's design increased accessibility by focusing on these 3 key components.

Figure 1. System architecture of CRCWeb, highlighting its 3 core components: navigation and program guide, educational components, and surveys. The educational components feature 5 multimedia sections: lectures, content, activities, resources, and quizzes. User progress is securely stored on our server, ensuring confidentiality while enabling administrators to monitor and track advancement. REDCap: Research Electronic Data Capture.



Functionalities of CRCWeb

As shown in Figure 2, CRCWeb's main interface includes 4 navigation tabs at the bottom of the screen: Home, Content, Survey, and Account. This streamlined layout is crucial for enabling users to easily access the app's core functionalities without confusion. By providing a consistent and simple navigation system, CRCWeb ensures that users, especially those with limited technological proficiency, can effortlessly switch between essential features, aligning with design principle 1. As shown in Figure 2A, users can also quickly navigate between sections using a button located in the top right corner. Additionally, the large blue buttons at the bottom of the screen, as displayed in Figure 2C, allow users to move to the next or previous sections within a module. When a user reaches the final section, the right button turns green, indicating that they have completed the current module. To further assist users in tracking their progress, as demonstrated in Figure 2B, a green check mark appears next to the title of a section when it is finished, providing a visual reminder of completion. The Home tab includes essential resources such as "How to Navigate?" and "FAQ" sections, designed to guide users through the platform and answer common questions. These features are critical for users who may not be familiar with technology, ensuring that everyone can easily access and use CRCWeb's resources. Users can also send direct messages to the research team for additional support by tapping the message icon in the top right corner. This feature is particularly useful for

disadvantaged users with limited access to advanced technologies who may require additional help to navigate the platform or understand the content. As shown Figure 3B, the Content tab grants users access to educational modules, complete with a progress bar that visually tracks their completion status. This progress bar is essential in keeping users motivated and aware of their learning journey. The Survey tab, illustrated in Figure 2C, enables users to complete pre- and postintervention surveys, as well as weekly symptom check-ins. This structure allows CRCWeb to deliver notifications that adjust the learning experience based on user progress and survey responses. Finally, the Account tab, shown in Figure 2D, enables users to manage personal information and settings and pair their account with a caregiver. This paired account feature fosters collaboration, enabling patients and caregivers to share learning progress and better coordinate care efforts.

One of the key tools supporting this interactivity is the smart content tagging system, which enhances the readability and accessibility of text-based materials. The content tagging system allows critical information to be highlighted using different font weights, colors, and multimedia elements. For example, key points can be bolded or marked in red or blue to guide users' attention, as shown in Figure 3. In addition, users can choose to increase font size in settings. Driven by design principles 2 and 4, this system ensures that important information is easy to spot, particularly for users with low literacy or cognitive challenges. Additionally, for users with reading difficulties or visual impairments, we integrated a text-to-speech option that allows users to listen to the content instead of reading it. This feature is available throughout the app, ensuring that all users—regardless of their abilities—can engage with the educational materials. The system is designed to strip out tags before converting the text to speech, preventing unnecessary audio distractions. To reinforce learning, each module concludes with a quiz, as shown in Figure 4D. The quizzes provide immediate feedback, informing users whether their answers are correct, followed by explanations to deepen their understanding. Users are encouraged to achieve at least 80% accuracy before moving on to the next module. Notifications are sent to remind users to retake quizzes if they do not meet this threshold, ensuring that learning is reinforced and that users fully comprehend the material before progressing.

To ensure CRCWeb can be accessed on a wide variety of devices, we built the platform using the React Native framework [19]. This allows the platform to be deployed as an iOS app, Android app, and web app from a single code base, ensuring maximum accessibility across platforms. Since most disadvantaged populations with limited health literacy or low income are using older versions of Android devices, we made additional efforts to optimize CRCWeb's performance in the Android environment to ensure a smooth, bug-free experience. Following an agile software development process [20], we continuously refined the platform based on feedback from internal testers and semistructured interviews with patients and caregivers, resulting in an iterative and user-driven design. The backend server of CRCWeb is built using the Express.js framework [21] and object-relational mapping [22] to accommodate any relational database, allowing flexibility in terms of database management while ensuring robust performance and scalability.

Figure 2. System architecture of CRCWeb, highlighting its 3 core components: navigation and program guide, educational components, and surveys. The educational components feature 5 multimedia sections: lectures, content, activities, resources, and quizzes. User progress is securely stored on our server, ensuring confidentiality while enabling administrators to monitor and track advancement.

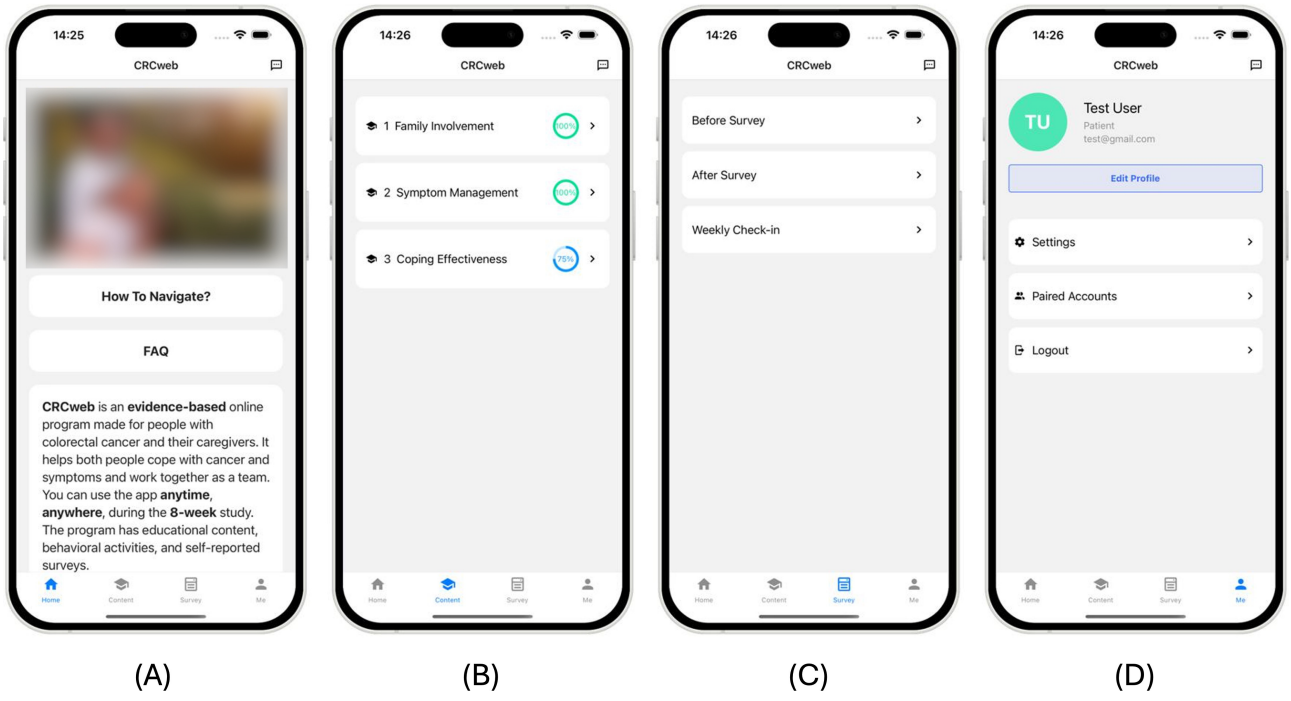


Figure 3. Examples of educational topics in CRCWeb: (A) Physical Activity, offering practical exercise recommendations; (B) Family Communication, guiding effective caregiver-patient discussions; and (C) Fatigue, providing practical strategies for managing energy levels during treatment.

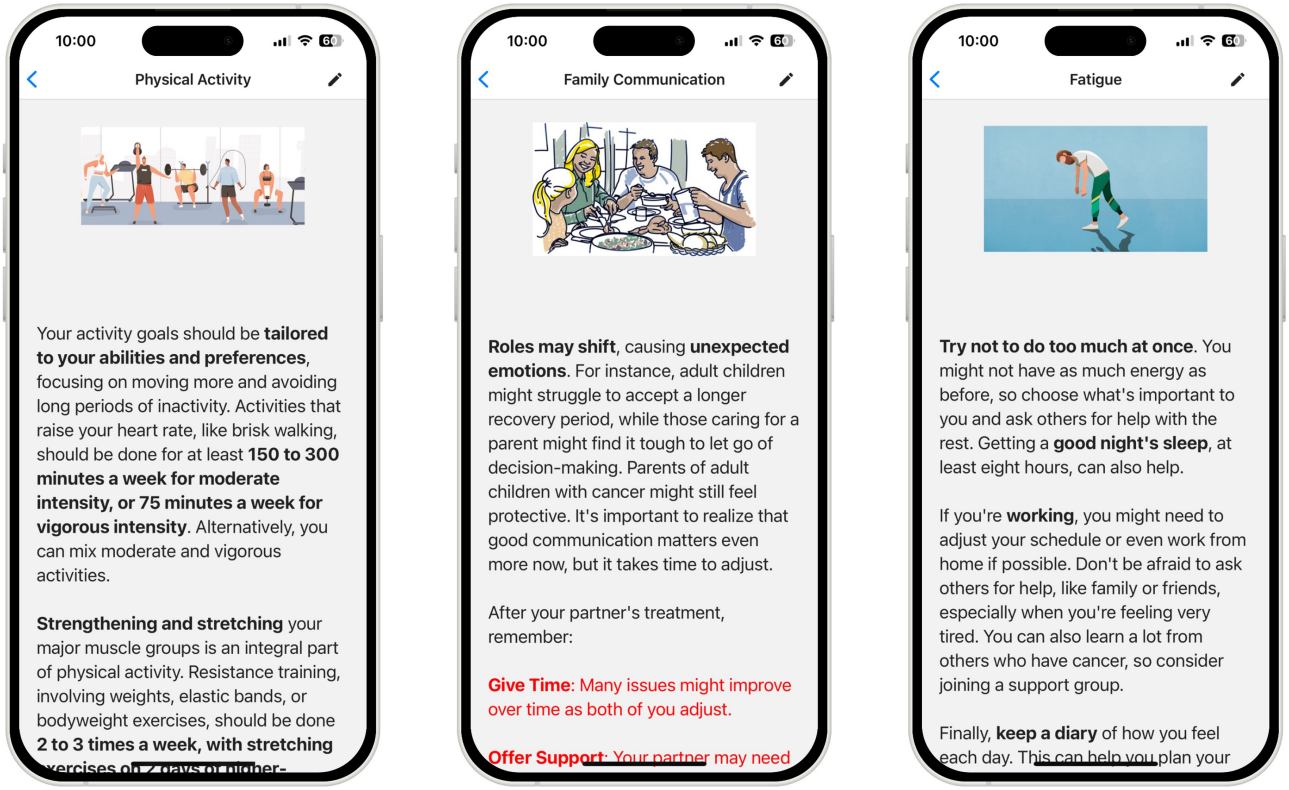
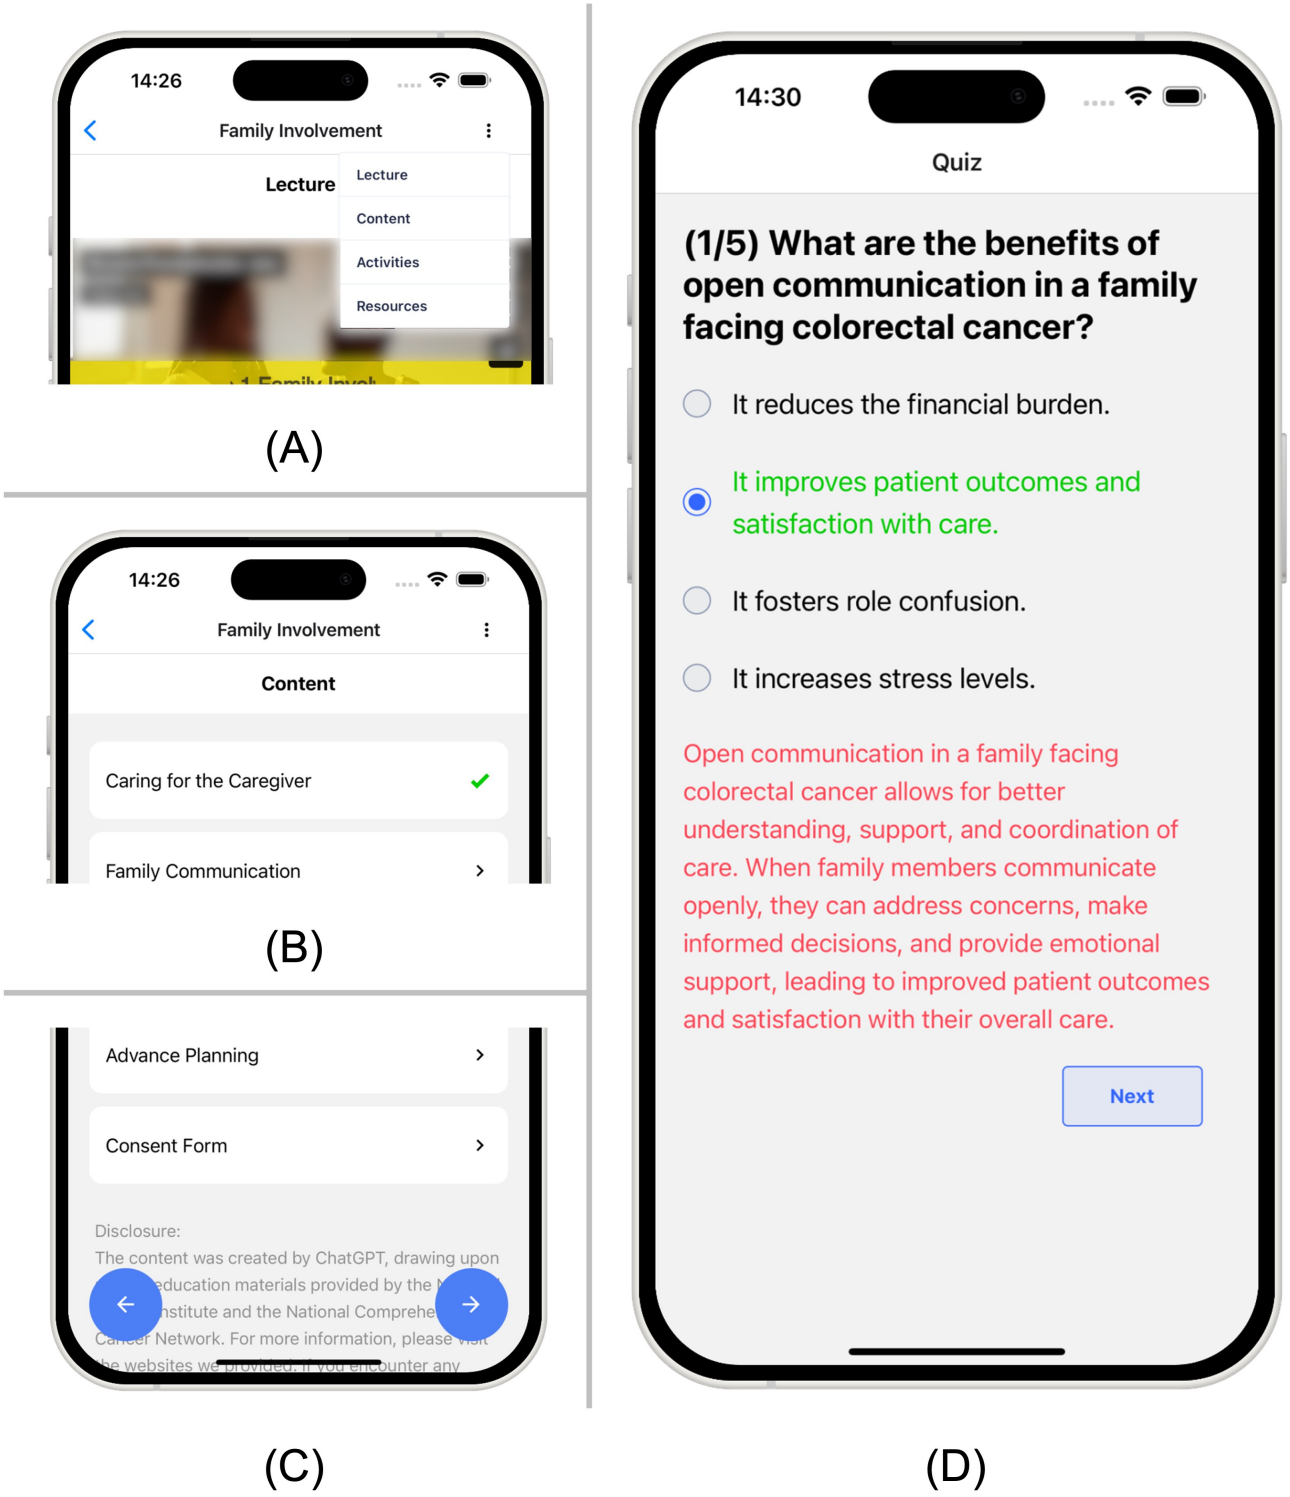


(A) (B) (C)

Figure 4. The user-friendly navigation features of CRCWeb: (A) a drop-down menu to quickly navigate through different sections; (B) a green check mark to indicate when a section has been reviewed; (C) large buttons for navigating between sections; and (D) quizzes with immediate feedback to inform users if they answer correctly and providing a detailed explanation.



Educational Content

Tailoring Educational Materials for Symptom Management Using GenAI

CRCWeb's educational content is organized around 3 core modules—Family Involvement, Symptom Management, and Coping Effectiveness—all of which are informed by Stress Coping Theory [23] and Family Systems Theory [24]. These theories emphasize the critical role that psychological resilience and family dynamics play in how individuals manage chronic conditions like CRC. Specifically, Stress Coping Theory highlights how emotional and cognitive responses influence symptom management, while Family Systems Theory indicates the importance of involving family members in the care process. By integrating these theoretical frameworks, CRCWeb was designed to improve both patient and caregiver outcomes and engagement, particularly for disadvantaged populations with

limited health literacy or low income. Therefore, we hypothesized that enhanced family involvement and targeted psychosocial education alleviated the symptom burden for patients with CRC and their caregivers. This tool aimed to provide the knowledge, strategies, and emotional support necessary to manage symptoms effectively, ultimately improving both the patients' and caregivers' quality of life.

Each module is structured into 5 key sections: lectures, content, activities, resources, and quizzes. As illustrated in Figure 1, the educational materials were tailored into 4 distinct formats and distributed across different sections of CRCWeb: videos in the lectures section, textual content in the content section, practical activities in the activity section, extra-textual and video-based resources in the resources section, and quizzes in the quiz section. These educational materials were developed in alignment with guidelines from the National Cancer Institute [25] and the National Comprehensive Cancer Network [26], ensuring that the content is evidence-based and authoritative. As shown in Figure 3, the topics address a comprehensive range of practical, emotional, and physical challenges faced by patients with CRC and their caregivers. These topics are crafted to not only educate but also empower patients and caregivers, encouraging them to take an active role in managing cancer treatment and improving overall well-being.

To improve both engagement and accessibility, we integrated multimedia content throughout all modules, in alignment with design principle 2. Drawing from the semistructured interviews, we developed 5 distinct types of content—videos, slides, textual content, practical activities, extra resources, and quizzes—tailored to fit within the 5 sections of the program. Each lecture section includes 2 short videos: a primary lecture video that provides a comprehensive overview of the module's content and a supplemental video featuring interviews with patients with CRC who share their lived experiences. These videos are complemented by slides that offer additional visual summaries, making the information accessible to users with different learning preferences. Each content section features concise textual information, complemented by images and highlighted key points. The activity section offers practical activities with detailed instructions, while the resources section provides additional more detailed resources. The quiz section at the end of each module includes 5 quizzes to reinforce learning.

In the activities section, users engage in 9 digital exercises (3 activities per module) designed to reinforce what they learned in the lectures and content sections. These activities are tailored to daily life routines, such as symptom tracking and communication exercises between patients and caregivers. The activities also include a rating feature that allows users to provide feedback on their experience through thumbs-up or down ratings and optional comments. This feedback loop is a crucial part of CRCWeb's design, as it enables continuous refinement of activities based on real-time user input, ensuring that the content remains relevant and effective.

The resources section offers optional supplementary materials for users who wish to delve deeper into specific topics. These include additional videos, articles, and external links to trusted cancer resources. In response to user feedback, we curated this section to ensure that it provides meaningful yet nonoverwhelming options for further exploration. For example, users can access interviews with others managing similar symptoms, providing both practical tips and emotional support through shared experiences.

Each module concludes with a 5-question multiple-choice quiz, generated by ChatGPT and reviewed by our expert panel. These quizzes serve as a reinforcement tool, helping participants solidify their understanding of the key concepts covered in each module. Immediate feedback is provided for each question, with detailed explanations to clarify any misunderstandings and further support the learning process.

This comprehensive design, grounded in theory and informed by direct user feedback, ensures that the educational materials are not only accessible but also actionable, empowering patients with CRC and caregivers to take an active role in symptom management and care.

Generating Accessible Multimedia Materials Using GenAI

To enable the accessibility and engagement of educational materials, CRCWeb incorporates a framework for using GenAI to develop multimedia content, as shown in Figure 5. This framework begins by using the PyPDF2 [27] package to extract textual information from the original PDF documents. ChatGPT then generates concise summaries of the extracted text for each module. In line with design principle 4, these summaries are further processed by Pictory to create lecture videos tailored to individuals with limited vision and reading disabilities.

Additionally, the extracted text is processed by ChatGPT to produce various content formats tailored to the needs of disadvantaged populations with limited health literacy or low income. For instance, concise, low-reading-level text is generated to teach symptom management, while practical activities and quizzes are created to support hands-on learning and retention. These tailored formats, in adherence to design principles 2 and 3, are designed to make the educational content more accessible and actionable. The majority of the educational materials are created by GenAI-powered tools and subsequently reviewed by a team of oncology experts to ensure accuracy and relevance before being made available to patients and caregivers.

In the lecture section, we use ChatGPT to distill the core content of each module into a brief, cohesive summary that highlights the key topics. This summary is then processed by Pictory, a leading GenAI-powered video generation tool, which swiftly transforms text into engaging video content. These videos provide an alternative to text, allowing users to watch or listen to the material, reducing cognitive load and increasing engagement. As shown in Figure 5, Pictory creates relevant videos by incorporating the transcript and automatically highlighting key terms to reinforce understanding. The videos also include relaxing background music and a human voiceover to ensure a smooth, engaging viewing experience. For users who prefer text, we provide video transcripts that offer the same content in written form.

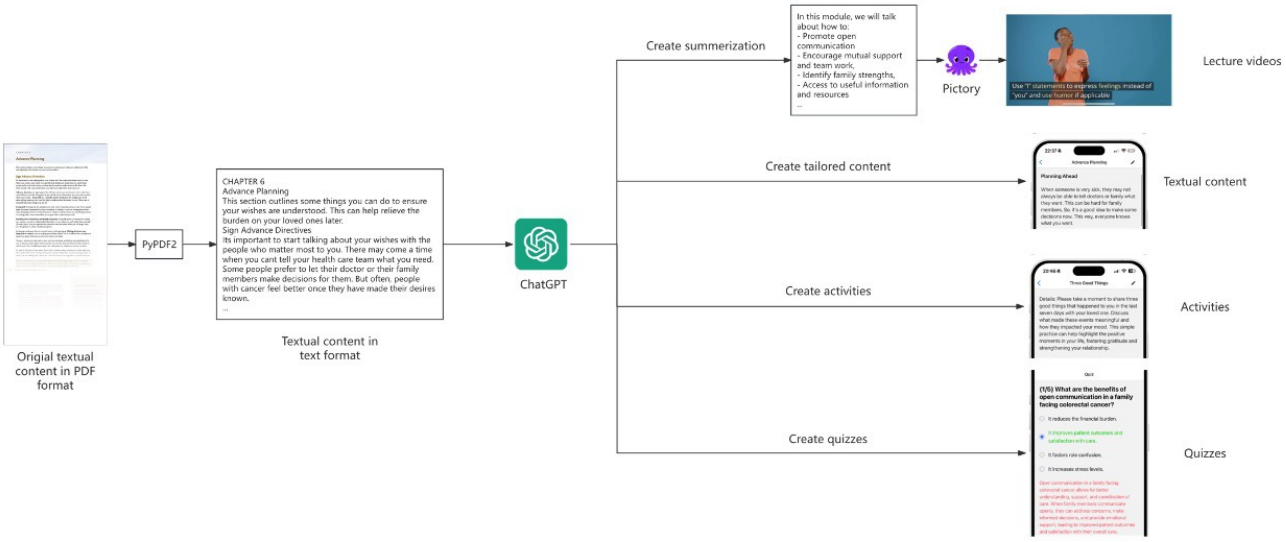
In the content section, CRCWeb presents text-based materials adapted from national guidelines for each topic. To ensure these materials are concise and easy to understand, as per design principle 3, ChatGPT is tasked with summarizing guideline documents into no more than 250 words with a Flesch-Kincaid Grade level of 6, making the content accessible to users of all literacy levels. A smart tagging system highlights key points using predefined tags, which are then reviewed and refined by our oncology experts to ensure clarity and relevance. Links to the original, full-length documents are included at the end of each section for users who wish to explore the source materials in more detail. Additionally, a text-to-speech feature powered by the React Native TTS package [28] provides an auditory option for users with vision impairments or reading difficulties. To prevent the tags from being read aloud, we use regular expressions to remove them from the audio transcript, ensuring a smooth listening experience.

In the activity section, we use ChatGPT to generate simple, practical activities that patients and caregivers can complete together. These activities are designed to reinforce the key concepts covered in the module and are structured to be easy to implement in daily routines. User feedback on these activities is collected through a rating system, which allows us to continuously improve their relevance and usability.

For the quiz section, ChatGPT generates 10 multiple-choice questions for each module, each accompanied by a detailed explanation of the correct answer. From these, we select the 5 most appropriate questions, refining them to match the challenge level needed to reinforce the material without overwhelming users. As shown in Figure 5, these quizzes provide immediate feedback with an explanation, helping participants reinforce the knowledge they learned from the module.

By integrating GenAI with expert review and accessibility features such as video, text, and audio options, CRCWeb ensures that its educational materials are engaging, user-friendly, and tailored to the needs of both patients with CRC and caregivers.

Figure 5. The framework was designed to leverage GenAI in creating multimedia content. First, the original PDF materials are converted into text using the Python package PyPDF2. The extracted text is then tailored by ChatGPT for 4 specific purposes: summarization of the topic, shortening the content to a lower reading level, creating practical activities, and generating quizzes. The topic summary is then processed by Pictory, which converts it into a video alongside a pleasant human reading voice. GenAI: generative artificial intelligence.



Performance Evaluation of Large Language Models in Tailoring Educational Content

We compared 3 models from the GPT family (GPT-3.5 Turbo, GPT-4, and GPT-4 Turbo) to generate tailored content for disadvantaged patients with CRC and their caregivers with limited health literacy using predetermined prompts. The GPT-generated content was then evaluated by oncology experts and applied to CRCWeb.

To promote the accessibility and comprehension of educational materials for disadvantaged patients with CRC and their caregivers with limited health literacy, we structured prompts to have large language models (LLMs) produce content at a low reading level (Flesch-Kincaid Grade level of 6), maintain a word limit of 250, and provide Spanish and Chinese translations for each topic.

Our primary sources for content generation were education materials from the National Cancer Institute and the National Comprehensive Cancer Network guidelines [26]. We carefully selected 30 distinct topics that encompass a broad spectrum of content, including fatigue, depression, anxiety, pain, cognitive impairment, nutrition, and more. A subset of the topics was implemented in CRCWeb.

As reported in our prior work [29], the GPT family of models exhibited outstanding capability in tailoring educational materials for disadvantaged patients with CRC and their caregivers with limited health literacy or low income, only with deviations from the designated reading level.

Pilot Study

We conducted an 8-week single-arm pre-post pilot clinical trial among patients and their caregivers in 2 cancer clinics as our

test users to guide the development of CRCWeb. Among all 40 enrolled participants (20 patients and their caregivers), 22 of them came from disadvantaged backgrounds (ie, income ≤250% Federal Poverty Level, Medicaid, and uninsured), while the remaining 18 were from nondisadvantaged backgrounds, including individuals with higher incomes and adequate insurance coverage. The participants were instructed to download and navigate through CRCWeb by a clinical coordinator.

Participant Satisfaction With CRCWeb

The average satisfaction score was 3.980 out of 5 (1=strongly disagree, 2=disagree, 3=partially agree, 4=agree, and 5=strongly agree), with minimal variation (0.004), indicating that participants found the platform helpful on average.

When comparing satisfaction levels between the nondisadvantaged and disadvantaged groups, the average scores were nearly identical: 3.985 for the nondisadvantaged group and 3.971 for the disadvantaged group, resulting in a minimal difference of 0.014.

A nonparametric Two One-Sided Test using the Mann-Whitney *U* test was applied. The results, presented in Table S3 in Multimedia Appendix 1, revealed that for Questions 1 and 2, which assessed overall satisfaction and perceived helpfulness of CRCWeb, the distributions between the 2 groups are equivalent (both $P<.05$). For Questions 3 through 6—addressing the relevance of content, clarity, understanding of personal situations, and skills for symptom management—both Test 1 and Test 2 were also significant ($P<.05$). This indicates that both groups rated CRCWeb similarly on these dimensions, with no notable differences in how they perceived the app's relevance, clarity, or utility in managing symptoms. This demonstrates strong equivalence in the experiences of both groups in these areas. Finally, for Question 7, which focused on whether CRCWeb provided practical suggestions for everyday life, only Test 2 was significant ($P=.001$), while Test 1 was not ($P=.05$). This suggests that the disadvantaged group seems to have found CRCWeb more useful for providing practical, everyday suggestions compared to the nondisadvantaged group. This observation further reinforces the usability of CRCWeb for disadvantaged populations, as they perceived the platform to provide more practical support than their nondisadvantaged counterparts.

User Engagement and Login Frequency

To assess user engagement, we tracked attendance records, adherence rate, and login frequency across the study period. A total of 40 participants were enrolled in the intervention and the retention rate was 75%. Among the 40 participants, 87.5% completed all 3 modules and logged into CRCWeb at least 3 times. There was a clear difference in engagement between the disadvantaged and nondisadvantaged groups. The disadvantaged group logged in 209 times in total, compared to 83 logins from the nondisadvantaged group, making the disadvantaged group 2.52 times more engaged. A Mann-Whitney *U* test was performed to verify whether this difference was statistically significant, and the results confirmed that the disadvantaged group had significantly higher login frequencies ($P=.047$).

Lessons Learned and Future Directions

This viewpoint presents that by transforming textual data into multimedia components and tailoring educational content to the needs of low-health-literacy populations, CRCWeb addressed the significant health disparities that exist for disadvantaged groups with limited health literacy or low income [30]. Our assessment suggests that CRCWeb significantly enhanced user engagement for disadvantaged groups with limited health literacy or low income and achieved high levels of user satisfaction. This result is particularly noteworthy, as prior research has often highlighted lower engagement among disadvantaged populations in digital health interventions [31]. While our results demonstrated CRCWeb's effectiveness in delivering accessible educational content, several limitations should be addressed in future directions.

First, language translations were not included in this pilot study as we only recruited English-speaking participants. Prior research indicates that LLM performance varies by language, performing better in high-resource languages like German, French, and Spanish, but less effectively in lower-resource languages such as Kannada and Occitan [32,33]. To make CRCWeb more inclusive for non-English speakers, future work will evaluate auto-translation features and incorporate LLM-based translation for additional languages. This will allow CRCWeb to serve a broader, multilingual population.

Second, while commercial GenAI-powered tools such as ChatGPT and Pictory help streamline content creation, they come with risks such as potential pricing increases and service suspensions. To mitigate these risks, future work will explore developing our own GenAI models based on open-source frameworks [34-36]. This will give CRCWeb greater control over its content generation processes and ensure long-term scalability and cost-effectiveness.

Finally, in terms of user engagement, while login frequency is an important metric, it does not fully capture the complexity of user interactions with CRCWeb. To improve measurement accuracy, future iterations will include native apps for each platform, enabling more detailed tracking of user behaviors such as screen time and in-app navigation. Although this approach requires greater development effort, it will provide more inclusive metrics of user engagement.

Conclusions

Improving the accessibility of educational content on symptom management is essential to empowering patients with CRC and their caregivers, enabling them to more effectively manage symptoms throughout treatment. This is particularly vital for disadvantaged populations with limited health literacy or low income, who often lack access to national guidelines or frequent hospital-based care. CRCWeb addresses this challenge by leveraging GenAI-powered tools to transform overwhelming health care guidance into accessible multimedia formats, specifically tailored for patients with CRC and their caregivers. With features like low-reading-level text, engaging videos, and user-friendly navigation, CRCWeb ensures that patients and

caregivers can better understand and manage their symptoms. Designed with a stakeholder-centered approach, the platform prioritizes the needs of its users, making it a valuable tool for improving health outcomes. Moreover, the scalable design of CRCWeb demonstrates its potential to be adapted for broader disadvantaged populations with limited health literacy or low income, extending its impact beyond patients with CRC and caregivers to enhance health care accessibility for diverse groups.

Acknowledgments

This work was supported by the Oncology Nursing Foundation Research Grant (2022 RE03). The authors also appreciate the support from Emory University School of Nursing, Winship Cancer Institute, and Grady Memorial Hospital. The front end of CRCWeb is available under an MIT license [37].

Data Availability

The datasets generated and analyzed during the current clinical trial are not publicly available due to their containing private sensitive patient information but are available from the corresponding author upon reasonable request.

Authors' Contributions

DL designed and developed the mobile app, analyzed and interpreted the data, and wrote the manuscript. YL was responsible for conducting the clinical trial, recruiting participants, collecting the data, and writing the manuscript. RY assisted with the technical aspects of the clinical trial and contributed to writing the manuscript. ZW also provided support with manuscript writing. DB developed the foundation of the backend server and cloud services. XH supervised the entire project and provided valuable insights and feedback throughout the process. All authors read and approved the final manuscript.

Abstract

Multidisciplinary team (MDT) meetings play a critical role in cancer care by fostering collaboration between different health care professionals to develop optimal treatment recommendations. However, meeting scheduling and coordination rely heavily on manual work, making information-sharing and integration challenging. This results in incomplete information, affecting decision-making efficiency and impacting the progress of MDT. This project aimed to optimize and digitize the MDT workflow by interviewing the members of an MDT and implementing an integrated information platform using the Fast Healthcare Interoperability Resources (FHIR) standard. MDT process re-engineering was conducted at a central Taiwan medical center. To digitize the workflow, our hospital adopted the NAVIFY Tumor Board (NTB), a cloud-based platform integrating medical data using international standards, including Logical Object Identifiers, Names, and Codes, Systemized Nomenclature of Medicine–Clinical Terms, M-code, and FHIR. We improved our hospital's information system using application programming interfaces to consolidate data from various systems, excluding sensitive cases. Using FHIR, we aggregated, analyzed, and converted the data for seamless integration. Using a user experience design, we gained insights into the lung cancer MDT's processes and needs. We conducted 2 phases: pre- and post-NTB integration. Ethnographic observations and stakeholder interviews revealed pain points. The affinity diagram method categorizes the pain points during the discussion process, leading to efficient solutions. We divided the observation period into 2 phases: before and after integrating the NTB with the hospital information system. In phase 1, there were 83 steps across the 6 MDT activities, leading to inefficiencies and potential delays in patient care. In phase 2, we streamlined the tumor board process into 33 steps by introducing new functions and optimizing the data entry for pathologists. We converted the related medical data to the FHIR format using 6 FHIR resources and improved our hospital information system by developing functions and application programming interfaces to interoperate among various systems; consolidating data from different sources, excluding sensitive cases; and enhancing overall system efficiency. The MDT workflow reduced steps by 60% (50/83), lowering the coordinated activity time from 30 to 5 minutes. Improved efficiency boosted productivity and coordination in each case of manager feedback. This study optimized and digitized the workflow of MDT meetings, significantly enhancing the efficiency and accuracy of the tumor board process to benefit both medical professionals and patients. Based on FHIR, we integrated the data scattered across different information systems in our hospital and established a system interoperability interface that conformed to the standard. While digitizing the work of MDT meetings, we also promoted the optimization and transformation of related information systems and improved their service quality. We recommend additional research to assess the usability of a tumor board platform.

(JMIR Cancer 2025;11:e53887) doi:10.2196/53887

Introduction

Cancer care is a complex process that requires collaboration among health care professionals to develop the best treatment strategies. A multidisciplinary team (MDT) approach, in which experts from various specialties come together to discuss and share knowledge on cancer cases, provides an effective platform for delivering comprehensive and personalized care [1]. The MDT typically includes oncologists, surgeons, radiation oncologists, oncology nurses, clinical psychologists, social workers, dietitians, pharmacists, and physical therapists. Each member contributes their expertise to ensure the patient receives the most appropriate treatment and support. The team conducts a thorough assessment of the patient's condition, considering factors such as cancer type, stage, physical health, psychological well-being, and social circumstances. From this evaluation, a tailored treatment plan is developed, addressing all aspects of patient care. This collaborative process fosters a patient-centered approach that not only aims to improve survival rates but also enhances the quality of life by addressing the diverse needs of the patient.

The MDT approach is particularly valuable in cancer care as it ensures continuous communication and coordination among health care providers, leading to more effective treatment and improved overall outcomes. MDTs enhance treatment efficiency and patient care by bringing together health care professionals from various disciplines to collaborate on treatment plans. This approach facilitates shared decision-making and provides comprehensive care by addressing the social, psychological, nutritional, and physical needs of patients with cancer [2]. By integrating the expertise of diverse professionals, the MDT approach enhances the comprehensiveness and precision of care, aiding patients in navigating the complexities of cancer treatment [3]. However, to fully realize the benefits of this approach, it is essential to overcome systemic barriers, attitudinal challenges, and knowledge gaps through multilevel interventions [4].

According to the requirements of the Taiwan National Cancer Diagnosis and Treatment Quality Certification, MDT meetings must be held regularly every year to discuss new diagnostic cases. However, the treatment course for patients with cancer is long, and patients are often cared for by different clinical departments. As a result, cancer clinical data are scattered across different information systems (eg, outpatient, inpatient, and personal cancer management) and cover various diverse data elements, including patient demographic data, laboratory reports, and medications. Convening an MDT of cancer care meetings requires coordinating the schedules of various specialized teams and collecting and consolidating data from different information systems. Medical staff work tirelessly, which can be challenging. It is necessary to collect and integrate patient data before the meeting and follow up on the comments afterward. Effective MDT decision-making requires having access to relevant information, giving structured case presentations, exercising leadership skills, and organizing an effective meeting infrastructure [5-7]. Meeting tools can help boost MDT meeting efficiency [8-10]. Moreover, considerations regarding the clinical workflows of end users and existing information systems (eg, electronic health records [EHR]) are increasing. It is challenging to integrate information tools into the current system to meet end user needs and expectations and to effectively improve MDT practices [11]. Therefore, a thorough understanding of the MDT decision-making process, information flow, and routine workflow of key stakeholders is required.

In recent years, hospital information systems (HISs) have vigorously developed, with various clinical departments increasingly using information systems to support their clinical work [12-15]. Although most of the work in hospitals has been digitized, when handling cancer cases, especially in MDT meetings, it remains necessary to communicate through multiple emails and telephone calls to complete treatment proposals. Repetitive manual operations are required when preparing and conducting MDT meetings. To prepare meeting materials, team members collect case- and patient-care-related information such as literature, guidelines, and clinical trial information from different information systems. The collected materials are scattered and stored separately by each team member, and the meeting minutes are stored in the cancer center in the form of paper documents, making it difficult for clinicians to read meeting discussion materials and minutes before making clinical decisions. MDTs involve many people, specialties, data, and knowledge, and there is often a lack of standard execution procedures for holding meetings and preparing data. Moreover, the varying team members in their respective professional groups can lead to complex dynamics regarding authority and responsibility [4]. Addressing these challenges requires effective management strategies to ensure the seamless operation of MDTs and the provision of high-quality care to patients. Few studies discuss the integration of data and workflow in oncology care. The rapid expansion of medical knowledge, especially in oncology, has led to information overload and requires well-designed digital tools to manage and use this data effectively. The digital tool has streamlined the preparation and conduct of multidisciplinary tumor board meetings, with potential future applications in virtual meetings and patient engagement [16]. To build a patient-oriented cancer precision medicine platform that integrates all the information for cancer care, clinical decision support is necessary.

Using international standards is a common practice for interoperability and data integration across systems. The commonly used international medical information exchange standard is Fast Healthcare Interoperability Resources (FHIR) [17]. FHIR is designed to enable quick and efficient health data exchange, including clinical and administrative data. It has a

strong focus on implementation and also strengthens health data interoperability. FHIR solutions are built from a set of modular components called “resources” that can be easily assembled into working systems. Existing medical data can also be exchanged with other information systems through FHIR resources. By adhering to the standard, all medical information, including EHRs, medical images, and laboratory results, can be transformed into a consistent and easily interpretable format. Its implementation means that health care data is converted and integrated, thus ensuring efficient communication among various information systems. The FHIR standard streamlines data conversion processes, making it easier for health care providers to rapidly access and interpret patient information. This leads to faster decision-making and better patient management in MDT meetings.

We aimed to optimize and digitize the workflow of MDT meetings in cancer care. This viewpoint article described the implementation of an integrated information platform using the FHIR standard to enhance the efficiency and accuracy of the tumor board process. By interviewing MDT members and re-engineering, the MDT process, we aimed to address the challenges of manual work, information-sharing, and coordination in MDT meetings. We hypothesized that digitizing the MDT workflow and integrating data using FHIR would significantly improve the efficiency, accuracy, and overall quality of cancer care provided by MDTs.

Setting and Project Overview

Overview

This project was conducted at a major medical center located in central Taiwan. The hospital is renowned for its comprehensive cancer care services, which include diagnosis, treatment, and follow-up care for various types of cancer. The hospital has a dedicated oncology center that provides multidisciplinary care to patients with cancer, ensuring that they receive the best possible treatment and support throughout their cancer treatment journey.

This hospital is a large medical facility with over 1800 beds and a wide range of specialized departments. It serves a diverse patient population from central Taiwan and beyond, offering advanced medical care and cutting-edge treatments. The oncology center at the hospital is equipped with state-of-the-art technology and staffed by a team of highly skilled health care professionals, including oncologists, radiologists, surgeons, specialized oncology nurses, clinical psychologists, social workers, dietitians, pharmacists, and physical therapists.

The team involved in this project includes members from various departments within the hospital. The MDT members include pulmonologists, pathologists, radiologists, radiation oncologists, and case coordinators. To optimize and digitize the workflow of MDT meetings in cancer care, we have developed an integrated information platform based on the FHIR standard to enhance the efficiency and accuracy of the tumor board process. A flow diagram is shown below (Figure 1).

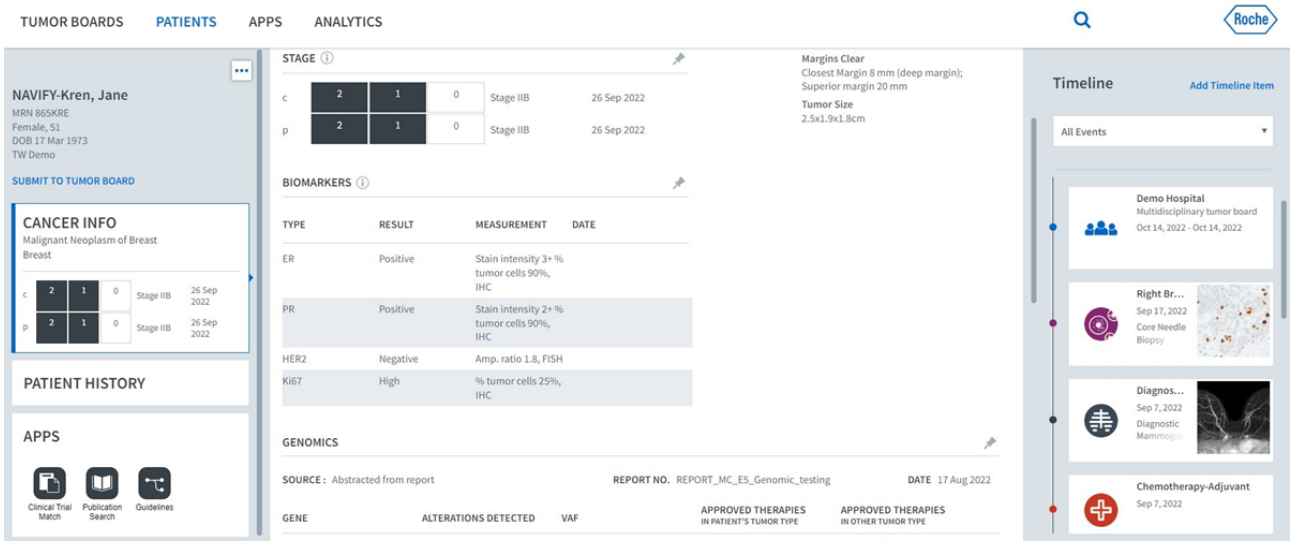
Figure 1. The research flow diagram. EHR: electronic health record; FHIR: Fast Healthcare Interoperability Resources.

Implementation of the Tumor Board Platform

In this project, the tumor board platform refers to a digital tool designed to streamline and enhance the workflow of multidisciplinary tumor board meetings. These platforms integrate various types of medical data, such as EHRs, medical images, laboratory results, and pathology reports, into a single, accessible system. This integration allows health care professionals, including oncologists, radiologists, surgeons, and other specialists, to collaboratively analyze, discuss, and develop personalized treatment plans for patients with cancer. The tumor board process involves regular meetings where an MDT of health care providers with different specialties come together to discuss cancer cases. During these meetings, the team reviews patient information, shares knowledge, and formulates comprehensive treatment plans tailored to the individual needs of each patient. The goal of the tumor board process is to ensure that patients receive the best possible care through coordinated and collaborative decision-making. To digitize the working process, an information system (NAVIFY Tumor Board [NTB]; Roche Molecular Systems), was adopted in our hospital. The NTB is a cloud-based workflow platform that integrates all relevant medical data to facilitate tumor board workflows [18]. This software as a tumor board platform uses various international standard terminologies (eg, Logical Object Identifiers, Names, and Codes, Systemized Nomenclature of Medicine–Clinical Terms, and M-code) and has a core database built using the FHIR standard to help prepare, present, and document the workflow of multidisciplinary tumor board meetings. In the early stages of system construction, we imported patient medical data into the information platform. The inclusion criteria for the patient data consolidated into the platform involve patients meeting the qualifications for multidisciplinary care. These include patients with stage III lung cancer, complex cases, patients with special events, and cases recommended for discussion by attending physicians. We excluded sensitive cases before integrating the medical data. Sensitive cases refer to patient histories of domestic violence and medical disputes, as defined by our hospital.

We also define standardized processes and operating procedures for various roles and provide system training courses to facilitate the use of this system. One of the key values that MDT members find in NTB is its ability to integrate data. In the past, patient data was scattered across different systems, requiring members of MDTs to log into multiple systems to review a single case. However, with NTB, they only need to log into the NTB platform to complete case reviews. In addition to data integration, NTB's interface visually presents patient examinations and treatment schedules through a "timeline," which helps MDTs understand the progression of a patient's condition more easily. Whether through data integration or the timeline feature, effective data exchange between systems is achieved using the FHIR standard. Moreover, the platform directly facilitates collaborative case editing among MDTs, allowing team members to prepare their respective data from different locations and times, thereby enriching the completeness of patient information (Figure 2).

Figure 2. User interface of NAVIFY Tumor Board.



We aggregated and analyzed the data requirements for interfacing with each information system. Additionally, we mapped and converted all of the data to align with the FHIR format. This comprehensive process involved the mapping of diagnosis and treatment information to the FHIR standard, ensuring integration with the tumor board information system. Moreover, to facilitate seamless data exchange, we designed an interoperability data model that adheres to internationally recognized FHIR standards. This approach enhances data compatibility and promotes efficient communication across diverse health care systems.

Our primary objective was to conduct process re-engineering in a multidisciplinary lung cancer team to address the difficulties and challenges faced by the teams in their workflow. To achieve this goal, we applied the user experience design approach to gain in-depth insights into the processes and requirements of lung cancer MDT.

This project uses "step reduction" as an indicator to assess workflow rather than "time reduction." The primary reason for this choice is that the complexity of cancer cases varies widely in clinical settings, ranging from standard treatments to complex cases. The preparation time for different cases varies

accordingly. Hence, “step reduction” is chosen as a metric for evaluating workflow processes. Additionally, qualitative observation is used for two reasons: (1) Participant perspectives: Qualitative methods capture direct participant involvement in workflows, allowing insights into personnel perspectives and experiences, thereby providing insights into human factors that influence efficiency and effectiveness. (2) Holistic observation: Qualitative methods offer a comprehensive view of workflow processes, considering various elements and their interactions, which is crucial for identifying potential areas for improvement [19,20].

We divided the work of process re-engineering into two phases: (1) before the use of the NTB and (2) after the integration of the NTB and the HISs. Through observations of the tasks of multidisciplinary decision-making and meetings, we recorded the workflow and working steps from the MDT and interviewed the members of the multidisciplinary cancer team members to understand the related work and information needs of their work. We participated in 2 observation meetings covering 3 cases in each meeting. Interview participants included: 1 supervisor from the oncology center, 1 case manager, 1 resident physician, 1 radiologist physician, 1 pathologist physician, 1 lung MDT leader, and 1 chest nurse practitioner. Participants involved in defining pain points for discussion included: 1 supervisor from the oncology center, 1 case manager, 1 resident physician, 1 radiologist physician, 1 pathologist physician, 1 lung MDT leader, and 1 chest nurse practitioner.

Ethical Considerations

This project was approved by the Institutional Review Board of the Changhua Christian Hospital (No. 200816). Ethical approval was obtained on December 30, 2021. The requirement for informed consent was waived by the Institutional Review Board because the research involved minimal risk to the participants and could not be practicably carried out without the waiver. All data collected were anonymized to ensure the privacy of the participants. No identifiable personal information was used in the analysis or reporting of the results. No compensation was provided to the participants as the study involved minimal risk and did not require active participation.

Process Re-Engineering Phase 1

Overview

In phase 1, we used AEIOU (Activities, Environments, Interactions, Objects, and Users), ethnographic observation, and stakeholder interviews to gather pain points and requirements. Through on-site observations, we gained a preliminary understanding of the team members, their discussion processes, and the content involved. Subsequently, we conducted stakeholder interviews to gather more information from the lung cancer MDT members. These methods enabled us to gain deeper insights into users’ needs and pain points.

The MDT workflow was divided into 6 activities: patient collection, coordination, preparation, meetings, documentation, and follow-up.

From phase 1 to phase 2, the number of steps in the workflow decreased from 83 steps to 33 steps. The coordinate activity saw the largest reduction, dropping from 35 to 12 steps (Figure 3). Phase 1 consisted of 83 steps across the 6 activities, most of which were carried out manually. We performed various tasks, including patient data collection, documentation, and follow-up, manually. During the coordination activity, MDT members had to repeatedly query and retrieve data from various HIS and EMR systems. These data were then compiled into Microsoft Word (Microsoft Corp) files containing diagnoses, radiology image reports, and pathological summaries, mostly in text format. During meetings, MDT members use their individual files and different information systems to present case details, which could lead to duplicate or inconsistent content among the different files. After meetings, case managers compile the meeting minutes in text form and store them at the tumor center. If physicians need to review the meeting content during follow-up, they must request access from the tumor center. This process is time-consuming and inefficient, leading to potential delays in patient care.

Figure 3. Workflow of MDT: (**A**) phase 1: before the use of the NTB and (**B**) phase 2: after optimizing workflow and integrating the information system. MDT: multidisciplinary team; NTB: NAVIFY Tumor Board.

Collect 4 steps	Coordinate 35 steps	Prepare 11 steps	Conduct 16 steps	Document 11 steps	Follow-up 6 steps

Collect 1 step	Coordinate 12 steps	Prepare 3 steps	Conduct 7 steps	Document 4 steps	Follow-up 6 steps
-Patient collection: 1	-Administration: 1 -Data query: 6 -Notify: 5	-Administration: 1 -Records summary: 1 -System switching: 1	-Data query: 4 -Prepare materials: 3	-Administration: 2 -Notify: 2	-Data query: 1 -Notify: 1 -Records summary: 2 -Recommendation: 2

(B) Phase 2

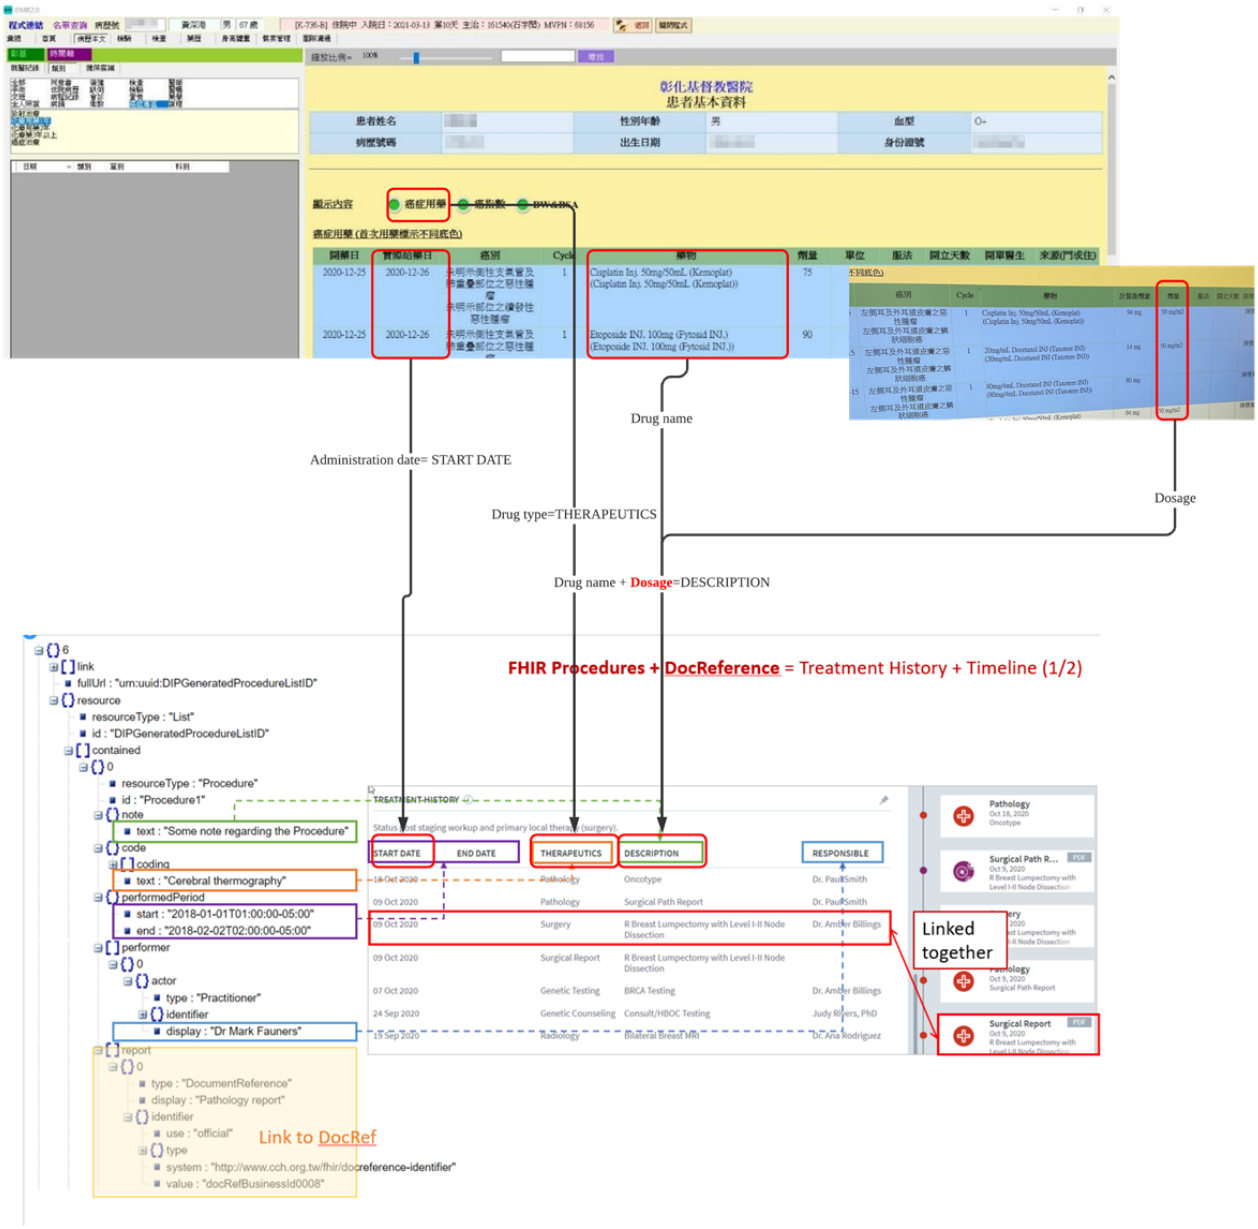
FHIR Adoption

For data integration, we conducted a thorough review of the medical charts and meticulously analyzed patient records and relevant information. To ensure accurate and effective data mapping, we engaged in extensive discussions with medical professionals and experts. Through these collaborative sessions, we identified the key data elements and attributes in the medical charts and carefully aligned them with the appropriate FHIR resources, which encompassed six major categories.

1. Patient: contains essential patient information (eg, name, date of birth, sex, medical record number, and other relevant data).
2. Condition: provides details of the clinical conditions, problems, diagnoses, or events that require attention, including key information (eg, the date of initial diagnosis).
3. Body structure: records information about anatomical structures (eg, location and laterality data).
4. Procedures: encompasses actions that are currently or have been performed on the patient (eg, surgical dates, preoperative and postoperative diagnoses, operating physicians, surgical images [JPEG format], medical orders, and radiation therapy information).
5. Diagnostic report: contains data on patient diagnostic results (eg, radiology images and other relevant findings).
6. Observation: comprises data from patient examinations (eg, genetic testing reports and other observational data).

We transformed medical data into a format that adheres to FHIR standards. This comprehensive process allowed us to seamlessly integrate medical data into the FHIR standard, thereby enabling smooth interoperability and data exchange across various health care systems. We mapped the data from the clinical information system to the corresponding fields compliant with the FHIR standard. We presented this comparison systematically through the system interface, allowing clinical physicians to review and confirm the accuracy of data transformation. An example of clinical data transformation into FHIR is shown in Figure 4.

Figure 4. Example of chemotherapy treatment history clinical data transformation into FHIR. FHIR: Fast Healthcare Interoperability Resources.



Process Re-Engineering Phase 2

Overview

In phase 2, we used the affinity diagram method to define pain points. First, we mapped the complete pre-, during-, and postdiscussion processes of lung cancer MDT. Then, using the affinity diagram method, we categorized pain points at various stages of the discussion. This approach helped us gain a clearer understanding of the process of pain points and design effective solutions more efficiently.

Integration of the Platform With EHR

We also improved our hospital's information system and modified some of its functions. We developed several functions and application programming interfaces (APIs) to interoperate these systems and consolidated the data from several information systems within our hospital, including patient demographics, inpatient and outpatient order data, the cancer registry, the American Joint Committee on Cancer stage data, surgical data, biomarkers, radiology, picture archiving and communication systems, pathology reports, and cancer treatment plans.

Figure 5 displays a sample code of the APIs developed to enable the system interface to meet the specified requirements. These APIs were instrumental in integrating 10 information systems into the NTB, thereby facilitating process digitization and automation. This seamless integration, coupled with process optimization, allowed MDT members to collaborate effectively on the platform, streamlining the coordination and preparation of the meeting content. The platform's data integration capabilities enable the simultaneous presentation of diagnoses, findings, images, and imaging reports during meetings. Participants can access the complete meeting materials, reports, and images together, ensuring an efficient and comprehensive discussion. Moreover, the platform automatically saves screenshots and image data during meeting minutes, thereby simplifying the documentation process. Physicians can

conveniently access the meeting content directly from the NTB during follow-up, thus enhancing accessibility and continuity of care. The successful development and implementation of these APIs significantly improved the efficiency and effectiveness of the MDT workflow at the NTB.

Figure 5. Sample code of the APIs. API: application programming interface.

```
class CancerInfoController : ApiController
{
    Dictionary<string, string> _connstrings;
    string CancerInfo(int chart)
    {
        string result = "";
        OracleConnection conn = new OracleConnection(_connstrings);
        OracleCommand cmdSel = null;
          OracleCommand cmdUpd = null;
        try
          {
            conn.Open();
            string selSQL = BuildSql(chart);
            cmdSel = new OracleCommand(selSQL, conn);
            cmdSel.CommandType = CommandType.Text;
            cmdSel.Parameters.Add("chart", OracleDbType.Decimal).Value = chart;
            DataTable dtCancerInfo = ExecuteQuery(cmdSel);
            result = ConvertToJson(dtCancerInfo);
        }
        catch (Exception ex)
          {
            result = HandleException(ex);
        }
        finally
          {
                string updSQL = BuildSql(chart);
            cmdUpd = new OracleCommand(updSQL, conn);
                cmdUpd.CommandType = CommandType.Text;
            cmdUpd.Parameters.Add("chart", OracleDbType.Decimal).Value = chart;
                cmdUpd.ExecuteNonQuery();
                conn.Close();
        }
        return result;
    }
}
```

In phase 2, we successfully reduced the number of steps in the tumor board process to 33 across 6 activities (Figure 3). To achieve this, we implemented several improvements to our HIS, specifically for the tumor board process. First, we introduced 2 new functions in the HIS to streamline the tumor board process. The “patient collection” function allowed MDT team members to easily request a tumor board workflow digitally, simplifying the initiation process. Additionally, we developed a new function tailored for pathologists. Through in-depth user interviews, we determined the system operation requirements and reorganized the pathology report entry process. In the original system, pathologists had to enter a template code, and the corresponding gross findings and descriptive content appeared in text fields. To improve the data structure and efficiency, we converted the gross findings and descriptions into a fixed structure and extracted vital information for inclusion in the primary diagnosis feature. We carefully discussed these templates with key users and pathologists to

ensure their accuracy and relevance. To minimize errors, we designed a check function for the proposed system. In cases where templates could not be converted into structured inputs, we extracted and converted the content of the remark field into structured information. Pathologists need only input keywords or key numerical values, and the system automatically converts the data into an edited narrative report. Furthermore, we provided a comment field for physicians to offer supplementary explanations when needed. These enhancements significantly improved the efficiency and accuracy of the tumor board process, benefiting both medical professionals and patients.

The pain points identified and categorized were as follows: phase 1: before the use of the NTB, there were a total of 48 pain points, which were reduced to 12 after optimizing workflow and integrating the information system (Table 1). For the detailed pain point with the MDT workflow, please refer to the Multimedia Appendix 1.

Table . Total pain points were identified in 6 activities.

Pain points	Collect	Coordinate	Prepare	Conduct	Document	Follow-up	Subtotal
Phase 1, n	4	22	5	8	6	3	48
Phase 2, n	0	4	0	4	1	3	12

Despite having the same number of activities in the MDT workflow, a significant reduction of 60% (50/83) in the number of steps was achieved in the tumor board process. This streamlining effort effectively optimized the efficiency and effectiveness of the tumor board process. Due to these improvements, the case managers reported a remarkable decrease in the average time spent on coordinated activities, from 30 to 5 minutes. Feedback from the case managers highlighted the considerable time-saving benefits generated by the enhanced workflow, leading to increased productivity and smoother coordination within the MDT.

Lessons Learned

Overview

We encountered several issues and challenges during the implementation of the FHIR standard. First, there is a significant scarcity of personnel proficient in both medical data content and the FHIR standard. Second, the data collected by existing information systems must meet the basic requirements of the FHIR standard format and be structured data. Throughout the project, we reviewed medical charts and engaged in discussions with medical and informatics experts to map our data into FHIR resources. Additionally, FHIR education training courses were organized to ensure that both clinical and information staff in our hospital could learn this medical information standard. Furthermore, the data fields of the HIS system were adjusted to meet the requirements of FHIR conversion.

Future Work and Implications for Practice

By implementing a framework and applying multispecialty discussions in cancer care, this study is expected to help medical information teams refer to available FHIR resources and provide a standard interface in an efficient, low-cost manner that does not affect daily operations. The interface integrates the complete diagnosis and treatment experience of cancer (eg, diagnosis, treatment, outpatient and inpatient consultations, previous discussions, and other imaging information) and can be used for in-hospital treatment, teaching, and research. FHIR resources, data models, and related systems used for MDT discussions on cancer can also be referenced by those who wish to construct FHIR standards.

Other MDTs engaged in cancer care can use our workflow optimization experience as a reference. With the growth in cancer cases and the development of precision medicine, genetic diagnosis, and digital medicine, the demand for digital assistance platforms for cancer care has gradually increased. At the same time, medical and health data are expected to increase at a rapid rate. These developments present additional challenges for clinical teams. Our optimized workflow can be used as a reference by other hospitals that wish to digitize their MDTs.

The development of a structured medical record entry system in our hospital was accelerated while digitizing the MDT meeting workflow. The essence of any successful structured medical record entry system lies in its ability to standardize or make data collection uniform across patients through an easy reporting system while allowing improved decision support, real-time quality assessment, and opportunities for patient-oriented clinical research [21]. The MDT meeting workflow provides incentives and application scenarios, prompting users to participate in the system design and development. However, with the NTB platform, MDTs experienced a profound improvement in their clinical discussions. The ease of accessing patient data, imaging results, pathology reports, and treatment histories allows for a more holistic understanding of each case. This comprehensive approach facilitates in-depth discussions and fosters collaboration in devising tailored treatment plans for patients. Furthermore, the platform streamlines operational processes, reduces the administrative burden, and saves time. Improved workflow and efficient decision-making contribute to enhanced patient outcomes and overall operational efficiency.

In addition to the NTB platform, the adoption of the FHIR international standard has revolutionized data exchange among cancer-related systems. By providing a consistent and standardized interface, FHIR enhances system openness and interoperability, allowing different systems to seamlessly communicate and share information. This standardized approach empowers health care providers to integrate patient data from various sources, including EHRs, imaging systems, laboratory results, and treatment records. Consequently, clinicians have a more comprehensive and real-time view of a patient's health status, leading to better-informed clinical decisions and improved patient outcomes.

The comprehensive rollout plan to other cancer teams can optimize the MTD workflow within the hospital, enhancing clinical work efficiency. We will modify the HISs to add a new function that enables physicians to read the NTB meeting outcomes through outpatient information systems, facilitating a closed-loop data use process. Moreover, additional data sources such as ultrasound reports and medical histories will be integrated to enrich the data sources.

This platform can be extended to other clinical settings. Attending physicians have found that the NTB platform is not only useful for multidisciplinary discussions, but also that the integrated data on NTB is suitable for team assessments and discussions before patient surgeries. Our educational department has also noted that storing comprehensive case discussion data in NTB can serve as gold cases for training post graduate year doctors, establishing a repository of gold cases without medical record numbers. Additionally, it provides case materials for teaching faculty and restricts access to post graduate year doctors only, achieving educational objectives. Furthermore, in response to Taiwan's cancer next-generation sequencing (NGS) reimbursement policy, establishing a Molecular Tumor Board to discuss NGS cases is an upcoming initiative for deeper application.

We also observed that, although the new NTB platform provided integrated data that could save data search time, it increased the working time to prepare meeting materials. Professional software tools often have a learning curve, and their initial use may require additional time. Although it might take a bit more time to learn how to use the software, as users become more proficient, their data preparation speed increases, and more time is saved. Additionally, an integrated platform can provide users with more comprehensive patient records, allowing them to gain insights from consolidated data rather than simply copying and pasting information from various systems, as was the custom in the past. This increased time usage may enhance the quality of health care deliveries. The NTB also has many new functions (eg, data annotation), which can make presentation materials more appealing; however, this takes more time. During follow-up, although they could access the NTB to view the meeting content, physicians looked forward to an efficient way to view the meeting minutes. The NTB platform is being continuously optimized and integrated with other information systems, in which medical professionals can view the meeting minutes directly. Inviting various clinical teams to use the platform to improve decision-making support is the next step.

After data integration, information can be reused in a format compliant with the FHIR standard. In Taiwan, NGS cases can be uploaded to national-level biobanks in FHIR format, as many disease and case notification data requirements also mandate the FHIR format. Using data for future clinical research will be easier, especially for studies involving cross-institutional or international clinical databases. Our research demonstrates the integration of full medical report data in meetings, allowing team members to review the reports together. If the data are insufficient, team members can directly enter the patient's timeline function to view other data without a cross-system query. A previous study [22] referred to information technology as a solution to achieve real-time data collection and imaging, which may improve patient-centered care coordination. In this study, we not only accomplished information integration but also optimized the workflow for tumor boards.

Conclusions

The use of information technology in MDT meetings has become common; however, the full potential of information systems for data collection, integration, and collaboration remains underused despite its immense value to health professionals. In this project, we attempted to optimize and digitize the workflow of MDT meetings. By leveraging the international data exchange standard, FHIR, we successfully integrated data from various information systems within our hospital, establishing a system interoperability interface compliant with the FHIR standard.

During the digitization process, we not only optimized and transformed related information systems but also enhanced the overall service quality of our hospital's information system. This digital transformation has facilitated physicians' use of medical record data for research by implementing a structured medical record entry interface, thereby improving the accessibility and availability of medical records.

In addition to the lung MDT, we encouraged other cancer care teams to adopt the new process and integrated platform. Currently, 4 cancer groups are using NAVIFY, and we anticipate that by the end of 2023, all cancer groups within our hospital will be on board, amounting to a total of 10 teams. Overall, we emphasize the importance of efficient processes that use standardized and leveraged technology to optimize the tumor board process and enhance cancer care delivery. We will share our experience of information systems and process improvement with other hospitals and health care professionals, and encourage further research to assess the usability of tumor board meetings for multidisciplinary care teams. We believe that sharing knowledge and experience will drive advances in health care and improve patient outcomes.

The most significant impact of an optimized workflow is its support for timely, data-driven decisions. By integrating fragmented processes and data, the oncology center can more effectively manage the operations of each tumor board workflow for different cancer types. This increases efficiency in the preparation of meeting materials and enables standardization of meetings.

Acknowledgments

The authors would like to express their appreciation to the lung cancer MDT members and participants from the Cancer Center, AI Center, and Information Systems Department in Changhua Christian Hospital. This study was supported in part by Roche Diagnostics Ltd.

Abstract

Therapist-guided eHealth interventions have been shown to engage users more effectively and achieve better outcomes than self-guided interventions when addressing psychological symptoms. Building on this evidence, this viewpoint aimed to describe the adaptation of iConquerFear, a self-guided eHealth intervention targeting fear of cancer recurrence, into a therapist-guided version (TG-iConquerFear) tailored specifically for survivors of colorectal cancer (CRC). The goal was to optimize patient outcomes while minimizing the need for extensive resources. The adaptation process followed the Information System research framework, which facilitated a systematic integration of knowledge and iterative testing. Drawing on insights from the original iConquerFear development, as well as feedback from end users, oncologists, and therapists, we began by identifying areas for improvement. These insights formed the foundation for the first design cycle. Initial internal testing revealed the need for several adjustments to enhance the intervention. While the core concept of iConquerFear remained unchanged, we made significant modifications to improve access by optimizing the platform for mobile devices, to support adherence by expanding the exercises, and to equip therapists with tools such as reflective questions and a monitoring control panel. External field testing with 5 survivors of CRC provided further validation. Participants reported a high level of acceptability, and their feedback guided additional minor points to consider incorporating in future versions. This study illustrates how a self-guided eHealth intervention can be successfully adapted into a therapist-guided format for fear of cancer recurrence, tailored to meet the needs of survivors of CRC. The described approach serves as a valuable framework for integrating therapist guidance into similar interventions, ensuring their relevance and effectiveness for targeted populations.

KEYWORDS

fear of cancer recurrence; therapist-guided; self-guided; online intervention; colorectal cancer; digital health; psychosocial intervention; survivorship; eHealth; adaptation; survivors; oncologists; therapists; acceptability; mobile phone

Introduction

eHealth interventions, defined as programs that provide information and support for physical or mental health problems via digital platforms [1], can overcome barriers to accessing support including travelling distance to site of intervention, time constraints, disease burden, financial issues, perceived stigma, and mobility or logistics constraints due to pandemics such as COVID-19 [2]. eHealth interventions in diverse cancer settings address challenges related to scalability and cost-effectiveness with effects comparable to traditional face-to-face therapy [3-7]. However, the initial development, evaluation, and implementation of effective eHealth interventions is a complex and multidisciplinary process [8], which requires substantive financial and human resources [9].

eHealth interventions may fill an important gap in psychosocial cancer care especially, by augmenting limited available services [10]. However, the efficacy of self-guided psychological eHealth interventions can be limited by low uptake and engagement [11]. Furthermore, these interventions might increase disparities in health care, as those with digital skills and more resources will be more likely to engage [12], while those with late effects such as peripheral neuropathy and fatigue might face challenges in using required devices (eg, computers, keyboards, or mice) [13]. Promisingly, meta-analytic evidence shows that adding guidance to interventions yields greater efficacy when treating anxiety, distress, fatigue [14], and fear of cancer recurrence (FCR) [7] in people living with cancer compared with nonguided interventions. However, guidance comes with greater costs and reduced scalability due to the use of health care personnel, infrastructure, and safety measures [15-19].

Leveraging existing self-guided eHealth interventions is one way of reducing resources required to design an entirely new guided eHealth service. Several psycho-oncological interventions have undergone successful adaptations, for example FindingMyWay [20] from Australia and Fear Of Recurrence Therapy [21] from Canada. FindingMyWay has undergone 2 adaptations: first, into a UK-version needing a contextual adaptation [22] to reflect the UK health care system and terminology, and second, to a metastatic-breast cancer specific version (Finding My Way-Advanced [23]). Fear Of Recurrence Therapy was adapted to family caregivers and to an eHealth format [24].

Intervention models that facilitate greater access to FCR treatment have been identified as a top international research priority [25]. To address this priority, Smith et al [26] adapted the effective face-to-face therapist-delivered ConquerFear [27] FCR treatment to an eHealth self-guided format (iConquerFear). However, feasibility testing of iConquerFear revealed that some individuals needed guidance and more relatable content for optimal engagement and benefit [28], as reported for other psychological symptoms [15,29]. To address these two key recommendations, this current study aimed to adapt iConquerFear into a tailored asynchronous therapist-guided eHealth version (TG-iConquerFear).

While guidance can be provided either in real time (synchronous) or as delayed (asynchronous), a systematic review by Cox et al [30] has shown the superior convenience, flexibility, and limited interruptions of daily routines with asynchronous guidance in telehealth interventions. As recommendations are mixed [31,32] the choice of asynchronous guidance will be evaluated.

To make intervention content more personal and relatable, a further aim of this study was to tailor iConquerFear specifically for survivors of colorectal cancer (CRC). CRC ranks as the third most frequently diagnosed cancer worldwide, with its prevalence steadily rising due to prolonged survivorship [33]. The prevalence and characteristics of FCR experienced by individuals affected by CRC have been described in detail [34-40]. However, no intervention customized to address FCR in survivors of CRC has been developed [7,41].

In summary, this paper describes the process of adapting iConquerFear into TG-iConquerFear targeting survivors of CRC. We report using the Information System research framework [42] to integrate recommended improvements from the original Australian development study [26] and pilot study [28] with end user feedback from field testing with oversight by a multidisciplinary research team as a template for other researchers seeking to make similar adaptations.

Methods

Intervention Content

The iConquerFear is a metacognitive intervention consisting of 5 modules. The content of each module is outlined in Table 1 [26].

Table . iConquerFear content and features. Features common across all modules include the following: web-based questionnaires, interactive exercises, downloadable hand-outs, progress graphs, email and SMS reminders, and safety plan.

Module	Content and features
1. Introduction and goal setting	• Introduction to FCR[a] and treatment model (survivor and clinician videos) • Values clarification and goal setting (interactive card sort exercise)
2. Attention training	• Introduction to attention training (survivor and clinician videos) • Attention training practice (audio, monitoring and feedback, and reminders)
3. Detached mindfulness	• Introduction to detached mindfulness (survivor and clinician videos) • Detached mindfulness practice (audio, monitoring and feedback, and reminders)
4. Learning to live well and manage worry	• Psychoeducation about appropriate threat monitoring (clinician video) • Compliance with follow-up and self-examination (assessment with feedback) • Challenging unhelpful metacognition (assessment with feedback) • Worry management techniques (textual overview and downloadable PDF)
5. Treatment summery and relapse plan	• Reflection on change in FCR during treatment (assessment with feedback) • Consolidation of new strategies for managing FCR through relapse prevention (personalized feedback and downloadable action plan)

[a]FCR: fear of cancer recurrence.

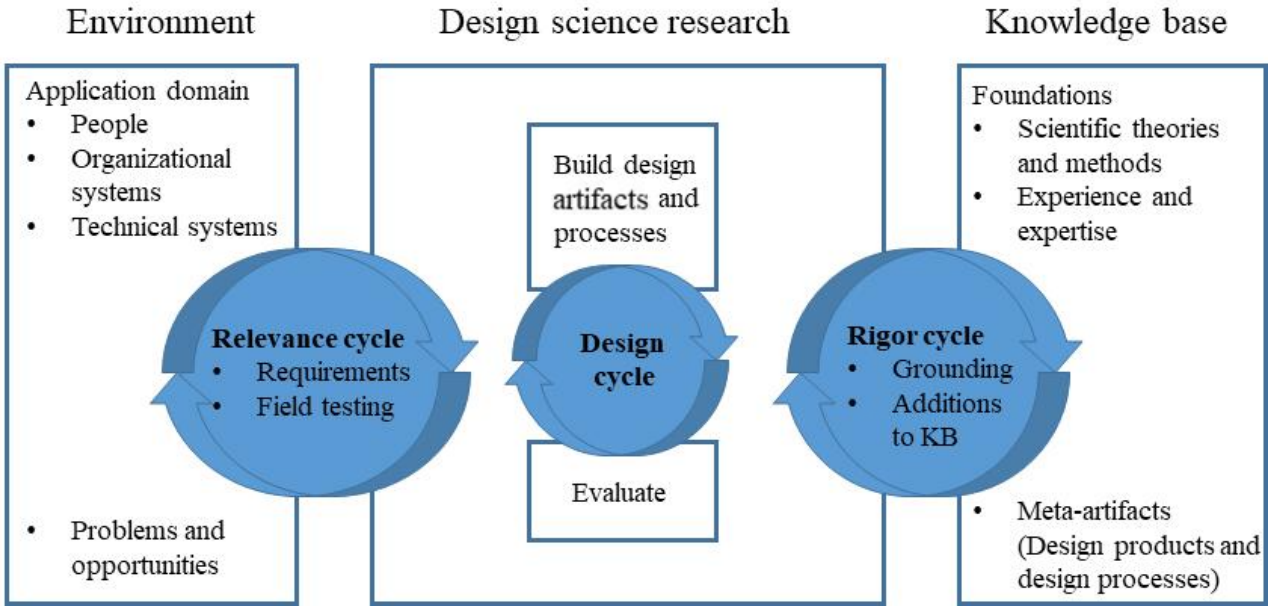
Language and Cultural Adaptation

The adaptation of iConquerFear to TG-iConquerFear was preceded by a draft translation and cultural adaptation of all written material from iConquerFear by a professional translator with experience in the psychiatric setting (Multimedia Appendix 1). This Danish draft was then built into an existing web-based treatment platform made available by the Department for Functional Disorders at Aarhus University Hospital in Denmark. The design of the Danish platform was comparable to that of iConquerFear. When needed, new technical features were programmed to reflect the intervention treatment content of iConquerFear.

Framework

A participatory design approach, guided by the Information System research framework [42], was used in the adaptation process. The Information System research framework urges end users' inclusion and active engagement in designing and evaluating information systems. The framework consists of 3 overarching user participatory design cycles: The relevance cycle determines end user requirements; the design cycle involves prototype development and evaluation; the rigor cycle focuses on assessing "past knowledge" from the knowledge base (KB) and underpinning theories (Figure 1) [42].

Figure 1. The Information System research framework. KB: knowledge base.



Adaptation Process

At each stage of adaptation, the intervention was reviewed by a multidisciplinary research team (8 members), comprised of: an oncologist specializing in CRC, a health psychologist with expertise in developing guided online interventions, one of the iConquerFear developers, 2 psychologists specializing in anxiety-related online therapy (the therapists), a health researcher with expertise in psycho-oncology, and 2 survivors of CRC.

Relevance Cycle

First, information related to the adapted intervention's relevance were gathered from the environment. Three consumer representatives (community partners from the Danish Bowel Cancer Association and the Association for Late Effects After Cancer), and 4 people with lived experience (survivors of CRC) were consulted for problem definition and justification of the interventions' relevance, including need and potential challenges. Within the same two 1-hour focus groups, the main elements from the iConquerFear intervention were presented to explore views on whether the online platform would be relevant in addressing survivors of CRC needs and how to promote engagement. The challenges raised in these interviews were validated with existing literature on online intervention engagement. The environment was revisited twice during internal and external field testing.

Rigor Cycle

Existing knowledge from the KB consisted mainly of expertise and experience from the development [26] and piloting of iConquerFear [28], which was rigorously developed based on the ConquerFear therapy manual [43] and iterative user feedback. This knowledge was complemented by feedback on the iConquerFear program from the TG-iConquerFear research team. Research team members evaluated iConquerFear content to assess suitability for survivors of CRC and the therapist-guided format. Feedback was collected via email or shared during live meetings. A selected group of research team members reviewed all aspects of the modules, including exercises, text, images, graphics, examples, and videos. Group discussions were held to assess their relevance to survivors of CRC experiencing elevated FCR. The unique needs and challenges specific for survivors of CRC were also deliberated, playing a crucial role in making intervention content more personal and relatable. The core therapeutic concept of iConquerFear, including general structure, therapeutic principles, and key goals remained unaltered in TG-iConquerFear.

Design Cycle

Insights added through the relevance cycle and rigor cycle contributed to the design science research consisting of implementation of all knowledge and suggestions into iConquerFear. The loop in the design cycle was between members of the research team and 3 software designers. Multiple iterations of the design cycle were conducted before internally field-testing TG-iConquerFear version 1 in the environment as part of a further relevance cycle. The 3 cycles allowed for an iterative process resulting in a second version, which was field-tested externally.

Field Testing

During both internal and external field testing, the intervention was used as intended based on the original manual from PoCoG (Psycho-Oncology Co-Operative Research Group) in Australia, with therapist guidance provided over a span of 10 weeks. The amount of therapist-guidance was measured by assessing the quality, quantity and length of messages exchanged between therapist and participant in each module. Every participant had a designated personal therapist and messages were answered within 3 working days. As the main focus of the guidance was to increase engagement and adherence, the substance of the guidance was not predetermined or restricted, and no limits were established concerning frequency of communication. It was planned that there would be communication between participant and therapist at least once a week. Both therapist and participant could initiate communication. Specific tasks for the therapist included welcoming the participant, addressing

inquiries regarding content and tools, providing feedback on exercises within the program, and motivating engagement and adherence.

Internal Field Testing

The internal field testing was performed within the research team. The 2 survivors of CRC were test-participants and the 2 therapists, who have extensive experience in online therapy, provided the guidance. Both the survivors of CRC and the therapists gave written feedback on various feasibility measures, including usability, adherence, acceptability, and safety after each module and at the end of the intervention.

External Field Testing

For the external field testing, interested volunteers from the bowel cancer association were informed about the project by telephone by the primary investigator and subsequently screened for eligibility via an online questionnaire sent directly to their digital citizen mailbox (used for communication between citizens and public authorities in Denmark). Volunteers were eligible if they were aged 18 years or older, had completed surgery for CRC with curative intent, were without sign of recurrence, and gave electronic informed consent. A minimum Fear of Cancer Recurrence Inventory–Short Form score of 13, indicating moderate or higher FCR levels [44], was also required. Volunteers were excluded if they self-reported clinical levels of depression, psychotic illness, or abuse of alcohol or drugs. Volunteer participants were given a unique link to the online platform of TG-iConquerFear. The guidance was performed by the same 2 therapists from the research team. Participants and therapists were encouraged to provide written feedback to the primary investigator on usefulness and suggestions for improvement after completing each module, and at the end of the intervention. This study was approved by the Regional Research Ethics Committee of Southern Denmark (S—20190061).

Results

TG-iConquerFear Version 1

During the initial relevance cycle, group interviews with representatives from the environment (consumer representatives and survivors of CRC) justified adapting iConquerFear to better engage prospective participants. Identified challenges included concerns about the complexity of pages overloaded with text (“You need to get to the point faster”), relevance of certain elements (such as sunscreen and breast palpation; “that just annoys me”), videos featuring only women (“seems like something only women have?”), and assessing further support if needed. “… Being on your own” was a major concern, and given that a large portion of end users are expected to be used, the focus group participants favored asynchronous communication. Suggestions for adaptations from the KB were either general or focused on 2 key recommendations: enhancing personal and relatable content, and adding guidance. Suggestions for adaptations from the research team centered on how to integrate therapist guidance, drawing from experience with eHealth interventions targeting health anxiety, and how to tailor hand-outs to address the specific needs of survivors of CRC, particularly regarding follow-up and late effects. These suggestions served as guidance for the design cycle, during which the adapted TG-iConquerFear version 1 was crafted. The specific adaptations made in response to these suggestions are outlined in Figure 2.

TG-iConquerFear version 1 then progressed to the relevance cycle, where it underwent internal field testing in the environment.

Figure 2. Specific adaptations made in response to suggestions from the environment and the knowledge base. CRC: colorectal cancer; FCR: fear of cancer recurrence.

Adaptions made in response to general suggestions:

- A forewarning about the difficulty of the attention training exercise was implemented.
- Clear links to additional support were added.
- The "How to" navigation video was replaced with a short descriptive text.
- Tailored automatic feedback was delivered more smoothly with fewer clicks.
- The text versus visual content balance was tipped toward more images.
- Measuring FCR was reduced from 5 times to twice during the 10 weeks of intervention.
- Emphasis was directed towards refining exercises and tools.
- Sections featuring nonessential descriptive text were succinctly edited.

Adaption made to enhance "personal and relatable" content:

- A male consumer consultant was added (65 years old).
- The mood of people appearing on the images was more representative for survivors with severe FCR.
- Pictures representing sex and age of CRCS were chosen.
- All content unrelated to CRC, such as advises on sunscreen use and instructions for breast self-examinations, was revised.
- Examples were made relevant and manageable to survivors of colorectal cancer.
- Existing handouts were modified to target Danish survivors of colorectal cancer (especially the handout on cancer follow-up).
- New handouts concerning late effects of cancer treatment and the Danish Colorectal Cancer Screening Program were formulated.

Adaptions made to add therapist guidance:

- A recognizable message-logo in the upper right corner on the dashboard was added.
- A securely encrypted message system for written communication that could gather and save all messages up to 6 months after intervention was added.
- Information pages were updated to inform about the collaboration with the therapist and how to be in contact.
- All "save" buttons in relation to exercises were changed to "send" buttons.

Internal Field Testing

The outcomes from the internal field testing are presented in Table 2. The feedback was presented to the research team, who determined that a second design cycle was necessary. Adjustments were made to TG-iConquerFear version 1 (last column in Table 2), leading to TG-iConquerFear version 2.

Table . Outcomes from internal field testing and adjustments.

Feasibility measure and feedback from end users		Adjustments
Usability		
	"It has proven to be a barrier for me that the system cannot be accessed via a smartphone. In an already busy daily life, I repeatedly find that I do not sit down at my PC." [Female participant, aged 51 years]	The intervention was adjusted to enable easier access on smart phone and iPad.
	"It takes really long time to figure out how far the participants are within the program, and if they had made any new exercises since last therapist log-in." [Female therapist, aged 38 years]	A therapist-monitored control panel with information on all active participants within treatment, including registration of activity for each participant, and expected date for completion of the program was added.
Usability of the asynchronous communication		
	"In many ways, it's easier to sit here and write with you than if we were face to face - I like that I have the opportunity to write something, consider, rephrase, etc - or just write freely in a flood of 'unloading,' depending on what I need on that day." [Female participant, aged 51 years]	No adjustments
	"For me as a therapist, asynchronous or delayed communication between me and the patient, means that I don't have to schedule specific agreed-upon sessions with patients… Additionally, I can take my time to consider the responses I give to patients. Sometimes, in face-to-face interactions, it can be challenging to find the right words or consider the right way to challenge the patient in the moment. Asynchronous communication with the patients makes my work less stressful and more flexible." [Female therapist, aged 48 years]	No adjustments
Adherence		
	"We need a clear indication from the participants on whether or not they have been working with the tools and find them useful." [Female therapist, aged 38 years]	In each module, two reflective questions with tailored feedback were added to monitor if the participants had engaged with the exercises of the previous module, and if and how the exercises had been helpful.
Acceptability		
	"The value-based module is too short for 14 days of training, and it is not clear how the participant should work with specific goals that are in line with their values. This results in a rather quick completion of the module and the participants state rather vague and abstract goals without a clear indication of when reaching the goal." [Female therapist, aged 48 years]	A lighthouse metaphor was added to explain values, see Multimedia Appendix 2, for the full formulation.
	"I find especially the first exercises (ref: the value clarification exercise) inadequately explained. For academics with a background in social sciences, the explanations are not so difficult to interpret, but they probably make up the smallest part of the target audience, which is likely more composed of older individuals from all social strata. Among them, there may be many who have difficulty benefiting from this module if they are not further guided." [Male participant, aged 67 years]	Information on the value-clarification exercise was made more concrete so that the program itself was able to guide the participant through the exercises leading the therapist to stand back and support and evaluate.
Safety		

Feasibility measure and feedback from end users		Adjustments
	"I hesitated to fully engage in this digital treatment. I needed my therapist to ensure confidentiality." [Female participant, aged 51 years]	A paragraph on confidentiality was added in the introduction.

TG-iConquerFear Version 2

Following the adjustments from the first relevance cycle, the second design cycle aimed to refine TG-iConquerFear version 1 further. Key modifications, as detailed in Table 2, were implemented to address user feedback and enhance the intervention's feasibility. This second version underwent external field testing within the environment.

External Field Testing

The external field testing took place from February to July 2022 at the Clinic for Functional Disorders at Aarhus University Hospital in Denmark. It involved 5 volunteers from the Danish Bowel Cancer Association. All 5 were survivors of colon cancer and most were female (n=4), married (n=4), and employed (n=4). Mean age was 54 (SD 10.2; range 42-71) years and average time since diagnosis were 2.3 (SD 1.6) years (8 months to 5 years).

Four test-participants completed all 5 modules, while 1 test-participant did not complete module 2. The amount of therapist guidance averaged 15.2 (range 12 - 23) messages per participant, equating to 2.7 (range 2 - 3.8) messages per module. The mean length of a message was 196.8 (range 12 - 745) words. The messages addressed topics such as welcoming participants, elaborating on goal setting (module 1), integrating attention training and detached mindfulness into daily routines (modules 2 and 3), and supporting participants in challenging unhelpful metacognitions. No messages were prompted by misunderstandings of the intervention content or technical issues. Four out of 5 test-participants accessed the intervention via smart phone or tablet. No test-participant reported troubles with smart phone access, and no comments related to the description of the values-clarification exercise, of which both were adjusted after the internal field testing. Outcomes are presented in Textbox 1.

Textbox 1. Outcomes from external field testing.

Positive feedback from test-participants

- "… I am slowly returning to life where cancer doesn't occupy as much space. Not because it's forgotten, but more integrated. The tools in your investigation were really useful." [Male, aged 71 years]
- "I use detached mindfulness regularly. Especially if I'm not occupied with something else at the moment, my mind tends to circle around cancer, and I find that the method helps to stop that." [Female, aged 43 years]
- "I am incredibly grateful that I was allowed to participate in this program. Even with the bumps along the way, it has been a huge help. In many ways, it's easier to sit here and write with you than if we were face to face - I like that I have the opportunity to write something, consider, rephrase, etc - or just write freely in a flood of 'unloading,' depending on what I need on that day... Gold!" [Female, aged 51 years]
- "I feel so lucky being part of this program. While I sit here and write, I hear the birds singing. And enjoy it. I live my life fully. I do not postpone things. I know there are late effects, but I will not have them ruin my mood…" [Female, aged 55 years]

Constructive feedback from test-participants

- "It could also be good if a notification could be sent in e-boks when there is a new message from my therapist." [Female, aged 49 years]
- "… There should be some form of notification when there is new activity on the platform." [Male, aged 71 years]
- "It could be good if one could see how far they are in the program - if the round circles on the front page could possibly change color when a module is completed. I personally know how difficult it is to remember such things when there are several days in between." [Female, aged 49 years]
- "I have copied my action plan step by step so that I can refer to it if I 'forget' it at times. Is it possible to have it compiled for printing at the end of the program? - good to hang up where it is visible in everyday life." [Female, aged 55 years]
- "…so that one can click into what concerns oneself - sometimes it can be quite depressing to read through a long list of late effects - it's not certain that one has them all oneself, but one is reminded of one's vulnerability. Possibly bubbles on a page under 'the box' with 'fatigue,' 'sleep problems,' etc…" [Female, aged 51 years]

The results were presented to the research team in April 2023. The research team deemed TG-iConquerFear version 2 as satisfactory. The minor suggestions from the external field testing were not implemented due to time and resource limitations but will be considered for future updates.

Discussion

Principal Findings

We adapted a self-guided eHealth intervention for FCR into a tailored therapist-guided eHealth intervention aimed at survivors of CRC guided by the Information System research framework. The process was overseen by a multidisciplinary research team including 2 survivors of CRC. Based on knowledge and

experience in this team, both minor and major adaptations were made. The addition of an embedded message system facilitating therapist-participant communication was the primary change in the iConquerFear program. However, during field testing it became evident that additional content (eg, the Lighthouse Metaphor or reflective questions) was necessary to optimize adherence and facilitate guidance. Consequently, TG-iConquerFear is more resource demanding than iConquerFear, and we will evaluate the efficacy and cost-effectiveness of these choices, which may limit scalability (ClinicalTrials.gov NCT04287218).

The smooth adaptation of iConquerFear into TG-iConquerFear was greatly facilitated by the extensive research led by the Australian PoCoG evaluating ConquerFear and iConquerFear [26-28,45]. This prior work served as a valuable foundation, allowing us to expedite the launch of the randomized controlled trial, as comprehensive testing of intervention content had already been conducted. Below, we discuss considerations related to the two key requests that emerged from pilot testing of iConquerFear [26] which we addressed in the first round of adaptation to TG-iConquerFear version 1.

Considerations on How to Enhance "Personal and Relatable" Properties

Some iConquerFear pilot test participants [26] indicated that certain content within the program felt impersonal or unrelatable. Two main directions were considered to promote engagement by tailoring the intervention [46]: targeting a specific gender (men) or targeting a single cancer type (CRC). Choosing a gender-based approach simplifies the selection of colors, images, patients featured in videos, and examples, aiming for enhanced engagement among participants of a specific gender. However, several modules include content pertaining to specific cancer types, for instance, living in alignment with one's values, where focusing on a specific cancer type such as CRC allows for framing personal examples closely tied to everyday life such as "what if my ostomy leaks?" Similarly, cancer type plays a defining role in shaping the cancer follow-up program, advisory elements, and the identification of alarm symptoms to be monitored. These elements do not apply universally to a specific gender, and one could argue that cancer type is a more defining factor in determining the specific needs reported by cancer survivors, rather than gender alone [47]. For instance, a female survivors of CRC is likely to have far more in common with a male survivor of CRC than a female survivor of breast cancer. By considering the cancer type and adjusting relevant advisory elements, the intervention was customized to meet the unique needs of individuals based on their specific cancer experiences. This tailored approach balances scalability and engagement by ensuring that the content remains relevant, relatable, and meaningful to participants, hopefully enhancing the engagement and effectiveness of the TG-iConquerFear intervention. No end user feedback was received regarding impersonal or unrelatable content after adaptation.

A third option involves the creation of distinct intervention versions with personalized content based on demographic factors such as age, gender, cancer type, or needs, thereby presenting only pertinent content to individual participants although this approach risks relevant content being excluded due to individual differences in patient needs and how they report them. However, the software used for our intervention was incapable of accommodating such customization. Furthermore, implementing this approach would have necessitated a substantial allocation of time and resources beyond our available capacity. Nonetheless, this avenue remains an intriguing prospect for future research endeavors, warranting further exploration and consideration.

Consideration on How to Add Therapist Guidance

Some participants in the iConquerFear pilot expressed a desire for personal contact with a researcher or clinician [26], which was seen as a potential way to motivate engagement with and potential benefit from the 8 - 10 week duration of the program. This is in line with a recent meta-review [46]. The potential benefit of adding guidance was also noted by researchers from the cancer recurrence self-help training trial, who found no effect of CBT-based online self-help training [48]. The choice of asynchronous communication was supported by end users and therapists, and the amount of guidance was consistent through the intervention. Reflective questions were incorporated into TG-iConquerFear version 1 at the therapists' request after each module to monitor adherence and perceived usefulness. Participants received automated tailored feedback momentarily, in accordance with recommendations from the literature [46,49], allowing them to seamlessly continue with the intervention, and these reflective questions facilitated a dialogue between participant and therapist regarding the usefulness of the module content, and strategies to enhance participant outcomes.

Other Strategies to Enhance Adherence

Easy Access

Difficulties in integrating the intervention into daily life activities, as exemplified by an internal test-participant, have also been reported in the literature as a barrier for adoption and adherence when targeting fatigue [50]. This issue is closely related to the barrier of perceived time burden associated with participating in digital interventions [46]. Given that only minor changes were required to adapt the TG-iConquerFear version 1 to fit a smart-phone layout, this aspect was prioritized.

Promoting Competence

In TG-iConquerFear version 1, the value-based model was inadequately explained, leading to a lack of self-competence reported by an internal test-participant. Competence can be promoted by encouraging users to set graded goals with smaller achievable steps, thereby increasing confidence through experiences of success as described in the person-based approach to intervention development [8]. Adjustments were made to clearly outline how to work with goals and values to fully use the module's potential. Additionally, tailored feedback was provided to congratulate success in goal achievement and offer remedial advice if goals were not attained [8].

Reminders

Technology-based reminders (eg, prompts) have the potential to promote engagement with digital interventions [1,46], particularly when participants choose to receive them [51]. Since

2 external test-participants explicitly suggested reminders, this could be considered for future updates. However, it should be noted that no studies in these reviews specifically targeted FCR, and the effect of distributing reminders, which could potentially trigger FCR, in this patient population remains unknown.

The TG-iConquerFear version 2 was deemed ready despite further suggestions for improvement, and in May 2023, a randomized controlled trial investigating TG-iConquerFear versus augmented treatment as usual was launched [52]. The suggestions, though noted, were seen as relatively minor, and addressing them would have required a significant allocation of resources disproportionate to their perceived impact. Given that each cycle typically generates some feedback, the multidisciplinary research team convened to make a decision regarding the intervention's readiness for the randomized controlled trial.

Strengths and Limitations

The process of adaptation was guided by an existing framework for information system research. The framework allows for multiple iterative processes, which were needed in this study. It is a strength of this study that the KB comprised insights from multiple sources. The therapists performing the guidance were experienced in delivering anxiety-related online therapy, and the software designers facilitating the adaptation process in the design cycle had expertise in health care software development. The field testing participants were relatively newly diagnosed and the females were younger than the average female patient with colon cancer. Changes due to their comments may have slightly shifted the focus of the final version of the intervention to address a somewhat younger audience. However, as FCR is more prevalent in younger than older survivors [53], and the incidence of CRC in younger patients continues to increase [54], this may be an advantage. Furthermore, we only included 5 participants in the external field testing, but all 5 participants completed all or almost all modules. This study aimed to test the adaptation of an already feasible and pilot tested intervention, which is why the small sample size was accepted. No patients with rectal cancer were included in the test group. We have no reasons to believe that their feedback would be any different as needs and late effects are comparable [55,56].

Clinical Implications

This study demonstrates a process to adapt a self-guided eHealth intervention into a tailored therapist-guided eHealth intervention, which could help efficiently address survivorship concerns such as FCR. Guided eHealth interventions are effective supplements to face-to-face intervention and could be a valuable step in a stepped-care model, where self-guided interventions might be the first step for survivors with mild symptoms [57,58]. Guided interventions require some level of involvement of health personnel, but can significantly increase the accessibility and reach of psychological interventions while promoting engagement and efficacy [14]. Determining the optimal dose of guidance for the severity of symptoms is needed [29].

Future Directions

The quality and content of therapist guidance will be assessed, alongside the investigation of TG-iConquerFear's efficacy in a larger, more diverse population across Denmark [52]. Additionally, further evaluation of TG-iConquerFear's performance across various devices, including smartphones or iPhone, tablets or iPads, and computers, will help refine its usability and ensure compatibility across platforms, thereby increasing scalability. Future studies should investigate the usability of eHealth interventions such as TG-iConquerFear for patients experiencing late effects such as fatigue and peripheral neuropathy, particularly in relation to content load and the touchscreen-based exercises. Finally, linking TG-iConquerFear with health apps or smartwatches could provide valuable insights into the usage of the intervention combined with, for example, participant activity levels and heart rate, allowing for an evaluation of the interplay between intervention content and bio-physiological and behavioral parameters.

Conclusion

It is possible to successfully adapt a self-guided eHealth intervention for people with FCR into a tailored therapist-guided intervention. This paper provides an overview of the process and lists considerations based on experience. The described procedure can be used in similar settings where the wish is to incorporate guidance in an existing self-guided eHealth intervention.

Acknowledgments

This study has been possible to conduct due to major support from the Department of Functional Disorders at Aarhus University Hospital. Our thanks to programmers Philip Riley, Nicolaj Knudsen, and Tobias Christensen and thanks to therapists Mie Wiklund, MSc, and Tina Carstensen. Our thanks to Harald Hammershøi and OPEN, Odense Patient Data Explorative Network, Odense University Hospital, to Alan Hevner, PhD, for copyright permission, and a special thanks to the 7 volunteer participants from The Danish Bowel Cancer Association. This study was supported by the Danish Cancer Society (grant R303-A17152), Trygfonden (grant 146250), Dagmar Marshalls Foundation, The Region of Southern Denmark, and Lillebaelt Hospital.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

In the preparation of this paper, ChatGPT (OpenAI) was used to refine and enhance the clarity of the English language. The artificial intelligence (AI) was specifically used for linguistic and grammatical improvements. No AI-generated content was used

to generate original research ideas, interpret data, or contribute substantively to the intellectual content of this study. The final paper was critically reviewed and approved by all authors to ensure accuracy and alignment with the intended research findings.

Authors' Contributions

JDL, AS, LHJ, and LF contributed to conceptualization and funding acquisition. JDL, AS, TBWC, LHJ, and LF participated in data curation and formal analysis. JDL, TBWC, and LF conducted the research and investigation process. JDL and LF were responsible for project administration. LF was responsible for software development. LF and LHJ worked on supervision and validation. JDL, AS, and LF handled visualization. JDL and AS wrote the first draft. All authors contributed to the design of the methodology, participated in the provision of study materials, and provided a critical review of the final draft before submission and during the publication stages.

Conflicts of Interest

AS, AB and BK hold the license with Blue Note for iConquerFear. The rest of the authors have no conflicts of interest.

Abstract

This Viewpoint proposes a robust framework for developing a medical chatbot dedicated to radiotherapy education, emphasizing accuracy, reliability, privacy, ethics, and future innovations. By analyzing existing research, the framework evaluates chatbot performance and identifies challenges such as content accuracy, bias, and system integration. The findings highlight opportunities for advancements in natural language processing, personalized learning, and immersive technologies. When designed with a focus on ethical standards and reliability, large language model–based chatbots could significantly impact radiotherapy education and health care delivery, positioning them as valuable tools for future developments in medical education globally.

(JMIR Cancer 2025;11:e66633) doi:10.2196/66633

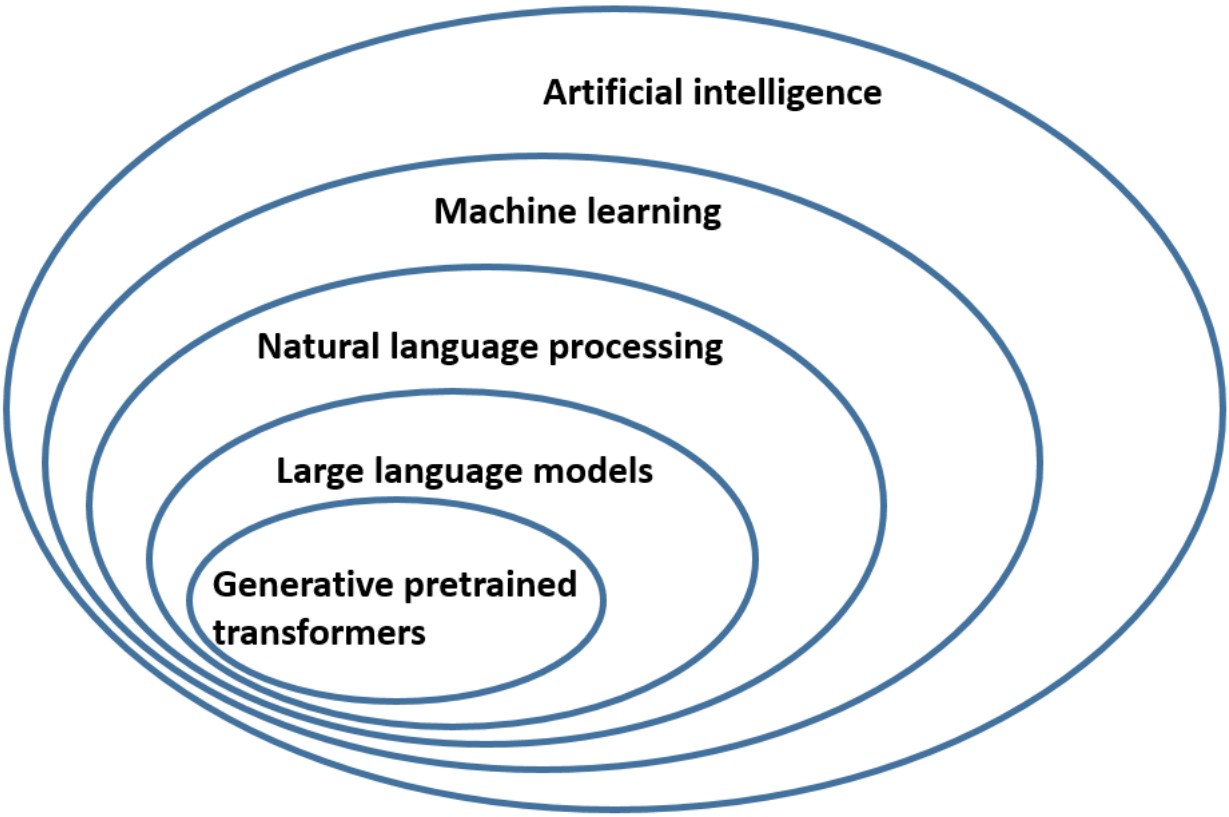
KEYWORDS

artificial intelligence; AI; AI in medical education; radiotherapy chatbot; large language models; LLMs; medical chatbots; health care AI; ethical AI in health care; personalized learning; natural language processing; NLP; radiotherapy education; AI-driven learning tools

Introduction

The integration of artificial intelligence (AI) in health care has rapidly evolved, with large language models (LLMs) such as ChatGPT at the forefront of this change [1-3]. These models, trained on vast datasets, have shown remarkable potential in various domains, including health care, by understanding and generating human-like text [4]. Unlike traditional rule-based chatbots, LLM-based systems can engage in complex conversations, answer medical queries, assist in symptom checking, and provide personalized health advice [5]. This capability is largely due to their training on extensive medical literature and patient data [6], which allow them to access and synthesize information in ways that were previously unimaginable [7]. The relationship between AI, machine learning, natural language processing (NLP), LLMs, and generative pretrained transformers is shown in Figure 1.

Figure 1. Relationships between key concepts in artificial intelligence, including machine learning, natural language processing, large language models, and generative pretrained transformers.



The deployment of LLM-based chatbots in health care is driven by the growing demand for accessible information and the need to alleviate the burden on health care systems [8]. These chatbots operate 24-7, providing immediate responses to patient inquiries; enhancing patient education; and supporting telemedicine, mental health, and chronic disease management [9-13]. However, their integration also presents challenges, such as ensuring the accuracy of information, avoiding biased responses, and safeguarding patient privacy [14].

Radiotherapy is a specialized field within oncology that demands precise and accurate information for effective treatment planning and education [15]. Unlike general medical topics, it involves complex concepts such as dose distribution, radiation physics, and the biological effects of ionizing radiation. Inaccurate information can lead to severe consequences, including inadequate treatment or harm to patients, making reliable dissemination critical [16].

Radiotherapy education serves 3 primary groups: patients, radiation staff, and the public. Patients require clear and empathetic guidance to understand their treatment, manage expectations, and make informed decisions, improving adherence and outcomes [17]. For health care professionals, education focuses on advanced training in treatment planning, safety protocols, and technological advancements to ensure high standards of care [18]. Public education, meanwhile, aims to demystify radiotherapy, reduce stigma, and promote awareness of its benefits, fostering trust in cancer treatment systems [19]. Providing accurate and ethically shared information across these groups is vital to ensure safety, informed decision-making, and the effective application of radiotherapy.

This Viewpoint explores a framework for integrating LLM-based chatbots in radiotherapy education, designed to ensure accuracy, reliability, and ethical integrity. The framework incorporates 3 key components: a controlled and curated database, a robust quality control system, and continuous monitoring mechanisms [20]. The curated database includes only verified and relevant medical literature and patient data, ensuring that the chatbot's responses are accurate and up to date. The quality control system involves regular audits, database updates, and algorithms to identify and correct inaccuracies or biases. Continuous monitoring tracks the chatbot's performance, enabling real-time adjustments and improvements [20]. By addressing challenges such as misinformation and patient privacy, this framework establishes a trustworthy and effective tool in radiotherapy education. Furthermore, it sets a new standard for AI-driven tools in specialized health care education by focusing on accuracy, reliability, and ethical integrity [20,21].

Ultimately, the ethical design and use of LLM-based medical chatbots involve collective efforts from policy makers and governments to maximize benefits while mitigating risks such as data privacy breaches and algorithmic bias [22].

Current State of Medical Chatbots

Development and Implementation of LLM-Based Chatbots

The development and implementation of LLM-based chatbots in health care have marked a significant evolution from earlier chatbot technologies. Unlike traditional rule-based systems that operated within a limited scope, LLM-based chatbots such as those powered by OpenAI's ChatGPT have demonstrated the ability to understand and generate natural language with remarkable fluency and contextual awareness [23]. This advancement has led to a broad range of applications in health care, where these chatbots are being used to support patient interaction, provide medical information, assist with diagnosis, and streamline administrative tasks. A review of current LLM-based medical chatbots reveals a diversity of functionalities tailored to various health care needs [24]. One prominent example is ChatGPT itself, which has been adapted for use in several health care settings. ChatGPT can engage in detailed conversations with patients, answering questions about symptoms, explaining medical conditions, and providing guidance on the next steps in care. Its ability to understand nuanced queries and generate contextually appropriate responses has made it a valuable tool for preliminary consultations, particularly in telemedicine where immediate access to health care professionals may be limited [25]. Another notable use case is the deployment of LLM-based chatbots for chronic disease management [13]. These chatbots are designed to assist patients in managing conditions such as diabetes, hypertension, and asthma by providing personalized advice, reminding them to take medication, and offering lifestyle recommendations based on their medical history and real-time data inputs; for example, some LLM-based chatbots integrate with wearable devices to monitor patient vitals and deliver timely interventions, improving adherence to treatment plans and potentially reducing the need for emergency care [26]. In addition to patient-facing applications, LLM-based chatbots have been implemented to support health care professionals. These chatbots can function as web-based assistants, helping clinicians with tasks such as documentation, coding, and accessing up-to-date medical literature; for instance, some systems are designed to summarize patient records, extract relevant clinical information, and even suggest differential diagnoses, thereby enhancing the efficiency of clinical workflows [27]. In research settings, LLM-based chatbots are used to assist in data analysis, generate research hypotheses, and streamline the process of literature review by quickly summarizing large volumes of academic papers.

The flexibility and scalability of LLM-based chatbots have also enabled their adoption in mental health support. Chatbots such as Woebot [28] and Wysa [29] use LLMs to engage in therapeutic conversations, offering cognitive behavioral therapy techniques, mood tracking, and crisis intervention. These tools provide users with immediate access to mental health support, which is particularly valuable in regions with limited access to mental health professionals or during times when in-person therapy is not feasible. While the functionalities and use cases of LLM-based chatbots in health care are vast, the implementation of these tools is not without challenges. Ensuring the accuracy and reliability of the information provided by these chatbots is crucial, especially in scenarios where they are used for diagnosis or treatment recommendations. Moreover, the ethical implications of using AI in patient care, particularly in terms of data privacy and informed consent, require careful consideration [30]. Despite these challenges, the ongoing development and refinement of LLM-based chatbots continue to push the boundaries of what is possible in health care, offering promising avenues for improving patient care, enhancing health care delivery, and supporting the work of health care professionals.

Strengths and Limitations

The implementation of LLM-based chatbots in health care, particularly in specialized fields such as radiotherapy, offers both significant strengths and notable limitations. As these advanced AI-driven tools become more integrated into medical practice, it is crucial to understand their advantages and challenges to optimize their use while mitigating potential risks.

Strengths

One of the primary strengths of LLM-based chatbots is their ability to process and generate natural language with a high degree of fluency and context sensitivity. This capability allows them to engage in detailed and nuanced conversations with both patients and health care professionals, making complex medical information more accessible and understandable. In radiotherapy, where patients often face intricate treatment regimens and technical jargon, an LLM-based chatbot can break down complex concepts into simpler terms, enhancing patient comprehension and engagement. This improved communication can lead to better patient adherence to treatment plans and a more informed patient population, which is essential for the success of radiotherapy [17]. Another significant advantage of LLM-based chatbots is their scalability and availability. These chatbots can provide consistent, round-the-clock support, making them particularly valuable in settings where access to health care professionals may be limited. In radiotherapy, where timely information is critical, a chatbot can offer immediate answers to patient queries, provide pretreatment education, and even guide patients through posttreatment care [31]. This constant availability helps reduce the burden on health care providers, allowing them to focus on more complex cases and personalized care. Furthermore, LLM-based chatbots can be regularly updated with the latest medical research and guidelines, ensuring that the information they provide remains current. In a field such as radiotherapy, where treatment protocols and technologies are continuously evolving, this ability to quickly incorporate new knowledge is a significant strength. It enables the chatbot to serve as a reliable resource for both patients and health care professionals, supporting evidence-based practice and reducing the likelihood of outdated or incorrect information being disseminated [32].

Limitations

Despite their strengths, LLM-based chatbots also present several limitations, particularly in specialized medical fields such as radiotherapy. One of the most pressing challenges is ensuring the accuracy and reliability of the information provided by these

chatbots [20]. While LLMs can generate text that seems plausible and coherent, they may occasionally produce incorrect or misleading information, especially when faced with highly specialized or uncommon queries. In radiotherapy, where precise details about treatment options, dosimetry, and potential side effects are crucial, even small inaccuracies can have serious consequences for patient care. Another limitation is the potential for LLM-based chatbots to oversimplify complex medical information. While simplifying language is essential for patient comprehension, there is a risk that crucial nuances may be lost, leading to misunderstandings or incomplete knowledge. In radiotherapy, where patients need to fully understand their treatment options, the risks, and the benefits, this oversimplification could impact their ability to make informed decisions [3]. Ethical considerations also pose significant challenges for the implementation of LLM-based chatbots in health care. Issues related to patient privacy, data security, and the potential for bias in the AI's responses are critical concerns. In radiotherapy, where patients are dealing with life-altering decisions and sensitive health information, ensuring that the chatbot operates within strict ethical guidelines is essential. There is also the challenge of maintaining transparency in how these chatbots operate and ensuring that patients are fully aware that they are interacting with an AI, not a human health care provider. Moreover, the reliance on LLM-based chatbots could potentially lead to an overdependence on AI at the expense of human interaction. In specialized fields such as radiotherapy, the human touch is often crucial for providing emotional support and addressing the psychosocial aspects of care. While chatbots can provide information and support, they cannot replace the empathy and personalized care that human health care providers offer [33].

Summary

Table 1 summarizes the key advantages and challenges associated with the deployment of LLM-based chatbots in health care, particularly in the context of radiotherapy, where precision, ethical considerations, and human interaction are critical. It is seen that while LLM-based chatbots offer significant strengths, including enhanced communication, scalability, and up-to-date information, they also come with limitations that must be carefully managed. In specialized fields such as radiotherapy, where there is a need for compassion in addition to accurate information as the users may be in stressful situations, the deployment of these chatbots requires a well–thought-out framework that maximizes their benefits while addressing their inherent challenges.

Table 1. Strengths and limitations of large language model–based chatbots in specialized medical fields such as radiotherapy.

Aspect	Strengths	Limitations
Natural language processing	• Fluent, context-aware communication • Simplifies complex medical information for better patient understanding	• Risk of generating incorrect or misleading information • Potential oversimplification of complex concepts, leading to misunderstandings
Availability and scalability	• 24-7 availability for patient and health care provider support • Reduces the burden on health care professionals by handling routine queries	• Overdependence on AI[a] could reduce human interaction, which is vital in emotionally supportive care, particularly in radiotherapy
Up-to-date information	• Can be regularly updated with the latest research and guidelines, ensuring that the information provided is current	• Challenges in maintaining the accuracy of specialized information, especially as new research emerges and medical knowledge evolves
Patient engagement	• Enhances patient education and engagement through personalized, accessible information • Supports informed decision-making in complex treatments	• Risk of inadequate personalization, potentially leading to generic advice that does not fully meet individual patient needs
Ethical considerations	• Can be programmed to follow ethical guidelines, ensuring responsible dissemination of medical information	• Issues related to patient privacy, data security, and AI bias • Potential lack of transparency in AI operations, affecting trust
Efficiency in health care	• Improves efficiency by assisting in documentation, coding, and access to medical literature for health care providers	• Dependency on chatbot accuracy for clinical tasks might introduce errors if the chatbot provides incorrect or incomplete information

[a]AI: artificial intelligence.

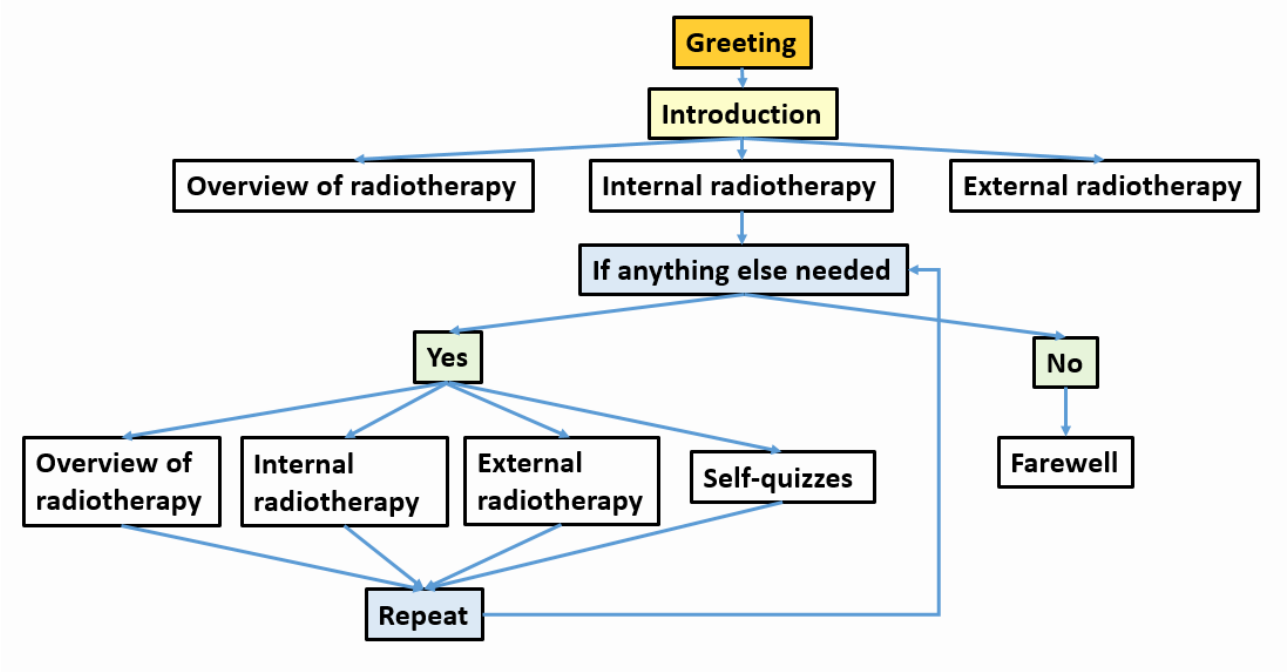
Impact on Patient Education and Health Care Delivery

Influence on Patient Education

LLM-based chatbots play a significant role in enhancing patient education by making complex medical information more accessible. In specialized fields such as radiotherapy, where patients must understand intricate treatment protocols and potential side effects, chatbots provide a valuable resource for simplifying and clarifying these concepts. By translating technical jargon into clear language, chatbots help patients grasp the fundamentals of their treatment, which can be crucial for their engagement and adherence. Moreover, chatbots can offer tailored educational content based on individual patient profiles; for example, a chatbot might provide specific information about

the type of radiotherapy a patient is receiving, potential side effects relevant to their case, and strategies for managing these side effects [31,34]. This personalized approach ensures that patients receive relevant information that directly pertains to their situation, enhancing their understanding and preparedness for their treatment journey. Figure 2 shows a typical dialogue flowchart for a chatbot in radiotherapy education.

Figure 2. Typical dialogue flowchart for a chatbot used in radiotherapy education.



Impact on Decision-Making

In addition to enhancing patient education, LLM-based chatbots significantly influence patient decision-making. By providing timely and accurate information, these tools empower patients to make informed choices about their treatment options; for instance, a chatbot can help patients compare different radiotherapy techniques, discuss the potential benefits and risks of each option, and address any concerns they may have. This support is especially valuable in radiotherapy, where patients often face complex decisions about their care [32]. The chatbot's ability to offer evidence-based information and answer questions in real time helps reduce uncertainty and anxiety, allowing patients to engage more effectively in their treatment planning. Furthermore, by facilitating a deeper understanding of their condition and treatment options, chatbots contribute to a more collaborative decision-making process between patients and their health care providers.

Enhancement of Health Care Delivery

The implementation of LLM-based chatbots also has a notable impact on the overall delivery of health care. These tools streamline administrative tasks, such as appointment scheduling, medication reminders, and follow-up care, thus freeing up health care professionals to focus on more complex patient interactions [35]. In radiotherapy, where treatment regimens are often intensive and require careful management, chatbots can help monitor patient progress, manage treatment schedules, and provide reminders for follow-up appointments or adherence to prescribed protocols. In addition, chatbots can assist in triaging patient queries, directing them to appropriate resources or health care professionals based on the nature of their concerns [36]. This efficient handling of inquiries helps ensure that patients receive timely and relevant support, which can improve their overall experience and satisfaction with their care.

Challenges in Deploying LLM-Based Medical Chatbots

Overview

Despite the promising advancements and benefits of LLM-based medical chatbots, their deployment in health care settings is accompanied by several significant challenges. These challenges span various critical areas, including the accuracy and reliability of the information provided, privacy and data security concerns, ethical considerations, and the potential for misinformation. Addressing these issues is essential to ensure that chatbots contribute positively to health care delivery while mitigating risks.

Accuracy and Reliability

Ensuring the accuracy and reliability of medical information provided by LLM-based chatbots is a critical challenge that affects their effectiveness and safety in health care settings. The complexity of medical knowledge and the rapid evolution of treatment protocols present significant hurdles in maintaining the precision of information delivered by these AI tools. One major challenge is the inherent nature of LLMs, which are trained on vast datasets that include a wide range of information sources. While this breadth of data allows chatbots to generate responses to a variety of queries, it also means that the information they provide can be inconsistent or outdated [37]. In the context of radiotherapy, where treatment guidelines and protocols are continually updated based on the latest research, ensuring that a chatbot reflects the most current and accurate

information is crucial. Failure to do so can result in the dissemination of outdated or incorrect treatment recommendations, potentially compromising patient safety [20].

In addition, LLM-based chatbots rely on pattern recognition and probabilistic inference rather than deep, context-specific understanding [38]. This approach can sometimes lead to the generation of plausible but inaccurate answers, especially when dealing with rare or complex medical scenarios; for example, a chatbot might provide general information about radiotherapy but struggle with specifics related to individual patient conditions or less common treatment modalities [4]. This limitation highlights the need for robust validation processes to ensure that the chatbot's responses are not only accurate but also relevant to the user's specific context. Another aspect of accuracy and reliability involves the management of the chatbot's knowledge base [39]. Regular updates and reviews are necessary to keep the information current and accurate. This process requires a continuous feedback loop from health care professionals who can assess and correct any inaccuracies or gaps in the information provided by the chatbot. Implementing such a system involves collaboration between AI developers and medical experts to ensure that the chatbot's responses align with the latest evidence-based practices. Moreover, there is a challenge in balancing the chatbot's ability to generate detailed responses with the need to provide clear and concise information [40]. Overly complex or technical explanations can be difficult for patients to understand, while overly simplified answers may omit critical details. Striking the right balance is essential to provide information that is both accurate and accessible to users with varying levels of medical knowledge.

Privacy and Data Security

Privacy and data security are paramount concerns when deploying LLM-based chatbots in health care, given the sensitive nature of patient information handled by these tools. Ensuring the protection of these data against unauthorized access and breaches is essential to maintaining patient trust and complying with regulatory requirements [19]. One of the primary challenges in safeguarding patient data involves ensuring compliance with privacy regulations such as the Health Insurance Portability and Accountability Act in the United States [41] or the General Data Protection Regulation in Europe [42]. These regulations mandate stringent measures for the collection, storage, and handling of personal health information. LLM-based chatbots must be designed to adhere to these regulations, incorporating robust data encryption methods, secure storage solutions, and strict access controls to protect sensitive patient information from breaches and unauthorized access. Data transmission security is another critical aspect. When chatbots interact with patients, the data exchanged—such as medical history, treatment details, and personal identifiers—must be encrypted to prevent interception by malicious actors. Implementing secure communication protocols, such as transport layer security, helps ensure that data transmitted between the chatbot and the user are protected from eavesdropping and tampering [43]. In addition, managing user consent and data use transparency is crucial for maintaining privacy. Patients must be informed about what data are being collected, how the data will be used, and their rights regarding their information. Clear consent mechanisms should be integrated into the chatbot's design, allowing users to provide informed consent before any data collection occurs. This transparency helps build trust and ensures that patients are aware of how their data are being handled.

Another challenge is ensuring that data anonymization and deidentification practices are effectively applied. Even when data are stored or processed for purposes such as improving chatbot performance or training new models, it is essential to anonymize the data to prevent the identification of individual patients. Proper anonymization techniques reduce the risk of sensitive information being exposed in case of a data breach. Moreover, continuous monitoring and auditing of the chatbot's security systems are necessary to identify and address potential vulnerabilities. Regular security assessments, including penetration testing and vulnerability scanning, help ensure that the chatbot's infrastructure remains resilient against emerging threats. Promptly addressing any identified weaknesses is crucial for maintaining the overall security of patient data.

Ethical Considerations

Overview

The deployment of LLM-based chatbots in health care raises several ethical dilemmas that must be carefully addressed to ensure the responsible and fair use of AI. Key ethical concerns include AI decision-making processes, transparency, and accountability, each of which plays a critical role in maintaining trust and integrity in health care interactions [44]. To address these concerns, transparency can be enhanced by developing clear documentation that explains the chatbot's decision-making processes, including data sources and logic. Bias detection and mitigation tools, such as fairness-aware algorithms, should be used to identify and correct biases in real time. Regular audits by independent third parties can ensure compliance with ethical standards.

User feedback mechanisms are essential for identifying and addressing ethical issues. Users should be able to report concerns or errors, which should be promptly reviewed and acted upon. In addition, clear guidelines for human oversight must be established, defining the roles of health care professionals in monitoring chatbot interactions. By incorporating these detailed suggestions, processes, and tools, we can better address ethical issues and promote the responsible use of AI in health care [18].

Long-Term Societal Impacts

The widespread adoption of ChatGPT and similar technologies could significantly reshape the job market, potentially leading to both job displacement and the creation of new opportunities, necessitating reskilling and upskilling programs to mitigate negative impacts. Moreover, AI technologies might exacerbate economic inequalities if their benefits are not equitably distributed, highlighting the need for policies that promote inclusive growth. The integration of AI into daily life could alter social interactions, reducing human-to-human contact and impacting social skills and relationships, thus requiring a balance between AI use and genuine human connection. These changes underscore the importance of robust ethical governance frameworks involving diverse stakeholders to ensure that AI development aligns with societal values and ethical principles,

addressing emerging challenges and opportunities through continuous dialogue and adaptive regulation.

AI Decision-Making

One of the central ethical issues is the decision-making capability of AI systems. Unlike human health care providers who can apply clinical judgment and empathy, LLM-based chatbots operate based on algorithms and data patterns [45]. This raises questions about the extent to which these systems can make ethical decisions, especially in complex or nuanced medical scenarios; for instance, while chatbots can provide general information and support, they may lack the ability to fully understand the context of a patient's situation or the ethical implications of certain recommendations [46]. Ensuring that AI-driven tools align with ethical guidelines and medical standards is essential to avoid potentially harmful outcomes.

Transparency

Transparency in AI decision-making is another critical ethical consideration. Patients and health care professionals need to understand how chatbots generate their responses and make recommendations. This includes clarity about the data sources and algorithms that drive the chatbot's behavior. Without transparency, there is a risk that users might overestimate the chatbot's capabilities or misinterpret its advice. Providing clear information about the chatbot's operational mechanisms helps build trust and allows users to make informed decisions about how to use the tool effectively [47]. Furthermore, transparency extends to the disclosure of limitations and potential biases inherent in the AI system. Chatbots are trained on datasets that may reflect existing biases or incomplete information, which can affect the fairness and objectivity of their responses [48]. Openly communicating these limitations and actively working to mitigate bias are crucial for maintaining ethical standards and ensuring that the chatbot serves all users equitably.

Accountability

Accountability is a significant ethical issue concerning the use of LLM-based chatbots. Determining who is responsible for the chatbot's recommendations and decisions is essential, particularly in cases where incorrect or harmful information is provided. Clear lines of accountability must be established, involving both the developers who create and maintain the chatbot and the health care providers who deploy it. This includes ensuring that there are mechanisms for addressing errors or issues that arise from the chatbot's interactions with users [49]. In addition, it is important to have protocols in place for managing situations where the chatbot's advice might lead to adverse outcomes [50]. This includes providing a way for users to report issues and seek redress, as well as ensuring that there are processes for continuous improvement based on feedback and incident analysis. Effective oversight and governance structures help ensure that ethical standards are upheld and that the chatbot contributes positively to patient care.

Potential for Misinformation

Overview

The potential for misinformation is a critical concern in the deployment of LLM-based medical chatbots. Given their reliance on vast datasets and sophisticated algorithms, these chatbots can inadvertently spread incorrect or misleading information, which poses significant risks to patient health and safety. As deep learning pioneer Geoffrey Hinton has noted, neural networks can share what they learn instantly [22]; therefore, any erroneous messages can spread instantaneously, making unwanted wide impact.

Sources of Misinformation

One key source of misinformation is the quality and accuracy of the training data used to develop the chatbot. LLMs are trained on diverse datasets that include information from various sources, some of which may be outdated, biased, or inaccurate. If a chatbot's training data contain erroneous or misleading content, there is a risk that the chatbot will replicate and disseminate these inaccuracies in its responses. In fields such as radiotherapy, where precise and current information is crucial, the presence of outdated or incorrect data can lead to harmful consequences for patients relying on the chatbot for guidance [51]. Another potential source of misinformation is the chatbot's ability to generalize information [52]. While LLM-based chatbots can handle a wide range of queries, they may not always be adept at distinguishing between general knowledge and specific, context-sensitive details. This limitation can lead to the generation of responses that are technically correct but fail to address the nuances of individual patient situations [53]; for example, a chatbot might provide general advice on radiation safety but miss specific recommendations tailored to a patient's unique treatment plan.

Risks and Consequences

The spread of incorrect or misleading information by medical chatbots can have serious repercussions for patient care. Patients may make health-related decisions based on inaccurate information, which can result in inappropriate or ineffective treatments. In radiotherapy, where treatment decisions are complex and require careful consideration of numerous factors, relying on incorrect information can lead to suboptimal care or adverse outcomes. Moreover, misinformation can erode trust in health care technology. If patients or health care providers encounter inaccuracies or inconsistencies in the information provided by a chatbot, their confidence in the tool's reliability and usefulness may be undermined. This loss of trust can diminish the chatbot's effectiveness and impact its acceptance and integration into health care practices.

Mitigation Strategies

To mitigate the risks associated with misinformation, several strategies can be used [54]. Regular updates and maintenance of the chatbot's knowledge base are essential to ensure that it reflects the most current and accurate information. Collaboration with medical experts and continuous validation of the chatbot's responses help identify and correct inaccuracies. Implementing mechanisms for user feedback and reporting can also provide valuable insights into potential issues and facilitate prompt

resolution. Furthermore, incorporating a system of checks and balances, such as providing disclaimers that emphasize the chatbot's limitations and the need for professional medical consultation, can help manage user expectations. Ensuring that the chatbot directs users to seek advice from qualified health care professionals when necessary can prevent reliance on potentially flawed or incomplete information [55].

Proposed Framework for a Resilient Medical Chatbot in Radiotherapy Education

Database Management and Control

Effective database management is crucial for developing a resilient medical chatbot in radiotherapy education. The integrity of the chatbot's responses depends heavily on the accuracy and timeliness of the information it accesses. To achieve this, a robust strategy for building and maintaining a controlled database is essential [56]. The first step in this strategy involves curating a comprehensive and authoritative database from verified medical sources, such as peer-reviewed journals, clinical guidelines, and expert consensus statements. This curated database should be dynamic, with automated systems in place for continuous updates. The proposed framework incorporates an AI-driven mechanism for real-time monitoring of new publications and guidelines, ensuring that the database remains current and reducing the risk of disseminating outdated or inaccurate information [57]. To implement this, automated updates could leverage web scraping tools or application programming interface integrations to collect and validate data against trusted sources. The database should use meta-tagging and hierarchical organization for efficient data management and retrieval. Meta-tagging can be achieved using NLP algorithms to assign contextual keywords, improving the chatbot's ability to interpret and respond to user queries accurately. A hierarchical data structure, such as a tree- or graph-based model, can prioritize data by relevance and reliability, ensuring that the chatbot provides the most appropriate responses [58,59]. In addition, periodic audits of the database should be conducted to verify its accuracy and adherence to updated guidelines.

Maintaining control over the database is equally important. This involves setting strict protocols for data entry and modification, with access restricted to authorized personnel who are well versed in radiotherapy and medical education. Regular audits of the database content should be conducted to identify and rectify any inconsistencies or errors [57]. In addition, using version control systems can help track changes, allowing for the restoration of previous database states if needed, which further enhances the reliability of the chatbot. To ensure that the database remains resilient against emerging challenges such as misinformation or biased data, a layered review process should be integrated. This involves cross-referencing new data entries with multiple sources and using machine learning algorithms to detect and flag anomalies or conflicting information [60]. By implementing these strategies, the database management and control framework will serve as the foundation for a resilient medical chatbot capable of providing accurate, reliable, and up-to-date information in radiotherapy education.

Quality Control System

A robust quality control system is vital for ensuring the reliability and effectiveness of a medical chatbot in radiotherapy education. The system must be designed to maintain the highest standards of accuracy, relevance, and trustworthiness in the chatbot's content, which requires regular reviews, timely updates, and stringent validation processes [61]. The cornerstone of this quality control system is the implementation of a multitiered review process. This begins with the periodic assessment of the chatbot's content by a panel of experts in radiotherapy and medical education. These experts should evaluate the chatbot's responses for accuracy, clarity, and consistency with current clinical practices. Regularly scheduled reviews ensure that the content remains aligned with the latest advancements in radiotherapy and adheres to evolving educational standards [4].

In addition to expert reviews, the quality control system should include automated checks and balances. Machine learning algorithms can be deployed to continuously monitor the chatbot's interactions, identifying patterns of errors or discrepancies in the responses [62]. These algorithms can flag potential issues for further human review, ensuring that errors are caught and corrected promptly. Automated processes should also include regular updates to the chatbot's knowledge base, triggered by new research findings, clinical guidelines, or changes in medical protocols. Another critical aspect of the quality control system is the validation of the chatbot's content before it goes live. This can be achieved through rigorous testing with simulated user interactions, covering a wide range of scenarios that the chatbot is likely to encounter. Feedback loops from these tests should be analyzed to refine the chatbot's algorithms and content delivery mechanisms, ensuring that it provides accurate and contextually appropriate responses [63]. Finally, the quality control system must be adaptable, with mechanisms in place for continuous improvement. This includes incorporating user feedback to identify areas where the chatbot's performance may be lacking and making necessary adjustments. Moreover, the system should be capable of responding to unforeseen challenges, such as the propagation of misinformation, and adapting to emerging trends in radiotherapy by swiftly updating the chatbot's content and protocols [17].

Monitoring and Feedback Loop

Establishing an effective monitoring and feedback loop is essential for the continuous improvement and reliability of a medical chatbot in radiotherapy education. This system ensures that the chatbot consistently meets user needs, adapts to new information, and addresses any issues that arise during its interactions. The foundation of this system is a comprehensive monitoring mechanism designed to track all chatbot interactions in real time. By recording user queries, responses, and outcomes, this monitoring system can identify patterns in user behavior and detect potential issues, such as inaccurate answers, misinterpretations, or gaps in the chatbot's knowledge base [64]. Advanced analytics tools can be integrated to automatically flag problematic interactions for further review by the development team, enabling swift corrective actions. In addition to tracking interactions, the monitoring system should

incorporate a robust feedback loop that allows users to provide direct input on the chatbot's performance [65]. This feedback can be collected through postinteraction surveys, ratings, or optional comment fields, giving users the opportunity to highlight areas where the chatbot excels or falls short. Aggregating and analyzing this feedback offers valuable insights into the chatbot's strengths and weaknesses, guiding future updates and enhancements.

To maximize the effectiveness of the feedback loop, it is crucial to establish a process for prioritizing and addressing the issues identified. A triage system can be implemented to categorize user feedback based on severity and frequency, ensuring that the most critical issues are addressed promptly [66]; for example, if multiple users report the same error or misunderstanding, this issue would be flagged as a high priority for immediate resolution. Less critical feedback, such as suggestions for improved phrasing or additional features, can be scheduled for consideration in future updates. Moreover, the feedback loop should be designed to foster continuous learning and adaptation. Regularly scheduled reviews of the chatbot's performance, informed by user feedback and monitoring data, should be conducted to identify trends and areas for improvement. This iterative process allows the chatbot to evolve over time, enhancing its ability to provide accurate, reliable, and contextually relevant information in radiotherapy education.

Ethical and Legal Safeguards

Implementing robust ethical guidelines and legal safeguards is paramount in developing a medical chatbot for radiotherapy education. These measures are critical to addressing concerns related to privacy, transparency, and accountability, ensuring that the chatbot operates within the highest ethical and legal standards. To begin with, the chatbot must be designed with stringent privacy protections. Given the sensitive nature of medical information, the chatbot should comply with all relevant data protection laws, such as the General Data Protection Regulation in Europe or the Health Insurance Portability and Accountability Act in the United States [19]. This involves implementing secure data encryption methods, anonymizing user interactions, and ensuring that any personal or health-related data collected during interactions are stored securely and used only for their intended purpose [67]. Access to these data should be strictly controlled, with clear protocols for who can view, modify, or delete the data, ensuring that user privacy is respected at all times. Transparency is another critical aspect of ethical chatbot design. Users must be fully informed about how the chatbot functions, including the sources of its information, the limitations of its advice, and the nature of its data collection practices. This can be achieved by providing clear and accessible information within the chatbot interface, such as disclaimers before interactions, a detailed frequently asked questions section, or links to privacy policies. In addition, the chatbot should be designed to clearly distinguish between general information and personalized advice, ensuring that users understand the context and limitations of the information they receive [68].

Accountability mechanisms are also essential to uphold ethical standards. The development and deployment of the chatbot should include a clear governance structure, where responsibilities for content accuracy, data management, and user interactions are well defined. Regular audits of the chatbot's performance and adherence to ethical guidelines should be conducted, with the results made available to relevant stakeholders [69]. Furthermore, there should be a clear process for users to report any ethical concerns or grievances, and these issues should be addressed promptly and transparently. To further enhance ethical and legal safeguards, it is important to establish an oversight committee consisting of experts in ethics, law, and medical education [70]. This committee would be responsible for reviewing the chatbot's operations, ensuring that it remains aligned with ethical principles and legal requirements. The committee should also be tasked with evaluating the impact of the chatbot on users, particularly in terms of potential biases, misinformation, or unintended consequences, and recommending corrective actions as needed. The proposed framework is summarized in Table 2.

Table 2. Summary of the proposed framework for a resilient medical chatbot in radiotherapy education. The key components, their essential elements, and their respective purposes in ensuring the chatbot's accuracy, reliability, and ethical operation are outlined.

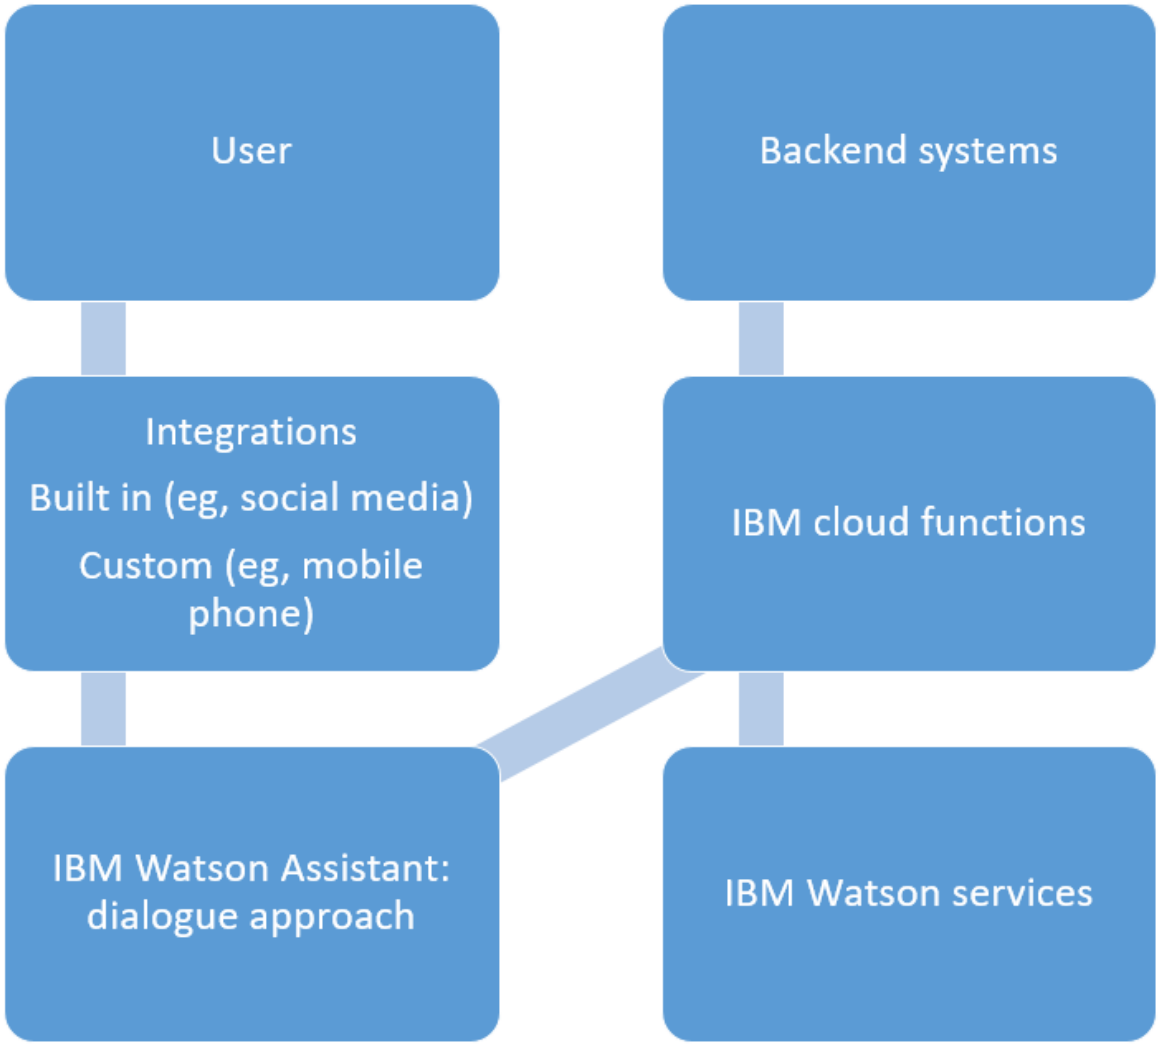
Component	Key elements	Purpose
Database management and control	• Curated and dynamic database • Automated updates • Hierarchical data structure	Ensures that the chatbot has access to accurate, up-to-date, and relevant information
Quality control system	• Multitiered expert review • Automated checks • Content validation	Maintains high standards of accuracy, relevance, and reliability in chatbot responses
Monitoring and feedback loop	• Real-time interaction tracking • User feedback integration • Continuous improvement	Tracks chatbot performance, identifies issues, and incorporates user feedback for ongoing enhancement
Ethical and legal safeguards	• Privacy protections • Transparency measures • Accountability mechanisms	Addresses concerns related to user privacy, ensures transparency, and upholds accountability

Case Study: Application of the Framework in Radiotherapy Education

Outlining the Process of Developing and Testing the Chatbot Using the Proposed Framework

The development of the radiotherapy education chatbot using the proposed framework commenced with a comprehensive needs assessment. This step involved engaging key stakeholders, including radiotherapy educators, clinical oncologists, medical physicists, and students, to identify the specific educational challenges and gaps that the chatbot aimed to address [32]. The focus was on creating a tool that could effectively supplement traditional education by providing accurate, accessible, and contextually relevant information on complex radiotherapy topics. Once the needs were clearly defined, the next phase involved designing the chatbot's conversational architecture. The framework emphasized the integration of AI-driven NLP capabilities with a structured knowledge base specific to radiotherapy [71]. This phase required meticulous curation and validation of content, ensuring that the information was not only accurate but also aligned with the latest guidelines and research in the field. A collaborative approach was adopted, involving experts from various disciplines to ensure that the chatbot's responses would be both scientifically robust and pedagogically sound [72]. The chatbot was then built using a hybrid approach that combined rule-based algorithms with machine learning models [73]. The rule-based components ensured that the chatbot could handle critical educational scenarios with precision, while the machine learning aspects allowed for more dynamic and flexible interactions. The integration with the IBM Watson Assistant cloud platform facilitated the deployment of advanced NLP algorithms, enabling the chatbot to understand and respond to user queries effectively [32]. Figure 3 shows the architectural diagram of a chatbot developed using the IBM Watson Assistant platform [74].

Figure 3. Architectural diagram showing how the chatbot is connected to the IBM Watson Assistant cloud platform.



Testing the chatbot was an iterative process. Initial prototypes were subjected to rigorous testing in simulated environments, where various scenarios were presented to evaluate the chatbot's performance in real time [75]. The testing focused on several key metrics: the accuracy of information, user engagement, response time, and the ability to handle unexpected or complex

queries. Feedback from educators and students was crucial during this phase, providing insights into the chatbot's usability and effectiveness in an educational setting. To ensure the reliability and safety of the chatbot, the testing also included a comprehensive evaluation of ethical considerations. The framework's built-in mechanisms for privacy protection, data security, and bias mitigation were scrutinized to prevent potential harm. The chatbot was tested for its adherence to ethical standards through a Delphi study involving international experts, ensuring that it met global expectations for AI-driven educational tools [76].

The final phase involved pilot-testing the chatbot in real educational settings, specifically within radiotherapy courses. These studies aimed to evaluate both the chatbot's technical performance and its educational impact. Observations from the pilot phase revealed notable improvements in student comprehension and engagement; for example, the chatbot, called RT Bot, was deployed on a website accessible by invitation and introduced during workshops and conferences to test its functionality. Participants were invited to complete a survey evaluating the chatbot's functionality and content. This survey, conducted with 60 participants, aimed to gather statistical insights and feedback for improving the chatbot in the future. The results, summarized in Table 3 [32], highlight varying levels of user satisfaction with RT Bot during its testing phase. The assessment used a scale ranging from 1 (lowest satisfaction) to 5 (highest satisfaction). The data indicate that a substantial 70% (42/60) of the respondents rated the content's helpfulness, understandability, and reading duration as above average.

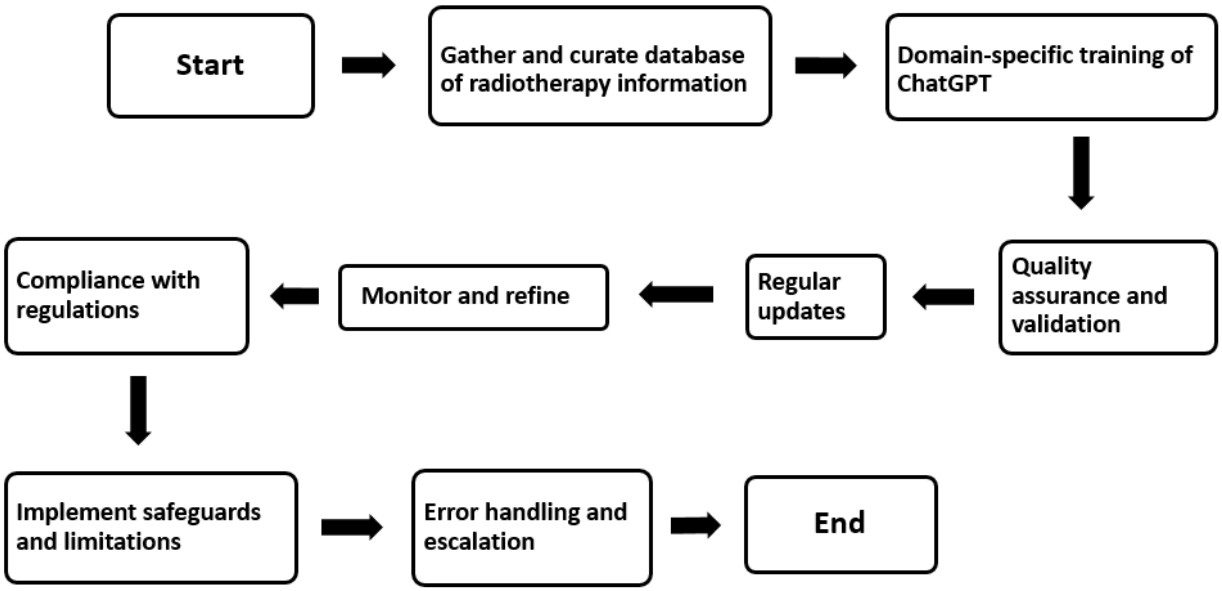
Table 3. Users' satisfaction ratings regarding the contents of RT Bot (N=60) [32].

Degree of satisfaction (ranging from 1=lowest to 5=highest)	Helpfulness of content, n (%)	Understandability of content, n (%)	Reading duration, n (%)
1	3 (5)	0 (0)	0 (0)
2	0 (0)	9 (15)	3 (5)
3	15 (25)	9 (15)	15 (25)
4	24 (40)	24 (40)	18 (30)
5	18 (30)	18 (30)	24 (40)

Specific feedback highlighted areas for improvement, such as the need for more intuitive methods to restart conversations and tailored hints for users with diverse backgrounds when answering radiation safety questions. These insights enabled developers to refine the chatbot's adaptability and responsiveness. Data collected from the pilot tests demonstrated a measurable positive effect on learning outcomes, as students achieved higher quiz scores and expressed increased confidence in applying radiation safety principles. The feedback loop established during this phase ensured that the chatbot evolved into a robust, user-centered educational tool, ready to support radiotherapy training effectively [34,77,78].

Figure 4 illustrates the workflow for creating and maintaining an LLM-based medical chatbot powered by ChatGPT, tailored for radiotherapy. The chatbot relies on a curated database of verified information and undergoes domain-specific training to understand radiotherapy nuances. However, several limitations exist. The quality of training data and the effectiveness of cross-checking mechanisms are crucial; any errors or biases can lead to inaccurate responses. Regular updates are necessary to keep the database current, but this requires significant resources. User feedback helps refine the system, although the feedback can be subjective and challenging to manage. Error-handling mechanisms allow for query escalation, but not all issues may be resolved, potentially affecting user trust. Despite these challenges, the iterative process aims to provide accurate and up-to-date information within the chatbot's expertise.

Figure 4. Flowchart providing a sequential representation of the steps involved in creating, maintaining, and improving a medical chatbot based on the large language model ChatGPT, with a focus on radiotherapy, ensuring accuracy, compliance, and continuous refinement.



This process is crucial because it ensures the reliability, accuracy, and ethical integrity of the medical chatbot in radiotherapy. By curating a precise and verified database, fine-tuning the AI model, and implementing rigorous validation processes, the system can provide trustworthy information. The continuous refinement loop, fueled by user feedback and updates, ensures that the chatbot stays current with evolving practices and advancements in radiotherapy. This reliability and adherence to medical standards instills confidence in users, guiding them with accurate information while emphasizing the chatbot's limitations and the necessity of seeking professional medical advice. Ultimately, this meticulous process not only educates and assists users but also upholds the ethical responsibility of providing reliable health care information through AI-driven technologies.

Performance Evaluation

Evaluating the chatbot's performance was a critical step to ensure that it met the high standards required for educational tools in radiotherapy. The evaluation focused on 3 main areas: accuracy, user satisfaction, and educational impact.

Accuracy

The accuracy of the chatbot was assessed through a multitiered validation process. First, a set of standardized queries covering a wide range of radiotherapy topics was developed. These queries were designed to test the chatbot's ability to provide correct and precise information. Subject matter experts in radiotherapy independently evaluated the chatbot's responses to these queries, comparing them against established medical literature and clinical guidelines [79]. The chatbot's performance was quantified using accuracy metrics such as precision and recall, ensuring that it consistently delivered reliable information [80]. In addition, the chatbot's ability to update and incorporate the latest research findings was tested, emphasizing the need for dynamic content management to maintain long-term accuracy [81].

User Satisfaction

User satisfaction was evaluated through extensive user testing, involving a diverse group of end users, including students, educators, and health care professionals. Surveys and feedback forms were used to gather qualitative and quantitative data on users' experiences with the chatbot. Key aspects such as ease of use, response time, clarity of information, and overall user experience were measured. The feedback loop was integral to refining the chatbot, addressing any issues related to user interaction, and ensuring that the chatbot met the expectations of its target audience. In addition to surveys, usability testing sessions were conducted where users interacted with the chatbot in controlled environments, providing real-time feedback on their experiences. This iterative process helped in identifying and rectifying any usability challenges, enhancing the overall user satisfaction [79].

Educational Impact

The educational impact of the chatbot was evaluated by analyzing its effectiveness as a learning tool in radiotherapy education. This involved conducting controlled studies where the performance of students who used the chatbot as a supplementary learning resource was compared to that of students who did not. Various educational metrics, such as knowledge retention, comprehension, and application of concepts, were measured through pre- and postintervention assessments [82]. The chatbot's impact on these metrics was statistically analyzed to determine its effectiveness in enhancing learning outcomes [77]. Furthermore, longitudinal studies were conducted to assess the sustained educational benefits of the chatbot, ensuring that its use had a lasting positive impact on students' understanding of radiotherapy concepts [83]. In addition to these formal evaluations, the chatbot's performance was assessed in real-world educational settings through pilot studies. These studies provided insights into how the chatbot influenced classroom dynamics, student engagement, and the

overall learning environment [84-86]. Feedback from these settings was crucial in understanding the practical implications of integrating the chatbot into existing curricula and further validated its educational impact.

Lessons Learned and Future Directions

As the radiotherapy education chatbot continues to evolve, there are numerous opportunities for innovation that could significantly enhance its capabilities. Future research and technological advancements hold the potential to expand the chatbot's functionality, improve user experiences, and further integrate it into the educational landscape.

Advanced NLP and Understanding

One of the most promising areas for innovation lies in the continued development of advanced NLP algorithms. Future iterations of the chatbot could benefit from more sophisticated NLP techniques, such as transformer-based models and deep learning architectures, which can better understand and generate human-like responses [87]. These advancements would enable the chatbot to handle more complex queries, recognize nuanced language patterns, and provide more contextually accurate answers. Enhanced NLP capabilities could also improve the chatbot's ability to engage in multiturn conversations, allowing for deeper and more meaningful interactions with users.

Personalized Learning Experiences

Another key area for innovation is the development of personalized learning experiences. Leveraging data-driven insights, the chatbot could be equipped with adaptive learning algorithms that tailor content and responses to individual users' needs, preferences, and learning paces [88]. By analyzing user interactions, the chatbot could identify areas where a student might be struggling and provide targeted educational resources or alternative explanations to enhance understanding. This personalized approach would make the chatbot a more effective tool for diverse learning styles and could significantly improve educational outcomes [89].

Integration With Virtual and Augmented Reality

The integration of the chatbot with virtual and augmented reality (VR/AR) technologies presents exciting possibilities for creating immersive learning environments. By combining the chatbot's informational capabilities with VR/AR platforms, users could engage in interactive simulations of radiotherapy procedures, enhancing their practical understanding of complex concepts [90,91]; for example, students could use the chatbot to guide them through virtual radiotherapy sessions, where they can visualize and manipulate different treatment parameters in a 3D space. This fusion of AI-driven education with immersive technologies could revolutionize how radiotherapy is taught and learned.

Enhanced Multilingual and Cross-Cultural Capabilities

As radiotherapy education becomes increasingly globalized, there is a growing need for the chatbot to support multilingual and cross-cultural communication. Future developments could focus on expanding the chatbot's language capabilities, enabling it to provide accurate and contextually relevant information in multiple languages. This would not only make the chatbot more accessible to non–English-speaking users but also allow it to adapt its responses to different cultural contexts, ensuring that the information is both accurate and culturally sensitive [92]. Such advancements would make the chatbot a valuable educational tool in diverse global settings.

Ethical AI and Bias Mitigation

As AI continues to advance, addressing ethical concerns and mitigating biases in the chatbot's responses will be paramount. Future research could explore more robust methods for ensuring that the chatbot's algorithms remain unbiased and that its responses adhere to ethical guidelines [93]. This might include developing advanced algorithms for detecting and correcting biases in real time, as well as enhancing the transparency and explainability of the chatbot's decision-making processes. By prioritizing ethical AI, the chatbot could set new standards for responsible AI use in education, fostering trust and reliability among users [20].

Integration With Broader Educational Ecosystems

Finally, future innovations could focus on integrating the chatbot with broader educational ecosystems, including learning management systems and other digital educational tools [94,95]. By doing so, the chatbot could become a seamless part of the educational workflow, providing continuous support to students and educators across various platforms. This integration would enable more comprehensive data collection and analysis, allowing educators to monitor student progress in real time and make data-informed decisions to enhance teaching strategies. The chatbot could also facilitate collaborative learning by connecting users with peers, mentors, or experts, creating a more interactive and supportive educational community.

Adaptability to Other Medical Fields

The framework developed for the radiotherapy education chatbot demonstrates significant potential for adaptation to other medical fields. By leveraging advanced NLP algorithms and personalized learning experiences, the chatbot can be tailored to provide specialized educational content across various medical disciplines, such as cardiology, neurology, and oncology. The integration of VR/AR technologies can further enhance learning by offering immersive simulations of medical procedures relevant to each field. Furthermore, the chatbot's multilingual and cross-cultural capabilities ensure that it can deliver accurate and contextually appropriate information to a diverse global audience. By addressing ethical AI considerations and integrating with broader educational ecosystems [18], the framework can support continuous learning and professional development for health care professionals worldwide, ultimately improving patient care and outcomes.

Conclusions

This Viewpoint paper has explored the development of a resilient framework for a medical chatbot tailored to radiotherapy education, addressing key aspects such as accuracy, reliability, privacy, ethics, and the potential for innovation. The framework emphasizes the importance of maintaining up-to-date and accurate information, ensuring user trust through robust privacy measures, and fostering an ethical approach to AI in

health care. Through performance evaluation, the chatbot demonstrated its capability to enhance learning outcomes and support health care professionals in their continuous education. Challenges such as bias, user engagement, and integration into existing systems were identified, with strategies proposed to overcome these obstacles.

Looking ahead, the future of LLM-based medical chatbots holds significant promise for radiotherapy education and health care as a whole. These technologies have the potential to revolutionize how complex medical knowledge is disseminated, making education more accessible, personalized, and interactive. By continuing to advance in areas such as NLP, personalized learning, and integration with immersive technologies, LLM-based chatbots can become indispensable tools in both educational and clinical settings. As these chatbots evolve, they will likely play a crucial role in shaping the future of health care, improving patient outcomes, and supporting the ongoing education of health care professionals worldwide. The framework presented in this paper serves as a foundational guide for the responsible and effective implementation of these powerful tools, ensuring that they contribute positively to the field of radiotherapy and beyond.

Abstract

Oncology patients often face complex choices between treatment regimens with different risk-benefit ratios. The 4D PICTURE (Producing Improved Cancer Outcomes Through User-Centered Research) project aims to support patients, their families, and clinicians with these complex decisions by developing data-driven decision support tools (DSTs) for patients with breast cancer, prostate cancer, and melanoma as part of care path redesign using a methodology called MetroMapping. There are myriad ethical issues to consider as the project will create data-driven prognostic models and develop conversation tools using artificial intelligence while including patient perspectives by setting up boards of experiential experts in 8 different countries. This paper aims to review the key ethical challenges related to the design and development of DSTs in oncology. To explore the ethics of DSTs in cancer care, the project adopted the Embedded Ethics approach—embedding ethicists into research teams to sensitize team members to ethical aspects and assist in reflecting on those aspects throughout the project. We conducted what we call an embedded review of the project drawing from key literature on topics related to the different work packages of the 4D PICTURE project, whereas the analysis was an iterative process involving discussions with researchers in the project. Our review identified 13 key ethical challenges related to the development of DSTs and the redesigning of care paths for more personalized cancer care. Several ethical aspects were related to general potential issues of data bias and privacy but prompted specific research questions, for instance, about the inclusion of certain demographic variables in models. Design methodology in the 4D PICTURE project can provide insights related to design justice, a novel consideration in health care DSTs. Ethical points of attention related to health care policy, such as cost-effectiveness, financial sustainability, and environmental impact, were also identified, along with challenges in the research process itself, emphasizing the importance of epistemic justice, the role of embedded ethicists, and psychological safety. This viewpoint highlights ethical aspects previously neglected in the digital health ethics literature and zooms in on real-world challenges in an ongoing project. It underscores the need for researchers and leaders in data-driven medical research projects to address ethical challenges beyond the scientific core of the project. More generally, our tailored review approach provides a model for embedding ethics into large data-driven oncology research projects from the start, which helps ensure that technological innovations are designed and developed in an appropriate and patient-centered manner.

Introduction

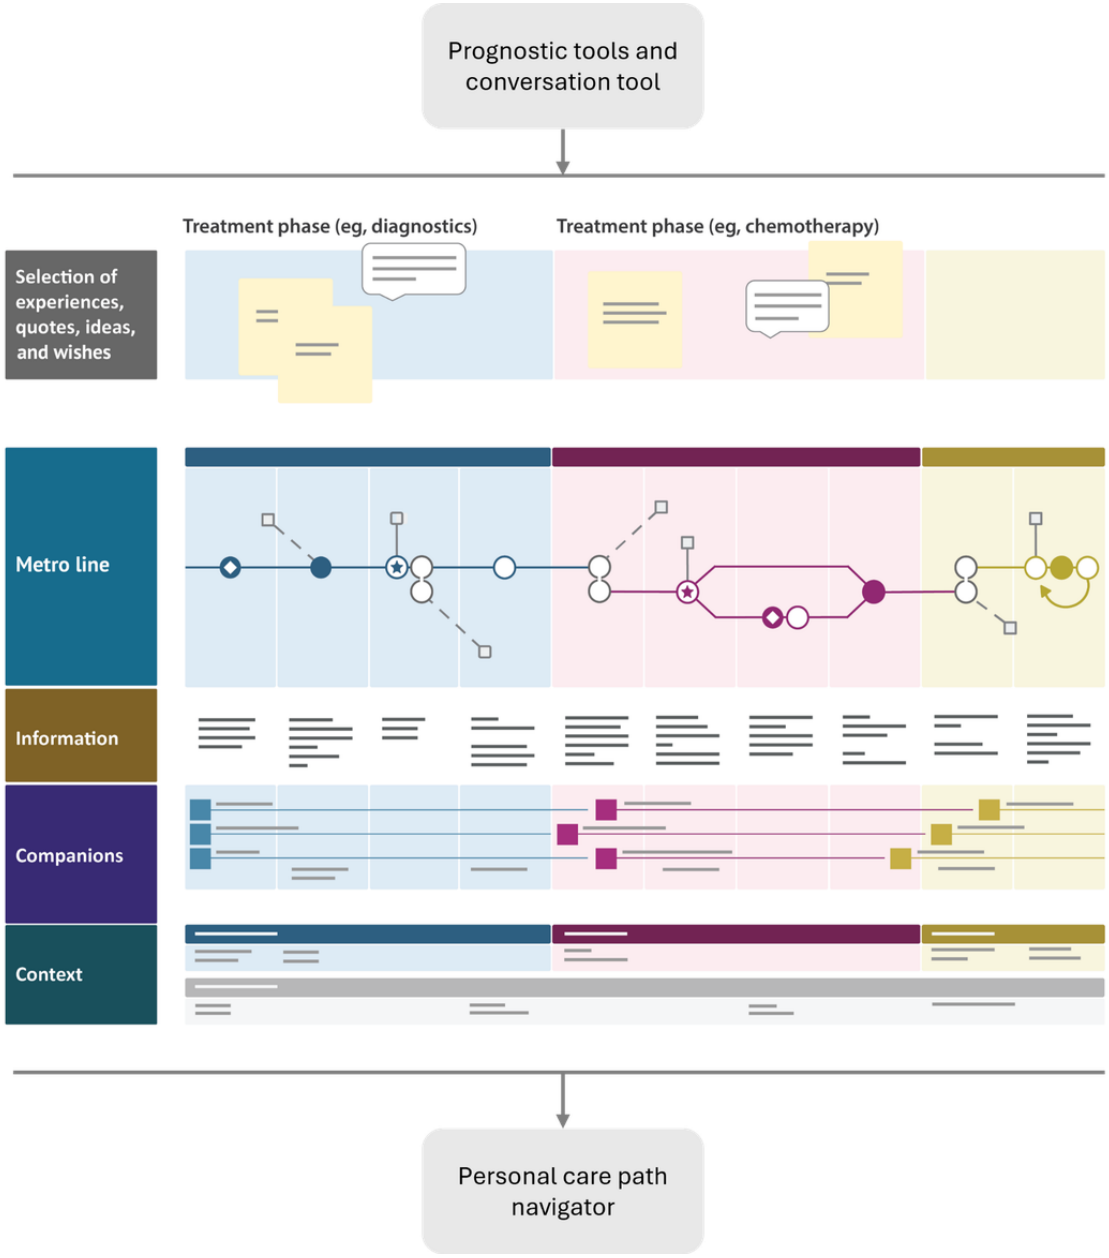
People diagnosed with cancer often face difficult choices regarding their treatment and potential impact on survival and quality of life [1]. Data-driven decision support tools (DSTs) hold significant potential in empowering patients, enhancing personalized care, and fostering health equity [2,3]. Nevertheless, most current DSTs do not account for individual preferences, which hinders their broader integration into clinical practice. To improve cancer treatment decision-making by addressing existing challenges in DSTs, a large European collaboration was started—the 4D PICTURE (Producing Improved Cancer Outcomes Through User-Centered Research) project [4]. Recognizing the complexity that patients face, the consortium seeks to use design methods (particularly the *MetroMapping* methodology, Figure 1) to improve care paths in oncology. This involves the development of innovative prognostic models and conversation tools that consider patient experiences, values, and preferences through models partly based on artificial intelligence (AI). Collaborating with patients and other stakeholders, the project focuses on breast cancer, prostate cancer, and melanoma, aiming to create comprehensive DSTs for these types of cancer. The use of these tools in the *MetroMap* for redesigning cancer care paths will be evaluated on effectiveness and cost-effectiveness, and social and ethical concerns will be addressed throughout the project.

Ethics is highly relevant to the development of data-driven DSTs for personalizing oncology care. For instance, the use of low-quality prognostic models may lead to incorrect and harmful decisions. When using AI-driven DSTs, concerns about quality are particularly warranted as there is still a lack of robust evidence on their effectiveness [5]. As such, normative principles such as data quality, algorithmic fairness, and data privacy are important to consider when developing data-driven DSTs. However, principles alone cannot guarantee that the developed tools are ethical and acceptable to patients and health care providers [6]. What is needed as well is guidance on how researchers can be practically assisted to anticipate, identify, and address ethical issues of data-driven care based on the specific case at hand. This can be done through the *Embedded Ethics* approach, which stimulates close collaborations between ethicists on the one hand and developers, researchers, and clinicians on the other who work together in an iterative and continuous manner [7]. In the 4D PICTURE project, ethicists are embedded into the project in this way to promote guidance and reflection on the ethics of the entire project.

The first task of the ethics *work package* in a large interdisciplinary project is usually to create an overview of potential ethical challenges that can be expected in that project based on the literature. However, we noticed that such literature surveys often come up with the same general issues. A database search on the ethical aspects of data-driven DSTs in medicine is necessarily broad and will provide high-level findings on the aforementioned principles, which still requires translation to the project at hand to derive actionable recommendations. Moreover, the ethical aspects of such interdisciplinary projects are too heterogenous for a systematic review on the "ethics of data-driven DSTs in healthcare"—ethical questions may also arise in parts of the project not directly related to DST development, such as their evaluation or the dissemination of results. Therefore, in the 4D PICTURE project, we took a different approach. As ethicists in the 4D PICTURE project, we discussed ethics in relation to the different work packages with the project researchers and looked for key publications in the ethics literature on the topics that came up in each work package separately. We moved back and forth between literature and practice in an iterative process to be as specific and close to practice as possible. This resulted in an agenda of aspects that may be ethically relevant within the project and serves as a basis for further empirical and theoretical ethics research.

This viewpoint describes this process and has two interrelated aims as it (1) introduces the *embedded review* approach for identifying ethical aspects within an interdisciplinary research consortium and (2) outlines key ethical challenges to be considered when developing data-driven DSTs for more personalized oncology care. In what follows, we describe our methodology before discussing ethical challenges related to data-driven DSTs in the project under study. This paper provides a detailed overview of the ethics of data-driven DSTs because of the link to a particular project, as well as reference to broader ethical aspects (eg, the ethics of interdisciplinary collaboration or psychological safety in research teams) that are often neglected. We find that this work has relevance beyond the 4D PICTURE project as it is the first review-type paper explicitly grounded in the *Embedded Ethics* approach. Our findings show that, even when simply looking for literature on ethical aspects, a lot can be gained when ethics is embedded into a project from the start.

Figure 1. Schematic illustration of the MetroMap that forms the core of the 4D PICTURE (Producing Improved Cancer Outcomes Through User-Centered Research) project. The MetroMap is a comprehensive visualization of the general care trajectory. Feeding into the MetroMap will be the results of two types of models developed in the project: (1) a treatment outcome prediction tool for each cancer type and (2) a conversation tool developed by analyzing patient experiences through text mining. The result of integrating these data-driven tools into the MetroMap will be a personal care path navigator for each patient that serves as a decision aid in shared decision-making.



Methods

Embedded Ethics Approach and Study Design

As ethics is about normative argumentation and conceptual analysis, a systematic literature study usually does not suffice for an overview of the ethical literature on a certain topic. Moreover, the ethical aspects of large interdisciplinary projects such as the 4D PICTURE project are too heterogenous for a traditional systematic or scoping review. Therefore, different methods for reviews have been described in the ethics literature suitable for different purposes, ranging from a *rapid review* to a *critical interpretative review* [8]. For the context of this study, our main aim was to sensitize researchers of the consortium to the ethical issues in their work packages and support them with a shared ethical framework, vocabulary, and argumentation to navigate the various ethical issues of the project deliberately and consciously. Our priority was to ensure that the literature was useful, comprehensible, and relevant for the consortium's needs, thus balancing methodological rigor and depth of analysis with practical applicability. In conducting this review, we aimed to develop directions for specific ethics guidance and further research as well as to "create a shared knowledge base among team members" [9]. Moreover, we wanted to include the ethics *of* the consortium (eg, ensuring psychological safety in research teams) rather than merely looking at the ethics *in* the consortium (eg, avoiding biased outcomes of the prognostic models).

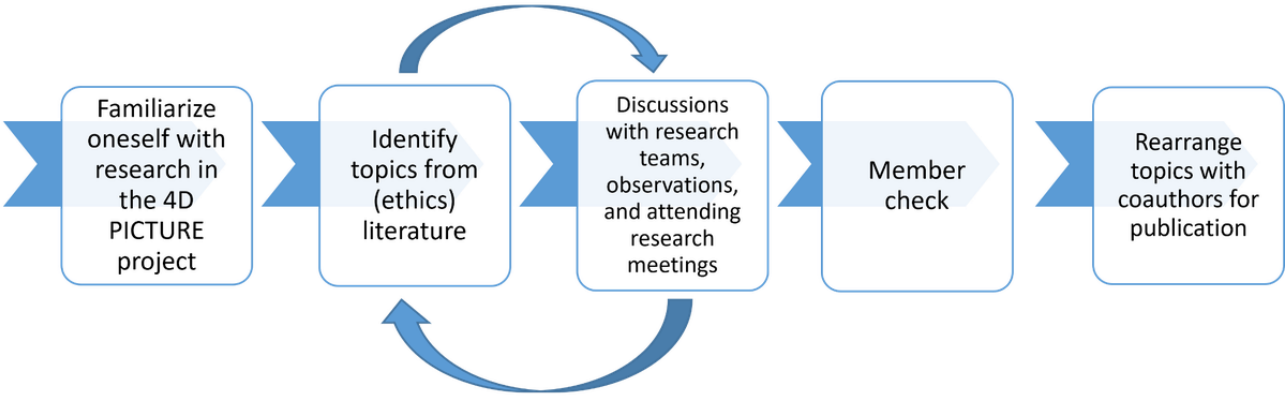
Therefore, we opted for an *embedded review*, which, in the typology of McDougall [8], could be best described as a critical

interpretative review, with the main difference that we established the analytical categories together with the researchers of the consortium. This is in line with the paradigm of *Embedded Ethics*, a relatively new approach for integrating ethics into interdisciplinary health care projects that focuses on delivering guidance for practical ethical dilemmas also when these are unexpected and come up ad hoc. This is done by embedding ethicists into these projects and stimulating close collaboration so that ethical aspects are taken into account in a continuous and iterative manner [7]. Various tools and methods are used to embed ethics into the development of new technologies; usually, a literature review is the starting point. As Willem et al [9] note, a literature review in an embedded ethics project "provides the opportunity to collectively interrogate the project's goals." Thus, the themes described in this paper are based on an iterative approach that we have called an embedded review—going back and forth between research meetings, reading and searching for literature, interactive discussions and meetings with 4D PICTURE researchers, joining trainings, and conducting observations of meetings. Hereafter, we describe how we conducted this embedded review of ethical aspects in the 4D PICTURE project.

Identification of Ethical Challenges and Member Check

First, 2 authors (LH and CG) familiarized themselves with the research objectives and activities of each work package in the 4D PICTURE project. They identified ethical themes that may be relevant for the activities and research of each work package and looked for key publications in the (empirical and theoretical ethics) literature on that particular topic. Some of these publications were known by the authors, whereas others were found through simple searches in PubMed and Google Scholar as well as through further snowball searches. Of note is that the iterative process of *identifying* did not simply consist of extracting issues from the project proposal or the ethics literature but required active interpretation by the authors to link the literature to the intended work in the various parts of the 4D PICTURE project. After having conducted an initial identification of ethical themes, these insights were summarized in such a way that the descriptions were readable and understandable by researchers without a background in ethics. This document was shared within the consortium and also included a *further reading* section for those interested in reading more. The categories of ethical themes were then further refined through conversations with researchers in the 4D PICTURE project. For instance, the points discussed in the *Results* section about the design of the MetroMap were extensively discussed with researchers at an in-person training in the Netherlands by LH and CG. Finally, 2 of the ethicists in the project (LH and MB) presented the findings of this embedded review during a general meeting that was attended by all the researchers of the 4D PICTURE consortium, which took place in 2023 and served as a *member check* to see whether relevant issues were included but also to stimulate researchers in the project to think about ethics in their work package. An overview of these methodological steps is provided in Figure 2. While our aim was explicitly not to conduct a systematic review of the literature, our methodology might still be further improved in future studies deploying this embedded review approach.

Figure 2. Method of conducting an embedded review in the 4D PICTURE (Producing Improved Cancer Outcomes Through User-Centered Research) project—flowchart of the process of identifying and refining ethical challenges based on the literature and discussions with researchers in the project.



In what follows, we discuss 13 specific ethical challenges related to the development of data-driven DSTs for cancer care that arose from our embedded review of the 4D PICTURE project. While we started from general themes (eg, ethical aspects regarding *semantic bias* and *fairness* in relation to text mining patient experiences to develop a conversation tool), we reframed the themes as challenges to provide a slightly more action-oriented overview that can serve as an agenda for embedding ethics into the project (a challenge is then "preserving meaning in the data and including underrepresented groups"). We note that there is no agreed-upon definition of what an ethical challenge is [10], but for the purpose of this paper, we defined it as follows: "an ethical challenge occurs when one does not know how to behave and act in the best way" [11]. To aid readability in our reporting of ethical challenges, in the text of this paper, we combined several 4D PICTURE work packages into more general headings (eg, combining "project management, dissemination and ethics," which are 3 separate work packages in the 4D PICTURE project, into 1 section), but a full overview of the project's work packages and related challenges is presented in Table 1.

Table 1. Ethical challenges related to the work packages (WPs) in the 4D PICTURE (Producing Improved Cancer Outcomes Through User-Centered Research) project. Descriptions of each WP's main objectives were taken from the 4D PICTURE project's website. It should be noted that challenge 13 is relevant across all WPs, although extra responsibility may be put on the project leads in WP 1.

WP	Main objectives	Ethical challenges
WP 2—modeling	The overall objective of WP 2 is to develop algorithms that provide predictions of outcomes for individual patients for each relevant treatment option for 3 major cancers. The algorithms will be translated into decision support tools and included in the MetroMap as developed in WP 4.	• Avoiding biased outcomes due to poor data quality (challenge 1) • Understanding how ethical values are built into models (challenge 2)
WP 3—text mining	The main aim of WP 3 is to use co-design methods to investigate the experiences of patients with cancer and their significant others, drawing upon novel text mining and qualitative analysis methodologies to improve outcomes for patients with cancer and their families and enhance the quality of a conversation tool to be used by citizens, patients, and clinicians across Europe.	• Preserving meaning in the data and including underrepresented groups (challenge 3) • Protecting the privacy of the data of patients with cancer in the public domain (challenge 4)
WP 4—design	The primary task of WP 4 is the redesign of care paths applying the service design method to experience a more individualized and personalized care path with the inclusion of innovative prognostic and conversational tools.	• Incorporating shared decision-making and death into the care path design (challenge 5) • Visualizing care paths responsibly through design justice (challenge 6)
WP 5—practice and WP 6—policy	In WP 5, researchers will evaluate MetroMapping in its entirety using mixed methods designs as well as evaluate the decision support tools to be developed. WP 6 aims to finalize the MetroMapping methodology, assess the generalizability of the methodology and decision support tools of MetroMapping, and provide guidance to policy makers about MetroMapping.	• Reflecting on good criteria for (cost-effectiveness) evaluation (challenge 7) • Balancing the adoption of technology with other values (challenge 8) • Anticipating techno-moral change and developing new ethical frameworks (challenge 9)
WP 1—coordination and WP 8—dissemination	WP 1 entails all aspects of the coordination, management, and progress monitoring of the project. The task of WP 8 is to disseminate project information and results of the research and innovation activities to key stakeholders through various channels and enable access to decision support tools to patients with cancer, their significant others, clinicians, and the public.	• Integrating patients' experiential knowledge to avoid epistemic injustice (challenge 10) • Negotiating shared knowledge in the trading zone between disciplines (challenge 11)
WP 7—ethics	WP 7 is a cross-cutting, integrative WP that establishes an embedded ethics approach within the 4D PICTURE project. It collaborates with all WPs and aims to ensure that ethical and social aspects of the planned tools and implications of their use are considered from the very start of their interdisciplinary development.	• Establishing the position of the embedded ethicist (challenge 12)
All	—[a]	• Ensuring psychological safety in research teams (challenge 13)

[a]Not applicable.

Results

Overview

Through our embedded review of ethics in the 4D PICTURE project, we identified 13 key ethical challenges related to the development of DSTs and the redesign of care paths for more personalized cancer care. These challenges are discussed in sections related to the various parts of this project: the prognostic model development; text mining of patient experiences to develop a conversation tool; the innovative design method of *MetroMapping* to develop a personal care path navigator; the evaluation of the MetroMap and integrated DSTs; and project management, dissemination, and ethics. An overview of how the identified ethical challenges relate to the 8 specific (but interrelated) work packages in the 4D PICTURE project, along with those work packages' main objectives, is provided in Table 1.

Prognostic Models for Individual Treatment Outcomes

Overview

One of the aims of the 4D PICTURE project is to develop models that predict individual patient outcomes for each relevant treatment option for breast cancer, melanoma, and prostate cancer. These prognostic algorithms will be translated into DSTs. Outcome measures will not only be related to survival but also operationalize different aspects of quality of life (eg, side effects or sexual well-being) per treatment option so that patients can make an informed treatment decision based on their personal circumstances and values. However, ethical aspects should be taken into account when developing such prognostic models. Hereafter, we discuss 2 key ethical challenges: the risk of data bias and the need for awareness that societal values are always built into models.

Ethical Challenge 1: Avoiding Biased Outcomes Due to Poor Data Quality

The accuracy of prognostic models depends heavily on the quality and representativeness of the data used. Data bias (ie, results being skewed because of unjust inaccuracies in the data used for modeling) can cause harm to individuals and increase existing inequities in society [12-14]. Biased outcomes can arise due to false assumptions incorporated into data collection, inconsistent definitions, small sample sizes, reproduction of societal trends influencing the data, and the underrepresentation of (minority) groups in datasets [15-17]. In the 4D PICTURE project, bias may be introduced as the input data for the prognostic models come from multiple European countries and from international randomized clinical trials and meta-analyses and, as such, may not be generalizable to, for instance, small patient groups or smaller European countries that lack representation in these datasets (let alone to countries in the Global South, although that is also not the aim of the 4D PICTURE project). For example, data may be predominantly derived from patients with European heritage, and ethnic minority groups may be underrepresented in the data, possibly leading the model to draw misguided conclusions about these patients [17-20]. In addition, models trained on a dataset in one setting often do not perform well in other settings [21]. To mitigate the impact of data bias, the 4D PICTURE researchers will weigh the quality and generalizability of the different data sources.

However, it may turn out that, for specific patient populations, the level of evidence is so low that a prediction tool may cause more confusion than clarity about treatment options for the patient [22,23]. If the evidence is relatively uncertain, does that mean that the clinician can refrain from presenting the patient with the model's outcome to prevent confusion? We find that clinicians should evaluate the usefulness of the model's output for each patient before consultation. However, open questions remain. At what level of certainty is the clinician obliged to share results with the patient to fulfill duties of openness and transparency? In addition, should the use of a prediction model, if available, be incorporated into the standard workflow or rather as an optional step that requires the patient's informed consent before inputting data? Or would providing patients with information and choice lead to an undesirable redistribution of responsibility in which the clinician shifts the burden of making difficult decisions to the patient [24]? These issues call for ethical reflection and careful consideration of how clinical practice changes when prognostic models are introduced in a specific cancer care setting.

Ethical Challenge 2: Understanding How Ethical Values Are Built Into Models

While prognostic models are sometimes thought of as objective calculators, in reality, no algorithm is perfect. Models are not value free and will always have certain undesirable outcomes even when they merely output a prediction without coupling it to advice [25]. Namely, if two developers create a model based on the same database, the resulting models will be different because certain choices about the functioning of the model are made by the developer (eg, whether to accept more false negatives vs more false positives). Clinical risk prediction models are often programmed to prioritize *sensitivity* (fewer false negatives) over *specificity* (fewer false positives) because this reflects the existing tendency of human clinicians to better be safe than sorry (ie, to prefer the risk of overtreatment to the risk of undertreatment) [15]. In the same way, the selection of outcome measures is loaded with values. Overall survival, recurrence-free survival, and progression-free survival are commonly accepted outcome measures. However, not every outcome may be equally important to each patient.

Thus, prognostic models may be perceived within clinical practice as more neutral, objective, certain, and reliable than they actually are. This is akin to what some scholars have called the *automation bias* of humans regarding automated systems—people tend to rely too heavily on automated systems such as AI technologies and forget the cultural and ideological choices that were made during the development of that system [26,27]. It is important for developers and users to understand that these choices often reflect existing societal bias and inequalities. Moreover, developers of prognostic models may be faced with difficult moral dilemmas in which no right solution can be readily modeled [28]. If there is then a lack of ethics guidance, this can lead to arbitrary decision-making based on technical features such as computing power [29]. Even if

developers themselves are very much aware of the limitations, uncertainties, value preferences, and subjective cutoff points of a model, these may not be immediately clear to the clinicians, patients, and policy makers who use the information generated by the model. Prognostic models are value laden and bring about ethical questions, but these are sometimes not recognized as such. Acceptability of certain choices during model development should be based on ethical reasoning and arguments, preferably in consultation with ethicists and a diverse range of stakeholders. The 4D PICTURE project offers a unique possibility to jointly study and discuss the ethical values built into the planned prediction models and their potential influence on actual cancer care practices.

This also includes discussion about *which variables* to include in predictive algorithms. For model developers, the accuracy of predictions has always been most important. However, depending on the intended use, a more accurate model may sometimes reproduce or even increase unfair inequalities in society. Imagine a model that calculates the expected quality of life after the treatment of a stroke. We know that, after a stroke, the average quality of life is much lower in neighborhoods where many people are of a lower socioeconomic status than in neighborhoods where most people are of a high socioeconomic status [30]. Including the postal code in the model might result in more accurate predictions of posttreatment quality of life. The question is then whether it is ethically justified to include postal code as a variable. The answer to this depends not only on the question of whether the variable makes the model more accurate but also on the intended use of the model. The reasoning is different for a model intended to allocate resources in a way that improves care in disadvantaged neighborhoods versus a model intended to decide who to give stroke treatment and for whom stroke treatment is not cost-effective because of a low predicted quality of life after the treatment. The latter use is problematic as it further unfairly disadvantages the already disadvantaged given that the low quality of life likely relates to factors outside individuals' control, such as housing or health literacy. Whether to include variables that might affect treatment options for disadvantaged or protected groups, such as postal code but also gender, ethnicity, disability, BMI, and smoking or diabetes status, is a question that is relevant in the context of cancer care and in need of more interdisciplinary research and ethical reasoning.

Text Mining of Experiences of Patients With Cancer to Develop a Conversation Tool

Overview

Another objective of the 4D PICTURE project is to conduct text mining analyses of *big* data on the experiences of patients with cancer to develop a conversation tool and obtain input for care path redesign. An interdisciplinary approach will be used that combines the strengths of AI tools (ie, text mining and natural language processing techniques), corpus linguistics, and qualitative (narrative) research to efficiently convert the stories of people with cancer and their significant others into usable knowledge. Key ethical challenges revolve around the risk of societal bias and loss of meaning in the data, as well as privacy and ownership questions regarding data scraped from online platforms.

Ethical Challenge 3: Preserving Meaning in the Data and Including Underrepresented Groups

In developing an algorithm for text mining of public forums, there is a risk of reproducing existing biases in society and even exacerbating them. Research has shown that applying machine learning to ordinary human language results in humanlike semantic biases. Namely, *text corpora* or language datasets contain imprints of our societal biases toward gender or race [31]. A well-known example is Google Translate's translation of job descriptions in gender-neutral languages that do not differentiate between *he* and *she* into English—until recently, this produced only biased sentences such as "she takes care of children" and "he is a lawyer." Moreover, subtle differences in meaning might be lost when transforming written experience into classifiable input for a conversation tool. If the eventual 4D conversation tool does not perform as well for each patient due to engrained societal biases or the loss of meaning in language processing, this can have a substantial impact in terms of fairness. For instance, if the tool works suboptimally for a certain minority group, this would not only be unfair but might also serve as a *microaggression*. A simple example of a microaggression is when an automatic soap dispenser cannot identify dark skin, which serves as a small (and unnecessary) reminder for people that their skin is not the *default* skin. Added up, these very small and unexpected daily encounters can truly affect a person's sense of belonging in a society [32]. Thus, it is important that metaphors used for capturing the experience of patients with cancer in the 4D PICTURE project are accurate and reflect not only the metaphors of dominant cultures but also the cultural languages of different minority groups.

Ethical Challenge 4: Protecting the Privacy of the Data of Patients With Cancer in the Public Domain

Data mining of public posts on web forums is not without ethical issues. A recent review [33] mentioned the following aspects: the privacy policies of public forums sometimes lack transparency [34]; users are not always aware of privacy settings or lack the digital skills to manage them according to their preferences [35]; even if users are aware that their posts are public, this does not mean that they agree with their posts being reused for just any purpose [36]; commercial use in particular (which is not part of the 4D PICTURE project) is deemed inappropriate by users [37-39], whereas reuse for the greater good is more accepted; and some users are even willing to put privacy concerns aside for public benefit [40]. There are 2 general issues that stand out. First, the use of social media posts for research brings about privacy risks and, in particular, the potential for reidentification. There is a risk of reidentification both on an individual and group level (eg, identifying a minority group). Patients fear that reidentification may lead to identity theft; could have consequences for employment and pension eligibility; and could lead to increased insurance costs and the use of their data for financial gain, social discomfort, or stigmatization in clinical settings or the community [33,41]. Although there is clear consensus about ensuring anonymity regarding research that scrapes data from web forums, this is

not always possible in practice. This first concern is only indirectly related to 4D PICTURE project, which will not use the data beyond its primary research aims, let alone to reidentify individual patients, but it does highlight the need for good data protection and security measures to protect the sets of data *scraped* from public forums.

Second, it is debated in the literature whether posts on public forums and social media should be considered as being part of the public or private domain given that notions of public and private are changing [40]. Legally, these posts are in the public domain, and no informed consent is needed regarding reuse, so many researchers do not ask for consent for scraping data from online forums [42-44]. However, citizens may have other intuitions about this. The distinction between *private* and *public* is probably too broad to reflect their moral intuitions about data ownership. The discrepancy between regulations and the views of citizens could lead to public outrage and less trust in science in general. Some ethicists have also argued that data may only be collected from social media platforms after explicit consent from the data subject [45]. It may be helpful in this setting to view privacy in terms of *contextual integrity*, a concept by Nissenbaum [46] based on the spheres of justice by Walzer [47]—simply put, contextual integrity says that privacy means something different in an airport security area than in a kindergarten. This is recognized by patients, who regard health data research as part of the (highly regulated) medical sphere and want their data to stay within that sphere [48], but what happens to contextual integrity when patients post their own health information on social media platforms? In the 4D PICTURE project, researchers will further explore these questions together with patient representatives to develop ethical guidance regarding the use of social media data for the project.

MetroMapping to Develop a Personal Care Path Navigator

Overview

In addition to the development of prognostic and conversation tools, the 4D PICTURE project aims to visualize the care trajectory for melanoma, breast cancer, and prostate cancer in 3 countries (the Netherlands, Spain, and Denmark). The new methodology of *MetroMapping*, which involves collaborative meetings with health care workers, is used to create a comprehensive visualization of the care trajectory for each specific cancer, representing various treatment options as metro lines [49]. The resulting MetroMap consists of different layers in addition to the metro line itself, which represents the overall structure of the care trajectory; other layers incorporate patient experiences at various points in this trajectory (eg, highlighting aspects such as magnetic resonance imaging being perceived as frightening) or provide information about the environment (eg, parking options or quiet routes within the hospital to accommodate heightened sensitivity to noise and smell after chemotherapy). The function of the MetroMap is to locate potential for improvements and *redesign* the care paths of people with cancer where needed. In the 4D PICTURE project, the prognostic models and conversation tools will be integrated into the MetroMap to also develop a personal care path navigator for each patient that serves as a decision aid in shared decision-making (SDM). There are 2 main ethical topics relevant here: first, SDM and, second, design justice and the influence of choice architecture.

Ethical Challenge 5: Incorporating SDM and Death Into the Care Path Design

The concept of SDM is increasingly recognized as an important aspect of personalized care, and it lies at the core of the 4D PICTURE project. The goal of SDM is to engage in conversations about relevant treatment options and the patient's values and preferences to arrive at a shared treatment decision aligned with their wishes [50]. In the 4D PICTURE project, the MetroMap design includes designated points labeled as *SDM moments* (indicated by stars). These moments signify important moments (eg, when test results are available) to allow for discussions between health care providers and patients regarding preferred treatment options. However, within actual care practice, SDM is complex and scattered along the care path, extending beyond a specific SDM moment occurring at a specific time point. Patients often struggle to express their values or preferences, necessitating support such as probing questions, multiple conversations, or sources of inspiration to determine what matters most to them in a given situation [51]. Some authors have argued that SDM runs the risk of putting too much responsibility on the patients and leaving patients "abandoned to their autonomy," as O'Neill [52] has said. However, the everyday reality of SDM in actual care practices shows that autonomy has a relational nature—there is an interdependence among patients, their support networks, and their health care providers [53,54]. Thus, when performed well, SDM seems compatible with a notion of autonomy that does not put too much responsibility on patients. However, of note is that patients differ in their preferences for how care is delivered (eg, in the number and duration of consultations in which treatment decisions need to be made [55]), so it is important to keep in mind that one patient may not represent the entire patient population in their preferences for SDM. Moreover, and this is a more general point, social determinants of health—such as economic status, social vulnerability, and access to resources—shape patients' capacity to engage in SDM, and health care systems should address these broader determinants to better support diverse patient needs related to SDM [56].

Another challenging aspect of the personal care path is the death of the patient. Death and mortality raise profound ethical questions, balancing values such as human dignity, patient autonomy, relieving pain, quality of life, and balancing the interests of an individual person within their network. As death carries cultural and social significance and ethical considerations vary across systems and belief systems, it is a notoriously sensitive topic in health care. Both health care workers and the systems of health care are mainly geared toward curing diseases and prolonging life—until relatively recently, clinicians were not taught to discuss end-of-life issues [57]. During the last decades, palliative care and advance care planning have been developed and professionalized [58], but how to incorporate end of life into the cancer care MetroMap is still an open question. Is there an end point? How should death be visualized? These are difficult questions and answers that may also differ by patient, country, and culture [59,60]. Studies show that

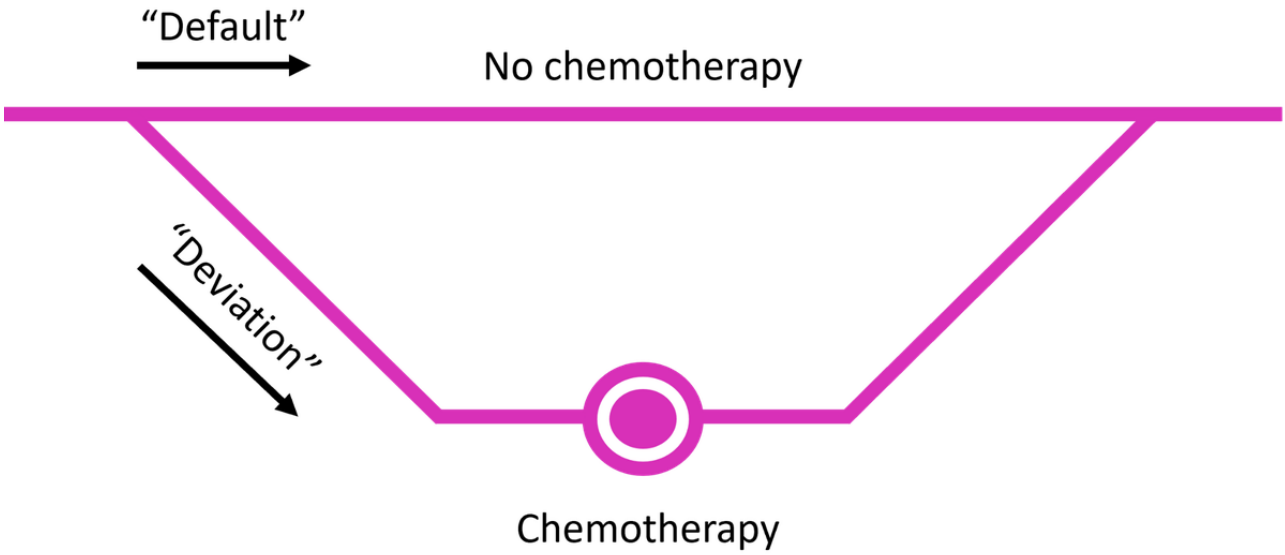
prognostic and conversation tools may be helpful for discussing end-of-life care [61], but their development should be accompanied by reflection on the experience of the patient.

Ethical Challenge 6: Visualizing Care Paths Responsibly Through Design Justice

In the 4D PICTURE project, service design methods will be developed and used by designers to help create the MetroMap. This methodology may give rise to ethical questions, for instance, because the design researchers will work with people with different levels of power (medical team vs patient and family) and need to be aware of sensitivities and vulnerabilities and also because there is a risk of bias on the part of the researcher who leads this process [62]. Moreover, we noted previously that technologies themselves (eg, algorithms) are not neutral but are packed with values [63]. The same is true for the cancer care path design as the way in which it is set up spatially may affect how information is perceived. The lens of *design justice* draws attention to this and shows how design enables or encourages certain actions while excluding or discouraging others. These design aspects are known as *affordances*—properties of an object that suggest possible actions that users can take (eg, a button affords pushing). In the context of the 4D PICTURE MetroMap, questions arise regarding its affordances and disaffordances. For example, if the map relies heavily on color, it may not be accessible to clinicians with color blindness. Identifying such issues within the design process is crucial to ensure that the MetroMap is inclusive. Thus, design justice brings awareness to often unconscious design decisions and seeks to rectify historical and systemic injustices perpetuated by design decisions (eg, a bridge that is too low for a public bus to pass under, allowing only car owners to take a certain road [64]). Design justice challenges power dynamics within design, advocating for the redistribution of resources and opportunities to address social, economic, and environmental disparities [63].

An important part of design justice in the 4D PICTURE project is the impact of what has been dubbed *choice architecture* (ie, the number of options presented simultaneously, or their order, influence which information is best retained by viewers and which choice is finally made [64-68]). To illustrate, it makes a difference whether treatment options are presented as “no treatment vs. treatment” or “no treatment vs. treatment option 1 vs. treatment option 2” because people divide their attention equally in considering all options [66]. The visualization of *default* and *deviated* decision paths (Figure 3) can also have a large effect on which choice is made [69]. There is little evidence from health care on this topic, but cartography research shows that the linearity of map routes matters in route choices made by travelers [70]. The effects of choice architecture are so strong that it works even if decision makers are aware of the mechanism [71]. One paper about default options in oncology concludes that further experimental studies are needed to select which default options successfully change behavior [72], and to this we add that such investigation should include consideration of design justice.

Figure 3. Choice architecture—visualization of the default and deviated decision paths.



Some ethics scholars suggest that choices should be presented in the least directive way, but others have argued for using conscious choice architecture to stimulate unpopular but beneficial choices (ie, nudging) [73]. For example, some types of localized prostate cancer generally present as slow-growing tumors, and active surveillance of progression while withholding or postponing treatment is a beneficial option in this case as treatment has a significant chance of producing complications [65]. However, medicine is biased toward acting rather than waiting, leading some clinicians to present patients more strongly with the different treatment options than with the possibility of active surveillance. In this example, a MetroMap might need to be designed as a choice between active surveillance and treatment first and then as a choice between treatments. MetroMap designers should deliberate regarding which effect they wish the MetroMap to have on decisions and how this is best achieved and underpin the acceptability of this choice with medical-ethical arguments. Although exerting as little influence as possible is preferable in most cases, there are

situations in which some nudging by using ordering effects or default options can be argued to be justified.

Evaluation and Development of Guidance for Policy Makers

Overview

The 4D PICTURE project also contains an evaluation of the MetroMapping design methodology, the MetroMap itself, and the prognostic model and conversation tool, as well as a cost-effectiveness evaluation and an assessment of the generalizability of the methods and developed tools. Moreover, the project will develop guidance for policy makers about MetroMapping using a framework that helps understand the nonadoption; abandonment; and challenges to the scale-up, spread, and sustainability (NASSS) of health technologies by professionals or patients [74]. With regard to the evaluation and policy aspects of the 4D PICTURE project, the following ethical topics are relevant: reflection on the criteria for evaluation, balancing ethics with technology adoption, and techno-moral change.

Ethical Challenge 7: Reflecting on Good Criteria for (Cost-Effectiveness) Evaluation

In the 4D PICTURE project, questionnaires among patients, significant others, and clinicians will be used to compare between the original and redesigned care paths and evaluate the developed tools. As is good practice within quantitative evaluation studies and expected by funding agencies, the criteria based on which the redesigned care paths will be evaluated were defined in advance. Researchers should consider, together with patient representatives, which evaluation method and criteria fit their project best. The same is true for cost-effectiveness analyses. The ultimate goal of such analyses is to help health care decision makers choose between competing alternatives based on some predetermined measure of economic efficiency, such as cost per life saved, cost per year of life saved, or positive net benefits. Just like we saw with prognostic models, an important ethical aspect of cost-effectiveness analyses is that they "expose...hidden assumptions, and require explicit judgements to be made about which ethical position is appropriate in a particular policy context" [75]. Should cost-effectiveness analyses be used at all, or is it inherently unjust to compare costs between persons [76]? Such ethical questions and specific dilemmas regarding cost-effectiveness have been discussed extensively in the medical ethics literature, but further work is still needed to see how existing arguments apply to the novel setting of data-driven and personalized cancer care.

Ethical Challenge 8: Balancing the Adoption of Technology With Other Values

Research shows that many innovations are eventually not adopted [77]. In the 4D PICTURE project, the NASSS framework is used to study how the developed tools can be designed to promote adoption and avoid wasting resources. However, strategies that increase the adoption potential of health innovations can simultaneously pose ethical dilemmas. An example is that of a research laboratory that developed care robots, where the adoption by health care workers was a major issue (eg, some nurses put the robots in a closet because they found them annoying) [78]. The researchers discovered that building gender stereotypes into the robots contributed to their acceptability and adoptability by health care workers. For instance, if they developed a robot that was interpreted as female, the tone of voice was expected to be much more modest and less authoritative than that of robots that were interpreted as male. This poses an ethical dilemma: what is the right thing to do [79]—contributing to acceptability by repeating gender stereotypes into the design or countering gender stereotypes? Ethical reflection with stakeholders is needed on how to balance adoption with other values. This can take the form of structured methods such as moral case deliberation [80] as well as structural collaboration between researchers and groups of patients and the publics, which is discussed under ethical challenge 10.

Ethical Challenge 9: Anticipating Techno-Moral Change and Developing New Ethical Frameworks

Innovations are almost never used in practice as intended, and they often produce unintended, unforeseen, and sometimes even counterproductive consequences—in other words, "things bite back" [81]. A simple example is how, when more highways are built to reduce traffic jams, more people will take their cars, so no reduction in traffic jams is realized. Often, new technologies or other innovations influence our concepts and conceptions of a good life [82,83]. Think of the introduction of the contraceptive pill that contributed to women's emancipation or of blood sugar measurement devices that influence the way in which patients with diabetes relate to their bodies [84]. This process of technology and ethics codeveloping has been referred to as *techno-moral* change [83]. Techno-moral change is notoriously hard to research or predict and may complicate the evaluations and policy development planned in the 4D PICTURE project and similar health technology projects. In addition, the 4D PICTURE project itself may contribute to techno-moral change through the development of prognostic models and the conversation tool and the redesign of care paths—these may influence patients' and clinicians' moral routines in unexpected ways or create new moral dilemmas. Possible techno-moral changes should be anticipated (eg, through qualitative interviews about the expectations of stakeholders or through ethnographic observation studies) during the research phase instead so that they may be acted upon in time.

A timely example of techno-moral change is the incorporation of sustainability into evaluation frameworks and to take the costs, harms, and burdens of health care technology with respect to the environment into account. Health care has always been a system with a significant carbon footprint due to the many single-use products, and now data are also becoming an important factor [85]. The increasing data storage and analysis possibilities bring about new moral questions. For instance, is it proportionate to slightly reduce a certain health risk using a method that puts a considerably larger burden on the environment? However, we currently lack ethical vocabulary, frameworks, and research on this topic. The connection and trade-offs between health care and planetary health need to be further studied, and this important aspect will be included in

the 4D PICTURE project despite not being in the original plan. For instance, to prime researchers about the topic, the authors of this paper organized an interactive session about environmental sustainability during the latest project consortium meeting and asked each work package to present in the next consortium meeting how they will address sustainability in their work.

Project Management, Dissemination, and Ethics

Overview

Similar to most large research projects, the 4D PICTURE project has several *work packages* focused on aspects bordering the science at the project's core—the coordination, management, and progress monitoring of the project, as well as the dissemination of findings and the embedding of ethics throughout the project. Although it is less obvious, even these work packages can give rise to ethical issues. We identified the following issues that are relevant for the 4D PICTURE project and other research projects on data-driven care: epistemic injustice, the *trading zone*, the position of the embedded ethicist, and psychological safety.

Ethical Challenge 10: Integrating Patients' Experiential Knowledge to Avoid Epistemic Injustice

The 4D PICTURE project integrates experiential knowledge from patient and public involvement (PPI) boards in all participating countries aiming to align care paths with patients' needs. However, bridging experiential and academic knowledge presents challenges. How to translate the information shared by the PPI boards into usable knowledge for the research group? What to do with contradictions or differences of opinion [86,87]? A helpful concept is that of epistemic injustice or, in other words, knowledge-related injustice [88]. This encompasses testimonial and hermeneutical injustices [89]. Testimonial injustice arises when dismissing patient experiences as unreliable, emotional, or irrelevant, potentially leading to a loss of confidence that causes patients to stay silent [90]. Hermeneutical injustice arises when patients lack the language or concepts to articulate their experiences [90]. This occurs because these concepts have not been developed yet, because patients do not have access to them, or because the concepts are not recognized by clinicians as the dominant group. In the 4D PICTURE project, the conversation tool is intended to allow patients to express their experiences and bridge this hermeneutical gap between patients and professionals. Awareness of the concept of epistemic injustice may help the researchers notice instances in which it may play a role and search for strategies to minimize epistemic injustice during the research process. Strategies include conveying patient contributions through stories or alternative mediums such as visual art, films, or metaphors [90,91]. Researchers must also undertake "role, emotion, and relationship work," which involves switching between different roles (eg, researcher, facilitator, advocate, relation manager, or coffee maker), handling loaded emotions with care and empathy (ie, rather than distancing oneself from the subject), and fostering relationships [92]. Awareness of these strategies helps minimize epistemic injustice, ensuring that patients' voices are valued and respected in the research process. A final note is that power dynamics leading to epistemic injustice are influenced by existing structural inequalities regarding race or socioeconomic class, for instance. In the 4D PICTURE project, the ethicists and other researchers will work with the PPI boards on appropriate ways (eg, payment of the PPI boards) to alleviate the harmful effects of such structural concerns to help ensure that all voices are heard equally.

Ethical Challenge 11: Negotiating Shared Knowledge in "the Trading Zone" Between Disciplines

Often, professionals from different disciplines use different concepts; ascribe different significance to objects or phenomena; use different conceptual frameworks; and may also have different value systems, accountability rules, and quality indicators. The same is true for clinicians and patients in the cancer care trajectory—clinicians' choices and priorities may conflict with the perspectives of patients (eg, streamlining and speeding up the care path vs preferring more time to deliberate treatment options between multiple consultations [55]). Understanding how to guide collaborations between different scientific disciplines and with patient representatives in the 4D PICTURE project can be based on the metaphor of a *trading zone*, which is often used to study multidisciplinary scientific collaborations [93]. In the *trading zone*, a shared understanding between the different disciplines and different types of (experiential) knowledge should be negotiated. This *trading* can be facilitated by an agent who is familiar with >1 discipline. Sometimes, this could be a nurse; in other cases, it can be an embedded ethicist. To do this effectively and fairly, it is important to have awareness of power differences and implicit value frameworks. Are all relevant voices heard and valued equally [94]? Who has a say in the structure and processes of collaboration? Whose knowledge counts (see the aforementioned concept of *epistemic injustice*)?

To avoid one perspective overshadowing another, collaborators should think about how to handle differences of opinion in meetings and how to ensure that all participants make sufficiently equal contributions. Strategies to divide power equally in the trading zone can consist of making the differences in vocabulary, systems of recognition, and value systems explicit; making use of *boundary objects* that facilitate exchange between multiple worlds [95]; develop meeting structures that stimulate an explicit deliberation; and decide in advance which agents in a project are best placed to facilitate collaboration in the trading zone (this is not always the project lead). Of note is that the trading zone metaphor is relevant not only during the conduct of research but also in the dissemination phase. Dissemination is in itself an ethical imperative, especially when the research was publicly funded, but also comes with ethical sensitivities [96]. Collaborative efforts between different types of partners (eg, clinician researchers, developers, and patient representatives) can help facilitate the *trading* or sharing of knowledge in a way that is valuable for reaching different stakeholders. As such, dissemination can help combat epistemic injustice as well as *demystify* scientific concepts and hypes such as those surrounding AI [97]. Dissemination should always be planned so that the outputs are contextualized and sensitive to the experiences of the group under study (in our case, patients with cancer) [98].

Ethical Challenge 12: Establishing the Position of the Embedded Ethicist

Ethicists are embedded in the 4D PICTURE project to conduct this literature review and several empirical studies about ethical issues, as well as to provide support with ad hoc ethical issues by joining scientific meetings and providing internal trainings. In bioethics, there have been long-standing debates about how empirical data relate to normative reasoning and about the role of the ethicist in health research [99]. Should an ethicist be a critical, distant outsider or be part of the research practice? We find that a more *embedded* role is called for right now. Take the example of AI—while several organizations have developed general principles for AI in health care, the ethical difficulties lie in applying these principles and making trade-offs in actual research practices. Embedded ethics can fill this gap between intentions and actions by engaging in practical and relational work on ethics within a specific research project or development process [7]. However, there are also some risks and disadvantages to embedded ethics. Namely, as the ethicist's normative analysis is so close to research practice, there is a risk that more fundamental ethical questions will not be discussed and researched. An example is the growing influence of *big tech* on our health care systems—as research ethics committees have only focused on topics such as privacy in individual research projects and specific tools to be developed, they lack an ethical framework to meaningfully weigh the broader collaboration with industry. Ethicists can sometimes secure power instead of challenging it because "they locate the source of the problem in individuals or technical systems instead of acknowledging structural power differences and working structurally towards dismantling them" [100]. In certain cases, there is a risk of this leading to *ethics washing* or lip service to industry [7]. Thus, in large interdisciplinary health research projects, one should not forget to consider "the ethics of the ethics work package." Moreover, we find that ethics should be recognized as a shared responsibility—the embedded ethicists can *sensitize* other consortium members to the ethical aspects but cannot be solely responsible for the normative assessments of the research and the tools being developed.

Ethical Challenge 13: Ensuring Psychological Safety in Research Teams

Finally, an underappreciated ethical aspect of research is psychological safety, which is defined as "the belief that one will not be punished or humiliated for speaking up with ideas, questions, concerns, or mistakes, and the team is safe for interpersonal risk taking" [101]. Safe environments are those where it does not feel risky to express one's thoughts, doubts, questions, and errors. As such, psychological safety is a key condition for high-performance research teams as this safe environment promotes takings risks as well as reporting mistakes and learning from them. Psychological safety also influences the degree to which people speak up about (research) misconduct and promotes open discussions about *grey areas* or so-called *questionable research practices* such as cutting corners due to time pressure [102]. In the same vein, it is a precondition for opening up about moral dilemmas in research and development. Strategies for promoting psychological safety include encouraging vulnerability, active listening, appreciating diverse perspectives, promoting a culture of feedback and learning, establishing clear expectations, celebrating experimentation, treating mistakes as learning opportunities, providing tools and training for effective conflict resolution, using metrics to regularly assess psychological safety levels, and leadership actively endorsing psychological safety [101]. Of course, in large projects, the level of psychological safety differs by collaborating partner, but it can still be influenced by the project and work package leads.

Discussion

In this paper, we have described relevant ethical challenges that should be considered when developing data-driven DSTs for more personalized cancer care. We based our review on the European 4D PICTURE research project, and as such, this paper is the first review grounded explicitly in the *Embedded Ethics* approach [7]. Using a collaborative and iterative methodology helped provide a broad overview of the ethics of this heterogeneous and interdisciplinary project. This overview serves as starting point for developing actionable guidance for the project and potentially beyond, as well as for further empirical and theoretical ethics research and future collaborations with developers, clinicians, researchers, and the PPI boards in the 4D PICTURE project. As such, we add to discussions in previous, more systematic literature reviews about data-driven DSTs in health care, which have mostly highlighted general, high-level ethical principles of respect for patient autonomy, prevention of harm, fairness, explicability, and privacy [103], as well as professional autonomy, bias and justice, and explicability [104]. Another study applied an ethical framework on AI-guided clinical decision support and used case examples to illustrate key issues of accountability and transparency, the potential for group harm, efficiency of health care, and conflicts between roles and responsibilities [105]. Such examples are insightful but provide less detail than a review of a complete research project. The iterative process of extracting themes by moving between key papers and discussions with the consortium helped us describe more specific examples of the universal themes in the literature and uncover additional challenges unrelated to the technical and medical core of the project. As such, our embedded review highlights ethical aspects previously neglected in the digital health ethics literature and zooms in on real-world challenges in an ongoing project.

Several identified ethical challenges (challenges 1-4) were related to the data and algorithms needed to develop data-driven DSTs in oncology. Prominent issues were indeed bias and privacy, which have been extensively described in previous literature reviews, yet our analysis gave rise to more specific, real-world questions for further research and advice (eg, "what are the arguments for including or excluding postal code in a prognostic model for cancer treatment outcome?" or "should posts on online patient fora be considered part of the public domain or is consent needed to use them for the development of conversation tools in oncology?"). Other topics (challenges 5 and 6) revolved around the specific design methodology used in the 4D PICTURE project. Questions arose about *design justice* that have not been previously addressed in the context

of DSTs for health care. Furthermore, we described various ethical aspects related to broader policy issues in health care (challenges 7-9). Lysaght et al [105] have previously mentioned the cost-effectiveness of data-driven DSTs and financial sustainability of health care systems as important ethical issues, and we have added that environmental sustainability is also a timely ethical consideration—currently, there is a lack of knowledge on how to apply sustainability in practice and how to balance it with competing values.

Finally, various challenges that we described in this paper do not relate directly to the DST as the outcome of the 4D PICTURE project but rather to the research process itself (eg, to the project management or results dissemination). We highlighted the importance of epistemic justice in the collaboration with patients and between different disciplines, questioned the role of the embedded ethicist who may not be fully independent themselves, and called for attention to psychological safety (challenges 10-13). The latter topic is increasingly discussed in various sectors of work, including health care, but is generally not an agenda point for international consortia even though project leaders seem to have an important role model function. Therefore, a key outcome of this embedded ethics review is that researchers and leaders in medical data-driven research projects should not forget the ethical challenges of the work that surrounds the scientific core of the project.

Our methodology is novel but not without limitations. The literature search was not systematic, so the results are not exhaustive, and the identification of ethical challenges was to a certain extent subjective and colored by the preferences and knowledge of the ethicists that conducted it. We addressed this by conducting a *member check* with 4D PICTURE researchers, but we propose that, in future projects, a check by an external ethicist could serve as additional validation. In addition, the definition of *ethical challenges* could be developed together with participants (in our case, the researchers in the 4D PICTURE project) to avoid variation and achieve clarity in the analysis and interpretation [10]. Moreover, new issues may come up after the publication of this paper as the project is still evolving. While these will be addressed in annual documents shared within the consortium (a sort of *rolling review*), this paper is not as dynamic or adaptable. Further thought is needed on how to better match the publication of ethics research with the developments in medical and data science and the possibility for techno-moral change (eg, should it be possible to update papers after publication in an academic journal to ensure that they remain up-to-date and relevant?). Finally, a general limitation of embedded ethics research is inherently tied to its main strength of providing actionable recommendations within a specific project—namely, ethicists should ensure not to lose sight of the broader structural and systemic issues underlying the particular questions discussed within the scope of a project. For instance, the focus on the 4D PICTURE project limited our discussions on data bias to *the* European context, if that even exists, whereas a huge concern is *data poverty* in low- and middle-income countries that may have fewer means to digitalize health care systems [106]. Another example relates to the more structural socioeconomic inequalities that influence digital inclusion efforts, which cannot be *solved* within applied research projects focused on developing digital tools [107]. We need to consider, in future work, how embedded ethicists can put such structural issues on the agenda when their work is tied to specific ethics work packages in highly delineated projects.

In conclusion, this viewpoint shows that a lot may be gained when ethics is embedded into a project from the start. Analysis of existing literature was deepened, and findings were made more actionable through the iterative collaboration between ethicists and other researchers in a large research consortium. For instance, the work on this embedded ethics review led to further collaboration with the design researchers in the 4D PICTURE project to pre-emptively reflect on ethical challenges that may arise during their fieldwork of *shadowing* patients to analyze oncology service design [62], thus laying the groundwork for responsible visualization and redesign of care paths (challenge 6) while ensuring that patients and their voices are respected in the research process (challenge 10). We suggest that ethicists working in interdisciplinary projects should not automatically opt for systematic or scoping reviews of a single question but rather consider whether a more applied *Embedded Ethics* review strategy might sometimes better fit their practical and theoretical aims. Ethics often formulates abstract, high-level principles, and in this paper, we have shown how these can be operationalized in practice, in particular when designing and developing data-driven support tools for improving cancer care. Taking on board the identified challenges and recommendations will help ensure that data-driven innovations in oncology are developed in an appropriate and patient-centered manner.

Acknowledgments

The authors thank all researchers in the 4D PICTURE (Producing Improved Cancer Outcomes Through User-Centered Research; see Multimedia Appendix 1 for a list of the members' names and affiliations) project for sharing their insights on the ethical challenges discussed in this paper. The research leading to these results was funded by the European Union under the Horizon Europe work program (101057332). However, the views and opinions expressed are those of the authors only and do not necessarily reflect those of the European Union or the European Health and Digital Executive Agency. Neither the European Union nor the granting authority can be held responsible for them. The UK team of the 4D PICTURE project is funded under the Innovate UK Horizon Europe guarantee program (UK Research and Innovation reference 10041120). The authors thank Panton for providing images of MetroMapping for the 4D PICTURE project.

Authors' Contributions

LH and MS conceptualized this paper. LH and CG collected the literature and conducted the analysis. LH wrote the report that served as the basis for this paper. LH and MB conducted the *member check* among the consortium members. MB wrote the original draft of the paper and led the revision process. MS, IJK, and AB acquired the funding for this study, were involved in the analysis, and reviewed and substantially edited the paper.

Conflicts of Interest

None declared.

Abstract

Background: People with advanced ovarian cancer and their caregivers report unmet supportive care needs. We developed a Collaborative Agenda-Setting Intervention (CASI) to elicit patients' and caregivers' needs through the patient portal before a clinic visit and to communicate these needs to clinicians using the electronic health record.

Objective: We aimed to assess the usability and acceptability of the CASI and identify barriers to and facilitators of its implementation.

Methods: We recruited English- and Spanish-speaking patients, caregivers, and clinicians from the gynecologic oncology program at a comprehensive cancer center. Participants used the CASI prototype and then completed individual cognitive interviews and surveys. We assessed usability with the System Usability Scale (scores range 0 - 100, scores ≥70 indicate acceptable usability) and acceptability with the Acceptability of Intervention Measure and Intervention Appropriateness Measure (scores for both measures range from 1 to 5, higher scores indicate greater acceptability). Interviews were audio recorded, transcribed, and analyzed using directed content analysis. Domains and constructs from the Consolidated Framework for Implementation Research comprised the initial codebook. We analyzed survey data using descriptive statistics and compared usability and acceptability scores across patients, caregivers, and clinicians using analyses of variance.

Results: We enrolled 15 participants (5 patients, 5 caregivers, and 5 clinicians). The mean System Usability Scale score was 72 (SD 16). The mean Acceptability of Intervention Measure and Intervention Appropriateness Measure scores were 3.9 (SD 1.0) and 4.1 (SD 0.8), respectively. Participants viewed the CASI content and format positively overall. Several participants appreciated the CASI's integration into the clinical workflow and its potential to increase attention to psychosocial concerns. Suggestions to refine the CASI included removing redundant items, simplifying item language, and adding options to request a conversation or opt out of supportive care referrals. Key barriers to implementing the CASI include its complexity and limited resources available to address patients' and caregivers' needs.

Conclusions: The CASI is usable and acceptable to patients with advanced ovarian cancer, caregivers, and clinicians. We identified several barriers to and facilitators of implementing the CASI. In future research, we will apply these insights to a pilot randomized controlled trial to assess the feasibility of comparing the CASI to usual care in a parallel group-randomized efficacy trial.

Introduction

Patients undergoing treatment for advanced ovarian cancer commonly experience burdensome disease- and treatment-related symptoms [1] followed by cancer recurrence after treatment completion [2]. Challenged to adapt to a chronic, life-limiting condition, more than two-thirds of patients with advanced ovarian cancer and their caregivers report at least 1 moderate-to-high unmet supportive care need [3]. Such needs negatively impact patients' and caregivers' health-related quality of life and are associated with a higher likelihood that patients will require emergency department visits and hospitalizations [4]. In 2022, a multidisciplinary expert panel recommended the provision of individualized and timely resources to address the unmet supportive care needs of patients with advanced ovarian cancer and their caregivers [5]. Likewise, health authorities in the United States, Canada, and the United Kingdom have advocated for the delivery of person-centered (alternatively, "patient-centered") cancer care [6-8].

Person-centered care entails eliciting and responding to patients' and caregivers' goals, values, and preferences in a system that supports high quality communication between patients, caregivers, and clinicians [9,10]. Research suggests the provision of person-centered care has the potential to improve health outcomes in patients with cancer [11]. In our prior work, we found that communication that fosters healing patient-clinician relationships is associated with better social and family well-being and lower symptom burdens among people with ovarian cancer [12,13]. Patients in these studies wanted their clinicians to be proactive and attentive to patients' psychosocial concerns and other supportive care needs [13]. However, time constraints, medical complexity, and inadequate resources for follow-up care may challenge clinicians to identify and manage nonmedical needs routinely [14-16].

To overcome these barriers, we used a design thinking approach to develop a Collaborative Agenda-Setting Intervention (CASI) to promote person-centered ovarian cancer care [17]. The CASI is a patient portal- and electronic health record (EHR)–integrated tool that aims to improve patient and caregiver well-being by routinely eliciting patients' and caregivers' values, preferences, and supportive care needs. The CASI supports agenda-setting and person-centered communication between patients, caregivers, and clinicians. The American Society of Clinical Oncology [18] and the European Society for Medical Oncology [19] have published guidelines for person-centered communication which direct clinicians to routinely set an agenda for visits by sharing their goals and eliciting topics that patients and caregivers wish to address. In the primary care setting, agenda-setting has been shown to increase person-centered care without prolonging visit duration [20] and to reduce clinician burden by preventing late-breaking concerns [21]. To date, however, research on agenda-setting interventions in cancer care is limited. The purpose of this study, therefore, was to assess the usability and acceptability of the CASI and identify barriers to and facilitators of implementing the CASI in this setting.

Methods

Study Design

We conducted a cross-sectional study using qualitative and quantitative methods. Our approach to data collection and analysis was guided by principles of design thinking [17] and the Consolidated Framework for Implementation Research (CFIR) [22]. According to the CFIR, the likelihood of successful implementation is affected by 5 domains: the inner setting (ie, the setting in which the innovation is being implemented), the outer setting (ie, the community or system in which the inner setting exists), the characteristics of the innovation itself, the characteristics of the individuals who will interact with the innovation, and the process by which the innovation is implemented [22]. We tested the CASI prototype and elicited stakeholder perspectives on each of the CFIR domains.

Recruitment

We recruited participants from the gynecologic oncology clinic of a National Cancer Institute–designated comprehensive cancer center. Patients were eligible if they were English- or Spanish-speaking adults with stage III, stage IV, or recurrent ovarian cancer. Caregivers were eligible if they were English- or Spanish-speaking adults who self-identified as the caregiver of a person with stage III, stage IV, or recurrent ovarian cancer. Enrollment in the cancer center's patient portal was not required for study participation. Patients and caregivers were purposively sampled to ensure representation of diverse demographic groups. We approached potentially eligible patients and caregivers in person during regularly scheduled clinic visits. Clinicians were eligible if they were an oncologist or advanced practice provider who cared for at least 4 outpatients per month with stage III, stage IV, or recurrent ovarian cancer. We introduced this study at a weekly provider meeting, then approached individual clinicians via email.

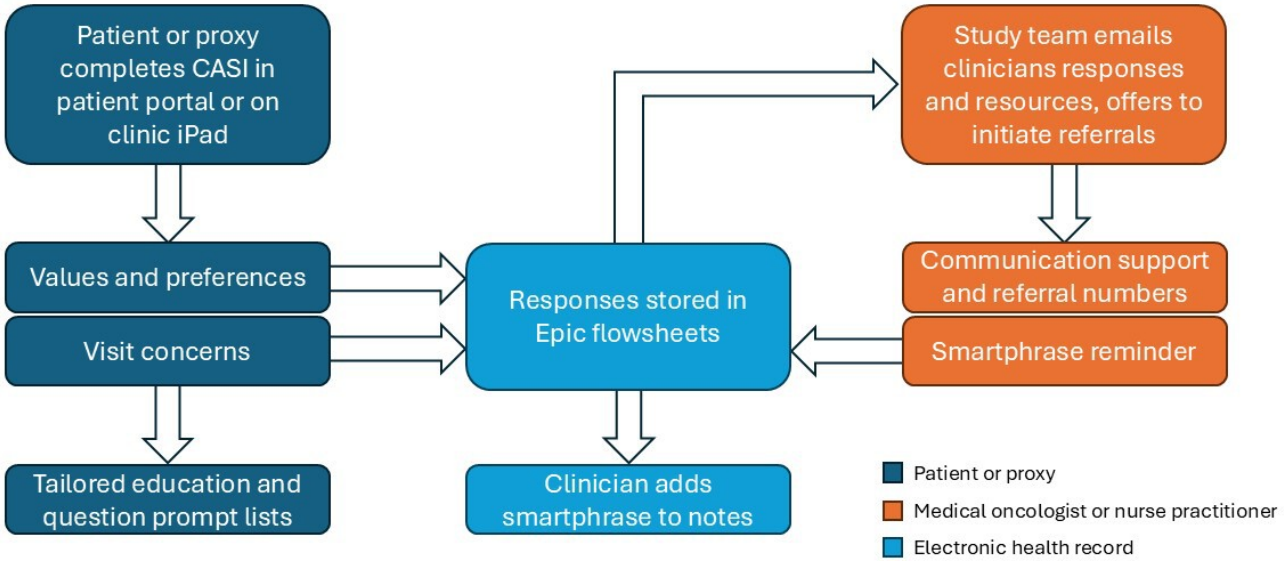
Ethical Considerations

All participants provided written informed consent and received US $25 upon data collection. Study data were deidentified before analysis. The Dana-Farber Cancer Institute Institutional Review Board approved all study procedures (protocol #21 - 322).

Intervention Characteristics

An intervention schema is provided in (Figure 1). The CASI has been integrated into Epic (Epic Systems Corporation), which is the most widely used EHR system in the United States [23]. The CASI is currently available in English and Spanish and has an English-language Flesch-Kincaid reading level of grade 6.9. Patients complete the CASI through the patient portal, which can be accessed on any smartphone, tablet, laptop, or desktop computer. Patients without a personal device may complete the CASI on a tablet provided by the clinic at the time of check-in. Caregivers with proxy access to the patient portal may complete the CASI in the same fashion as patients. Clinicians access the patient's or caregiver's responses to the CASI in Epic hyperspace, which is the clinician-facing EHR platform.

Figure 1. CASI schema. CASI: Collaborative Agenda-Setting Intervention.



Patients and caregivers are prompted through the patient portal to complete the CASI no more than 7 days before an upcoming clinic visit. Completing the CASI involves responding to 2 questionnaires as frequently as once every 3 weeks. The first questionnaire includes items about values, preferences, and communication needs. Selected items were derived from the Control Preferences Scale [24], which is a validated measure of patients' preferred level of involvement in medical decision-making, and the SHARE questionnaire [25], a communication intervention designed to elicit patients' preferences and goals. Patients and caregivers complete the first questionnaire the first time they use the CASI. Thereafter, patients and caregivers have the option to update their responses but are not required to repeat the questionnaire. The second questionnaire includes items derived from the National Comprehensive Cancer Network Distress Thermometer Problem List [26], which asks respondents to select the physical, emotional, social, practical, spiritual, and other concerns experienced during the past 7 days. Patients and caregivers complete the second questionnaire every time they use the CASI. Patients and caregivers receive standardized question prompt lists through the patient portal for each of the concerns they identify. In addition, a member of this study's team assists with follow-up navigation and initiating referrals when warranted.

Responses to both questionnaires are stored in Epic and associated with the appropriate upcoming clinical encounter. Clinicians can view CASI questionnaire responses in the rooming tab of the visit note (which contains patient-reported symptoms, vital signs, and information collected by the clinic assistant before the patient is seen by the physician or advanced practice provider), during chart review, or by using a smart phrase to populate the narrative history of present illness with the most recent CASI questionnaire responses. When a patient or caregiver completes the CASI, a member of this study's team emails the clinician a summary of the CASI responses, offers to initiate referrals, shares links to evidence-based communication guidance, and reminds the clinician how to use the CASI smart phrase to populate their visit note.

Data Collection

Participant Characteristics

All participants self-reported age, gender, ethnicity, and race. Patients and caregivers self-reported marital status, annual household income, and educational attainment. Caregivers self-reported their relationship to the patient and the number of clinic visits they attended with the patient in the last 6 months. Clinicians self-reported their clinical role and specialty, number of patients seen with advanced ovarian cancer per month, and number of years spent caring for patients with advanced ovarian cancer.

Cognitive Interviews

We conducted individual, semistructured cognitive interviews with patients, caregivers, and clinicians in person and over Health Insurance Portability and Accountability Act–compliant video conferencing software (Multimedia Appendix 1). To identify potential usability challenges, participants were instructed to think aloud as they used the CASI in a testing environment that was not linked to the EHR. Trained interviewers (RAP, JB, and PB) observed participants, made note of any sections of the CASI that were difficult for participants to navigate, and invited participants to comment on aspects of the CASI's content and design. Interviews with Spanish-speaking participants were conducted in Spanish by a bilingual member of this study's team (JB). All participants reviewed patient- and caregiver-facing content, but only clinicians reviewed clinician-facing content. To identify potential barriers to implementing the CASI, interviewers asked participants to consider integration of the CASI into their existing routine, identify barriers to using the CASI regularly, and identify strategies to minimize patient, caregiver, and clinician burden. Interviews were audio recorded, professionally transcribed, and professionally translated from Spanish to English when applicable. Following cognitive interviews, participants completed a REDCap (Research Electronic Data Capture; Vanderbilt University) [27,28] survey that included quantitative measures of usability, acceptability, and burden.

We refined the CASI in response to cognitive interview feedback.

Usability

The System Usability Scale (SUS) is a 10-item scale that assesses the usability of electronic systems. The SUS yields a single number representing a composite measure of the overall usability of the system being studied. Scores for individual items are not meaningful on their own. Total scores range from 0 to 100; higher scores indicate better usability [29], and scores of 70 or greater are acceptable [30].

Acceptability

The Acceptability of Intervention Measure (AIM) and Intervention Appropriateness Measure (IAM) are 4-item scales that each assess a single dimension of intervention acceptability. Response options range from 1 (“completely disagree”) to 5 (“completely agree”). Total scores for each measure range from 1 to 5. While cut scores have not yet been established for these measures, higher scores represent better acceptability [31].

Participant Burden

We assessed participant burden by asking participants to rate the extent to which they agreed with the statement “using the CASI placed a considerable burden on me.” Response options ranged from 1 (“strongly disagree”) to 5 (“strongly agree”).

Analysis

Cognitive Interviews

We analyzed transcripts of cognitive interviews using directed content analysis [32]. Directed content analysis involves drawing key constructs from existing theory to develop an initial codebook. When one or more text segments are not represented in the initial codebook, the investigator creates new codes. Our initial codebook was based on the 2009 version of the CFIR domains and constructs. Author RAP, a nurse scientist with expertise in qualitative research, read and coded all transcripts in their entirety. To enhance trustworthiness and foster reflexivity, coding was reviewed by members of this study’s team with expertise in clinical research (JB) and health informatics (PB). Differences in data interpretation were resolved through discussion. We used MAXQDA 2022 (VERBI Software GmbH) to support qualitative data management.

Quantitative Measures

We summarized participant characteristics and SUS, AIM, and IAM scores using descriptive statistics. We performed analyses of variance to identify differences in SUS, AIM, and IAM scores across patients, caregivers, and clinicians and considered values of $P<.05$ significant.

Results

Participant Characteristics

Data collection took place between August 2023 and July 2024. Interviews lasted an average of 40 (SD 10) minutes. A total of 15 participants (5 patients, 5 caregivers, and 5 clinicians) completed this study. Characteristics of each participant group are detailed in Table 1. Briefly, participants were predominantly women (11/15, 73%), White (12/15, 80%), non-Hispanic (11/15, 73%), and working full- or part-time (9/15, 60%). Patients and caregivers were most commonly married or partnered (5/10, 50%) college graduates (5/10, 50%) and reported a range of annual household incomes: less than US $24,000 (2/10, 20%), US $75,000 to US $119,000 (2/10, 20%), or US $120,000 or more (2/10, 20%) per year. Caregivers identified as spouses or partners (2/5, 40%), parents (2/5, 40%), and friends (1/5, 20%) of patients. Caregivers had most often attended between 5 and 9 clinic visits with patients in the last 6 months (2/5, 40%). Clinicians were primarily physicians working in medical oncology (3/5, 60%) who reported caring for more than 20 patients with advanced ovarian cancer each month (5/5, 100%) and had 15 - 19 years of experience caring for patients with advanced ovarian cancer (3/5, 60%).

Table . Participant characteristics.

		Total	Patients	Caregivers	Clinicians

Usability, Acceptability, and Burden

SUS, AIM, and IAM scores by participant group are reported in Table 2. Briefly, the overall mean SUS score was 72 (SD 16), which is above the threshold of acceptable usability [30]. The overall mean AIM score was 3.9 out of 5 (SD 1), while the overall mean IAM score was 4.1 out of 5 (SD 0.8). There were no statistically significant (P<.05) differences in SUS, AIM, or IAM scores across patients, caregivers, and clinicians. Moreover, 1/15 (7%) participants reported that the CASI was burdensome; this participant was a patient who experienced difficulty adjusting the font size on the CASI questionnaires during usability testing.

Table . Usability and acceptability of the Collaborative Agenda-Setting Intervention.

	Overall (n=15), mean (SD)	Patients (n=5), mean (SD)	Caregivers (n=5), mean (SD)	Clinicians (n=5), mean (SD)	*F* test (*df*)	*P* value
SUS[a]	72 (16)	64 (15)	78 (12)	73 (20)	0.82 (2)	.47
AIM[b]	3.9 (1)	3.8 (0.8)	4 (1)	4 (1.2)	0.05 (2)	.95
IAM[c]	4.1 (0.8)	4 (0.8)	4.2 (0.8)	4.2 (0.8)	0.07 (2)	.93

[a]SUS: System Usability Scale. Possible scores range from 0-100. Higher scores indicate greater usability, and scores ≥70 suggest above-average usability.

[b]AIM: Acceptability of Intervention Measure. Possible scores range from 1 - 5. Higher scores indicate greater acceptability and appropriateness, respectively.

[c]IAM: Intervention Appropriateness Measure. Possible scores range from 1 - 5. Higher scores indicate greater acceptability and appropriateness, respectively.

Cognitive Interview Findings

Suggested Revisions

Participants made numerous suggestions to improve the clarity and helpfulness of CASI questionnaire items. For example, several participants suggested reducing the number of response options on the Control Preferences Scale from 5 to 3. Participants also identified several items they felt were redundant. Caregiver participants suggested explicitly instructing caregivers to respond on behalf of the patient. Clinician participants were concerned about patients and caregivers being "locked in" to a specific preference or decision. For example, these participants suggested the CASI ask patients and caregivers what topics they would like to discuss rather than giving them the opportunity to identify topics they would like to avoid. Furthermore, 1 clinician observed that this modification would allow clinicians to raise topics they believed needed to be addressed even if the patient or caregiver was not previously interested in discussing it. Finally, some participants wanted the option to request a follow-up phone call or to opt out of navigation (ie, a follow-up phone call that would arrange for them to see social work or chaplaincy). A detailed list of suggested and incorporated revisions is provided in Table 3.

Table . CASI[a] revisions derived from cognitive interviews.

Participant recommendations	Number recommending (n)				Actions taken
	PT[b]	CG[c]	CL[d]	All, n (%)	
Rephrase items for clarity	5	4	2	11 (73)	Rephrased items to improve clarity.
Eliminate redundant items	4	0	1	5 (33)	Revised items to eliminate redundancy.
Provide an option for personal interaction	3	2	0	5 (33)	Added item that reads: "Would you like someone to contact you about your options for additional support?"
Avoid locking patients and clinicians into a preference or decision	0	1	2	3 (20)	Rephrased Control Preferences Scales to refer to "most decisions." Removed items allowing patients to indicate they "never" want to talk about a specific topic or undergo a specific procedure.
Consider limiting administration to patients who are not on their first line of treatment	1	0	2	3 (20)	Planned: Will confirm with clinicians whether potential participants are appropriate for pilot RCT.[e]
Revise items to reduce anxiety	0	1	2	3 (20)	Reframed items to allow patients to indicate that they would like to discuss a certain topic with their clinician.
Account for different caregiving roles	1	1	0	2 (13)	Added option for caregiver respondent to report their name and relationship to the patient.
Administer every 3 - 4 weeks	0	1	1	2 (13)	Planned: Will enroll participants receiving treatment every 3 weeks into pilot RCT.
Clarify instructions for caregivers	0	2	0	2 (13)	Added the following instructions: "The following questions should be answered from the patient's perspective. Please respond on behalf of the patient."
Account for preferences for in-person versus digital communication	1	0	0	1 (6.7)	Added item that reads: "Would you like someone to contact you about your options for additional support?"
Allow for preference tracking over time	0	1	0	1 (6.7)	Improved readability of provider-facing Epic flow sheet.

Participant recommendations	Number recommending (n)				Actions taken
	PT[b]	CG[c]	CL[d]	All, n (%)	
Ask an open-ended item about what is meaningful to the patient	0	1	0	1 (6.7)	Added open-ended item that reads "What does a good day look like to you?"
Ask what caregiver is going through	0	1	0	1 (6.7)	Added open-ended item that reads "What, if anything, can we do to help you support the patient?"
Consider removing the option to request exact numbers and statistics	0	0	1	1 (6.7)	Rephrased to "with a lot of detail" and "without a lot of detail."
Differentiate between ongoing and new or acute concerns	0	0	1	1 (6.7)	Planned: In emails to clinicians, study team will highlight changes in concerns.
Ensure mechanism for prompt follow-up	0	0	1	1 (6.7)	Planned: Study team will provide first-line follow-up and will track time spent responding to patient concerns.
Alert clinicians to unmet needs or changes in CASI responses	0	0	1	1 (6.7)	Planned: In emails to clinicians, study team will highlight changes in concerns.
Make follow-up navigation optional	1	0	0	1 (6.7)	Added item that reads: "Would you like someone to contact you about your options for additional support?"
Prompt patients to consider code status discussion	0	0	1	1 (6.7)	Added "the care I would like to receive if my health worsens" as a possible discussion topic.
Reduce number of response options for items about shared decision-making and communication preferences	0	0	1	1 (6.7)	Reduced the number of response options on the Control Preferences Scales from 5 to 3. Revised items related to communication preferences.

[b]PT: patient.

[c]CG: caregiver.

[d]CL: clinican.

[e]RCT: randomized controlled trial.

Barriers to and Facilitators of Implementation

Overview

Participants identified barriers to and facilitators of implementing the CASI across 4 CFIR domains: outer setting, inner setting, innovation characteristics, and individual characteristics. Exemplary quotes for the CFIR constructs addressed by participants are provided in Table 4. Definitions of each construct as they pertain to the CASI are incorporated into the Results section below.

Table . Potential barriers to and facilitators of implementing the Collaborative Agenda-Setting Intervention.

CFIR[a] domain and construct		Participants reporting, n (%)	Role in implementation	Exemplary quotes
Outer setting				
	Needs and resources of those served	15 (100)	Facilitator	"I think the tool worked nicely. Provocative, but I think helpful. I think some people-- there is my good friend with cancer who does not want to know anything, absolutely nothing, but what has to happen today-- and I am the one who wants to know the future. So I think it is helpful." [Female patient, aged 62 years]
Inner setting				
	Compatibility	5 (33)	Facilitator	"I do think any way you can streamline information to actually come to the clinician will help a lot in terms of its usability." [Female advanced practice nurse, 10 - 14 years of experience]
	Available resources	5 (33)	Barrier	"I mean there is unfortunately a huge problem now with social work in that there are no social workers. We have one remaining social worker in GI; we have two social workers in GYN, but they are really strapped, and I have found meaningful social work contact almost impossible." [Female medical oncologist, 20+ years of experience]
	Relative priority	3 (20)	Both	"There are very few patients who are like, 'I feel great, and I don't have any of these things,' you know, but the things that they have are often the same and constant from visit to visit." [Female medical oncologist, 15 - 19 years of experience]
	Tension for change	3 (20)	Facilitator	"That would be helpful because you know that question about anxiety and stuff I mean I have anxiety, I have anxiety about the finances I am primarily the one that has been managing the finances and seeing us through all of this." [Male spousal caregiver, age not reported]
	Networks and communications	1 (6.7)	Barrier	"I think it is important for us to know that the patients are approached so we expect what will happen because there are going to be questions which is fine." [Male medical oncologist, 15 - 19 years of experience]

CFIR[a] domain and construct		Participants reporting, n (%)	Role in implementation	Exemplary quotes
Innovation characteristics				
	Complexity	12 (80)	Barrier	"It's not clear to me whether it's me you're asking about or you're asking about her, and I should be answering questions about her." [Female friend, aged 79 years]
	Design quality and packaging	12 (80)	Barrier	"Okay… So now I should press here? Where should I press now?" [Female patient, aged 63 years]
	Relative advantage	5 (33)	Facilitator	"It is nice to know if what kind of person they are so I can start understanding their values." [Female advanced practice nurse, 10 - 14 years of experience]
	Adaptability	4 (27)	Both	"[One concern would be if] you can't go do this other thing that you were supposed to because you made a [different] decision back then." [Male adult child caregiver, age not reported]
	Trialability	4 (27)	Both	"And for a caregiver, how would you present this to them? I mean I'm certainly not on her patient [portal]." [Female friend, aged 79 years]
Individual characteristics				
	Other personal attributes	11 (73)	Barrier	"I like just to talk. I'm not a person that likes filling out answers, to be honest with you." [Female patient, aged 61 years]
	Knowledge and beliefs about the innovation	3 (20)	Barrier	"Even if they are finished with treatment, the last thing they want to think about is a conversation about death and dying when they think they are cured." [Female advanced practice nurse, 15 - 19 years of experience]
	Self-efficacy	3 (20)	Both	"Would I know some of these things? Yes, perhaps, but I would not feel comfortable with [reporting them on the patient's behalf]." [Female friend, aged 79 years]
	Individual stage of change	2 (13)	Barrier	"The only one that would make me change my management style would be the last one, which is, 'I prefer to leave all treatment decisions to my doctor.'" [Female medical oncologist, 15 - 19 years of experience]

CFIR[a] domain and construct		Participants reporting, n (%)	Role in implementation	Exemplary quotes
	Individual identification with organization	1 (6.7)	Barrier	"I have other sources [of health care]." [Female friend, aged 79 years]

[a]CFIR: Consolidated Framework for Implementation Research.

Outer Setting

All participants (15/15, 100%) addressed the needs and resources of those served, referring to the extent to which the needs of end users are accurately known and prioritized by the CASI [22]. Comments related to this construct were overwhelmingly positive. Participants reported that the topics addressed by the CASI are important, and they appreciated that the CASI was brief and easy to use. Further, 1 caregiver was especially enthusiastic about being able to update his or the patient's preferences as they evolve over time. However, 1 caregiver observed that not every caregiver has proxy access to the patient portal, and 1 clinician worried that asking about preferences for prognostic communication may exacerbate patients' anxiety.

Inner Setting

In total 5 (33%) participants addressed the CASI's compatibility, which refers to how well the CASI will fit into existing practice norms, workflows, and systems [22]. Overall, participants approved of the CASI's integration into the clinical workflow. Clinicians especially appreciated having the opportunity to follow up on needs that may not be addressed during a visit and the ease with which they could populate their visit notes with patients' and caregivers' CASI questionnaire responses. Further, 5 (33%) participants discussed the available resources for implementing the CASI [22]. Each of these 4 clinicians and 1 caregiver were concerned there would not be enough staff or supportive care services available to address patient- and caregiver-reported concerns. Furthermore, 3 (20%) participants addressed the CASI's relative priority, which refers to the importance of implementing the CASI relative to other innovations [22]. Moreover, 1 clinician was concerned about the amount of information clinicians already review before a visit. A second clinician noted that, despite the importance of addressing supportive care needs, patients' medical needs would likely take priority. Additionally, 3 (20%) participants addressed tension for change, which refers to the degree to which stakeholders believe current practices need to change [22]. While none of these participants shared a negative opinion of current practice, each acknowledged there is room for improvement in certain aspects of care. For example, 1 patient described an experience of suboptimal communication that was distressing to her, while 1 clinician expressed that it would be helpful to know a patient's decision control preferences. Finally, 1 (6.7%) participant addressed networks and communications, which refers to the nature and quality of formal and informal communication within an organization [22]. This clinician wanted to be sure they would be notified when a patient completed the CASI.

Innovation Characteristics

A total of 12 (80%) participants addressed the CASI's design quality and packaging, which refers to the level of perceived excellence in how the CASI is bundled and presented [22]. Participants appreciated the clean, simple layout of the CASI. However, participants made several suggestions related to font size and screen layout. Further, 12 (80%) participants also addressed the CASI's complexity. As noted above, participants identified items they felt were redundant or overly complex and made suggestions to clarify user instructions. Furthermore, 5 participants addressed the CASI's relative advantage, which refers to the advantage of implementing the CASI versus an alternative solution [22]. Patients appreciated being able to report their concerns in addition to their preferences, and clinicians observed that the CASI addresses topics that are not captured in our institution's existing patient-reported symptom questionnaire. Additionally, 4 (27%) participants addressed the adaptability of the CASI, which refers to the extent to which the CASI can be adapted, tailored, or refined to meet user's needs [22]. Participants provided suggestions to enhance the CASI's adaptability. For example, 2 patients suggested making follow-up navigation optional. Moreover, 4 (27%) participants addressed the CASI's trialability and approved of the iterative process through which it is being developed and tested.

Individual Characteristics

A total of 11 (73%) participants identified personal attributes of end users that may influence adoption of the CASI. Specifically, participants emphasized the need to consider patients' and caregivers' overall literacy, digital literacy, preferences for face-to-face or digital communication, patients' time since diagnosis, and caregivers' caregiving role. Further, 3 (20%) participants expressed knowledge and beliefs about the CASI content that may influence its adoption. For example, as noted above, 1 clinician wondered whether items about prognostic communication would exacerbate patients' anxiety. Furthermore, 3 (20%) participants addressed potential challenges related to patients' and caregivers' self-efficacy to complete the CASI. In addition, 1 clinician suspected that patients who need supportive care services often lack the self-efficacy to seek assistance because they are experiencing symptoms of depression. Besides 1 caregiver did not feel comfortable responding to questions on the patient's behalf. Additionally, 2 (13%) participants addressed their individual stage of change as it pertains to adopting the CASI. These clinicians expressed that they were unsure of the extent to which they would change their practice style in response to patients' or caregivers' CASI responses. Finally, 1 (6.7%) participant addressed her identification with the organization that created the CASI. This caregiver expressed that while she appreciated being asked about her supportive care needs, she would turn to her primary care provider rather than the cancer center for assistance.

Discussion

Principal Results

The findings of our study suggest that the CASI is a usable and acceptable intervention to foster person-centered ovarian cancer care. Participants suggested several revisions that have since been incorporated into the CASI. Participants identified several facilitators of implementing the CASI, including that the CASI meets the needs of patients, caregivers, and clinicians; is well-designed; and is compatible with the existing workflow. Additionally, participants indicated that the CASI offers a relative advantage over usual care and that there is interest among stakeholders in standardizing the way supportive care needs are identified and documented.

Participants also identified potential barriers to implementing the CASI, and the CFIR provided a relevant organizing framework for these barriers. The most frequently identified barriers were the complexity of the CASI and the resources available to address patients' and caregivers' supportive care needs. Our approach to intervention development has preemptively addressed some of these potential barriers. According to the Expert Recommendations for Implementing Change taxonomy [33], intervention complexity can be managed by eliciting local knowledge, conducting small tests of cyclical change, and providing ongoing training. Accordingly, we have prioritized stakeholder engagement throughout the process of intervention development and have taken an iterative approach to refining and testing the CASI [17]. Our next planned study will assess the feasibility of conducting a full-scale efficacy trial of the CASI in a pilot randomized controlled trial (RCT). During this trial, we will aim to manage the perceived complexity of the intervention by training participants to use the CASI and providing written training materials and resources in advance.

To address the potential barrier of limited available resources, the Expert Recommendations for Implementing Change taxonomy recommends securing additional funding and developing resource sharing agreements [33]. In our planned pilot RCT, members of this study's team will be responsible for following up with patients and caregivers who report unmet supportive care needs. We will track the frequency with which these needs arise and will document the resources (eg, time and personnel) needed to address them. Upon completion of the pilot RCT, we hope to have a more robust understanding of the resources that will be required to implement the CASI. These findings will inform our funding application for a subsequent efficacy trial and may eventually inform resource allocations to support the integration of the CASI into routine care.

Strengths and Limitations

There is a growing recognition of the potential for EHR-integrated supportive care interventions to improve health outcomes among patients with advanced cancer. Leaders in communication research have specifically called for the development of interventions that integrate into the clinic workflow and are disseminated through existing mechanisms [34,35]. The CASI meets this need and was developed according to stakeholders' needs and feedback [17]. In the current study, we conducted usability testing in a linguistically and socioeconomically diverse sample of patients with advanced ovarian cancer, caregivers, and clinicians. In addition, our study design was informed by an established implementation science framework [22]. Nevertheless, this was a single-site study with 15 participants, and the generalizability of our findings to other settings may be limited. Additional research is needed to assess the feasibility of conducting a full-scale efficacy trial of the CASI, to compare the effect of the CASI on outcomes to that of usual care, and to assess implementation of the CASI in diverse real-world settings.

Comparison With Prior Work

To our knowledge, the CASI is the first EHR-integrated supportive cancer care intervention to use an agenda-setting approach. Our finding that the CASI is usable by and acceptable to patients, caregivers, and clinicians is consistent with prior studies of EHR-integrated supportive care interventions. In a sample of patients with heterogeneous cancer types and their caregivers, a biopsychosocial care need screening system had above-average usability [36]. Similarly, in a sample of patients with heterogeneous cancer types, a patient-reported symptom and needs monitoring system was usable and relevant [37]. In a sample of more than 100 health professionals, a centralized location for storing patients' values, goals, and preferences was viewed positively [38]. Our study adds to these findings by demonstrating that patients' and caregivers' values, preferences, and supportive care needs can be assessed and communicated as part of the same intervention without sacrificing usability or acceptability.

Widespread implementation of EHR-integrated supportive care interventions has not yet been realized, and research describing barriers to and facilitators of implementing these interventions is limited. However, in an evaluation of patient perspectives related to implementing a patient-reported symptom and needs monitoring system, Lyleroehr et al [37] found that low clinician engagement and suboptimal communication about the intervention were key barriers to implementation. Similarly, Wickline et al [39] found that more than half of patients with advanced ovarian cancer using a remote symptom and quality of life monitoring system felt it was not obvious their clinician used the system's reports. In both studies, patients valued having the option to speak directly to their care team about their concerns [37,39]. In our planned pilot RCT, we will attempt to mitigate these potential barriers by offering patients and caregivers follow-up phone calls, providing clinicians with a summary of patients' and caregivers' responses ahead of a scheduled visit, and offering to initiate referrals to reduce clinician burden.

Conclusions

Agenda-setting is a novel approach to promoting person-centered care for individuals with ovarian cancer. Our findings suggest the CASI is usable and acceptable to patients, caregivers, and clinicians. Guided by an implementation science framework, we identified several barriers to and facilitators of implementing the CASI. In subsequent research, we will assess the feasibility of conducting an efficacy trial comparing the CASI to usual care.

Acknowledgments

RAP received funding from the National Palliative Care Research Center and the National Institute of Nursing Research (K23NR020219-01A1) in support of this work. This study's sponsors did not play a role in this study's design; in the collection, analysis, and interpretation of data; in the writing of the report; or in the decision to submit this paper for publication.

Data Availability

The datasets generated during this study are available from the corresponding author on reasonable request.

Generative artificial intelligence was not used at any point in the preparation of this paper.

Authors' Contributions

RAP did the conceptualization, methodology, investigation, formal analysis, writing of the original draft, and funding acquisition. JAT, DLB, CJL, and PCD worked on the conceptualization, methodology, and review and editing of the writing. JB and PB handled the investigation, formal analysis, and review and editing of the writing. MM, UAM, and NJM assisted with resources and review and editing of the writing. AAW aided the conceptualization, methodology, formal analysis, and review and editing of the writing.

Abstract

Background: The introduction of oral anticancer therapies has, at least partially, shifted treatment from clinician-supervised hospital care to patient-managed home regimens. However, patients with breast cancer receiving oral cyclin-dependent kinase 4/6 inhibitor therapy still require regular hospital visits to monitor side effects. Telemonitoring has the potential to reduce hospital visits while maintaining quality care.

Objective: This study aims to develop a digital home-based health care center (DHHC) for acquiring electrocardiograms (ECGs), white blood cell (WBC) counts, side effect photo documentation, and patient-reported quality of life (QoL) data.

Methods: The DHHC was set up using an Apple Watch Series 6 (ECG measurements), a HemoCue WBC DIFF Analyzer (WBC counts), an iPhone SE (QoL assessments and photo documentation), a TP-Link M7350-4G Wi-Fi router, and a Raspberry Pi 4 Model B. A custom-built app stored and synchronized remotely collected data with the clinic. The feasibility and acceptance of the DHHC among patients with breast cancer undergoing cyclin-dependent kinase 4/6 inhibitor therapy were evaluated in a prospective, single-arm, monocentric study. Patients (n=76) monitored side effects—ECGs, WBC counts, photo documentation, and QoL—at 3 predefined time points: study inclusion (on-site), day 14 (remote), and day 28 (remote). After the study completion, patients completed a comprehensive questionnaire on user perception and feasibility. Adherence to scheduled visits, the success rate of the data transfer, user perception and feasibility, and the clinical relevance of remote measurements were evaluated.

Results: Mean adherence to the planned remote visits was 63% on day 14 and 37% on day 28. ECG measurements were performed most frequently (day 14: 57/76, 75%; day 28: 31/76, 41%). The primary patient-reported reason for nonadherence was device malfunction. The expected versus the received data transfer per patient was as follows: ECGs: 3 versus 3.04 (SD 1.9); WBC counts: 3 versus 2.14 (SD 1.14); QoL questionnaires: 3 versus 2.5 (SD 1.14); and photo documentation: 6 versus 4.4 (SD 3.36). Among patients, 81% (55/68) found ECG measurements easy, 82% (55/67) found photo documentation easy, and 48% (33/69) found WBC measurements easy. Additionally, 61% (40/66) of patients felt comfortable with self-monitoring and 79% (54/68) were willing to integrate remote monitoring into their future cancer care. Therapy-induced decreased neutrophil count was successfully detected (P<.001; mean baseline: 4.3, SD 2.2, $\times 10^9$/L; on-treatment: 1.8, SD 0.8, $\times 10^9$/L). All-grade neutropenia and corrected QT interval prolongations were detected in 80% (55/68) and 2% (1/42) of patients, respectively.

Conclusions: Adherence to scheduled remote visits was moderate, with nonadherence primarily attributed to device-related complications, which may have also affected the success rate of data transfer. Overall, patients considered remote monitoring

useful and feasible. The prevalence of reported adverse events was comparable to existing literature, suggesting clinical potential. This initial feasibility study highlights the potential of the DHHC.

Introduction

Systemic therapies, such as chemotherapy, targeted therapies, or immunotherapy, are accompanied by several side effects that require continuous and regular monitoring. Monitoring of side effects is particularly important for treatment approaches involving oral medications, as these medications are usually administered at home. Side effect monitoring enables the early detection and prevention of adverse events and is crucial for treatment benefits and adherence to the treatment schedule [1].

In recent years, highly effective oral therapeutic options, such as cyclin-dependent kinase 4 and 6 inhibitors (CDK4/6i), have been introduced for the treatment of patients with hormone receptor-positive breast cancer. Even though these CDK4/6is are administered orally, the associated side effects, such as neutropenia, leukopenia, and corrected QT interval (QTc) prolongation, necessitate regular hospital appointments [2-10]. For patients in rural areas, such appointments present unique challenges. Due to a lack of nearby medical facilities, patients often have to travel long distances to receive adequate medical care, which can be physically and emotionally taxing. If these patients do not receive comprehensive cancer care, including side effect monitoring, they may experience delayed detection and treatment of serious adverse events, potentially affecting their quality of life (QoL), and survival outcomes [11-15]. Remote monitoring and eHealth options may be particularly valuable in addressing these challenges [16].

Remote, home-based monitoring using eHealth options such as apps, wearables, or mobile medical devices can allow health care providers to monitor patients' health status and potential side effects in real time. Multiple studies have shown that remote monitoring of cancer treatment symptoms is linked to improved QoL, fewer treatment disruptions, and increased survival rates [13,17-19]. However, most of these studies included only remote patient-reported outcome assessments. Recently, home- and sensor-based technologies, including various wearable devices, have also been shown to be suitable tools for cancer care. For example, smartwatches and fitness trackers have been used to promote physical activity and monitor heart rate [20-23].

Even though remote monitoring systems, eHealth apps, and wearable devices have the potential to improve cancer care, several challenges still need to be addressed. In particular, while current smartwatch technologies can monitor heart rate and record Food and Drug Administration–approved electrocardiograms (ECGs), and several apps on the market can be used to document patient-reported outcomes, assess QoL, and track side effects, using these individual tools alone is not sufficient to provide comprehensive medical care at home. Therefore, we aimed to establish a digital home-based health care center (DHHC) that includes a smartphone to assess QoL and document visual side effects, a smartwatch to record ECGs, and a white blood cell (WBC) system to analyze a patient's WBCs from capillary blood. The primary focus of this study was to assess the feasibility and acceptance of such a digital remote system for cancer care in order to tailor a patient-centered solution and improve access to quality care.

Methods

Study Design

The SMILER study ("Smart and Interactive Home-Based Health Care Project—A Digital Healthcare Feasibility Pilot Study Including the d.H2C2 Initiative") was a monocentric, single-arm study with the primary objective of assessing the feasibility of remote WBC and ECG measurements, as well as data transmission of remote measurements using a DHHC. The study was conducted at the Department of Gynecology and Obstetrics at the University Hospital Erlangen (Universitätsklinikum Erlangen) in Germany.

Inclusion criteria were an indication for or current treatment with a CDK4/6i (regardless of cycle number) and an age of 22 years or older (in accordance with the minimum age requirements for the use of DHHC devices as specified by their respective manufacturers). Patients could not be included if they had pacemakers or implantable cardioverter defibrillators, severe blood coagulation disorders, abnormalities in the last known ECG, or other comorbidities that might impact at-home measurements. The study was conducted between October 2021 and December 2022.

CDK4/6i therapy was administered according to the Summary of Product Characteristics. All patients who had an indication for CDK4/6i therapy, as determined by the treating physician, or who were already receiving CDK4/6i therapy, were screened for the SMILER study. In general, palbociclib was started at 125 mg/day, and if necessary, reduced to 100 or 75 mg/day. Ribociclib was started at 600 mg/day, and if required, reduced to 400 mg/day and subsequently to 200 mg/day. Abemaciclib was initiated at 300 mg/day, with potential dose reductions to 200 and 100 mg/day.

After study inclusion, participants received the DHHC along with an initial introductory training. Study-relevant measurements were scheduled at study inclusion (on-site), day 14 (d14—remote), and day 28 (d28—remote; Figure 1A). At each of these time points, WBC counts, ECGs, and QoL (Q-5D-3L questionnaire) were monitored. Additionally, photo documentation of the ankle (as an exploratory subproject for the capturing of 3D photo data) was included. The ankle was

chosen as an accessible location for photo acquisition where peripheral edema, a known side effect of CDK4/6i therapy, could be detected.

All participants continued their routine treatment and attended scheduled clinical visits. After the study had been completed, participants filled out a paper questionnaire on the acceptance, success rate, and usability of the DHHC. The SMILER study concluded after the predefined number of patients had been enrolled.

Figure 1. SMILER study ("Smart and Interactive Home-Based Health Care Project—A Digital Healthcare Feasibility Pilot Study Including the d.H2C2 Initiative") design and technology setup. (A) The SMILER study included an initial training session, followed by 2 scheduled at-home tasks on day 14 (d14) and day 28 (d28). (B) Patients received a large case with (C) integrated charging for all devices, (D) specifically designed for at-home use, (E,F) or a smaller and lighter case with foam material to securely hold all devices. (G) The associated SMILER.one app featured a home screen displaying the trial tasks, (H) a data archive for storing all collected data, and (I) functionality for collecting and visualizing specific parameters such as WBC counts. ECG: electrocardiogram; QoL: quality of life; WBC: white blood cell.

Ethical Considerations

The study was conducted in accordance with local guidelines and regulations. Ethical approval was obtained from the Ethics Committee of the Friedrich-Alexander Universität Erlangen-Nürnberg (April 1, 2020: 47_20B). The original protocol was amended on March 22, 2022, to also include patients already receiving CDK4/6i therapy, as previously, patients could only be enrolled in the SMILER study at the start of CDK4/6i therapy. This change was implemented to improve study enrollment. All participants provided written informed consent before participation. Participants did not receive any form of compensation. Data were collected in a pseudonymized manner.

Outcomes

The outcomes of the study were: adherence (primary objective), success rate of the data transfer, usability and feasibility of the DHHC, and clinical relevance. Adherence to scheduled study visits was assessed as the percentage of patients who completed the prescheduled measurements (±2 d around the scheduled visit). The success rate was evaluated as the number of remotely transferred measurements relative to the number of expected measurements. Feasibility was assessed based on the number of enrolled versus screened patients. Furthermore, patient-reported perception and usability were evaluated using a comprehensive paper-based questionnaire at study completion, which included Likert-scale questions on perceived usability. Usability was further assessed using the System Usability Scale (SUS), with the SUS score calculated as the respective outcome measure [24]. Clinical relevance was determined by the number of detected adverse events, specifically neutropenia and QTc prolongations.

DHHC Hardware

The DHHC consisted of the following components: (1) Apple Watch Series 6 (Apple Inc., Cupertino, CA, United States) for ECG measurements, (2) HemoCue WBC DIFF Analyzer (HemoCue AB, Ängelholm, Sweden) for WBC counts, (3) iPhone SE (Apple Inc.) for QoL questionnaire completion and photo documentation, (4) mobile Wi-Fi router TP-Link M7350-4G (TP-Link Corporation Limited, Düsseldorf, Germany), and (5) Raspberry Pi 4 Model B (Raspberry Pi, Cambridge, United Kingdom).

Two cases were designed to enable safe and easy transport and handling of the devices (Figure 1B-F). Case 01 (Figure 1B-D; Fa. Karl Lettenbauer, Erlangen, Germany) featured a plastic base plate to accommodate the HemoCue WBC DIFF Analyzer, Raspberry Pi, power cable, and socket strip (installed under the upper mount with a 14412 - 02 detachable partition protected against tampering), along with all device cables. The iPhone, Apple Watch, and TP-Link were integrated into a raised platform. Case 02 (Figure 1E-F) consisted of a case from MyCaseBuilder.eu (FOAM Studio, the Netherlands) with a custom Pro-Cell interior and Prolife Soft-Cell foam lid. For both cases, the devices could be charged, and WBC measurements could be taken without the devices being removed from the cases.

SMILER.one App and DHHC Software

The custom study app (SMILER.one) was developed by REFINIO GmbH, based on their REFINIO ONE architecture. REFINIO GmbH is a German company specializing in custom software for secure data collection. The software was programmed in TypeScript on NodeJS and had platform abstractions for internet browsers and Linux. All ONE instances of a person formed a federation called the Internet of Me (IoM), where identities, connections, settings, and content could be distributed, ensuring that devices only needed to be registered once.

Data storage in ONE was based on HTML files containing microdata objects, which were stored in individual files within the file system or in the IndexedDB of the browser or WKWebView on mobile devices. The objects were named according to the hash of their content and referenced through their name in parent objects. Data transmission in ONE was facilitated through WebSocket services provided by a commServer, which established connections between devices. Data sharing was based on subtree sharing and conflict-free replicated data types, with encryption occurring at the individual instance level.

The DHHC integrated several REFINIO ONE software components, including the Web Server, SMILER.one Mobile, SMILER.one Pi, SMILER.one Headless, and the SMILER.one representational state transfer application programming interface (REST API). The Web Server was installed and configured with HTTPD software (nginx) to deliver the SMILER.one Progressive Web App and mobile content. SMILER.one Mobile managed patient data in a WebView (IndexedDB) on an iPhone and synchronized it with the clinic's data (SMILER.one Headless) and the patients' IoM instances. It also imported and synchronized ECG data from the Apple HealthKit on patients' iPhones. SMILER.one Pi was installed on the Raspberry Pi, importing WBC data from the HemoCue device. Within the patients' IoM, it acted as a headless replication of the patients' complete dataset. SMILER.one Headless mirrored all settings and storage operations of SMILER.one Mobile and SMILER.one Pi while incorporating the SMILER.one REST API, which provided pseudonymized patient data to the clinic's SQL server (Figure S1 in Multimedia Appendix 1).

The SMILER.one app served as a user interface for study participants. The app featured a registration or login mechanism with password encryption to ensure restricted private access. Within the app, the "My Tasks" screen allowed participants to complete visits (questionnaires, photo documentation, ECG measurements, and WBC counts) and provided an overview of upcoming tasks (Figure 1G). In the "Data Archive," completed data were stored and could be viewed by the participants (Figure 1H). The "Blood Count Chart" displayed a chart of WBC readings from the HemoCue device (Figure 1I). Patients also had the option to enter additional data beyond the scheduled remote visits under "Voluntary Data Entry."

Data Management

Data from the DHHC was stored in a dedicated relational database on an SQL server. The data transfer from the REFINIO

REST API to the SQL database was facilitated via the JSON data format. Parsing of the JSON-formatted data and transformation into a relational tabular format were performed within the database itself. QTc times were calculated from the transmitted ECG curves using the Fridericia formula by a physician (PK). Based on the QTc times and measured neutrophil concentrations, the severity of QTc prolongations and neutropenia was graded according to the Common Terminology Criteria for Adverse Events version 5.0. Clinical data were collected by trained staff and documented in an electronic case report form. Data monitoring was conducted using automated plausibility checks and on-site monitoring. These data included patient and tumor characteristics, as well as details on treatment approaches.

Statistical Analysis

Sample size calculations for this feasibility study were based on the assumption that 70% of ECG measurements and 65% of WBC counts would be successful (two 1-sided exact binomial tests with a significance level of α=2.5%). A total of 212 ECG measurements and 237 blood measurements were required to demonstrate this with a power of 90%, which corresponded to 80 patients, each with three ECG measurements and three WBC count measurements.

The majority of the presented statistics are descriptive. Categorical variables are reported as counts and percentages, while continuous variables are presented as mean (SD). Missing values were omitted from analyses. A 2-sided Wilcoxon rank sum test was used for statistical comparisons, with $P \leq .05$ considered statistically significant. Data are presented as box plots, displaying the median, IQRs, and whiskers representing the 5th and 95th percentiles. Statistical analyses were performed using R (version 4.2.1; The R Foundation) or SPSS Statistics (version 29.0.1.0; IBM Corp). Likert plots were generated using the R library “Likert” (version 1.3.5). The distribution of Likert scale questionnaire scores ranged from 1=I fully agree to 5=I do not agree at all.

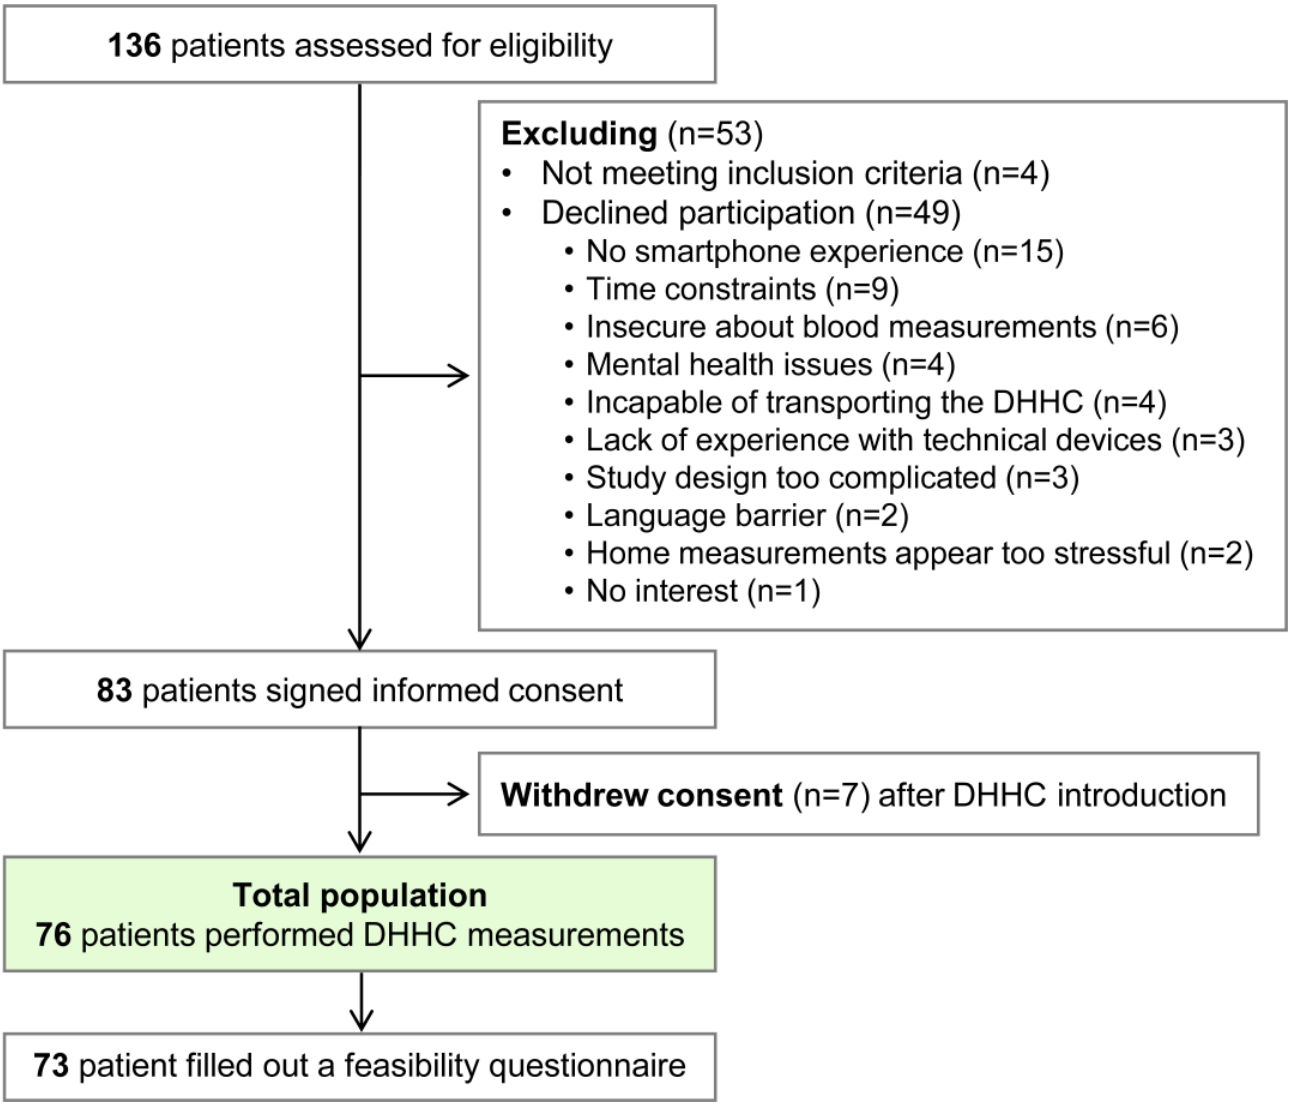
Results

Feasibility

Recruitment

Between October 2021 and December 2022, 136 patients with breast cancer were screened for eligibility. Of the 132 eligible patients, 49 patients declined participation. The most common reasons for nonparticipation were lack of smartphone experience (n=15) and lack of time to complete study procedures (n=9; Figure 2). Of the 83 patients who provided informed written consent, 7 patients withdrew their consent after being introduced to the DHHC (Figure 2), resulting in 76 patients who participated in the SMILER study. Of these 76 patients, 73 (96%) completed the questionnaire on acceptance, success rate, and feasibility of the home-based procedures at study completion.

Figure 2. Patient flowchart. This flowchart illustrates the progression of patients throughout the study, including screening, enrollment, and final study participants. DHHC: digital home health care center.



Patient Characteristics

Participants had a mean age of 58.9 (SD 9.74) years (Table 1). The majority of participants received CDK4/6i for advanced or metastatic disease (54/76, 71%). Abemaciclib was administered to 49% (37/76) of participants, while 39% (30/76) and 12% (9/76) of participants received ribociclib and palbociclib, respectively. Additional baseline patient characteristics are listed in Table 1. Case 01 was assigned to 33% (25/76) of participants, while Case 02 was provided to 67% (51/76) of participants.

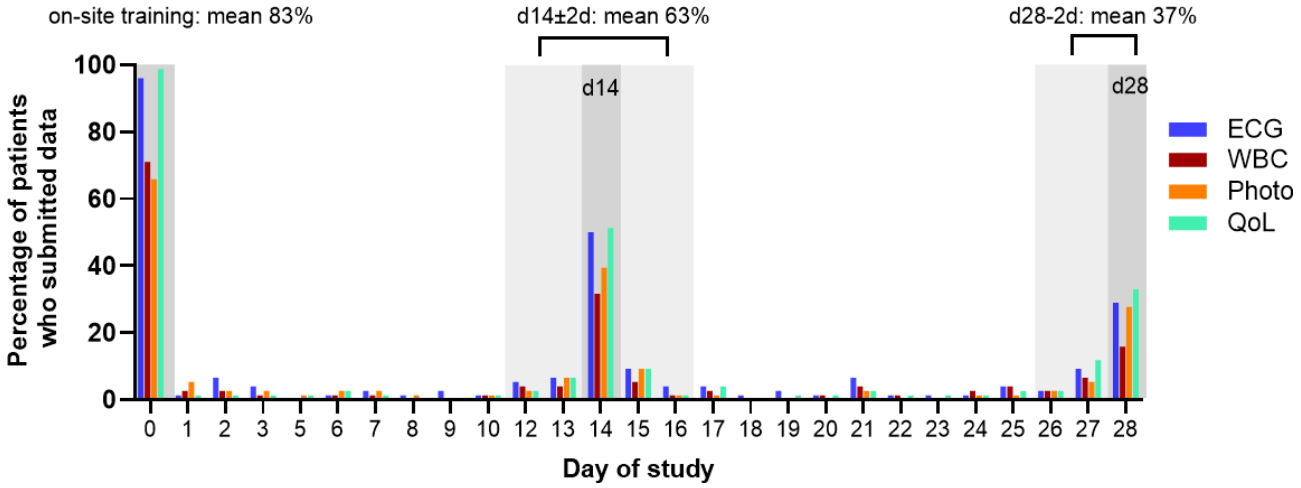
Adherence

Study-relevant measurements were scheduled at study inclusion (introductory on-site training), day 14 (d14—home-based), and day 28 (d28—home-based). The average adherence was 63% at d14±2d and 37% at d28-2d (Figure 3). Among individual remote measurements, ECGs were recorded most frequently (d14±2d: 57/76, 75%; d28-2d: 31/76, 41%), followed by QoL questionnaires (d14±2d: 54/76, 71%; d28-2d: 36/76, 47%).

Figure 3. Patients who submitted data during the study. The percentage of patients who submitted data via the digital home-based health care center is presented for various measurements, including ECG, WBC counts, photo documentation, and QoL questionnaires. The bars indicate the data submission rates over the study duration, with dark gray sections representing planned study visits (day 14, d14; and day 28, d28) and light gray sections representing the days around the study visits (d14±2, d28-2). The mean percentage represents the average data submission rate for each study visit. ECG: electrocardiogram; QoL: quality of life; WBC: white blood cell.



The most common patient-reported reasons for missing scheduled tasks were device malfunction (ECG or Apple Watch: 11/36, 31%; WBC or HemoCue: 16/43, 37%; photo documentation: 5/31, 16%), handling issues (ECG or Apple Watch: 11/36, 31%; WBC or HemoCue: 12/43, 28%; photo documentation: 2/31, 6%), and time constraints (ECG or Apple Watch: 10/36, 28%; WBC or HemoCue: 10/43, 23%; photo documentation: 11/31, 35%; Table 2). Among the patient-reported reasons listed as "other reasons" for failed adherence were "measurements were not performed in time," "unsure about the handling of the devices," "no reception," "mentally too stressed," or "sickness." Among these, "unsure about the handling of the device" was the most common other reason for missed WBC measurements (5/13, 38%).

[c]WBC: white blood cell count.

[d]N/A: not applicable.

Success Rates

Throughout the 28-day study period, data transfer was expected from three ECG measurements, three WBC measurements, three QoL questionnaires, and six photo documentations (each ankle per time point) per patient. The mean number of successfully transferred data per patient during the study period was 3.04 (SD 1.9), ECGs was 2.14 (SD 1.1), WBC measurements was 2.5 (SD 1.1), QoL questionnaires and photo documentations was 4.4 (SD 3.4; Table S1 in Multimedia Appendix 1).

Study participants indicated how many times a measurement had to be repeated before it was successfully completed in the end-of-study questionnaire. The highest number of repetitions was required for WBC measurements, with an average of 1.07 (SD 1.0) additional measurements per patient (Table S1 in Multimedia Appendix 1).

Identified Problems

Several issues may have affected both study adherence and success rates. The incidence of any type of DHHC malfunction (ie, problems with either WBC or ECG measurements) was 24% (18/76) during first use (initial introductory training) and 43% (33/76) during remote measurements (as reported in the end-of-study questionnaire).

For WBC measurements, handling problems with the HemoCue microcuvettes requiring repeat WBC measurements were observed in 8 (out of 76, 10%) patients during on-site training. Of these, 2 (25%) patients also reported handling issues with WBC measurements during remote monitoring. Patients who experienced handling problems during initial training (8/76) and those who reported handling issues as a reason for nonadherence to remote monitoring visits (12/76) appeared to be older than those without handling issues (initial training: handling issues 59.4, SD 9.6 y vs no handling issues 55.0, SD 10.3 y; *P*=.30; remote monitoring: handling issues 63.3, SD 7.6 y vs no handling issues 58.1, SD 9.9 y; *P*=.02).

At initial training, technical problems with the HemoCue WBC DIFF IEC 61010 system (failure to turn on or instant error messaging) prevented measurements in 4 (out of 76, 5%) patients and data transfer from the HemoCue WBC DIFF IEC 61010 system to the SMILER.one app and SQL server in 11 (out of 76, 14%) patients. In two of these cases (2/11, 18%), a lack of an internet connection was reported.

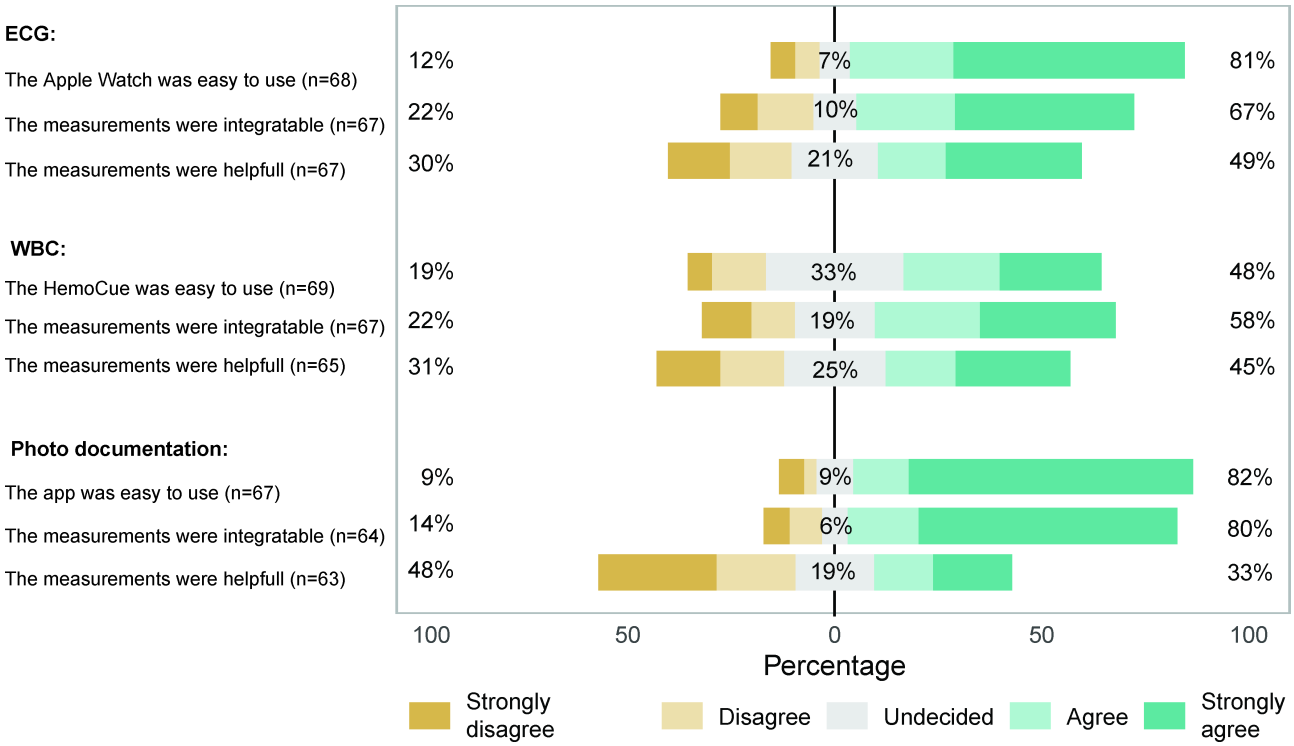
Defective data transfer occurred more often with Case 02 than Case 01 (8/11, 73% vs 3/11, 27%) and in two instances, the same Case 02 DHHC experienced defective data transfer. However, the case type was not statistically associated with defective data transfer (*P*=.80). Among 3 (out of 11, 27%) DHHCs with defective data transfer during on-site training, study participants also reported an inability to perform remote measurements due to device malfunction.

For ECG measurements, defective data transfer was observed in 3 (out of 76, 4%) individual DHHCs during on-site training, and 1 (out of 3, 33%) patient also reported subsequent technical issues with the Apple Watch during remote monitoring. Additionally, 4% (3/76) of patients reported being unable to use the SMILER.one app due to a lack of mobile network coverage.

User Perception of Feasibility

The feasibility of home measurements was assessed at study completion. While most patients found photo documentation with the SMILER.one app (55/67, 82%) and ECG measurements with the Apple Watch (55/68, 81%) easy to use, only 48% (33/69) of patients found the HemoCue System easy to use. Good integration into daily life was most commonly reported for photo documentation (51/64, 80%), followed by ECG (45/67, 67%) and WBC measurements (39/67, 58%). ECG and WBC measurements were seen as helpful by 49% (33/67) and 45% (29/65) of patients, respectively, while only 33% (21/63) of participants found photo documentation helpful (Figure 4).

Figure 4. User perception of the home-based health care system's feasibility. The Likert scale illustrates responses from a user perception questionnaire regarding the Apple Watch ECG, HemoCue WBC measurement, and photo documentation via the SMILER.one app. ECG: electrocardiogram; WBC: white blood cell.

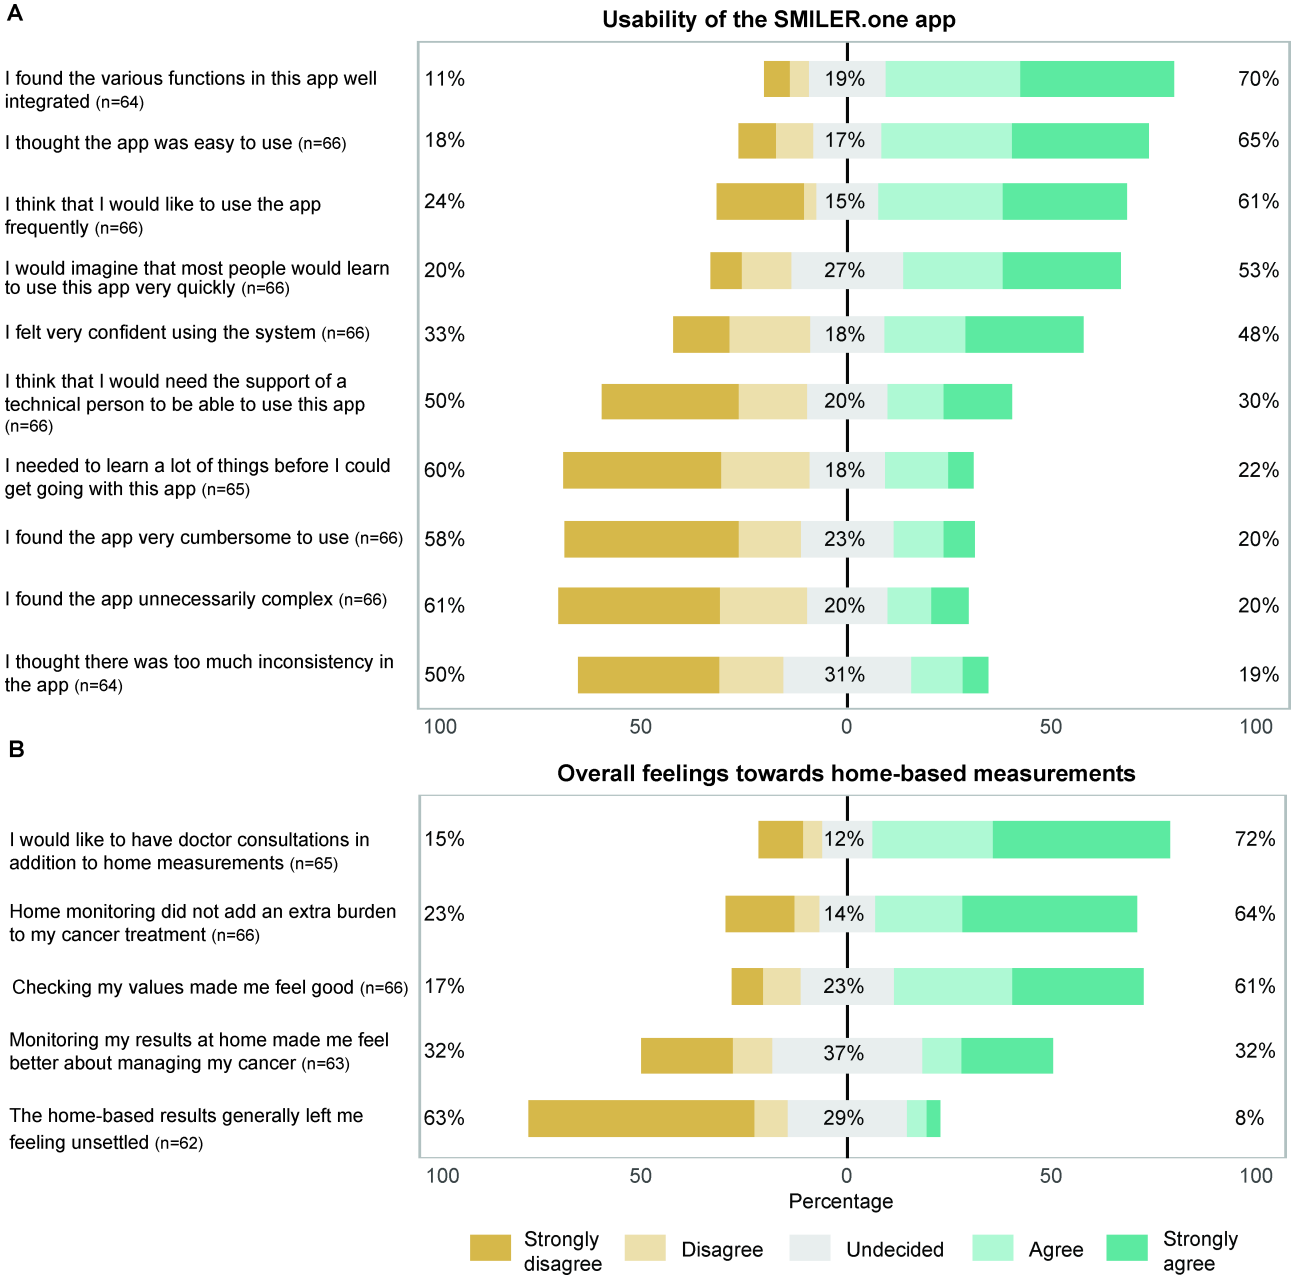


Acceptance

User acceptance of the SMILER.one app and the perception of the DHHC and its future use were assessed through the end-of-study questionnaire. For the SMILER.one app, 70% (45/64) of participants agreed that the technical features of the app were well-integrated, 65% (43/66) of participants found the app easy to use, and 61% (40/66) of participants could imagine using the app regularly. However, 30% (20/66) of participants reported that they would need technical support to use the app (Figure 5A). The corresponding SUS score for the SMILER.one app was 65.2. Regarding the DHHC, 61% (40/66) of participants felt comfortable with self-monitoring, and 64% (42/66) of participants did not consider home-based measurements to be an additional burden. However, 72% (47/65) of participants stated that they would like to have consultations with a doctor in addition to the DHHC measurements (Figure 5B).

When asked about their intention to use, 79% (54/68) of participants expressed a willingness to use home measurements as part of their future cancer care. Additionally, 79% (54/68) of participants were willing to collect data for research purposes at home using the SMILER.one app. Participants who were unwilling or reluctant to integrate the DHHC and remote data collection into future cancer care reported that they would need help interpreting results (9/17, 53%), were concerned about the time required for data collection (11/23, 48%), and would experience difficulties or stress related to the technology (home-based measurements: 3/17, 18%; collection and sharing of data with the SMILER.one app: 7/23, 30%; Table S2 in Multimedia Appendix 1).

Figure 5. User perception and acceptance of the SMILER.one app and the home-based health care system. (A) The Likert scale illustrates responses from a user perception and acceptance questionnaire of the SMILER.one app and (B) the complete home-based health care system.



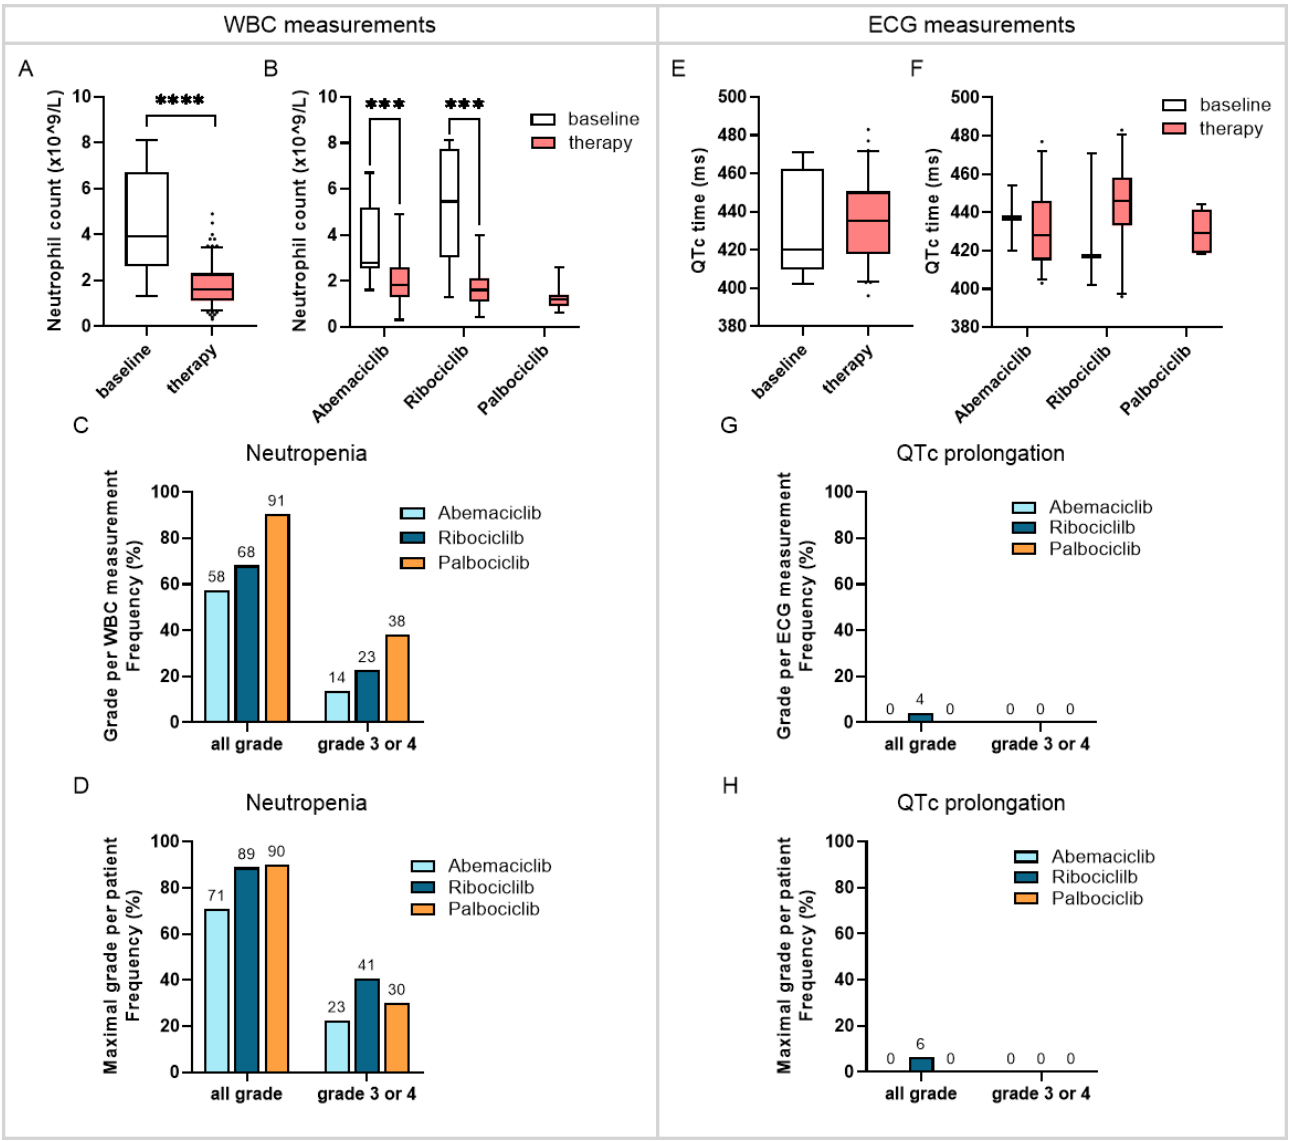
Clinical Relevance

Transferring routine monitoring from the clinical setting to the at-home environment requires the evaluation of WBC counts and ECG values. WBC monitoring is necessary for all CDK4/6i therapies, whereas ECG monitoring, specifically assessing QTc intervals, is required only for ribociclib treatment.

Compared with patients initiating CDK4/6i therapy, those who had been on treatment for more than five days had lower neutrophil counts (mean 4.3, SD 2.2, $\times 10^9$/L vs mean 1.8, SD 0.8, $\times 10^9$/L; P<.001; Figure 6A), regardless of the specific CDK4/6i received (Figure 6B). Mild neutropenia (grade 2) was present in 27% (45/167) of WBC measurements, while severe neutropenia (grade 3 or 4) was detected in 20% (34/167) of WBC measurements (Table S3 in Multimedia Appendix 1). At the patient level, this corresponded to 32% (22/68) of patients experiencing mild neutropenia and 31% (21/68) presenting with severe neutropenia under CDK4/6i therapy, as detected by the DHHC (Table S4 in Multimedia Appendix 1). Regarding individual CDK4/6i therapies, grade 3 or 4 neutropenia was observed in 23% (7/31) of patients receiving abemaciclib, 41% (11/27) of those on ribociclib, and 30% (3/10) of those on palbociclib (Figure 6C-D and Table S5 in Multimedia Appendix 1).

QTc time remained stable under CDK4/6i therapy (Figure 6e,f). Only one measurement indicated QTc prolongation, corresponding to 2% (1/61) of all quantifiable QTc times from ECG measurements and 2% (1/42) of all patients (Tables S5 and S6 in Multimedia Appendix 1). The affected patient was receiving ribociclib (Figure 6g.h and Tables S5 and S6 in Multimedia Appendix 1).

Figure 6. Detection of adverse events with the digital home health care center. Neutrophil counts were measured with the HemoCue system. (A) Neutrophil count before starting CDK4/6i therapy (n=15) and under therapy (>5 days; n=167) of all combined WBC measurements and (B) per CDK4/6i (baseline: abemaciclib, n=9; ribociclib, n=6; under therapy: abemaciclib, n=80; ribociclib, n=66; palbociclib, n=21). Neutropenia was graded according to CTCAE version 5.0. Frequency of neutropenia under CDK4/6i therapy as (C) the grade of each individual WBC measurement (abemaciclib, n=80; ribociclib, n=66; palbociclib, n=21) and (D) the maximal observed grade per patient (abemaciclib, n=31; ribociclib, n=27; palbociclib, n=10). QTc times were calculated from ECGs measurements with the Apple Watch. (E) QTc time before starting CDK4/6i therapy (n=5) and under therapy (>5 days; n=61) of all combined ECG measurements and (F) per CDK4/6i (baseline: abemaciclib, n=2; ribociclib, n=3; under therapy: abemaciclib, n=33; ribociclib, n=23; palbociclib n=5). QTc prolongation was graded according to CTCAE version 5.0. Frequency of QTc prolongation under CDK4/6i therapy as (G) the grade of each individual QTc measurement (abemaciclib, n=33; ribociclib, n=23; palbociclib n=5) and (H) the maximal grade per patient (abemaciclib, n=21; ribociclib, n=16; palbociclib n=5). ***$P \leq .001$, ****$P < .001$; Wilcoxon rank sum test. CDK4/6i: cyclin-dependent kinase 4/6 inhibitor; CTCAE: Common Terminology Criteria for Adverse Events; ECG: electrocardiogram; QTc: corrected QT interval; WBC: white blood cell.



Discussion

Principal Findings

The SMILER study assessed the feasibility and acceptance of a DHHC system for remote monitoring of side effects in patients with breast cancer receiving CDK4/6i therapy. Adherence to remote study visits was moderate and declined over time, with patients who were unable to perform measurements reporting time constraints and handling issues with the devices. Correspondingly, the transfer of remotely collected data was lower than expected, and patients reported needing to perform repeat measurements. Self-monitoring of ECGs and side effect photo documentation was considered easy to use and easily integrable into daily life, whereas WBC measurements were generally found to be more challenging. Nevertheless, the majority of participants felt positive about self-monitoring and expressed a willingness to incorporate home-based measurements into their future cancer care. Additionally, home-based ECG and WBC measurements were effective in detecting QTc time prolongations and neutropenia, demonstrating the clinical relevance of the DHHC.

Comparison to Prior Work

Our findings contribute to the emerging field of digital health and remote monitoring, highlighting the potential of such

interventions in improving patient care and outcomes. Patients receiving oral CDK4/6i therapy can take their anticancer medication at home; however, clinic visits remain necessary to monitor potential side effects [25-27]. Severe neutropenia (grade 3 or 4) is commonly observed under CDK4/6i therapy (ribociclib: 57% - 62% of patients in randomized controlled trials [RCTs] and 15% - 69% of patients in real-world studies [3,28-33]; abemaciclib: ~20% of patients in RCTs and 2% - 24% in real-world studies [9,31,33,34]; palbociclib: 62% - 70% of patients in RCTs and 60% - 63% in real-world studies [5,33,35-37]). Home-based WBC measurements by patients with breast cancer detected severe neutropenia in 41% of patients on ribociclib, 23% of patients on abemaciclib, and 30% of patients on palbociclib, aligning with real-world data for abemaciclib and ribociclib. Severe neutropenia under palbociclib may be underestimated due to the small number of patients receiving palbociclib in this study population. Nevertheless, these findings support the clinical relevance of home-based WBC monitoring with the DHHC.

QTc prolongation is a specific potential side effect of ribociclib therapy and has been reported in 2% - 5% of patients in the different RCTs [2-4]. In this study, prolonged QTc times were detected in one patient, corresponding to 6% (1/76 patients) of those receiving ribociclib therapy, which is in line with RCT findings [2-4]. Patients receiving abemaciclib or palbociclib did not develop QTc prolongations during the SMILER study.

Further research is needed to evaluate the clinical and psychological effects of home-based monitoring. A recent randomized trial involving patients with breast cancer receiving palbociclib therapy found that patients using an eHealth app (CANKADO PRO-React) experienced a longer time to QoL deterioration compared with those who did not use the app [19]. This study further highlights the clinical potential of digital interventions in improving patient outcomes and well-being. Notably, mobile health apps developed by health care professionals appear to have the highest overall quality [38], emphasizing the need to integrate clinical expertise with innovative digital approaches.

User perception and acceptance of the DHHC were generally positive. Both the ECG measurements with the Apple Watch and the photo documentation with the SMILER.one app were considered easy to use. The integration of the measurements into daily life was perceived favorably. However, concerns about result interpretation, time-consuming data collection, and technological difficulties were reported as barriers to engagement. The SUS score also indicated moderate usability. These findings emphasize the importance of providing adequate support and guidance to patients in using and interpreting the collected data. Additionally, the preference for consultations with health care professionals highlights the need to integrate home-based monitoring with clinical care and medical expertise. For future developments, integrating a communication tool into the provided app could be a suitable solution. Implementing a direct, automated digital feedback system based on home-based measurements could offer patients a more immediate and informed understanding of their health status, potentially reducing the need for frequent consultations with doctors. Interestingly, both using medical apps for medical questions and consulting Google appear to result in comparable adverse emotional and behavioral effects associated with cyberchondria [39].

Virtual and remote trials often have high dropout rates or low adherence to visits [40-42]. In the SMILER trial, adherence rates varied across different measurements, with the highest adherence for QoL questionnaires and lower adherence for WBC and ECG measurements. Additionally, adherence to the scheduled remote visits gradually declined over the course of the study, with 63% on d14±2d and 37% on d28-d2. Notably, several patients performed home-based measurements before or after the scheduled visits. Some patients also reported being unable to complete the final measurement due to the automatic deactivation of the SMILER.one app at the end of the study (day 28), suggesting that adherence rates may be underestimated.

The most common reason for missed scheduled measurements was device malfunction, with both technical and handling issues reported. Notably, the incidence of any type of malfunction during the first on-site introductory training was 24% (18/76 participants), and patients reported problems with 43% (33/76) of the DHHCs during remote monitoring. Not all patients with partially malfunctioning DHHC devices at the introductory training reported subsequent issues during remote monitoring, which may indicate that these devices were functional again during remote measurements or that the patient-reported failure rate was incomplete. Technical problems with the HemoCue device and the lack of an internet connection may partly explain DHHC malfunctions. Although the underlying cause of defective data transfer could not be definitively determined, server issues and complications with the Raspberry Pi software may have contributed. It is possible that unplugging the DHHC between remote measurements affected the Raspberry Pi and its software, which facilitates data transfer from the HemoCue device to the SMILER.one app. While there was no clear correlation between case design and the reported issues, data transfer problems occurred at varying rates across the different cases.

Handling problems with the HemoCue microcuvettes, such as an incomplete filling or air bubbles in the sample, was observed in approximately 10% (8/76) of patients during their first on-site WBC measurement. This is comparable to findings from another study that evaluated the feasibility of WBC self-testing with the HemoCue system in patients with cancer [43]. Additionally, handling issues during WBC measurements were associated with older age, highlighting the need for either a more intensive training session or remote assistance from a trained nurse, particularly for older patients. In general, tailoring support to specific patient needs may be essential to ensure successful implementation alongside a robust and reliable technological infrastructure.

Recruitment and patient characteristics also play a crucial role in the success of a study. In the SMILER study, only 76 out of the 136 screened women ultimately participated. Reasons for nonparticipation included lack of smartphone experience, time constraints, and concerns about performing WBC count independently. This underscores the importance of understanding the target population and their readiness to engage with digital health interventions. It is crucial to design digital

interventions in a way that ensures a lack of digital literacy does not contribute to health inequality [44,45].

Strengths

This study demonstrates several strengths in the implementation and evaluation of a DHHC system for patients receiving CDK4/6i therapy. First, it confirms the clinical relevance of remote monitoring by detecting known side effects, such as neutropenia and QTc prolongations, consistent with the established side effect profiles of these therapies. Although not designed to detect differences in the incidence of neutropenia or ECG changes between CDK4/6i, commonly known differences were observed [46]. Patients treated with ribociclib and palbociclib experienced neutropenia more frequently than those treated with abemaciclib. The only patient who had a QTc prolongation was receiving ribociclib.

Second, the study successfully integrated multiple technologies, including WBC measurement systems, smartwatches, and smartphones, into a comprehensive system tailored to the patient's needs. The high level of patient acceptance, with 79% (54/68) of participants expressing a willingness to use such systems in their future care, highlights the feasibility of this patient-centered approach. Moreover, the developed DHHC system and study findings underscore the potential of remote monitoring to reduce disparities in cancer care, particularly for patients in rural areas.

Limitations

This study has several limitations. First, the small sample size, specific patient population, and potential selection bias due to nonparticipation may limit the generalizability of the results. Second, adherence rates were suboptimal, and technical issues were encountered, highlighting challenges in implementing and maintaining home-based health care systems. Further optimization of the remote monitoring system is needed to improve usability. Additionally, a detailed analysis of the reliability of the DHHC could not be performed due to insufficient data. Third, self-reporting bias may have influenced the reported perceptions and experiences of the participants. Fourth, the short study duration limits our understanding of the long-term feasibility and acceptance of remote monitoring interventions. Fifth, the study lacked a control arm with patients receiving traditional nursing care, making direct comparisons with standard care models difficult. Sixth, as this was a pilot study, we did not predefine specific thresholds for the evaluated outcomes, such as adherence, usability, and feasibility, which limits our ability to determine whether the observed rates met predefined success criteria. Finally, this study did not include an analysis of the economic feasibility of the DHHC.

Future Directions

Based on the outcomes of this first feasibility study, several areas for improvement were identified. The technical issues encountered may be related to the DHHC devices, internet connection, server, Raspberry Pi software, and other factors that need to be addressed. Furthermore, longer-term randomized controlled studies are needed to better assess patient compliance, system reliability, and economic impact.

Conclusions

The findings of this study demonstrate that implementing remote monitoring of side effects in the care of patients with breast cancer undergoing CDK4/6i therapy is feasible. Patients with breast cancer generally accepted the idea of remote monitoring, which successfully identified clinically relevant side effects. Future studies with an improved system are required to further evaluate the potential clinical, socioeconomic, and individual benefits of this approach.

Acknowledgments

This research was partially funded by Pfizer (grand 61016789) and supported by the Bavarian State Ministry of Health and Care (grant MGP-2008 - 0003-digiOnko). Pfizer played no role in study design, data collection, analysis, and interpretation of data, or the writing of this manuscript. Adrian Kottas contributed to this publication in partial fulfillment of the requirements for obtaining the doctoral degree "Dr med."

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

HH designed the digital home-based health care center (DHHC) and the feasibility study, analyzed and visualized data, wrote the original manuscript draft, and managed and supervised the project. LAW designed the DHHC and the feasibility study, and managed and supervised the project. CG provided patients with on-site training, analyzed and visualized data, wrote the original manuscript draft, and managed the project. ME analyzed and visualized data, and performed statistical analyses. AM recruited patients for the feasibility study. AK recruited patients for the feasibility study. MK maintained the DHHC software and hardware during the feasibility study. JG and ML developed the DHHC software. KS recruited patients for the feasibility study. MR provided scientific input and designed the DHHC setup. PK analyzed electrocardiogram data. FH recruited patients for the feasibility study. MH recruited patients for the feasibility study. BV helped set up the DHHC hardware and provided scientific input. ER maintained the DHHC software and hardware during the feasibility study. CCH recruited patients for the feasibility study. MWB provided funding and infrastructure. SU supervised the data management and provided scientific input. PAF designed the DHHC and the

feasibility study, supervised the project, wrote the original manuscript draft, and provided funding. All authors reviewed the final manuscript.

Conflicts of Interest

PAF has received institutional funding from BioNTech, Cepheid, and Pfizer and personal honoraria from Novartis, Pfizer, Roche, Daiichi Sankyo, AstraZeneca, Lilly, Eisai, Merck Sharp & Dohme, Pierre Fabre, SeaGen, Agendia, Sanofi Aventis, Gilead, and Mylan for consulting, participation in advisory boards, and steering committees, or lectures. His institution conducts research for Novartis. HH received speaker honoraria from Novartis Pharma GmbH and LEO Pharma GmbH, and grant or research support from Novartis Pharma GmbH. KS received travel support from Gilead and Lilly. CCH received honoraria from AstraZeneca, Daiichi Sankyo, Eisai, Novartis, Pfizer, Roche, Gilead, and MSD, as well as support for attending meetings from Daiichi Sankyo. AK received honoraria from Gilead, as well as support for attending meetings from Lilly. CG received speaker honoraria from Novartis Pharma GmbH and ClinSol GmbH & Co. KG. MH received travel support from AstraZeneca, Lilly Deutschland GmbH, and Novartis. LAW received speaker honoraria from LEO Pharma GmbH.

Abstract

Background: Brain tumors are characterized by the high burden of disease that profoundly impacts the quality of life in patients and their families. Digital health tools hold tremendous potential to enhance supportive care and quality of life for patients with brain tumors and their caregivers.

Objective: This study aims to generate ideas and concepts, through a co-design paradigm, to inform the development of a digital health tool to address the unmet needs of people affected by brain tumors.

Methods: Patients with brain tumors, caregivers, and health professionals from 2 large public tertiary hospitals in Victoria, Australia, were invited to complete a qualitative interview discussing their unmet needs of care. Overall, 35 qualitative interviews focusing on unmet needs and concepts for a digital health tool were conducted with 13 patients, 11 caregivers, and 11 health professionals. Interviews were audio recorded and transcribed, and a 5-step framework analysis approach was used to analyze data.

Results: Four themes of unmet supportive care needs emerged: (1) emotional and psychological, (2) information, (3) physical and practical, and (4) social connectedness. Participants expressed the desire for early and proactive mental health intervention, noted the importance of providing mental health support to caregivers, and emphasized the need for positive stories and affirmative language. From an information perspective, participants noted a sense of information overload, especially at the beginning. They also underscored the variety of information needed on an ongoing basis, including life after treatment, and comprehensive care assistance to maintain quality of life. Participants also described unmet supportive care needs relating to symptom burden, and practical and administrative support to facilitate the logistics of accessing treatment and accomplishing daily life tasks. Finally, they expressed the desire for greater social connectedness and safe spaces to engage with other people in a similar situation. Our findings are consistent with previous research on this subject and were integrated into the development of a web-based platform.

Conclusions: Participants' perspectives informed the development of content for a web-based digital health platform called "Brain Tumours Online." The platform comprises three pillars—(1) "LEARN": a repository of vetted information about a range of biomedical and psychosocial care topics; (2) "CONNECT": a digital peer support community with a health care professional interface; and (3) "TOOLBOX": an emerging library of validated digital therapeutics for symptom management.

Introduction

Despite comprising only 1.2% of all cancers in Australia, the impact of brain tumors on the quality of life is profound [1-3]. Patients with brain tumors experience persistent, distressing, and disabling physical, psychosocial, cognitive, and financial challenges. These challenges are compounded by barriers to connecting and communicating with their treating team, establishing peer support networks, managing their symptoms, and accessing personalized supportive care [4-8]. These issues are exacerbated when patients reside distant from metropolitan, specialist treatment centers [9] without equitable access to comprehensive supportive care services.

Digital health tools hold tremendous potential to revolutionize support that enhances the quality of life for patients with brain tumors and their caregivers within convenient time frames and comfortable environments. Notably, they have the ability to address inadequate cancer services access by overcoming geographical, physical, and psychological barriers, and facilitating treatment access, support, and education [10]. When compared to usual care, health care augmented with digital health interventions has been shown to improve symptom management, reduce distress, decrease unplanned hospitalizations and associated care–related costs, and improve survival and quality of life [11]. While a number of digital supportive care tools for patients with brain tumors have been described [12], there are currently none tailored to the Australian context. In addition, existing tools are limited by a lack of evidence of their effectiveness and impact, development and implementation, and little consumer engagement in their development [7]. Building on our prior research on the quality of life of patients with brain tumors [2,3,13], their patterns of social media use for disease management [8], and needs and expectations from a digital health model of care [7], we engaged with Australian patients with brain tumors, their caregivers, and treating health professionals to co-design a digital health solution to address the unmet supportive care needs of this population. The aim of this study was to generate ideas and concepts to inform the development of a digital health tool to support the needs of Australian patients with brain tumors, their caregivers, and treating health professionals.

Methods

Co-Design Approach

Co-designing with patients and end users is widely recognized as critical to the design and development of digital health interventions and is used extensively across a range of physical and mental health conditions [14]. According to Sanders and Stappers [15], co-design may be conducted at various stages of a project life cycle, for example, (1) predesign (to understand lived experiences), (2) generative (to produce ideas), (3) evaluative (to summatively assess solutions), and (4) postdesign (to assess users' experience of the solution). We adopted a multimodal co-design approach, which included one-on-one interviews, focus groups, workshops, a fortnightly forum called a Design Reference Group, an end-of-life working group to inform design decisions for palliative care resources, and preliminary usability testing of a high-fidelity prototype. This paper reports the findings of one-on-one interviews conducted with patients, informal caregivers, and health care professionals in the project's "generative" phase. The other co-design activities will be addressed in subsequent research papers and are not included within the scope of this paper.

Participants and Recruitment Procedure

Three participant cohorts were recruited for this interview study: (1) adult patients (aged over 18 years) with a primary brain tumor, (2) current and bereaved caregivers of adults with a primary brain tumor, and (3) multidisciplinary health care professionals involved in the care of people affected by brain tumors. We excluded patients with secondary brain tumors from systemic cancer and their caregivers. Neurosurgeons were integral to the predesign phase and research team; thus, the generative phase focused on recruiting a variety of other health care professionals, including nursing and allied health staff.

Purposive sampling was used to identify participants with a wide variety of experiences in relation to aspects such as time since diagnosis, age, sex, postcode, tumor types, and types of treatment received. Researchers AB and VS maintained a spreadsheet of participants with the aforementioned salient information and sought to proactively seek out participants from a wide breadth of lived experience.

Participants were recruited from 2 major metropolitan hospitals in the State of Victoria (Australia). Patients were also asked to nominate a caregiver to take part in the study. Bereaved caregivers were also nominated by brain tumor advocacy organizations and consented by a study researcher. Health professional participants (including medical and radiation oncologists, clinical care coordinators, palliative care physicians, neuro-oncology nurses, and other allied health professionals) were identified through research team networks and invited via email.

Data Collection

The interviews were conducted over a period of 6 months, from October 2021 to March 2022. All consenting participants completed 1 audio-recorded semistructured telephone interview of 20 - 60 minutes with a research assistant. Verbal consent was reconfirmed and recorded prior to the commencement of the interview, along with basic demographic information. Semistructured interview guides were developed for each

participant cohort (Multimedia Appendices 1-3). Patient and caregiver interviews sought to elicit their lived experiences from diagnosis, their unmet supportive care needs, and their desires and preferences for digital solutions to address identified unmet needs. Health care professional interviews explored their perception of patient and caregiver needs, their experience with the provision of digital-based health care, and their perceptions of the need and preferences for digital health solutions to support patients with brain tumors and their caregivers.

Data Analysis

The audio recordings from each interview were transcribed verbatim, and the transcripts were inputted into QSR International's NVivo (version 12.6) for Mac software for coding and qualitative data management. All transcripts were quality-checked and deidentified for analysis by author AB. Data were analyzed using a 5-step framework analysis method [16], as follows:

- Familiarization: Researchers AB and VS read all the interview transcripts to familiarize themselves with the data.
- Identifying a framework: Fitch's 2008 Cancer Supportive Care Framework [17] was used to develop an a priori thematic framework to guide early data analysis. This is an evidence-informed framework that directly relates to the focus of the study to explore and describe unmet supportive care needs as experienced by people affected by brain tumors and their caregivers. The framework articulates 7 domains of supportive care needs: physical, informational, emotional, psychological, social, spiritual, and practical.
- Indexing: The thematic framework was applied to the data. Three researchers (AB, VS, and M Kalla) first indexed an initial set of 10 interview transcripts using Fitch's 7 supportive care categories. After this initial application, overlaps were found across the 7 domains, and the analytical framework was revised into 4 thematic categories for this study: emotional and psychological, information, physical and practical, and social connectedness needs. Subsequently, researchers AB and VS indexed all the interview transcripts independently, meeting regularly to ensure consensus around the final relevant themes and subthemes.
- Charting: The indexed data were organized into a manageable chart format to enable within- and cross-case analyses. NVivo's "Organise" function retrieved charted summaries of the indexed data for each thematic category and individual participant transcripts [18].
- Mapping and interpretation: Finally, mapping and interpretation of the data were conducted through the lens of the 3 pillars of the digital health tool proposed in the original funding proposal, that is, Learn, Connect, and Toolbox. Researchers AB, VS, and M Kalla synthesized the findings into summary presentations, describing how unmet supportive care needs could be addressed through one or more pillars.

Research Rigor

Our research team was comprised of a multidisciplinary team of academics, health service researchers, clinicians, technology developers, and lived experience experts. The multidisciplinary perspectives afforded by our team members strengthened the conceptualization, analysis, synthesis, and dissemination of our research findings. The majority of the interviews were conducted by the second author (AB), who has experience conducting health services research with patients with cancer and their caregivers using qualitative methods, having worked in a nationally reputed cancer treatment center. A small subset of interviews was also conducted by the first author (M Kalla), who is a digital health and qualitative research expert, and the third author (VS), who has experience as a nursing clinician and qualitative health researcher. This study was overseen by the last author (M Krishnasamy), who is a professor of nursing and qualitative research expert. The overall project was led by author KJD, who is the head of neurosurgery at a major metropolitan hospital in Australia.

To ensure credibility in the analysis of the research findings, 2 researchers (AB and VS) independently analyzed the interview transcripts to generate initial codes. Subsequently, a working group involving authors AB, VS, M Kalla, SCEB, and M Krishnasamy met at fortnightly intervals during the entire data collection and analysis process to compare, refine, synthesize, and establish the final themes. Interviews were conducted until data saturation was reached, and no new topics were discovered, resulting in a total of 35 interviews (13 patients, 11 caregivers, and 11 health care professionals), which is within the suggested range of 9 - 17 interviews in qualitative research [19]. Member checking was not conducted with participants to respect the limited available time of patients with brain tumors and caregivers to participate in a research project. Instead, we sense-checked the themes with a lived experience expert (a bereaved caregiver) who was part of our project's steering group. Finally, the findings were presented to the broader research team, including health care professionals and consumer advocates.

Ethical Considerations

The study was approved by the Royal Melbourne Hospital's Human Research Ethics Committee (HREC/77238/MH-2021). The ethics committee is accredited with Australia's National Health and Medical Research Council and is operated in accordance with the National Statement on Ethical Conduct in Human Research. The data presented in this paper are the primary data that were collected as part of this ethical approval. Potential participants were emailed an information and consent form to read and sign to agree to be interviewed. To ensure privacy and confidentiality, all study data were deidentified prior to analysis. Author AB reviewed all interview transcripts in their entirety to ensure that they had been fully deidentified prior to the commencement of analysis. Identifiable participant information was securely stored with password protection and accessible only to researchers authorized under the ethical approval.

Interviews were conducted over the telephone, with costs for the phone calls borne by the research team. Participants were not required to travel, and the interviews were conducted at a time suitable for them. Therefore, participants did not face any financial burden from participating in the study. Thus, reimbursement was not provided for their voluntary participation. The aforementioned arrangements for participant

involvement were approved by the ethics committee, as articulated in the research study protocol submitted at the time of application. As part of the ethics approval, our team was also required to submit annual progress reports and a final report, as well as notify the committee of any adverse events. These reports were provided to the committee in a timely manner. There were no adverse events reported from the conduct of this research.

Results

Overview

A total of 35 participants (13 patients, 11 caregivers, and 11 health care professionals) were recruited (Table 1).

The emergent themes and their subthemes are presented in Figure 1. Detailed and illustrative quotes from each of the 4 support needs domains—emotional and psychological, information, physical and practical, and social connectedness—are presented. All data fit within these themes on completion of the iterative process.

Table . Overview of participant demographics (N=35).

Demographic	Patients (n=13)	Caregivers (n=11)	Health professionals (n=11)
Age (years), mean (range)	42.1 (22 - 67)	55 (32 - 86)	47.1 (40 - 60)
Sex, n (%)			
Male	5 (39)	2 (18)	3 (27)
Female	8 (62)	9 (82)	8 (73)

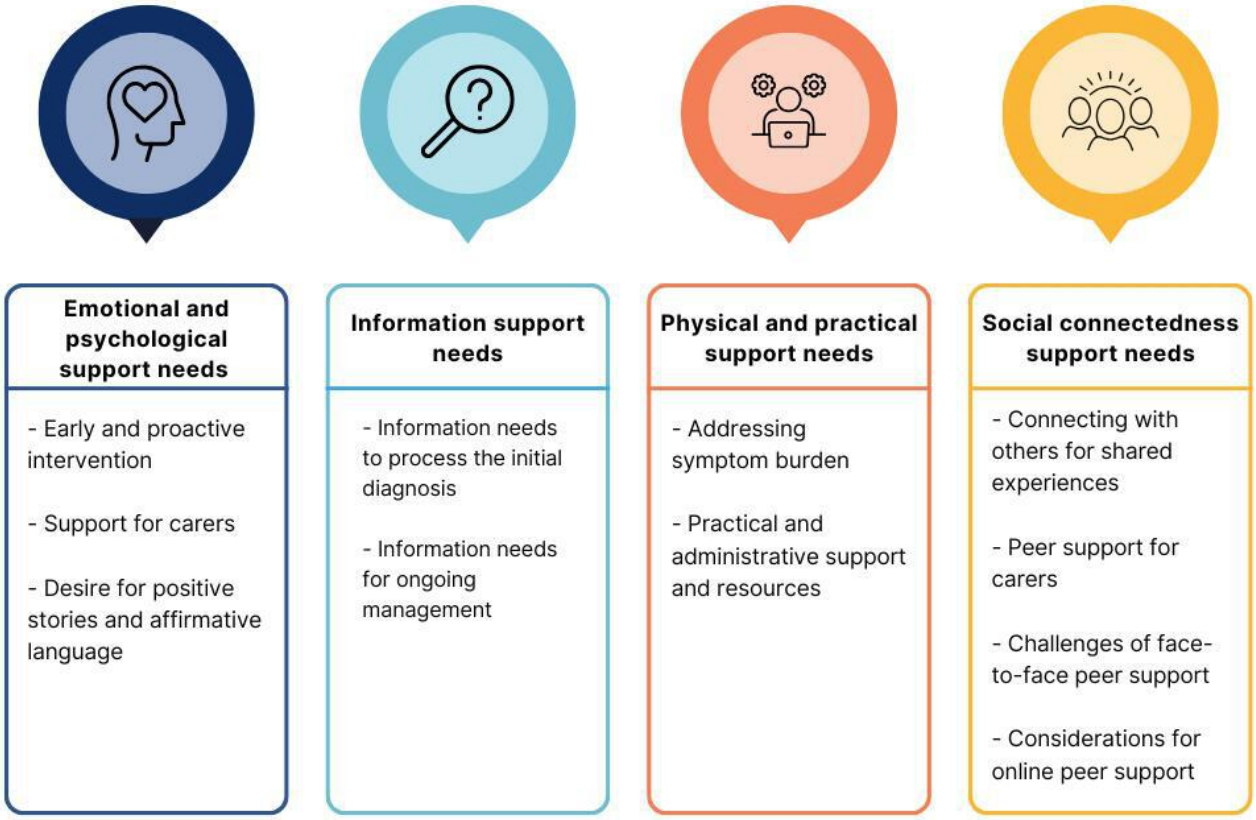
Figure 1. Overview of emergent themes and subthemes.



Theme 1: Emotional and Psychological Support Needs

Within the theme of patient and caregiver emotional and psychological support needs, 3 subthemes highlighted the need for early and proactive psychological intervention, the importance of emotional support for caregivers, and the desire for positive stories and affirmative language.

Early and Proactive Intervention

Participants reported delayed help-seeking for mental health assistance due to a lack of awareness of relevant services and the benefits of intervention. They described frequent reliance on informal mental health support from family and friends, or those with similar experience. Some participants delayed addressing mental health needs until after treatment. Almost all participants wished they had been encouraged by their treating team to access mental health services or provided with links to resources and tools at diagnosis.

> *I didn't start seeing a psychologist until after treatment which isn't good...I wish someone kind of forced me to see one, not forced...like just did a referral for me to see one...I did like a year of treatment and...you're trusting your family [but] there's only so much they can really do...Before treatment would have been good...Once I was diagnosed, I wish I had saw [sic] someone.* [Patient 3, female, 22 years]

Health care professionals reported varied levels of proactiveness for mental health service referrals. Lack of referral was often driven by insufficient clarity regarding the best service or intervention for their patient's specific needs. Often, health care professionals deferred to brain tumor advocacy organization services and web-based resources.

> *I have...people saying...I'm quite distressed...and then me...going through this list...so we've done the referral to Cancer Council, you're on a wait list for a counselling session...What exactly is the issue, can it be worked through with a counsellor, is it more affecting...do we need psychology support, or do we need some...medication intervention...do I need psychiatry...I think just having that information a bit more available.* [Health care professional 10, neuro-oncology nurse consultant, female, 39 years]

Support for Caregivers

Participants highlighted the importance of mental health support for caregivers, with mental health discussions often focused on the patient and inadequate recognition of caregivers' needs.

> *I think as carers you don't recognise...oh actually your life is going to be significantly impacted in the future and...right here and now you actually need to look after yourself as much as you can, to be the best carer that you can [be].* [Caregiver 2, female, 37 years]

> *I was offered counselling...I reckon it should be available to both parties...I feel that my partner...she was going through more than me.* [Patient 6, male, 31 years]

Desire for Positive Stories and Affirmative Language

Participants expressed the need for information and lived experience stories, framed positively and fostering a sense of hope. Some participants actively sought people with brain tumors on social media who were living fulfilling lives, as it gave them hope for their own future.

> *Just to really emphasise that your life isn't over, and you can still have a normal life after it...I found there's a few people on Instagram that had been diagnosed with it and they're still out there...really doing well.* [Caregiver 4, female, 32 years]

Affirmative explanations of complex medical treatments and procedures were useful in creating a greater understanding of the treatment plan and reducing fear.

> *A lot of people are actually frightened...having brain surgery whilst you're awake, is such a morbid type of experience, where I found it exactly the opposite...It's hard to describe the experience that I went through, but being able to listen to what's going on whilst it's happening...oh we're removing some of the tumour now, having all that conversation...I found that [I was] more in control...more knowledge, more knowing...everything that was going on.* [Patient 7, male, 50 years]

Theme 2: Information Support Needs

Participants described significant initial information needed to process their diagnosis and ongoing information needed to manage the physical, social, and psychological impacts of a brain tumor on their lives and that of their families.

Information Needs to Process the Initial Diagnosis

Information requirements were greatest at diagnosis and reported a sense of overwhelm with "information overload." Patients and caregivers reported difficulty understanding the information presented by their health care professionals and expressed a strong need for tailored, personalized information, appropriate for the type and location of tumor and patient age and sex. Similarly, health care professionals recognized that deconstructing medical jargon while providing the appropriate breadth of information is crucial to support patients and their caregivers in decision-making around treatment options.

> *I think you've got to find a balance between not overloading people with information but giving them access to resources and that's never easy.* [Health care professional 8, medical oncologist, male, 55 years]

At diagnosis, patients and caregivers described turning to internet searches to learn more about the tumor, treatment options (including clinical trials and integrative therapies), life expectancy, and survival statistics. Many participants reported that in these early stages, they struggled to discern credible information and found "Dr Google" overwhelming.

> *I still wanted to know...as much information as I could about...my diagnosis...but I needed accurate information and that's where I say the internet didn't really supply me that accurate information about my particular case.* [Patient 7, male, 50 years]

Information Needs for Ongoing Management

Patients and their caregivers described an ongoing need for information about life after treatment, the impacts of the illness and its treatment, and assistance to maintain quality of life.

> *Help processing what the treatment plan looks like...and knowing where to go for help and answering questions. Not only about diagnosis but also about treatment once they're discharged...The discharge happens pretty quickly from surgery, usually...six to nine days or sometimes sooner.* [Health care professional 5, cancer care coordinator, female, 51 years]

Additionally, patients and caregivers expressed the need for on-demand information in a consolidated space and the ability to learn from experts from the comfort of their homes.

> *Video would be good...hearing from experts and doctors about things would be really helpful...And maybe even a Q&A session where you can ask questions, and they can answer...interactively.* [Caregiver 7, female, 60 years]

Theme 3: Physical and Practical Support Needs

Participants described unmet supportive care needs relating to symptom burden, practical and administrative support to facilitate the logistics of accessing treatment, and accomplishing daily life tasks.

Addressing Symptom Burden

Participants described a variety of symptoms associated with the brain tumor or its treatment, which significantly impacted patient quality of life and caregiver burden. Participants expressed a strong desire for access to resources and interventions to support symptom management, including sleep disturbance, fatigue, cognitive dysfunction, poor concentration, imbalance, and incoordination. Participants indicated that symptoms were clustered, for example, an interaction of sleep disturbance and fatigue.

> *If there was something to help with sleep, I would definitely jump...that would be one of the biggest things...I basically always went to the GP about...I would go to say I can't sleep, I just get...rundown...I can't sleep, I can't sleep, I'm tired...* [Patient 1, male, 53 years]

Seizures were considered particularly burdensome and "frightening" with management options often not well understood by patients or caregivers.

> *Managing seizures and what to do in, in the event of a seizure...I mean not everyone needs to come to hospital if they have a seizure, it depends on...what type...Partial seizures...you can pretty much manage at home. And then...talk to someone the next day or go through the GP...there's certain steps that you could take. I think that would be a really good [pause] thing to put in...if you're uploading information [on*

the platform]. [Health care professional 5, cancer care coordinator, female, 51 years]

We asked about the role of self-monitoring by patients for symptom management, with participants presenting mixed responses. Some health care professionals, particularly in allied health and palliative care contexts, used symptom monitoring to support patients. Nevertheless, participants agreed that symptom monitoring regimes, whether digital or paper-based, would need to be considered contextually within broader clinical workflows to be useful or effective.

> *I guess the key thing would be somebody taking responsibility for that and...following up where concerning symptoms have been presented...I don't know that just collecting symptoms for the sake of collecting symptoms is going to be particularly useful. You've got to have somebody who's going to be reviewing that information and...acting upon it.* [Health care professional 9, radiation oncologist, female, 51 years]

Practical and Administrative Support and Resources

Participants expressed the need for support and resources to manage practical, logistical, or administrative challenges. Information to navigate transport, permission to continue or return to driving, government welfare and advocacy agency support, and accommodation during treatment and management of insurance were commonly difficult to obtain.

> *The thing that really frustrated me is every time I'd try and talk to someone about...things like financial information...life insurance...income protection...just to try and get some information and help with trying to sort through...how I can access [it].* [Patient 1, male, 53 years]

Participants also emphasized the particular need for practical, logistical, and administrative support for patients and caregivers in rural or regional areas.

> *We need to keep in mind the...regional family as well because...there are types of cancer that can't be treated in...regional areas. They need to be treated at a specialist centre. So...demands placed on that around travel...the financial impacts of that...paying for accommodation, parking, travel all those sorts of things. There are subsidies and things that people can get access to but that does have impacts that are ongoing...taking time off work...all those sorts of things are quite huge.* [Health care professional 1, exercise physiologist, male, 42 years]

When asked about telehealth, all patients and caregivers reported having used telehealth and found it time-saving and convenient. However, for important appointments, a face-to-face conversation was preferred.

Theme 4: Social Connectedness Support Needs

Patients and caregivers expressed the need for social connectedness and suggested these may be met by a digital platform. Four subthemes emerged: the importance of connecting with others for shared experiences, the significance of peer support for caregivers, challenges and lessons learned from face-to-face peer support programs, and considerations for creating safe and beneficial digital peer support communities.

Connecting With Others for Shared Experiences

Participants noted that a brain tumor can be alienating, with feelings of isolation further compounded for those in rural or regional areas. Thus, opportunities to connect with others with similar experiences can offer solace.

> *When you find someone who you can relate to and they've got a level head, it just puts your mind at ease.* [Patient 6, male, 32 years]

Participants noted that in addition to helping cope with stressors, peer support could also normalize living with this illness.

> *This is the absence that we have in brain cancers and tumours...you can see the hard, the scary facts, but...it is really to understand what next, who else is out there like me, who else is young and also about to get married, or just about to have a baby, or just got the promotion at work or...I feel like there's a lot of people that sit in this category.* [Caregiver 2, female, 37 years]

Peer Support for Caregivers

Participants also highlighted the need for social connectedness and peer support for caregivers and noted that digital solutions could offer a helpful on-demand avenue for busy caregivers.

> *Online [peer support] is actually like a great entry point...You're so consumed by...needing to do everything for that person...I can't remember how many times I would've been awake at 2 am in the morning or something because my brain was racing, and being able to may be connect with somebody or...something like that, not necessarily to chat right there in that moment.* [Caregiver 2, female, 37 years]

Participants also emphasized the importance of peer support for caregivers in all situations, including those currently undertaking caring duties, as well as bereaved caregivers. Some participants had found established grief support groups, but not for current caregivers, while other participants reported a lack of formalized support structures for bereaved caregivers.

> *Our focus is on the patient and of course we support the partner while they're coming to the centre. But once that patient's passed away our involvement sort of ends, and I think these partners are left...often they're very fatigued because I think [for] the carers of these types of patients...the carer burden is huge.* [Health care professional 4, nurse, female, 46 years]

Challenges of Face-to-Face Peer Support

Participants expressed that despite their desire for social connection with others with similar experiences, they had either not been able to find an in-person support group that was the right fit for them, or they had found the support networks unhelpful or not relatable with members of varying experiences, ages, sexes, or life stages. Additionally, in-person support groups

could be confronting, and digital peer support was considered a helpful alternative.

> *She didn't want to go to a room and sit in a chair around in a circle and tell her story...Some of those support groups can be a bit too full on. So that's why something that isn't quite as full on like an app or online story or...live chat, something...you can still...perhaps talk to someone, so you're...not in a room full of strangers...But something in between they can just have on their smart phone or computer and just send off an enquiry and if that's all you need at the time, then that's fine.* [Caregiver 1, male, 37 years]

Health care professionals with experience in running in-person support groups also highlighted the logistical challenges of facilitating face-to-face groups. They reported high attrition rates, emphasized the need for distress protocols in the event that a participant is emotionally affected, and noted the complexities of running in-person support groups involving people with varying prognoses.

> *If you're meeting in person you've got to have reasonable leaders...Normally the social worker would do it with me...because if someone gets upset, you've got to have enough people to take them out and talk to them separately as well...I think the support groups do help but...you have to be careful, and you can't mix the low grade with the high grade. That's another problem because...the high grade have very immediate needs.* [Health care professional 7, care coordinator, female, 72 years]

Considerations for Digital Peer Support

Challenges to create a safe, relatable, and where possible, customizable web-based peer support platform were recognized as important considerations. Participants commented on the importance of regulation and moderation in digital peer communities. They expressed concerns over harsh language, individuals with domineering personalities and negative responses, or harmful opinions being promoted within an already vulnerable group.

> *You have different...personalities, and I'd be worried if you did an online group that some people might be afraid to speak up because there could be other people that are quite boisterous.* [Caregiver 3, female, 49 years]

Participants emphasized the need for control over the visibility of information and the social media posts of others. They reported that social media news feeds can be jarring and compound emotional distress.

> *My sister joined this Facebook group for...brain tumour and she...added me along. I've sort of been a little bit up and down about that...because it just comes up on my news feed and then you know some...things that I read...is okay, but then...some things that I read that aren't so great, I sort of tune off a little bit you know.* [Patient 9, female, 38 years]

Similar to in-person peer support groups, digital peer communities need to consider the implications of varying prognoses due to different tumor types. When asked about different digital peer support formats, such as a "buddy" program, participants expressed concerns that those who bond with other unwell individuals may open themselves to grief if their "online buddy" dies or becomes too unwell to participate.

> *What happens when something happens to my buddy, you know, like, what does that gonna traumatize? [sic]...I don't know.* [Patient 12, female, 39 years]

Integration of Emergent Findings Into the Platform

The participants' insights were used to inform the development of content for our web-based platform now called "Brain Tumours Online." The Brain Tumours Online platform features three key elements or "pillars": (1) a repository of vetted, evidence-based information about a myriad of health, social care, and administrative supports available to patients and their caregivers ("LEARN"); (2) a digital peer support community to enable connections with other patients, caregivers, and health care professionals ("CONNECT"); and (3) an emerging library of validated digital symptom management therapeutic solutions ("TOOLBOX"). Herein, we describe how participants' insights were synthesized and addressed by the various components or "pillars" of the Brain Tumours Online platform.

Based on the emotional and psychological and social connectedness themes, participants' perspectives on face-to-face and digital peer support informed the design of our web-based peer community under the CONNECT pillar. Our digital peer community mitigates the access barriers (eg, time and geographical constraints, privacy concerns) for people who noted challenges with in-person support groups. Our platform's CONNECT pillar provides a range of avenues for sharing stories, experiences, and knowledge, for example, topic-specific chat forums, users' individual posts, and digital webinars. The CONNECT pillar also provides an avenue for sharing other patients' and caregivers' past hopeful stories, addressing the unmet need for positive stories that foster a sense of hope. The participants' preference for a safe space was also translated into the implementation of a moderator group, which includes moderator-trained patients, caregivers, and health care professionals. The CONNECT pillar also provides health care professional interface, including via digital webinars, and in their capacity as community moderators, to answer any questions on chat forums and vet information.

Within the information theme, participants expressed the unmet need for trusted and bespoke medical and social care information. Our platform's LEARN pillar provides a consolidated repository of brain tumor expert-endorsed information that is relevant to the Australian context, with signposting to specific tumor types, life stages, and personal situations. Examples of information available on the platform range from social care options for childcare, treatment-related travel subsidies for patients in remote and regional areas, eligibility for motor vehicle driving, and what to expect in various biomedical treatment options. The LEARN pillar contains a combination of curated existing external (trustworthy and vetted) resources and new resources freshly developed for

our digital health platform where an existing suitable resource was not already available.

Within the physical and practical theme, participants noted their unmet needs for resources and interventions to manage symptom burden. These needs are addressed by the Brain Tumours Online platform's TOOLBOX pillar. The TOOLBOX is intended to become a growing library of validated digital therapeutic tools for symptom management. The first tool that is currently available in the TOOLBOX is "Somryst," a Food and Drug Administration–approved digital therapeutic tool for chronic insomnia. Additional tools will be incorporated into the platform TOOLBOX in due course, in response to our user community's needs.

Discussion

Principal Findings

In this study, we set out to generate ideas and concepts to inform the development of a digital health tool to support the unmet needs of Australian patients with brain tumors, their caregivers, and treating health professionals. The data revealed 4 themes of unmet support needs that could be addressed by a digital health tool or platform: emotional and psychological, information, physical and practical, and social connectedness. Participants expressed the desire for early and proactive mental health intervention, noted the importance of providing mental health support to caregivers, and emphasized the need for positive stories and affirmative language. From an information perspective, participants noted a sense of information overload, especially at the beginning. They also underscored the variety of information needed on an ongoing basis, including life after treatment, and comprehensive care assistance to maintain quality of life. Participants also described unmet supportive care needs relating to symptom burden, practical and administrative support to facilitate the logistics of accessing treatment, and accomplishing daily life tasks such as work and study. Finally, they expressed the desire for greater social connectedness and safe spaces to engage with other people in a similar situation.

Comparison With Prior Work

The unmet supportive care needs identified in our study echo some of the previous literature published in this area. For example, Janda et al [20] conducted a qualitative exploration of the supportive care needs of patients with brain tumors and their caregivers. They identified the need for greater practical support (eg, support with financial issues and dealing with government agencies), the need for information and coping with uncertainty, as well as support to deal with social isolation. They found that technology could be a helpful avenue for patients in obtaining information and supporting caregivers. Our Brain Tumours Online platform seeks to provide a digital peer support mechanism to help mitigate social isolation and bridge information access gaps.

Indeed, the literature also emphasizes the changing needs of patients and caregivers over time. Previous studies indicate that information and mental health support needs are often greatest at the start and can change over time [4]. Thus, past literature emphasizes the need for bespoke and adaptable information and supportive care resources that can assist patients and caregivers in accordance with their evolving needs over time. Furthermore, past studies also indicate patients and caregivers wish to stay abreast of the latest developments in research and treatment of brain tumors [21]. To this end, our Brain Tumours Online platform seeks to serve as a living resource that can support patients and caregivers at different stages of diagnosis, treatment, and posttreatment living, and present a synthesis of the latest developments in this field.

Based on past research, it appears that a key factor in the mitigation of patients' and their caregivers' unmet needs was the awareness of available psychosocial support services and consequently their service use [22]. Therefore, a key aim of the Brain Tumours Online platform will be to provide a consolidated set of evidence-based resources on a variety of subjects ranging from availing social care services through government agencies to managing physical symptoms through allied health supports.

While our research findings are consistent with the past literature, our team recognized that existing tools for cancer care have often had little direct consumer engagement in their conceptualization, development, and implementation [7]. Thus, our qualitative exploration reported in this study was essential to validate previous literature and ensure that the emergent Brain Tumours Online platform meets the needs of Australian patients with brain tumors and their caregivers.

Limitations

First, it should be noted that some of the unmet needs expressed by our study's participants related to more systemic medical practice challenges, and could not be feasibly addressed through our digital solution, for example, the timeliness of referrals to mental health services. Nevertheless, by providing access to a supportive community, a vetted repository of trusted medical and psychosocial information, and easily accessible digital therapeutics, the Brain Tumours Online platform seeks to bridge comprehensive care and access gaps for a vulnerable patient and caregiver community. Second, we note that this study was aimed at adult participants only. Due to human research ethical constraints, and the scope of our study, pediatric patients were not included. The unmet needs of pediatric patients will need to be explored in a future program of work.

Finally, we note that there were also some limitations associated with our methodological approach. To minimize participant burden, particularly for patients and caregivers, we conducted interviews over the telephone. However, the conduct of interviews over the telephone, as opposed to in-person or via video call, meant that there was limited to no opportunity for identifying nonverbal communication such as body language and facial cues, which can be invaluable in qualitative lived experience research. Similarly, the opportunity for building personal rapport between the researcher and participant is limited in a telephone interview as compared to an in-person interview, which can in turn impact how freely participants share their personal experiences.

Conclusions

To our knowledge, when we began this project, there were no comprehensive digital health supportive care solutions for

Australian patients with brain tumors and their caregivers. Building on our prior research on the quality of life of patients with brain tumors [2,3,13], their patterns of social media use for disease management [8], and needs and expectations from a digital health model of care [7], we engaged with Australian patients with brain tumors, their caregivers, and treating health professionals to co-design a digital health solution to address the unmet supportive care needs of this population. Participants' insights were distilled to develop content for a web-based supportive care platform called "Brain Tumours Online." The platform comprises three pillars—(1) LEARN: a repository of vetted information about a range of biomedical and psychosocial care topics; (2) CONNECT: a digital peer support community with a health care professional interface; and (3) TOOLBOX: an emerging library of validated digital therapeutics for symptom management.

Acknowledgments

The authors would like to thank Meredith Layton, Ann Borda, Olivia Metcalf, Kit Huckvale, and Teresa O'Brien for their input on this paper and its foundational work. The authors thank consumer experts Diana Andrew, Julia Fin, Samantha Wright, and Janet Micaleff for providing their expertise and perspectives to inform this work. Additionally, the authors would like to thank the members of our Design Reference Group and the other lived experience experts who participated in our co-design activities. The study described in this paper was supported by the methodological expertise of the Digital Health Validitron, a collaborative and interdisciplinary research group at the University of Melbourne that assists digital health innovators from health care, academia, and industry to accelerate the creation of evidence that proves the real-world value of their ideas and products. This research received grant funding from the Australian Government through the Medical Research Future Fund 2020 Brain Cancer Survivorship Grant Program (MRFBCII000014).

Data Availability

The datasets generated and analyzed during this study are not publicly available due to the sensitive nature of the data.

Abstract

Background: Cancer-care complexity heightens communication challenges between health care providers and patients, impacting their treatment adherence. This is especially evident upon hospital discharge in patients undergoing surgical procedures. Digital health tools offer potential solutions to address communication challenges seen in current discharge protocols. We aim to explore the usability and acceptability of an interactive health platform among discharged patients who underwent oncology-related procedures.

Methods: A 4-week exploratory cohort study was conducted. Following hospital discharge, a tablet equipped with an integrated Personal Virtual Assistant (PVA) system was provided to patients who underwent oncology-related procedures. The PVA encompasses automated features that provide personalized care plans, developed through collaboration among clinicians, researchers, and engineers from various disciplines. These plans include guidance on daily specific assignments that were divided into 4 categories: medication intake, exercise**,** symptom surveys, and postprocedural specific tasks. The aim was to explore the acceptability of the PVA by quantification of dropout rate and assessing adherence to each care plan category throughout the study duration. The secondary aim assessed acceptability of the PVA through a technology acceptance model (TAM) questionnaire that examined ease of use, usefulness, attitude toward use, and privacy concerns.

Results: In total, 17 patients were enrolled. However, 1 (5.8%) patient dropped out from the study after 3 days due to health deterioration, leaving 16/17 (94.2%) completing the study (mean age 54.5, SD 12.7, years; n=9, 52% Caucasian; n=14, 82% with a gynecological disease; n=3, 18% with a hepatobiliary disease). At the study end point, adherence to care plan categories were 78% (SD 25%) for medications, 81% (SD 24%) for exercises, 61% (SD 30%) for surveys, and 58% (SD 44%) for specific tasks such as following step-by step wound care instructions, managing drains, administering injectable medications independently, and performing pelvic baths as instructed. There was an 80% patient endorsement (strongly agree or agree) across all TAM categories.

Conclusion: This study suggests the potential acceptability of the PVA among patients discharged after oncology-related procedures, with a dropout rate of less than 6% and fair-to-good adherence to tasks such as medication intake and exercise. However, these findings are preliminary due to the small sample size and highlight the need for further research with larger cohorts to validate and refine the system.

Introduction

Ineffective communication between cancer patients and health care providers can result in heightened distress, compromised quality of life [1], reduced treatment adherence [2,3], and suboptimal quality of care [4]. The complexity of cancer care, coupled with the necessity for a multidisciplinary approach, exacerbates communication challenges in this population [4,5]. For instance, multiple health care professionals including surgeons, medical and radiation oncologists, pathologists, nurses, physical therapists, social workers, and nutritionists, amongst others, can be involved in one single treatment plan [6]. This multidisciplinary approach, while essential to provide comprehensive care, often results in multiple hospital follow-ups, varied medication regimens and heterogeneous instructions, which can lead to misunderstandings, failure of cancer treatment protocols, and physical and psychological harm [4].

These communication issues in cancer patients become especially evident in those undergoing surgical procedures and transitioning from hospital to home settings [7]. Upon hospital discharge, cancer patients are commonly provided with a list of extensive instructions based on written or printed summaries, which are lengthy and tedious [8-11], making it difficult to understand and follow [12,13]. In recent years, there has been a shift toward using computer generated programs to create quick and interactive materials in the form of educational websites, audio, and videos [14]. However, they still fall short in providing interactive and bidirectional communication with health providers.

During the COVID-19 pandemic, digital health emerged as an alternative to address communication challenges through technology platforms and remote health monitoring [15]. Digital tools such as telemonitoring, telemedicine, mobile health apps, and wearable devices [16] became useful tools for improving treatment compliance, symptom management, and patient communication. However, as these tools become more widely adopted, it has become evident that numerous challenges must be addressed to improve their usability, accessibility, and effectiveness, particularly in cancer care. Key challenges in adopting digital technologies for cancer patients include disparities in technology literacy, poor integration into clinical workflows, time-intensive processes, and limited bidirectional communication. Furthermore, content may be biased if created by those without health-related expertise. To address these challenges, a collaboration between academia (Baylor College of Medicine, Houston) and industry (Smartek21, Seattle) developed an interactive digital platform, called Personal Virtual Assistant (PVA). The PVA is designed to virtually coach patients in adhering to their postoperative care plans and enhance communication after hospital discharge. This exploratory study examined the usability and acceptability of the PVA among patients undergoing oncology-related procedures, aiming to identify its successful components, adoption barriers and areas for improvement.

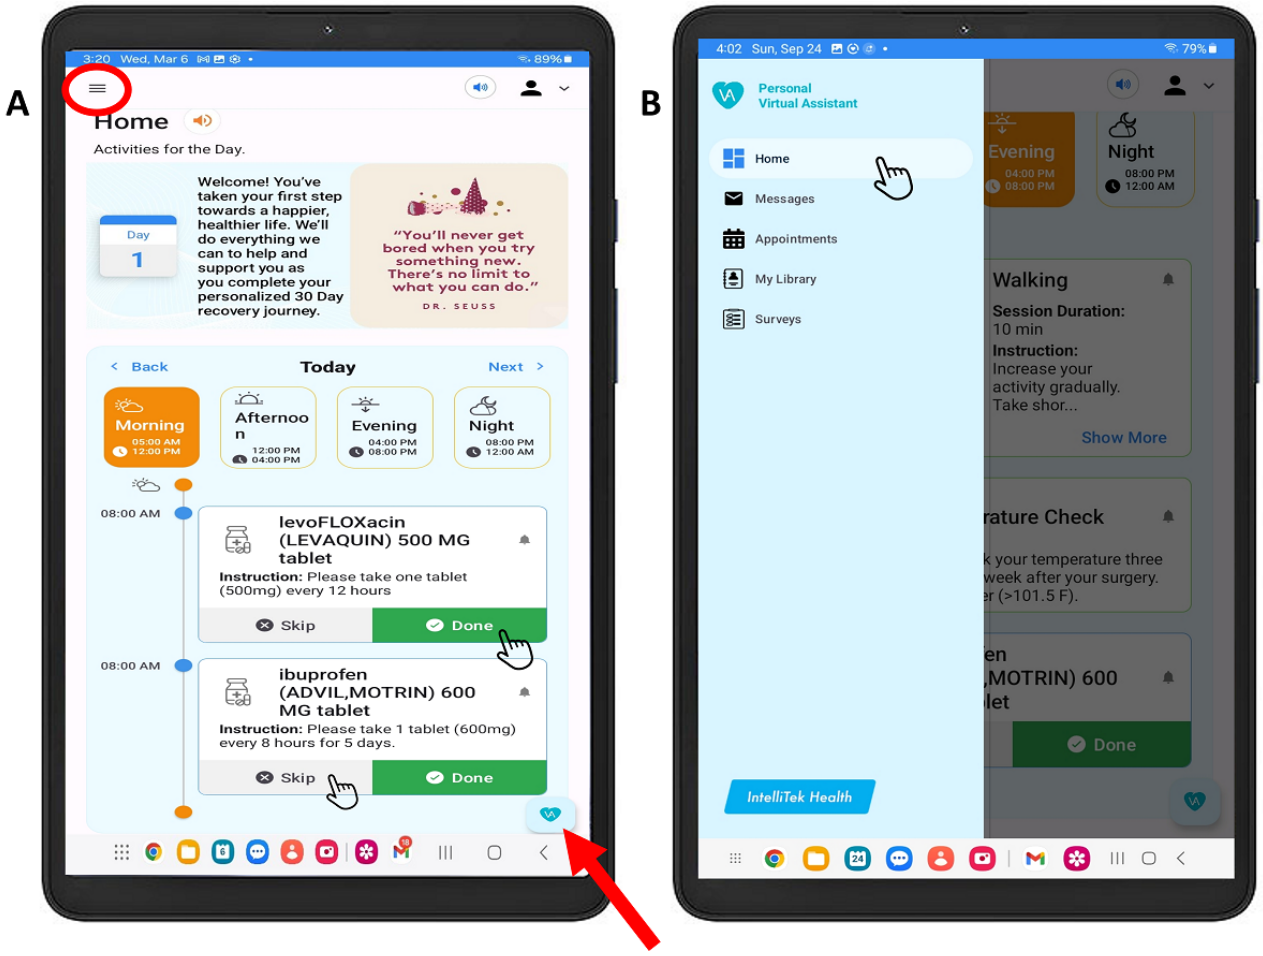
Methods

Personal Virtual Assistant Development

The PVA streamlines posthospital discharge care plans through 3 key elements: an interactive patient platform, a care provider portal, and a secure cloud backend interface.

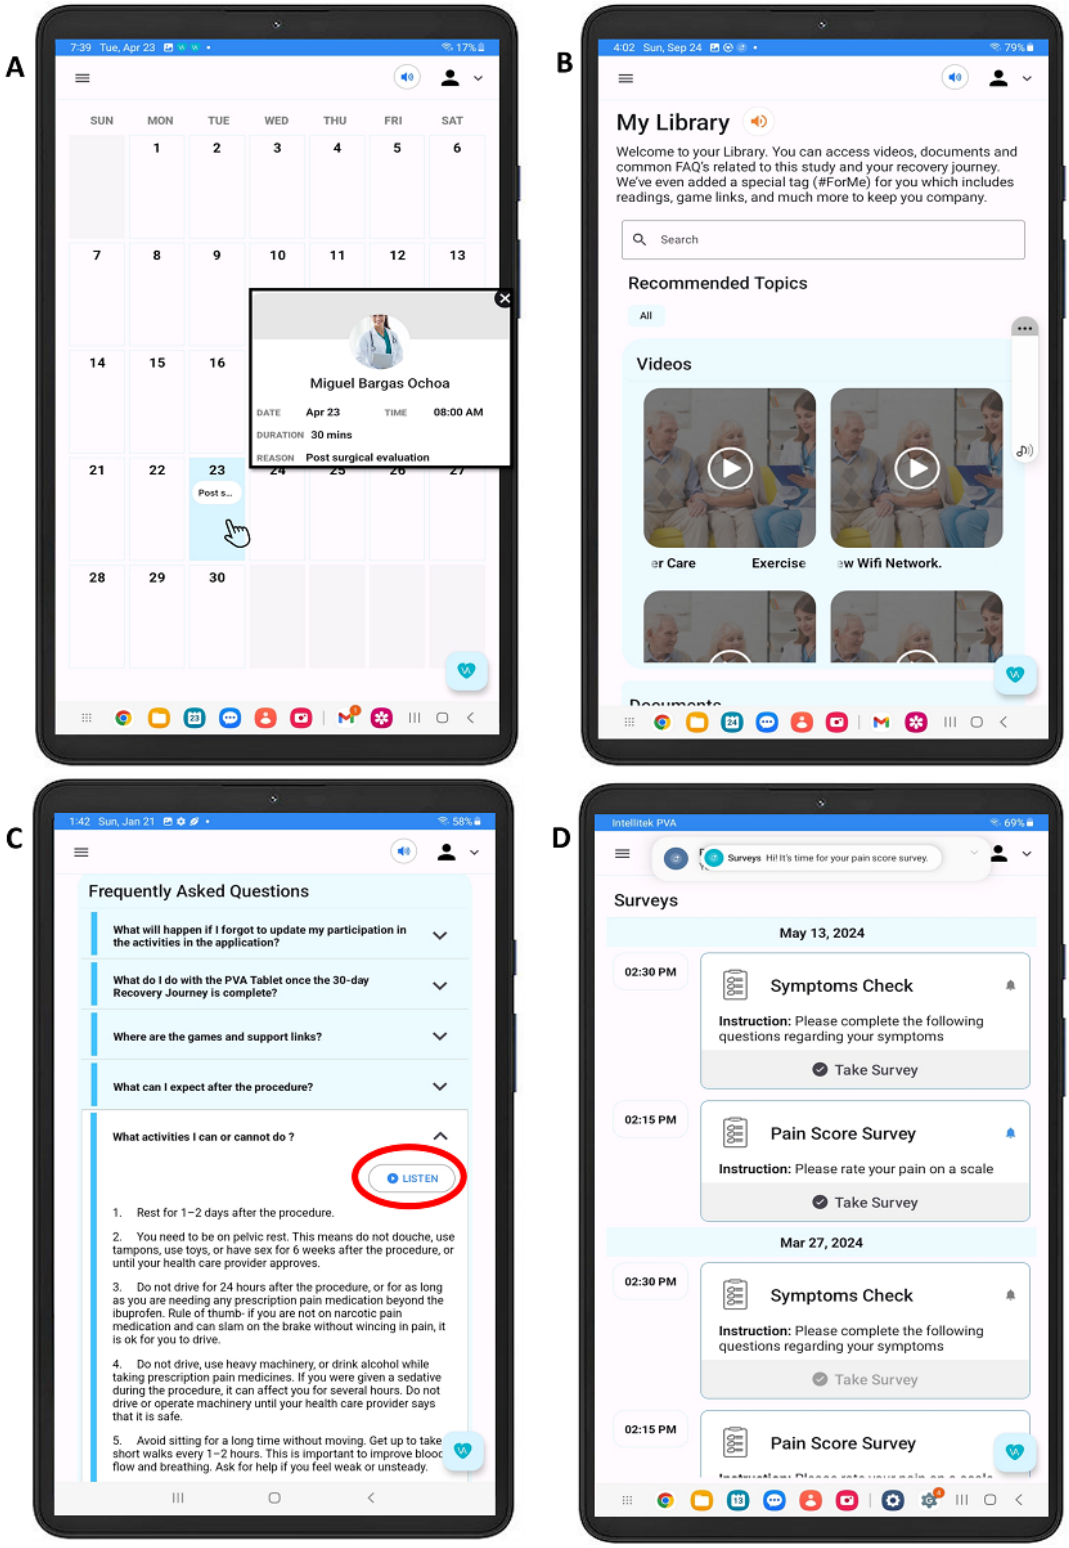
The Interactive Patient Platform uses an app integrated into a tablet that works through internet connection. Upon launching the app, the home screen displays the patient daily care plan (Figure 1A), which can include “prescribed medications,” “exercises,” “symptom surveys,” and “postprocedural specific tasks.” The assignments that appear on the home screen depend on the time and day of recovery. Patients have the option to navigate through these assignments by manual selection or by using natural language voice-commands upon pressing the “voice-command” button and speaking aloud the category name. In addition, the app has an alert notification system to remind patients to complete the assignments by marking each one as “done.”

Figure 1. Personal Virtual Assistant displaying the patients' portal home screen. (**A**) Personal Virtual Assistant displaying the home screen once opened. When scrolling down, all 4 categories (medications, exercises, symptom surveys, and specific tasks) are seen. The red circle represents the button to navigation sidebar and the red arrow depicts the voice-command button. (**B**) Navigation sidebar options displaying additional navigation tools such as messages, appointments, my library, and symptom surveys.



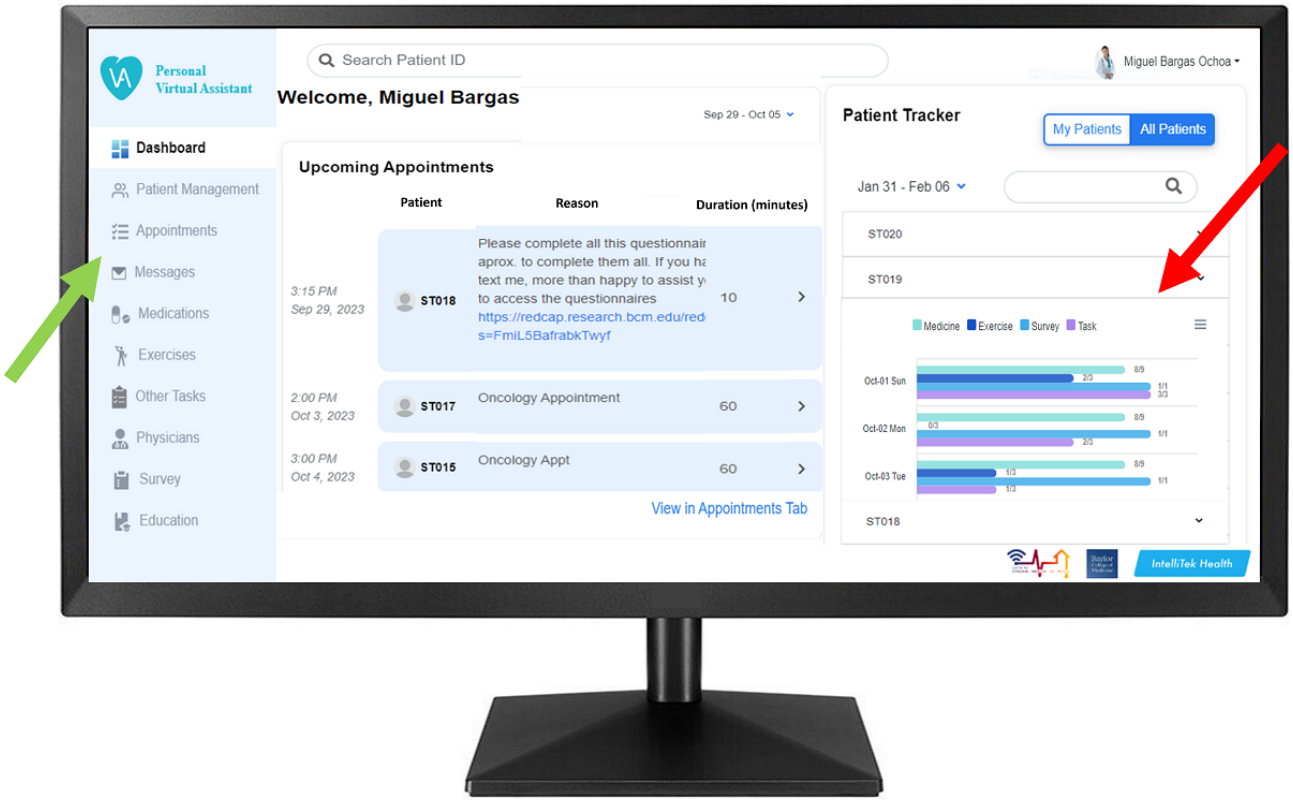
On the top left side of the screen, a menu sidebar button is available to allow patients to navigate into other aspects of their care plan such as "Appointments," "My Library," "Messages," and "Surveys," (Figure 1B). By manually selecting or speaking aloud "Appointments" on the PVA, a calendar appears displaying upcoming clinic visits. Then, more details are available upon selecting the desired appointment (Figure 2A). The "My library" tab offers educational video content covering various topics such as guidance on how to use the tablet, exercise during cancer care, and guidance on postsurgical recovery (Figure 2B). Within this tab, a frequently asked questions section is also available, in which patients have the option to listen to them outload by pressing the "listen" button located above the text (Figure 2C). In addition, the "My Messages" tab opens a chat box where patients can communicate with the user behind the care provider portal, in this case the clinical research team. Finally, the "My Surveys" tab redirects to the home-screen symptom surveys.

Figure 2. Personal Virtual Assistant displaying the patients' portal additional navigation tabs. (**A**) Appointment tab displays a calendar. Details appear upon clicking on the date. (**B**) My Library contains educational content about Personal Virtual Assistant and surgical recovery. (**C**) Frequently Asked Questions about technology troubleshooting and recovery process includes audio option for listening to these explanations. (**D**) Surveys patient must complete that inquire about symptoms and pain.



The Care Provider Portal is accessed through a website on any computer with an internet connection. In this study, the portal was personalized for use by the clinical research team. Once accessed by the user, a dashboard screen listing all patients with their upcoming appointments and weekly logins to the PVA system is displayed (Figure 3). On the left side of the screen, a menu sidebar including 10 different tabs allows the user to individually customize each patient care plan. For instance, in the "Patient Management" tab, the user can customize each patient's posthospital discharge instructions. In the "Medications" and "Exercises" tabs, users can manage drug dose, frequency, duration, and mobility sessions, respectively. All information provided through these tabs are stored as repositories, feeding an electronic library for future care plans.

Figure 3. Personal Virtual Assistant displaying the care provider portal. Main dashboard on any computer with internet connection. Green arrow: points to the navigation sidebar. Red arrow: points at the adherence tracker, which opens a drop-down menu that shows daily adherence for each of the 4 categories in the care plan.



The cloud backend is a secure cloud-based platform that allows for instant updates to care plans, sends alerts, monitors adherence to care plans, arranges appointments, enables communication, and creates a resource library with relevant content for patients and care providers.

Integration of Clinical Content Into the Personal Virtual Assistant

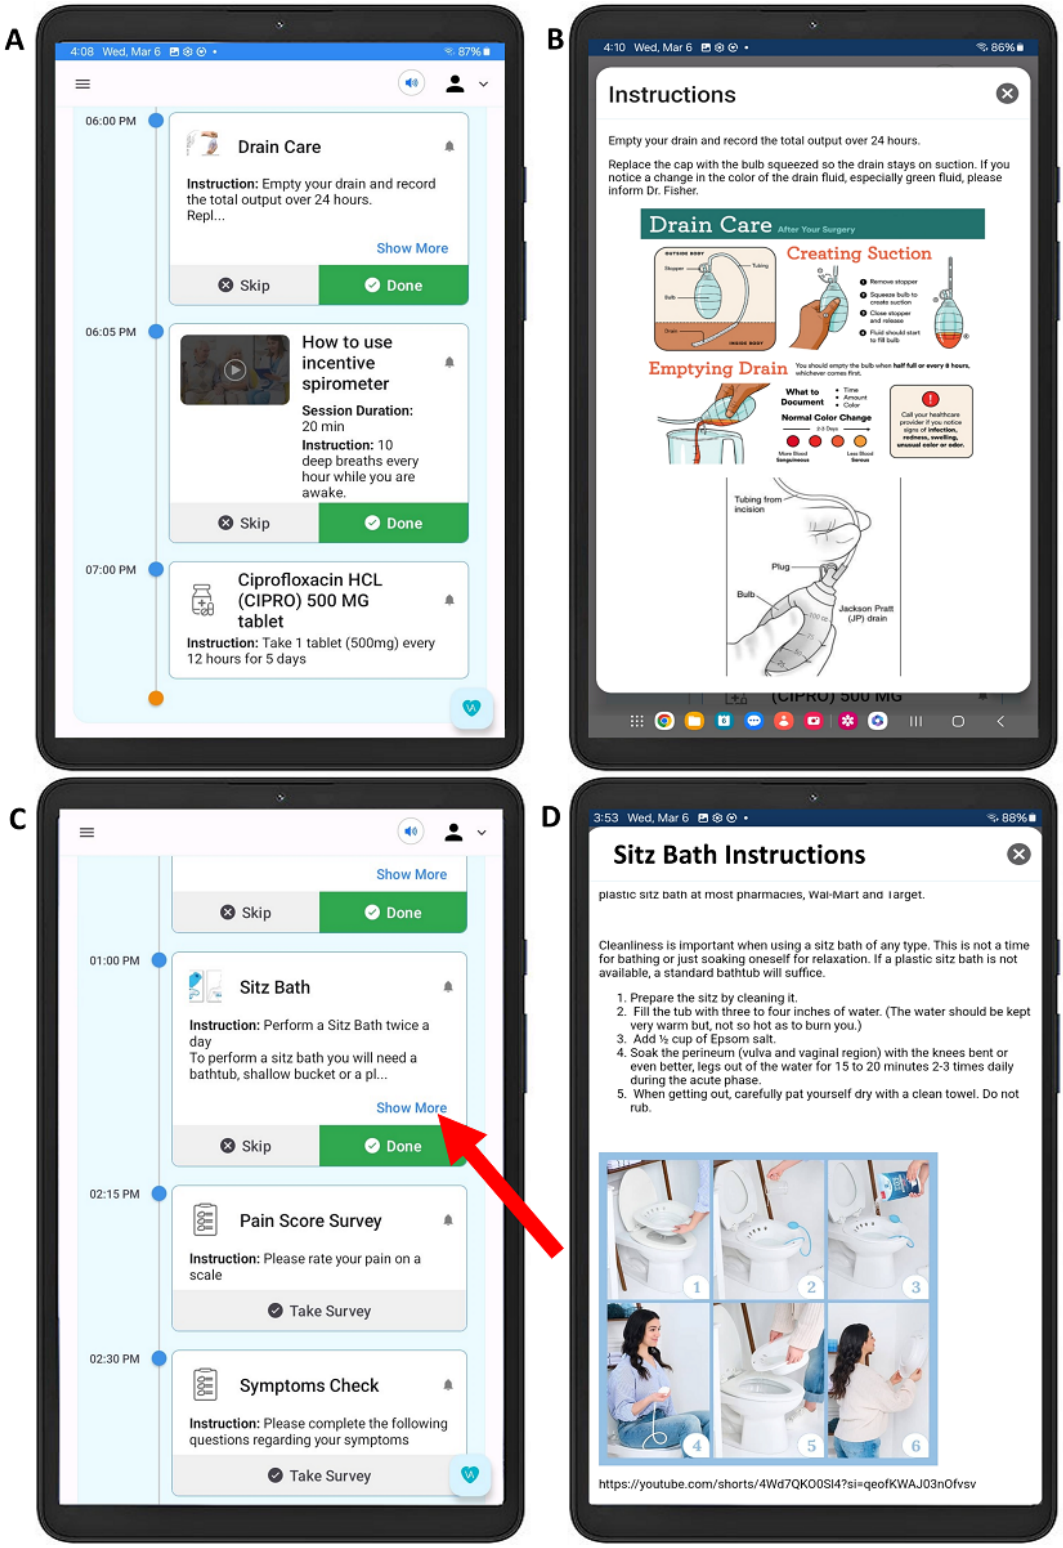
The PVA clinical content was developed by a multidisciplinary team including expert physicians in surgical oncology, medical oncology, pulmonology and critical care, and medical researchers from 1 academic institution (Baylor College of Medicine, Houston). As a result, specific discharge care content was created for 2 medical specialties: hepatobiliary surgery and gynecologic oncology. Engineers from 1 industry (Smartek21, Seattle) assigned the developed content into the different PVA features previously described.

The hepatobiliary surgery content was directed to pancreatic cancer procedures (ie, distal pancreatectomies and Whipple procedure). Content displayed in the home screen included prescribed medications, exercise guidance on respiratory therapy, symptom surveys, and specific tasks detailing wound care for surgical incisions, drain management, and video guides for self-administration of medications (Figure 4A and 4B).

The gynecologic oncology content focused on hysterectomies, radical vulvectomies, and cytoreductive surgeries. Content displayed in the home screen included prescribed medications, exercise guidance on lower extremity mobility (ie, walking, calf pumps, and leg raises), symptom surveys, and specific tasks detailing step-by-step incision care, and revision of instructions for healing of pelvic and genital areas (ie, sitz baths description, Figure 4C and 4D). In addition, information on postsurgery expectations, permissible and prohibited activities, warning signs requiring immediate medical attention, and recommended over-the-counter medications were included in the “My Library” tab.

In total, 2 symptom surveys were included in the content for both specialties, 1 monitored pain through a 10-point Likert scale, and the other monitored deep vein thrombosis (DVT) and assessed bleeding signs from mucosa or surgical incisions, using questions suggested by the clinical team.

Figure 4. Personal Virtual Assistant displaying the patients' portal "specific tasks" tab. (**A**) Home screen displaying the specific task "drain care" for patients undergoing hepatobiliary procedures. (**B**) Explanation of drain care (adapted from Go et al [17] which is published under a Creative Commons Attribution-NonCommercial International License [18]). (**C**) Home screen displaying the specific task "sitz bath" for patients undergoing gynecologic oncology procedures. (D) Upon clicking on the "show more button," an explanation in the form of text and images appears. Image taken from SitzBliss sitz bath (SitzBliss in AMAZON).



Study Design

To test the PVA's feasibility, a 4-week pilot prospective study in individuals undergoing hepatobiliary and gynecologic oncology procedures was performed between November 2022 and October 2023.

Eligible patients were aged ≥18 years old; scheduled to undergo ambulatory surgery due to suspected malignancy; willing to engage with a PVA for 4 weeks following hospital discharge. Patients were excluded if they had: major foot and ankle problems (eg, major amputation and severe neuropathy); unable to provide informed consent; documented (confirmed through

electronical medical records) major cognitive impairment, a psychiatric condition or abnormal laboratory results that, in the judgment of the clinical investigator, would interfere with the ability to participate in the study; active thrombotic condition or were using therapeutic anticoagulants; and were non-English speakers. In addition, individuals with uncorrected severe vision or hearing impairments that prevented them from effectively interacting with the PVA tablet, as determined by the investigators' judgment, were excluded.

Before their surgery, patients received a 10-minute tutorial on PVA navigation. At hospital discharge (baseline), the research team manually customized the patients' PVA content, incorporating the standard care plan detailed in their electronic medical record (EMR) by the attending surgeon. Demographic information was collected, and the patients were given the tablet with instructions to begin using it within 24hrs. After 4 weeks (end point), acceptability, and perceptions of the PVA were assessed by telemedicine, and adherence data was collected through a built-in tracking system within the PVA. Then, patients were asked to ship back the tablet. Weekly phone or video calls by the research team were performed during the study to address questions regarding the PVA functionality, content, or updates on their postoperative care according to their EMR.

Feasibility, Adherence, and Acceptability Outcomes

Feasibility was assessed by quantification of dropout rate set to ≤10% throughout the study period (4 weeks). Adherence was quantified by completion of assignments (marked as "done") in each of the 4 categories included in the care plan (ie, prescribed medications, exercises, symptom surveys, and specific tasks). For each patient, the percentage of each category was calculated by dividing the number of completed assignments by the number of days in which they were assigned during the study period.

Acceptability was assessed using a 12-item Technology Acceptance Model (TAM) questionnaire rated with a 5-point Likert Scale and ranging from strongly agree to strongly disagree, or very easy to very difficult. The TAM assessed 4 key areas: perceived ease of use, perceived usefulness, attitude toward use, and privacy concerns [19].

Furthermore, open-ended questions collected feedback on the user experience and suggestions for enhancing the PVA in Multimedia Appendix 1.

Ethical Considerations

Patients signed an informed consent at the Dan L Duncan Comprehensive Cancer Center at Baylor College of Medicine before study enrollment. The protocol was approved by Baylor College of Medicine's Institutional Review Board (protocol number: H-51654), and research procedures were conducted in accordance with the Declaration of Helsinki.

Results

Patient Characteristics

A total of 212 potential candidates were screened from the Duncan L Cancer Center at Baylor College of Medicine. Out of these, 166 were not eligible for surgery, 12 were non-English speakers, 7 did not respond to calls, and 7 declined to participate. This led to 20 eligible patients who consented and enrolled in the study, however 3 were withdrawn before study initiation due to surgery cancellation. In total, 17 patients initiated the study and received a tablet with the PVA app integrated. All patients were female (mean age 54.5, SD 12.7, years; mean BMI 33, SD 11.5, kg/m2). Out of these, 14 patients had gynecologic oncology procedures, and 3 had hepatobiliary oncology procedures. Ten out of 17 (59%) patients confirmed malignancy on biopsy (Table 1).

Table . Patient demographic information.

Characteristic			Participants (N=17)
Sex (female), n (%)			17 (100)
Age (years), mean (SD)			54.5 (12.7)
Race, n (%)			
	White		11 (6)
	Black		5 (29)
Ethnicity, n (%)			
	African American		5 (29)
	Caucasian		9 (52)
	Hispanic		2 (12)
	Asian		1 (7)
BMI, kg/m^2, mean (SD)			33 (11.5)
Pathology report, n (%)			
	Benign (n=7)		
		Gynecological	7 (100%)
	Malignant (n=10)		
		Gastrointestinal	3 (30%)
		Gynecological	7 (70%)

Feasibility and Adherence

One out of 17 patients (5.8%) dropped out from the study at postoperative day (POD) 3 due to health deterioration (reported feeling very weak and sick) and unwillingness to interact with the tablet. All other patients (16/17, 94.2%) completed the study and were included in the adherence and acceptability analyses. Among the analyzed patients, there was a mean adherence rate of 78% (SD 25%) for prescribed medications, 81 (SD 24%) for exercises, 61 (SD 30%) for symptom surveys, and 58 (SD 44%) for specific tasks. Detailed adherence data for each patient over the 4-week period is available in Multimedia Appendix 1. The responses to the open-ended questionnaire regarding technology acceptance, including perceived ease of use and perceived benefits, are available in Multimedia Appendix 2.

Acceptability

There was an 80% patient endorsement across all TAM categories (Table 2 and Table 3). The highest endorsed items were regarding the simplicity of managing daily tasks (93.8%) and medications (93.8%), in the perceived ease of use category. Perception assessment is depicted in Multimedia Appendix 1.

Table . Responses (n=16) to perceived ease of use in the Technology Acceptance Model (TAM) questionnaire of patients who completed 4 weeks.

Perceived ease of use	Responses, n					Endorsement (very easy + easy), %
	Very easy	Easy	Neutral	Difficult	Very difficult	
Navigating my patient engagement app	11	1	3	1	0	75
Managing my appointments	11	2	1	2	0	81
Managing my medications	12	3	1	0	0	94
Managing daily tasks	11	4	0	1	0	94
Managing my messages	11	3	2	0	0	88
Connecting to my video calls	8	1	6	1	0	56
Accessing my exercise guidance	10	4	4	0	0	88

Table . Responses (n=16) to perceived usefulness, attitude toward use, and privacy concerns in Technology Acceptance Model (TAM) questionnaire of patients who completed 4 weeks.

Category and item		Responses, n					Endorsement (strongly agree + agree), %
		Strongly agree	Agree	Neutral	Disagree	Strongly disagree	
Perceived usefulness							
	I do not need the support of a technical person to use this app	10	1	1	3	1	69
	The patient engagement app is a useful resource in managing my post hospital care	8	4	4	0	0	75
	Reminders via the app effectively reminded me to complete my tasks	8	5	3	0	0	81
Attitude toward use							
	When this patient engagement app becomes available, I will use it	8	4	2	0	0	75
	I would recommend this patient engagement app to other friends or family members who are discharged from the hospital	8	5	3	0	0	81
Privacy concerns							
	I do not have privacy concerns while using this patient engagement app	10	0	4	1	1	62

Reported Events During Study

Events were retrospectively collected via EMR in patients who completed the study. Three events were found; all were noted from patients undergoing gynecologic oncology procedures. One patient reported a falling incident to the research staff by phone call, but not through the PVA. This event did not require hospital readmission. Furthermore, 1 patient visited the emergency room (ER) on POD-17 due to sepsis secondary to acute cystitis or intra-abdominal abscess (per EMR note). Symptoms included pain during urination, lower back pain, and chills, which were not reported in the PVA chat. Symptom surveys recorded pain levels of 2/10 and 3/10 days before the ED visit. Treatment included computed tomography–guided needle aspiration, drain placement, and antibiotics. Another patient visited the ER on POD-28 due to lower abdominal pain and was diagnosed with an intramuscular rectus sheath hematoma (per EMR note). The patient experienced pain the previous week but did not report it in the PVA chat. Pain levels recorded in the PVA surveys were 7/10 just 2 days before the ER visit. The patient reported ineffective pain control through EMR chat (EPIC MyChart) and was advised to visit the ER by the health care team. Treatment consisted of analgesics and hospital observation for 24 hours.

Discussion

Principal Findings

This study explored the usability and acceptability of providing individualized postoperative care plans through a PVA system in patients undergoing hepatobiliary and gynecologic oncology procedures. This system is composed of 3 key elements, a tablet

with an integrated app provided to the patient (patient portal), a website for care providers to manage from any computer (care provider portal), and a secure cloud backend system that links both portals. Through the care provider's portal, the research team entered the patients' postoperative care plans assigned by their attending physician which included guidance on daily personalized assignments divided into 4 categories (ie, medications, exercise, symptom surveys, and specific tasks). Then, a tracking system assessed the adherence to such categories. In total, 16 (93.7%) patients completed the study, showing an 80% acceptability rate evaluated through a technology acceptance model questionnaire. Adherence to the care plan surpassed 70% of assignments completed in the medications and exercise categories.

Digital health applications for postoperative recovery have shown efficacy for enhancing communication between patients and care providers in different areas [20,21]. Strategies used for such enhancement include symptom monitoring surveys [21-29] educational videos for wound care [17] and exercise implementation [30], which support patients in complying with their postoperative management. Other apps may alert care providers to detect warning signs for faster communication of adverse events [21,29,31]. Our multidisciplinary team integrated these features in an interactive, practical, and simple manner through a personalized tablet (Figure 2). This strategy ensures that compliance notifications remain separate from personal devices, thereby minimizing the risk of overlooking care management assignments. In addition, this system's integrated "voice-enabled" navigation commands facilitate usability in those who have challenges on interpreting and inputting text. Emphasis was placed on presenting care plan assignments in an organized format, starting with the home screen, with the objective of creating a daily routine that patients could complete. Importantly, all features were integrated through direct consultation with clinicians, something we believe was crucial for patient engagement. Subhi et al [32] emphasized that without adequate professional input, digital health tools may deliver content that fails to meet patients' needs and deploy interventions that are ineffective. Thus, the success of digital health tools relies on the proper combination of evidence-based systems with realistic content that involves individualized care plans guided by clinical minds.

Today, few authors have explored digital health applications for postsurgical oncologic care, all reporting high feasibility. Graetz et al [31] designed a mobile app for 26 patients undergoing gynecologic oncology procedures, incorporating progressive reminders regarding discharge instructions, medication adherence and completion of symptom surveys. The study was performed in 4 weeks, resulting in 88% of participants completing the study. In a similar population, Temple-Oberle et al [33] conducted a 6-week randomized controlled trial using a mobile app, in which patients uploaded wound pictures, drain volume data, reported symptoms or wound complications, and received unidirectional messages from their physicians. The approach was compared to standard of care, having only 1/36 patients (2%) in the intervention group dropping out of the study. Similarly, the majority of participants in the present 4-week study who used the PVA were those undergoing gynecological oncologic procedures, with 13/14 (93.7%) completing the study. We attribute this rate to the personalized content that was created for each patient. For instance, gynecologic patients undergoing surgery are recommended to perform sitz baths to relieve pain, swelling, and improve wound healing in the pelvic area [34]. However, proper instructions on the right equipment, water level and temperature, duration, and frequency of baths, are often forgotten [35]. The PVA reminds and guides patients to perform this task by notifications and banners on the screen (Figure 4C). This notification system has been shown to increase usability of digital health tools in gynecologic oncology patients [31]. Noteworthy, it is difficult to ascertain if the notification system influenced patient compliance and study completion the most. In addition, the known low-risk of postoperative complications in the group of gynecologic oncology patients could have been another factor contributing to a less pronounced dropout rate [31,33].

Another important aspect for assessing feasibility of digital health tools is the quantification of adherence to such systems. For instance, Mata et al [36] considered adherence as completion of 5 specific daily tasks (ie, early mobilization, gum chewing, consumption of oral liquids, breathing exercises, and consumption of protein drink) by following instructions from a tablet in 40 hospitalized patients who underwent colorectal surgery. Among these, 60% had a cancer diagnosis. Interestingly, a 94% adherence rate was seen on POD-1 but declined to 43% at POD-3. Similarly, Low et al [37] measured in-hospital adherence among patients undergoing abdominal cancer surgery, based on symptom survey responses via a mobile app and quantification of daily usage of a smart band (Fitbit). Adherence rates reported were 22% and 35%, respectively. However, when measuring adherence in the posthospital discharge phase, both rates increased (41 and 65%, respectively). This highlights how the timing and setting of digital health tools usage can impact adherence, particularly in those employed once patients have cleared hospitalization. In this study, posthospital discharge adherence was evaluated upon completing the assignments within the 4 care plan categories. This resulted in a high adherence rate for medications and exercises (78% and 81%, respectively). However, the patients' freedom to mark each assignment as "done" could have biased our results, as it is difficult to verify whether these were truly completed. On the other hand, there was a 61% and 58% adherence rate for symptom surveys and specific tasks, respectively. Perhaps this was reflected on the 46% rate of patients who recommended including fewer surveys and questions in the PVA in Multimedia Appendix 1. Nonetheless, an interventional study evaluating clinical outcomes (ie, faster recovery, adverse events, and hospital readmission) is warranted to confirm associations with adherence.

To evaluate acceptability, the present study used a TAM questionnaire tailored for the PVA system, showing an 88.75% ease of use, 86.62% perceived usefulness, 85% attitude toward use, and 81% privacy concerns rates. No notable differences in technology acceptability were observed between younger (<60 years old) and older (>60 years old) patients, with overall scores appearing similar across age groups. While a small number in both groups indicated needing technical support or gave neutral

responses regarding app usage, these differences were minimal and not statistically analyzed. Other cancer digital health apps using acceptability queries have shown similar high rates. Karlsson et al [38] utilized the System Usability Scale revealing a 77% ease of use score for an app that encourages mobility in patients recovering from abdominal cancer surgery (Pedatim, Phystec), surpassing the threshold (68 points) for high acceptability of this query [39]. Hwang et al [40] used the Patient Satisfaction Survey to evaluate an app that enables remote monitoring of wounds and communication with care providers in patients undergoing breast cancer surgery (Medeo), revealing a 90% ease of use, 90% attitude toward use, 95% perceived usefulness, and 100% of privacy concern rates. These results reflect the potential use of digital health tools in cancer patients recovering from surgical procedures and encourage researchers for future and continuous development of such systems.

Although the present study focused on exploring the PVA's feasibility and acceptability, we sought to retrospectively collect incidents that happened during the study period to understand the challenges that can be addressed for future system improvement of the PVA. For example, one patient was readmitted to the hospital on POD-28 due to rectus sheath hematoma. Interestingly, this patient reported a poor adherence rate in all categories (39% for medications, 61% for exercises, 54% for symptom surveys, and 0% to specific tasks). Despite patients being instructed to directly communicate postoperative incidents or complications to their care providers, our system's alternative monitoring options (ie, bidirectional chat and Likert pain scales) failed to collect such incidents. In fact, neither the patient's care providers nor the PVA system had evidence of the three reported incidents. We attribute this to the lack of warning sign surveys evaluating fever, wound complications, urinary tract infections, hematomas, or ileus (in gynecologic procedures) [41]. We also believe that proper patient education on warning signs should be included in the home screen. In addition, the system could be equipped with advanced monitoring features such as vital signs (ie, temperature, heart rate, and respiratory rate) and symptom reporting surveys integrated with automated alarms to alert users when certain thresholds are exceeded. These technological enhancements could facilitate prompt detection of postoperative complications to avoid hospital readmissions.

The study findings highlight opportunities to enhance the clinical application of this interactive digital technology, particularly in improving adherence to symptom reporting and supporting the successful completion of specific tasks, that may benefit from more detailed, step-by-step education incorporating comprehensive images or videos. Acceptability and usability are essential first steps in deploying interactive digital solutions to support posthospital discharge care plans. While these solutions hold promise for preventing surgical complications and reducing hospital readmissions, such outcomes remain the ultimate goals of these technologies and require further validation. Research suggests that remote patient monitoring during postsurgical recovery phases can significantly lower hospital readmissions and minimize unnecessary clinic visits compared to standard of care [40]. We speculate that the PVA could meaningfully improve clinical outcomes by enhancing patient adherence to postdischarge care plans, including medication adherence, exercise routines, symptom reporting, and task completion. However, this speculation requires validation through future interventional studies. Further research should also explore how the PVA can optimize communication between patients and care providers, fostering a more seamless and effective recovery process.

Limitations

There are several limitations to our study. Major limitations of this study are its exploratory design, small sample size, and the absence of a control group. These factors restrict our ability to evaluate the PVA's effectiveness compared to standard postdischarge care, limiting our understanding of its overall impact. The low dropout rate and high adherence observed could be attributed to the weekly monetary compensation offered to patients, which may have influenced their participation levels. The questions included in the TAM for evaluating participant's adherence and perceptions might have introduced an acquiescence bias, with patients predisposed to agree with the assessment statements. In addition, we did not examine variations in technology acceptance across different age groups, ethnicities, or cancer types. Such an analysis could provide valuable insights and broaden the applicability of our findings. In the next phase of the study, we plan to incorporate demographic analysis to better understand PVA acceptability and tailor its use to diverse patient populations. Another significant limitation was the lack of integration between the PVA system and electronic medical records, requiring research teams to manually enter each participant's discharge plan. This manual process was not only time-consuming but also involved transcribing detailed instructions in each category of the care plan. Even though the system adherence tool identifies which specific assignments within each category of the care plan (ie, medications, exercise, tasks, and surveys) have been completed by the patient, the clinical study coordinator or health care provider must continuously revise this data on a daily basis. In addition, the health care provider portal, although intended for provider use, was managed by the research team. Thus, the absence of direct contact between patients and health care providers could have affected their experience or willingness to engage fully with the PVAs messaging tool. Regarding the surveys used in the PVA (ie, pain scales and DVT symptoms), patients' answers require continuous revision on a daily basis by the user. However, the research team only reviewed these surveys at the end of the study, highlighting a critical limitation. The absence of real-time symptom collection likely affected the ability to assess the PVA's effectiveness in early prevention and detection of common postsurgical complications.

To address this limitation, future iterations will focus on redesigning surveys to facilitate real-time symptom reporting and efficient review by the clinical care team. This redesign aims to enhance usability while avoiding time-consuming processes, ultimately improving the PVA's role in patient care and early intervention. Furthermore, the app requires internet connection to function and receive real-time updates to the care plan. At the time of this study, it was not available on Google Play Store or Apple platforms, which meant that updates had

to be manually downloaded through a link provided by our industry partner (Smartek21) from the web. Finally, while the PVA allows for picture uploads through a secure chat with researchers, this feature was not instructed as part of the study protocol. We believe this feature should be used in future studies, as it is crucial for the prompt identification of clinical warning signs [21,22,24,25,27-29,42].

Conclusion

This exploratory study demonstrated the usability and acceptability of an interactive digital solution designed to provide an organized, step-by-step guide for postsurgical care, and simplify adherence to care plans in patients undergoing gynecological oncology and hepatobiliary oncology procedures. The findings suggest perceived acceptability, ease of use, and intention to use the platform, although privacy concerns remain a limitation for broader scalability. The results showed fair-to-good adherence to certain postdischarge tasks, such as recommended exercises and prescribed medications, while adherence to symptom surveys and specific tasks was notably lower. Integrating additional features, such as notification reminders and voice-enabled systems, appeared promising for improving compliance. Furthermore, information retrospectively gathered from postsurgical complications provided valuable insights for enhancing the PVA system in future iterations. These findings underscore the potential for interactive digital health solutions to improve communication between patients and care providers while coaching patients to adhere to prescribed postdischarge tasks, which may ultimately enhance recovery outcomes. However, these observations are preliminary and need to be confirmed in studies with larger sample sizes. In addition, future research should focus on validating the effectiveness of this solution in improving posthospital discharge outcomes.

Acknowledgments

The authors would like to thank Drs William E Fisher, Ernest Ramsay Camp, Ang Li, Amir Sharafkhaneh, and Feibi Zheng from Baylor College of Medicine for their expert advice in evaluating and building content for the Personal Virtual Assistant (PVA). The authors would also like to thank Martyn Molnar, Paul Costello, and Dr Sammer Sood from SmartTek21 and IntelliTek Health for their in-kind and technical support for PVA used in this study. We also extend our gratitude to Maria Noun and Naima Rodriguez for their support with the institutional review board and operations, and to the Digital Health Access Center team as well as the clinical team at the Baylor College of Medicine (BCM) Dan L Duncan Comprehensive Cancer Center and the BCM St. Luke’s Medical Center for their assistance with patient referral and recruitment. This research was supported by the National Science Foundation's Industry-University Cooperative Research Centers program under award numbers NSF 2052514 and C2SHIP (Center to Stream HealthCare in Place) Y01-BCM-P026. Additional support was provided by the National Institutes of Health, National Cancer Institute under award number 5P30CA125123-17S1, and in-kind support from Smartek21 and IntelliTek Health. The content is solely the responsibility of the authors and does not necessarily represent the official views of the sponsors.

Authors' Contributions

MBO contributed to writing – original draft, writing – review and editing, patient recruitment, data collection, visualization, PVA connect development, and formal analysis. AZR handled writing – original draft, and writing – review and editing. MGF managed review and editing, and data analysis. ABC handled patient referral, patient care, PVA content development, and review and editing. AFC conducted patient recruitment, data collection, PVA content development, and review and editing. ROB managed patient recruitment, data collection, PVA content development, and review and editing. MP conducted patient recruitment, data collection, and review and editing. TP contributed to patient recruitment, data collection, data analysis, and review and editing. AK managed patient recruitment, data collection, data analysis, and review and editing. BN contributed to conceptualization, writing – review and editing, and supervision.

Conflicts of Interest

BN serves as a consultant for BioSensics LLC on projects unrelated to the scope of this study. The other authors report no conflicts of interest relevant to this study.

Abstract

Background: Cancer survivors and their caregivers, particularly those from disadvantaged backgrounds with limited health literacy or racial and ethnic minorities facing language barriers, are at a disproportionately higher risk of experiencing symptom burdens from cancer and its treatments. Large language models (LLMs) offer a promising avenue for generating concise, linguistically appropriate, and accessible educational materials tailored to these populations. However, there is limited research evaluating how effectively LLMs perform in creating targeted content for individuals with diverse literacy and language needs.

Objective: This study aimed to evaluate the overall performance of LLMs in generating tailored educational content for cancer survivors and their caregivers with limited health literacy or language barriers, compare the performances of 3 Generative Pretrained Transformer (GPT) models (ie, GPT-3.5 Turbo, GPT-4, and GPT-4 Turbo; OpenAI), and examine how different prompting approaches influence the quality of the generated content.

Methods: We selected 30 topics from national guidelines on cancer care and education. GPT-3.5 Turbo, GPT-4, and GPT-4 Turbo were used to generate tailored content of up to 250 words at a 6th-grade reading level, with translations into Spanish and Chinese for each topic. Two distinct prompting approaches (textual and bulleted) were applied and evaluated. Nine oncology experts evaluated 360 generated responses based on predetermined criteria: word limit, reading level, and quality assessment (ie, clarity, accuracy, relevance, completeness, and comprehensibility). ANOVA (analysis of variance) or chi-square analyses were used to compare differences among the various GPT models and prompts.

Results: Overall, LLMs showed excellent performance in tailoring educational content, with 74.2% (267/360) adhering to the specified word limit and achieving an average quality assessment score of 8.933 out of 10. However, LLMs showed moderate performance in reading level, with 41.1% (148/360) of content failing to meet the sixth-grade reading level. LLMs demonstrated strong translation capabilities, achieving an accuracy of 96.7% (87/90) for Spanish and 81.1% (73/90) for Chinese translations. Common errors included imprecise scopes, inaccuracies in definitions, and content that lacked actionable recommendations. The more advanced GPT-4 family models showed better overall performance compared to GPT-3.5 Turbo. Prompting GPTs to produce bulleted-format content was likely to result in better educational content compared with textual-format content.

Conclusions: All 3 LLMs demonstrated high potential for delivering multilingual, concise, and low health literacy educational content for cancer survivors and caregivers who face limited literacy or language barriers. GPT-4 family models were notably more robust. While further refinement is required to ensure simpler reading levels and fully comprehensive information, these findings highlight LLMs as an emerging tool for bridging gaps in cancer education and advancing health equity. Future research should integrate expert feedback, additional prompt engineering strategies, and specialized training data to optimize content accuracy and accessibility.

large language models; GPT-4; cancer survivors; caregivers; education; health equity

Introduction

More than 18.1 million individuals with a history of cancer were alive in the United States in 2022, and that number is projected to reach 26 million by 2040 [1]. Cancer survivors receive a wide range of treatments, often experiencing severe symptoms or side effects, including fatigue, depression, anxiety, sleep disturbance, pain, cognitive impairment, nausea, vomiting, and neuropathy [2-7]. These symptoms negatively impact survivors' functional status, quality of life, and overall survival rates [8-11]. Cancer caregivers, typically family members or significant others offering primary emotional and physical support for cancer survivors, experience an array of similar distressing symptoms [12-14]. These symptoms are linked to high caregiving burden, emotional distress, and communication barriers with cancer survivors and providers [15]. In addition, disparities in health care access further exacerbate the challenges faced by cancer survivors and their caregivers, especially those from disadvantaged communities that have limited health literacy or language barriers [16]. Those with limited health literacy and racial and ethnic minorities facing language barriers are at greater risk for poorer access to care [17-19]. Consequently, they tend to experience a heavier symptom burden and poorer health outcomes during and after cancer treatments [20].

With over 3-quarters of the disadvantaged population owning smartphones or computers [21], technology-based intervention programs can bridge the accessibility gap and promote health equity [22,23]. The advent and growth of artificial intelligence have enabled researchers to design tailored and personalized interventions and educational content to meet individual unmet needs [24]. Large language models (LLMs) are advanced artificial intelligence systems that can understand and generate human-like text by training on vast amounts of data [25]. LLMs perform various language tasks, such as answering questions and translating languages. How questions are asked can significantly affect the performance of LLMs. This process, known as prompt engineering, is crucial for obtaining accurate and relevant responses from LLMs [26,27]. While LLMs have demonstrated remarkable potential in cancer research [28-31], their efficacy in real-world scenarios, such as cancer care and education, which often require advanced levels of comprehension, have yet to be thoroughly assessed.

Recent advancements in LLMs, such as GPT-4 and GPT-4 Turbo (OpenAI) [32,33], have demonstrated their exceptional proficiency in completing various tasks, including coding, design, and content summarization. Previous research [34,35] indicates that LLMs can capture large volumes of text effectively, even without specialized domain knowledge. This ability highlights its sophistication in processing and understanding information across a broad spectrum of topics, and its potential to significantly aid in analyzing unstructured data in clinical environments (eg, clinical notes) [34,35]. However, there are several notable gaps in the current knowledge. First, while LLMs have demonstrated high levels of accuracy in understanding extensive texts [34,36,37], even minor inaccuracies can have detrimental effects on patient outcomes [38], particularly regarding actionable advice. Therefore, the content they generate still necessitates additional expert verification to ensure it is error-free and ready to be presented to patients and their caregivers. Second, although previous research [36,37] has demonstrated promising results in content summarization, these LLMs are often not applied in clinical environments, or they specifically address cancer care and education among disadvantaged groups that has limited health literacy or language barriers [39]. Finally, most educational resources for cancer care are available exclusively in English, which can create comprehension challenges for non-English speakers (eg, Hispanic individuals and immigrants). Also, cancer survivors and their caregivers, already overwhelmed by treatment, often lack the time to read lengthy content. Therefore, it is essential to provide educational content in multiple languages and in concise content to ensure effective communication and education [40].

To address these gaps, our team aimed to evaluate how LLMs perform in tailoring educational content to enhance accessibility and comprehension for cancer survivors and their caregivers. In this study, our primary task was to evaluate and compare the capabilities of multiple GPT-based LLMs in generating concise, low-literacy-level, and multilingual educational content tailored for cancer survivors and their caregivers with limited health literacy or language barriers. Specifically, we aimed to evaluate the overall performance of LLMs in generating tailored educational content that adheres to a strict word limit, a sixth-grade reading level, and high-quality criteria (clarity, accuracy, relevance, completeness, and comprehensibility), compare the performances of 3 GPT models (GPT-3.5 Turbo, GPT-4, and GPT-4 Turbo), and explore how different prompt structures (textual vs bulleted format) influence the quality of the generated content. This approach helps them manage their symptoms more effectively, thereby reducing health disparities and promoting health equity.

Methods

Design

This study involved a multistep methodology that included: (1) specifying the exact task requirements for the LLMs, to produce educational content on 30 selected cancer care topics written at a sixth-grade reading level, limited to 250 words, and translated into Spanish and Chinese; (2) generating tailored educational content using 3 GPT models (GPT-3.5 Turbo, GPT-4, and GPT-4 Turbo) with 2 prompt styles (textual and bulleted); (3) expert evaluation of the generated content's adherence to word count, reading level, and 5 quality criteria; and (4) statistical analyses (ANOVA [analysis of variance] and chi-square test) to compare performance across models and prompt formats.

Prompt Engineering

To promote the accessibility and comprehension of educational content for cancer survivors and their caregivers with limited health literacy and language barriers, we structured prompts to have LLMs produce content at a low reading level, maintain a word limit of 250, and provide Spanish and Chinese translations for each topic, as described below [41].

The Flesch-Kincaid Grade Level (FKG) system [42] was used to assess the readability of content produced by the LLMs. The FKG level is a readability test designed to indicate how difficult a text is to understand. It calculates the grade level required for someone to comprehend the text. The FKG is based on word length and sentence length, providing a numerical score that corresponds to US grade levels [42]. The National Institutes of Health (NIH) and the American Medical Association (AMA) suggest that patient education materials should be written at a reading level no higher than the sixth grade [43]. This recommendation is in place to guarantee that the information is reachable by a broad spectrum of individuals, encompassing those with limited health literacy. Therefore, our research targets an FKG level of 6 to align with this guidance.

We set a 250-word limit for our educational content, recognizing that cancer survivors and their caregivers are frequently preoccupied with treatment schedules and daily responsibilities, leaving them with limited time for reading [44]. This word limit is designed to ensure that participants can complete the reading within 5 minutes, making the task both manageable and feasible within their schedules.

Furthermore, it is shown that prompts exert a considerable impact on the responses generated by LLMs [45]. Therefore, we compared different prompts, including both textual and bulleted formats, to determine which approach yields better results.

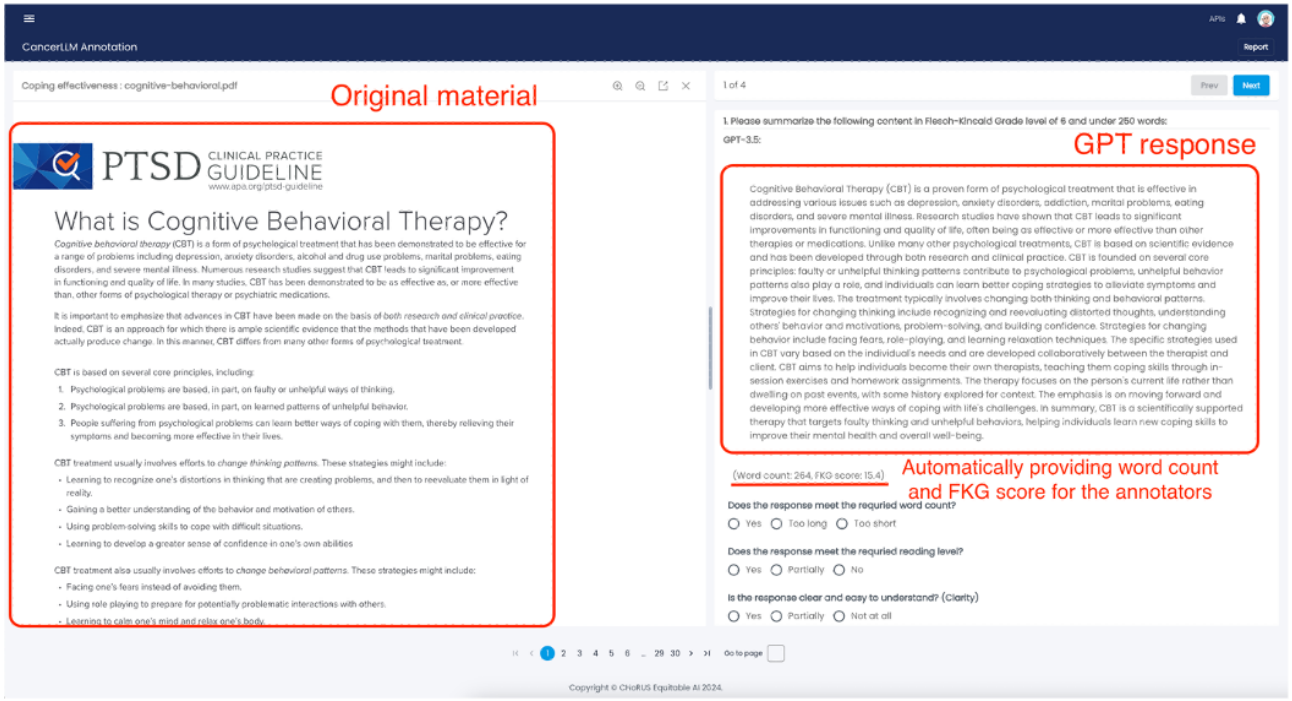
The prompts we used are as follows:

1. Textual format: “Please summarize the following content in Flesch-Kincaid Grade level of 6 and under 250 words: [original text]”
2. Bulleted format: “Please summarize the following content into bullet points in Flesch-Kincaid Grade level of 6 and under 250 words: [original text]”
3. Spanish translation: “Please translate the following content into Spanish: [tailored text]”
4. Chinese translation: “Please translate the following content into Chinese: [tailored text]”

Expert Evaluation

We assembled a panel of 9 oncology experts, comprising 4 oncology professors, 4 doctoral students, and 1 medical resident. Among them, all are fluent in English, with 4 experts proficient in Chinese and 1 proficient in Spanish. Each response generated by the LLMs was evaluated by at least 2 experts to ensure a comprehensive assessment, except for the Spanish translation task, which was evaluated by a single expert. The panel conducted several Zoom meetings: the initial meeting provided training on content evaluation, and 3 additional meetings were held to discuss the results and feedback. Each expert was assigned 10 topics to evaluate and was required to provide feedback on the errors committed by the LLMs. These experts critically reviewed and annotated the LLM-generated content using a web-based Cohort Adjudication and Data Annotation (CADA) application [34] (Figure 1) developed by our team.

Figure 1. A screenshot of Cohort Adjudication and Data Annotation application.



Data Sources

Our primary sources for content generation were cancer survivors and caregiver education materials from the National Cancer Institute and the National Comprehensive Cancer Network guidelines [46,47]. We selected 30 distinct topics covering a range of content such as fatigue, depression, anxiety, pain, cognitive impairment, nutrition, physical activity, healthy lifestyle, family communication, coping skills, and more. The selection of topics was informed by insights from our previous qualitative interviews with cancer survivors and their caregivers [48] and an extensive review of the literature [49-51]. We identified the key areas of interest and specific needs of cancer

survivors and their caregivers with limited health literacy or language barriers, resulting in these 30 topics.

Appraisal Criteria

Based on a previous study of evaluating responses from LLMs [34], we formulated a set of multidimensional criteria to thoroughly assess the performance of LLMs, which include adherence to a word limit of 250 words, achieving a reading level as per the FKG of below 6, and quality assessment: (1) clarity (ie, ease of understanding in the response); (2) accuracy (ie, the response does not contain errors, like medical or language errors, that could negatively impact patients and their caregivers); (3) relevance (ie, the response is fully grounded in the materials we provided); (4) completeness (ie, the response encompasses all critical points from the materials); (5) comprehensibility (ie, the response is understandable that readers can apply it to their daily routine).

In terms of word limit, "yes" refers to a word limit within 250 words, and "no" refers to a word limit of more than 250 words. The reading level was evaluated using "yes" for an FKG level ≤6; "partial" for an FKG level of 6 to ≤8; and "no" for an FKG level >8). The FKG level was calculated by the Python package Textstat (version 0.7.3, Azu). For the quality assessment criteria, we implemented a scoring system in which evaluations were quantified based on their alignment with the expected outcomes. A score of 2 was assigned for "yes" evaluations, indicating full compliance; a score of 1 was given for "partial" evaluations, reflecting partial compliance; and a score of 0 was allocated for "no" evaluations, indicating noncompliance. The quality assessment included 5 criteria (1-5), each contributing a maximum of 2 points, for a total possible score of 10. The overall quality assessment ranged from 0 to 10, with 0 representing the absence or lowest quality and 10 indicating the highest quality. For translation tasks, "yes" indicates a completely accurate translation, "partially" refers to a generally correct and understandable translation with minor errors, and "no" refers to a completely inaccurate translation containing incorrect or misleading information. Accuracy scores are calculated as the proportion of evaluations labeled as "yes."

Data Analysis

Descriptive analyses were conducted to determine the frequencies, percentages (for word limit, reading levels, and translations), mean and SDs (for quality scores) of major variables. Quality scores were determined by calculating the mean scores for each criterion and then obtaining the overall scores through their summation. To compare the differences in each model or prompt, we used ANOVA or chi-square tests, as applicable. Values of $P<.05$ were considered to indicate a significant level. All analyses were conducted using Python statistical packages.

Ethical Considerations

The study protocol (STUDY00004750) was approved with exemptions by the institutional review board at Emory University. Oral consent was obtained from 9 oncology experts, as no protected health information was collected. All participants were informed of the voluntary nature of their participation and their right to withdraw at any time without consequence. No protected health information or personally identifiable information was collected, and all research data were anonymized to maintain confidentiality. Study materials were securely stored and accessible only to authorized research team members. Participants did not receive any monetary or nonmonetary compensation for their involvement. The study was conducted in accordance with the US Common Rule (45 CFR 46) [52].

Results

Overall Performance of Large Language Models

In this study, 360 annotation values were collected from 9 experts. Overall, LLMs have shown excellent performance in tailoring content based on our criteria. For word limit, 267/360 responses (74.2%) were within the word limit (less than 250 words) set for the task. The result indicates the excellent ability of LLMs to produce responses that adhere to specified word limit requirements. Regarding reading levels, LLMs demonstrated moderate performance, with 105/360 responses (29.2%) fully meeting the specified FKG level (FKG level ≤6), 107/360 (29.7%) being partially satisfactory (FKG level of 6 - 8), and 148/360 (41.1%) not aligning with the provided FKG level (FKG level >8).

LLMs demonstrated consistently high average scores across all quality criteria (total score: 8.933 out of 10). The highest average score achieved was 1.91 on relevance, highlighting the LLMs' ability to generate content that was highly pertinent to the given prompts. The lowest average score observed was 1.58 out of 2 in the category of completeness, indicating a moderate adherence to providing responses that capture all key points. In the translation tasks, the LLMs demonstrated high performance, with 87/90 accuracy translations (88%) for Spanish and 73/90 (81%) for Chinese translation.

Three Generative Pretrained Transformer Models Comparisons: GPT-3.5 Turbo, GPT-4, and GPT-4 Turbo

GPT-4 demonstrated a superior capability in adhering to the specified word limit, with 101/120 responses (84.2%) falling within 250 words (Table 1). In contrast, GPT-3.5 Turbo and GPT-4 Turbo exhibited a relatively lower proficiency, with 86/120 (71.7%) and 80/120 (66.7%) responses meeting the word limit, respectively. As shown in Table 2, when comparing the models based on word limit, the chi-square test demonstrated a significant difference among the three models ($P=.006$).

[a] PR(>F): probability that the F-statistic is greater than the observed value under the null hypothesis.

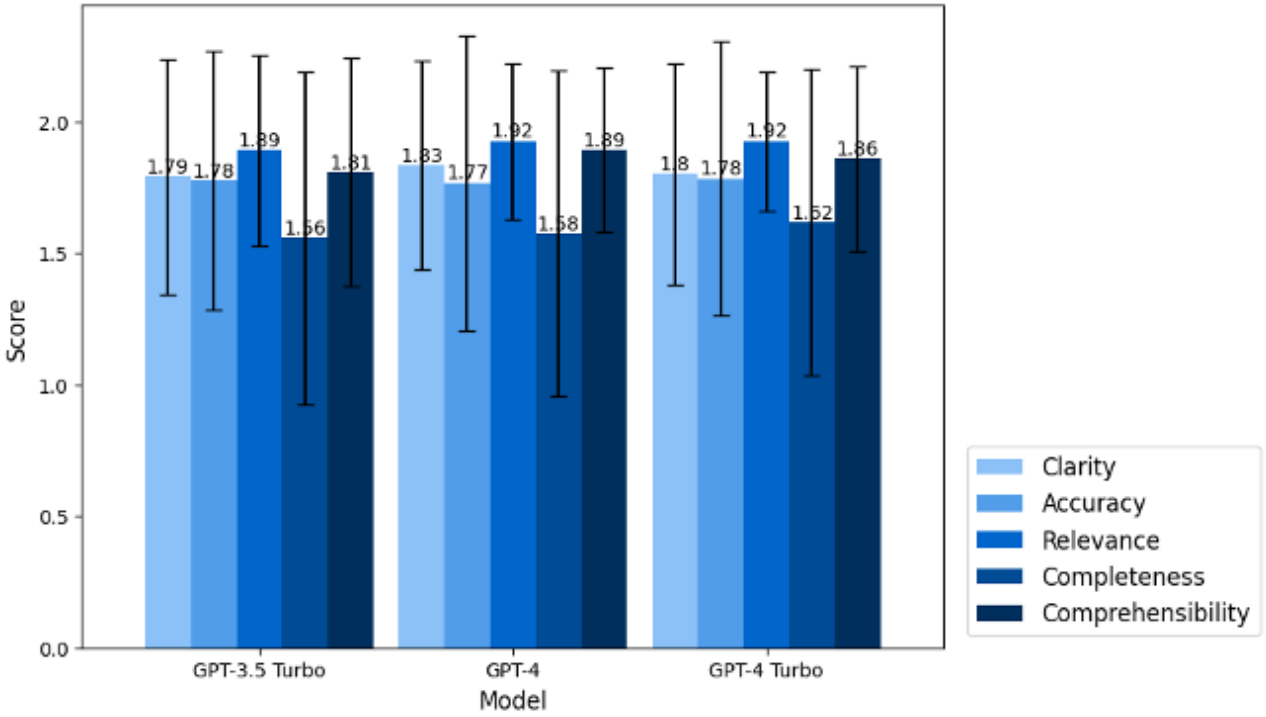
[b] —: not applicable.

Regarding the assessment of reading level, GPT-4 Turbo met the required FKG level of 6 in 51/120 (42.5%) cases, nearly doubling the performance of the other 2 models: 26/120 (21.7%) for GPT-4 and 28/120 (23.3%) for GPT-3.5 Turbo. The result indicated significant discrepancies among the models in adherence to the specified reading level (P<.001), with GPT-4 Turbo performing better compared with the other 2 models.

In terms of quality assessment, each of the LLMs attained a high score exceeding 8.8 out of 10, with GPT-4 and GPT-4 Turbo achieving 8.992 and 8.983, respectively, and GPT-3.5 Turbo trailing slightly at 8.825. Upon evaluation of each criterion, the performance of all models was found to be similar (Figure 2). The application of ANOVA tests to each criterion revealed no significant differences among the 3 models (P=.57).

In the translation tasks, GPT-4 Turbo exhibited perfect accuracy with a 30/30 (100%) success cases in Spanish translation, whereas GPT-4 and GPT-3.5 Turbo exhibited slightly lower, yet commendable success rates of 29/30 (97%) and 28/30 (93%), respectively. For the Chinese translation task, GPT-4 outperformed the other models with an accuracy of 26/30 (87%). In contrast, GPT-3.5 Turbo and GPT-4 Turbo achieved 23/30 (77%) and 24/30 (80%), respectively. The 3 models did not show a significant difference in the translation task (P=.48).

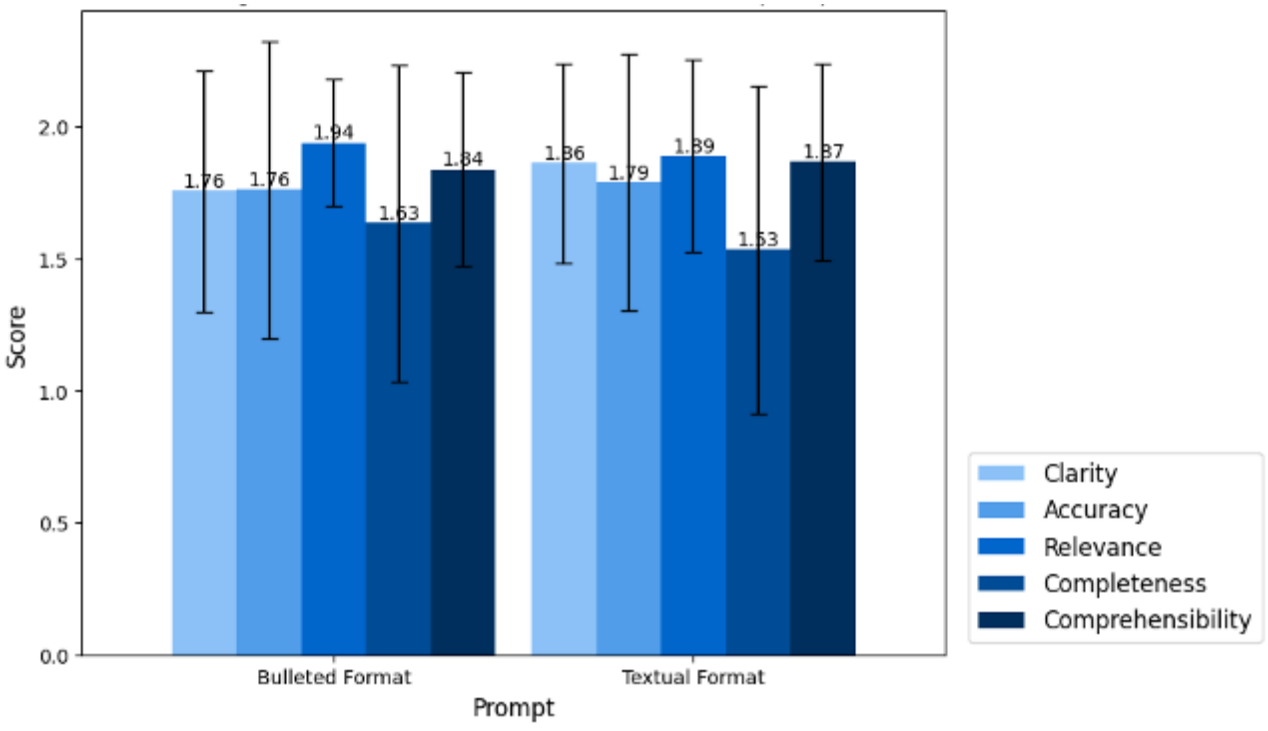
Figure 2. Assessment scores on each criterion between different models. GPT: Generative Pretrained Transformer.



Two Different Prompt Comparisons: Textual and Bulleted Formats

We compared 2 prompting methods in terms of word limits, reading level, and quality assessment. The major difference noted in the comparison of the 2 prompts was that responses generated from prompt 2 (bulleted format) were superior in adhering to the target word limit. Specifically, 153/180 responses (85%) from prompt 2 successfully achieved the word limit, in contrast to 114/180 responses (63.3%) from prompt 1 (textual format) that fully satisfied the word limit. Using prompt 1 resulted in only 56/180 responses (31.1%) meeting our desired reading level, with a slight decrease to 49/180 (27.2%) for prompt 2. For the 5 quality criteria, both prompts achieved high scores (Figure 3). Upon performing an ANOVA test to assess the differences in performance between the 2 prompts (Table 2), it was found that the variations between them were not significant (P=.939). However, the 2 prompt formats demonstrated a significant difference in the clarity criterion (P=.03).

Figure 3. Assessment scores on each criterion between different prompts.



Error Analysis

The errors that LLMs committed were categorized into inaccurate scope, inaccurate definition, inaccurate expression, meaningless points, and inaccurate word. Some examples are shown in Table 3.

Table . Error cases and analysis.

Model	Topic	Output	Error type	Reason
GPT-3.5 Turbo	Nutrition	"It advises limiting animal-based food, processed food, and alcohol consumption."	Inaccurate scope	The chapter only mentions to limit red meat, not all animal-based foods (says it can make up half or less of diet).
GPT-3.5 Turbo	Sexual Health Issues in Men with Cancer	"It is still important to maintain intimacy with a partner."	Inaccurate expression	The tailored content sounds a little judgmental whereas the original document says, "probably still important" and is less assuming.
GPT-3.5 Turbo	Relaxation	"多喝液体"	Inaccurate word	Based on the English sentence: " Drinking plenty of liquids", "liquids" can be better translated into "水."
GPT-4	Mindfulness	"These practices involve focusing the mind on present sensations, such as breathing, a sound, or an image."	Inaccurate definition	It seems to define meditation and mindfulness in one overarching definition, which only defines meditation. The model merged definitions of MBSR[a] and MBCT[b] together and did not include difference between types.
GPT-4	Family Communication	"El apoyo de la comunidad podréda ser beneficioso durante este difícil período."	Inaccurate word	Based on the English sentence: "Support from the community might be beneficial during this difficult period. ", "difícil período" should be "período difícil"
GPT-4 Turbo	Making a Difference	"Learning: Educating yourself about cancer can empower you to assist others. Resources are available online, by phone, and in print."	Meaningless point	The customized content falls short in terms of actionability. The purpose of tailoring content is to educate patients and caregivers, rather than expecting them to educate themselves.

[a]MBSR: Mindfulness-based stress reduction.

[b]MBCT: Mindfulness-based cognitive therapy.

A common error observed with LLMs is their tendency to integrate their own knowledge and interpretation rather than adhering strictly to the provided materials, such as an inaccurate scope. For instance, when the text specified "to limit red meat." in the Nutrition topic, GPT-3.5 Turbo inaccurately generalized this advice to "limiting animal-based food." This interpretation is not entirely correct, as animal-based food encompasses more than just red meat, including white meat such as chicken, which the original material did not intend to restrict.

Other observed errors involve inaccurate expressions. For instance, in the Sexual health issues in men with cancer topic, the original content suggested, "It is probably still important to maintain intimacy with a partner." However, GPT-3.5 Turbo revised this to "it is still important to maintain intimacy with a partner." This alteration results in a tone that may seem judgmental, deviating from the original's more tentative stance.

An example of inaccurate definition was identified within the Mindfulness topic, where GPT-4 defined meditation and mindfulness in one overarching definition for meditation. It also merged definitions of mindfulness-based stress reduction and mindfulness-based cognitive therapy without highlighting differences between the mindfulness interventions.

LLMs may also include information that, while accurate, might not be actionable for patients. For instance, in the Making a difference topic, GPT-4 Turbo correctly sourced from the material that "Learning: Educating yourself about cancer can empower you to assist others. Resources are available online, by phone, and in print." However, this information becomes less useful in the absence of specific links or directions that could guide patients on where to start their education.

Finally, with respect to translation quality, the primary error observed related to inaccurate word choice. In particular, when

an English term offers multiple potential translations, LLMs often encounter difficulty in selecting the most contextually appropriate option. For example, in the Relaxation topic, GPT-3.5 Turbo translated “多喝液体" as “drink more liquids.” Although “液体" does literally translate to “liquids,” the more natural and contextually appropriate term would be “水.”

Discussion

Principal Findings

To our knowledge, this is the first study to evaluate the capability of LLMs in tailoring educational content for cancer survivors and their caregivers with limited health literacy or language barriers. In our study, all 3 LLMs have demonstrated overall excellent performance in most criteria. The more advanced GPT-4 family models showed better overall performance compared with GPT-3.5 Turbo. GPT-4’s high adherence to word limits and GPT-4 Turbo’s better compliance to reading level compliance proved their ability to meet our requirements when tailoring content. Prompting GPTs to produce bulleted-format content is likely to result in better educational content compared with textual-format content. All models exhibit strong capability in generating highly relevant content. However, they fall short in terms of completeness. Overall, it is proven that LLMs are highly effective in tailoring, condensing, and translating educational content for cancer survivors and their caregivers with limited health literacy or language barriers. These findings inform future versions of LLMs to focus more on the reading level and completeness of their output and the development of tailored intervention materials for cancer survivors and their caregivers. These promising results also indicate that LLMs can be a valuable tool in making educational content more accessible and comprehensible to diverse patient populations.

The capabilities of LLMs in text analysis have been well studied. For example, our previous study [34] examined the potential of LLMs to categorize clinical concepts from patient notes. Yet, this study focused solely on the LLMs’ comprehension of patients’ conditions from clinical notes rather than educational content. Study by Veen et al [53] assessed approaches for LLMs to summarize clinical texts. Although it demonstrated overall preferred performance, especially GPT-4, over human experts, the study was limited to the summarization of radiology report findings and confined to 3 attributes: completeness, correctness, and conciseness, whereas our study expanded on this topic by evaluating LLMs against 7 distinct criteria. Furthermore, none of the existing studies focus on education regarding supportive care in cancer, whereas our innovative findings make a significant contribution to the literature in this field.

Despite the excellence of LLMs in adhering to specified word limits and generating high-quality content, several challenges remain. One notable area where LLMs struggle is in adjusting the reading level of the content to accommodate patients from various educational levels. The content tailored by LLMs often does not meet the intended FKG level. This oversight implies that some individuals might find the content overly complex, potentially hindering their understanding of health information and educational content [54,55]. Addressing this challenge is essential for maximizing the applicability of LLMs and ensuring that all cancer survivors receive the support they need to manage their cancer effectively. In future work, in-context learning could be used to offer more detailed guidance to LLMs, focusing on the potential vocabularies frequently appeared in content exceeding the specified FKG level of 6. In addition, retrieval-augmented generation could be implemented to embed vocabularies aligned with an FKG level of 6, thereby enhancing the model’s performance.

It is also observed that the accuracy of Spanish translations is significantly higher than that of Chinese translations. This finding is expected, given the abundance of Spanish content available on the internet compared with Chinese content that can serve as training materials. Previous studies [56,57] have shown that LLMs’ performance in different languages has a clear correlation with the proportion of each language in the pretraining corpus. Without fine-tuning, LLMs have a much higher performance in high-resource languages like German, French, and Spanish, and a significantly lower performance in low-resource languages like Kannada, Occitan, and Western Frisian [56,57]. In future work, integrating high-quality bilingual medical corpora that includes parallel texts of patient education materials, clinical guidelines, and culturally tailored health information could be a promising approach. Fine-tuning LLMs on such specialized corpora may provide them with domain-specific vocabulary and context, thereby increasing their ability to produce accurate, culturally sensitive translations.

The educational content errors could be detrimental to cancer survivors and their caregivers by providing false physical activity, diet, or medication suggestions. Therefore, content produced by LLMs should undergo thorough evaluation and validation before the content is used in a clinical setting [38,58,59]. Our analysis has identified multiple errors in the outputs from LLMs, including inaccuracies in scope, expression, and definition. These types of errors can lead to the dissemination of misinformation, potentially causing harm to patients [60]. Therefore, such inaccuracies must be identified, analyzed, and rectified to prevent any negative impacts on patient care. Our study also detected some meaningless points that were not actionable in LLMs’ outputs, which could increase the reading burden on patients and their caregivers. Recommendations should highlight actionable information for cancer survivors and their caregivers to reduce the burden of reading educational content, emphasizing the need for LLMs to prioritize the use and applicability of the information they present. In addition, education content should be evaluated and validated by content experts before the it is available to cancer survivors and their caregivers.

In addition, both Xiao et al’s and Asthana et al’s studies [36,37] evaluated the performance of fine-tuned LLMs in nonclinical environments. Their results highlighted the significant potential of LLMs in summarizing general text through the adoption of advanced fine-tuning techniques. It is possible that fine-tuning could further improve LLMs’ capacity to analyze educational content specifically tailored for groups such as cancer survivors and their caregivers with limited health literacy or language barriers. With this additional data, more advanced fine-tuning techniques such as instruction tuning [57,61,62] and

parameter-efficient fine-tuning [63] can be implemented, and are likely to further enhance the performance.

Limitations

While the study has shown promising results, it has several limitations. First, the dataset size remains relatively small, which could restrict the generalizability of the findings to broader topics. Second, we lacked participant assessment. Relying solely on oncology experts to evaluate the outputs from LLMs might create obstacles when applying these findings to actual cancer patients and their caregivers. While our oncology experts deeply value caring for disadvantaged populations with limited health literacy or language barriers, it's important to note that they are highly educated and might have unintentional biases. This could make it challenging for them to view educational content from the perspective of individuals with low health education and literacy. Therefore, future studies can be broadened to include a wider range of educational topics and additional annotations from cancer patients and their caregivers. Third, this study was limited to zero-shot learning because of the lack of training data. It could be expanded by collecting tailored content from human experts to serve as training data to incorporate few-shot learning and fine-tuning techniques. In addition, chain-of-thought reasoning and in-context learning also present promising avenues for future exploration, particularly because they do not rely on additional training data. Finally, due to a limited number of annotators from diverse backgrounds, our study was only able to evaluate translations in 2 languages. Our analysis suggests that translation performance can vary between languages, influenced by the availability of content in each language. It is important to note that these findings may not be generalizable to languages spoken by smaller populations, where content availability and linguistic nuances could further affect translation accuracy. In future research, more extensive evaluations of translation tasks involving other languages, especially low-resource languages, should be conducted to expand the applicability.

Conclusions

The study highlights the application of LLMs in cancer care while being cognizant of their potential limitations. All 3 LLMs have demonstrated overall high capability in tailoring educational content for cancer survivors and their caregivers with limited health literacy or language barriers. GPT-4 family models showed better overall performance compared with GPT-3.5 Turbo. Prompting GPTs to produce bulleted-format content can generate better educational content. The findings from this study inform the intervention development and implementation in cancer symptom management and health equity. Additional studies are warranted to expedite the integration of AI-driven solutions into clinical settings.

Abstract

Background: Patients with cancer frequently encounter complex treatment pathways, often characterized by challenges with coordinating and scheduling appointments at various specialty services and locations. Identifying patients who might benefit from scheduling and social support from community health workers or patient navigators is largely determined on a case-by-case basis and is resource intensive.

Objective: This study aims to propose a novel algorithm to use scheduling data to identify complex scheduling patterns among patients with transportation and housing needs.

Methods: We present a novel algorithm to calculate scheduling complexity from patient scheduling data. We define patient scheduling complexity as an aggregation of sequence, resolution, and facility components. Schedule sequence complexity is the degree to which appointments are scheduled and arrived to in a nonchronological order. Resolution complexity is the degree of no shows or canceled appointments. Location complexity reflects the proportion of appointment dates at 2 or more different locations. Schedule complexity captures deviations from chronological order, unresolved appointments, and coordination across multiple locations. We apply the scheduling complexity algorithm to scheduling data from 38 patients with breast cancer enrolled in a 6-month comorbidity management intervention at an urban hospital in the Washington, DC area that serves low-income patients. We compare the scheduling complexity metric with count-based metrics: arrived ratio, rescheduled ratio, canceled ratio, and no-show ratio. We defined an aggregate count-based adjustment metric as the harmonic mean of rescheduled ratio, canceled ratio, and no-show ratio. A low count-based adjustment metric would indicate that a patient has fewer disruptions or changes in their appointment scheduling.

Results: The patients had a median of 88 unique appointments (IQR 60.3), 62 arrived appointments (IQR 47.8), 13 rescheduled appointments (IQR 13.5), 9 canceled appointments (IQR 10), and 1.5 missed appointments (IQR 5). There was no statistically significant difference in count-based adjustments and scheduling complexity bins (χ^2_4=6.296, *P*=.18). In total, 5 patients exhibited high scheduling complexity with low count-based adjustments. A total of 2 patients exhibited high count-based adjustments with low scheduling complexity. Out of the 15 patients that indicated transportation or housing insecurity issues in conversations with community health workers, 86.7% (13/15) patients were identified as medium or high scheduling complexity while 60% (9/15) were identified as medium or high count-based adjustments.

Conclusions: Scheduling complexity identifies patients with complex but nonchronological scheduling behaviors who would be missed by traditional count-based metrics. This study shows a potential link between transportation and housing needs with schedule complexity. Scheduling complexity can complement count-based metrics when identifying patients who might need additional care coordination support especially as it relates to transportation and housing needs.

Introduction

Background

Patients with cancer frequently encounter complex treatment pathways, often characterized by challenges with coordinating and scheduling appointments at various specialty services and locations [1-3]. Previous studies have shown that the burden of scheduling and attending visits across multiple providers and specialties not only burdens patients, but also has ripple effects on families, work, and personal lives [4-6]. In a qualitative study with patients with metastatic breast cancer, patients pointed to the need for someone to coordinate appointments and a need for managing work-related barriers to attending appointments [7]. Furthermore, scheduling complexities do not fall on all patients equally. Patients facing social inequalities, such as unequal access to transportation, housing, and social support, face additional complexities in their cancer care appointments. For instance, patients with cancer without insurance, indicating financial vulnerability, are at high risk of no-show appointments [8,9]. A recent review illustrates that most research on multiappointment scheduling problems in oncology focus on solutions using metaheuristics and multiagent methods to ensure appointment adherence [2]. However, if scheduling complexities reflect underlying socioeconomic barriers, such solutions may not solve the structural issues.

To address structural access challenges around scheduling appointments, some health care institutions employ individuals such as community health workers (CHWs) or patient navigators, who play a pivotal role in guiding patients with cancer through their care journey by offering support for nonmedical needs [10]. CHWs and patient navigators have a wide variety of skills and can provide critical assistance coordinating appointment scheduling and overcoming barriers to attending care [4,11,12]. Patients who might benefit from this additional assistance are largely identified manually by CHWs or by care providers aware of possible challenges and social needs [13], or some clinics may assign all patients to CHWs to screen, a resource intensive process [14-16]. Workflows reliant on staff to identify those who might benefit the most from navigation can be time-consuming and resource-intensive, making it difficult to comprehensively identify patients in need of assistance. While ideally all patients would be offered navigation services, in light of staffing shortages and overall limited patient navigation resources, many institutions may be limited in who they can provide extra supportive services to [17]. A data-driven solution that alleviates burden from support staff (ie, reviewing charts to identify patient needs) or relying on clinician referrals would be ideal to effectively and efficiently allocate limited CHW and patient navigator resources.

Potential of Scheduling Data

A potential way to identify patients with unmet transportation or housing needs is to use scheduling data to examine who is experiencing high scheduling complexities. Scheduling data for most cancer care is electronic, providing detailed data about when appointments are scheduled, cancelled, rescheduled, or no shows. This data is automatically recorded, and thus could be used to identify patients who are struggling to manage the complexity of cancer care. In past research, appointment data has primarily been used to optimize appointment scheduling for patient satisfaction and resource allocation [18-21]. Analyses tend to focus on developing and testing scheduling methods to best balance patient satisfaction (eg, wait times) with clinic resources. For example, using model simulations to optimize the scheduling of oncology visits and chemotherapy treatments [19], or optimizing scheduling rules based on chemotherapy infusion [21]. Other research using scheduling data examines the efficiency of appointment self-scheduling processes [22], optimizing scheduling for cost savings [20], and identifying ways to reduce wait times for patients [18]. A study designed an algorithm that used appointment data to identify patients' primary care physician [23]. However, to our knowledge, researchers have yet to design tools for analyzing scheduling data to identify patients with possible unmet transportation or housing needs during their cancer care.

Contributions

Our study used existing scheduling data to identify patients with complex scheduling patterns which may reflect unmet social needs in transportation and housing. We introduce a novel algorithm to calculate scheduling complexity from scheduling data using a sample of patients with breast cancer with initiating cancer treatment from a larger parent study intervening on comorbidity management [24]. Scheduling complexity is an aggregation of sequence, resolution, and facility components. Each component is motivated by the characteristics of scheduling data, an appointment's anatomy, and possible outcomes. The scheduling complexity algorithm is then applied to the scheduling data of 38 patients with breast cancer as a case example. The resulting scheduling complexities are compared with count-based metrics and call notes between CHWs and patients to identify unmet transportation or housing needs.

Methods

Anatomy of an Appointment

Every appointment has a unique appointment identification (AID) and is scheduled on a specific date and time and scheduled for a specific date, time, and location. An appointment is scheduled for a specific visit reason and is associated with the corresponding visit identification (VID). Typically, 1 date will have 1 appointment scheduled with 1 associated VID, Figure 1 (top). Figure 1 is an illustration of AID and VID possible scenarios. Sometimes there can be multiple appointments with different VIDs scheduled for the same date. This is illustrated in an example patient schedule in Table 1. A magnetic resonance imaging (MRI) and mammogram are both scheduled for January 15, 2023. The MRI and mammogram appointments have different AIDs (AID-5 and AID-6 respectively) and VIDs (VID-4 and VID-5 respectively) because they have different reasons for visit and will be at different locations, 1 on the ground floor and 1 on the second floor of the hospital. There can also be multiple AIDs for different dates associated with the same visit reason and at the same location, VID, Figure 1 (bottom). A common example of this pattern is for daily treatments as illustrated in Table 1. There are 4

appointments for the same treatment at the same location with the same VID (VID-7) but with different AIDs (AID-9, AID-10, AID-11, and AID-12). All the AIDs are for the same treatment and at the same location and would have the same VID.

Figure 1. Illustration of appointment ID (AID) and visit ID (VID) possible scenarios.

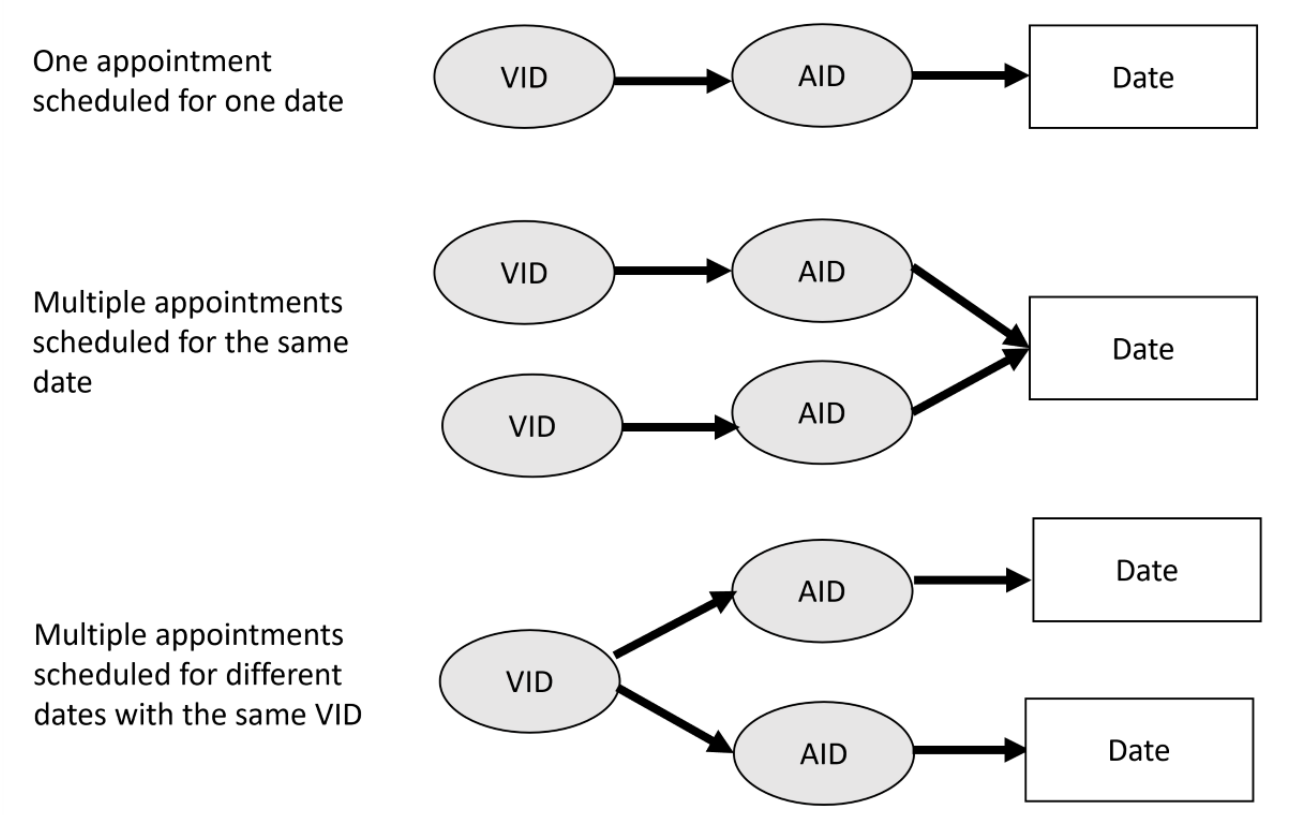

Table . Example individual patient scheduling temporal pattern.

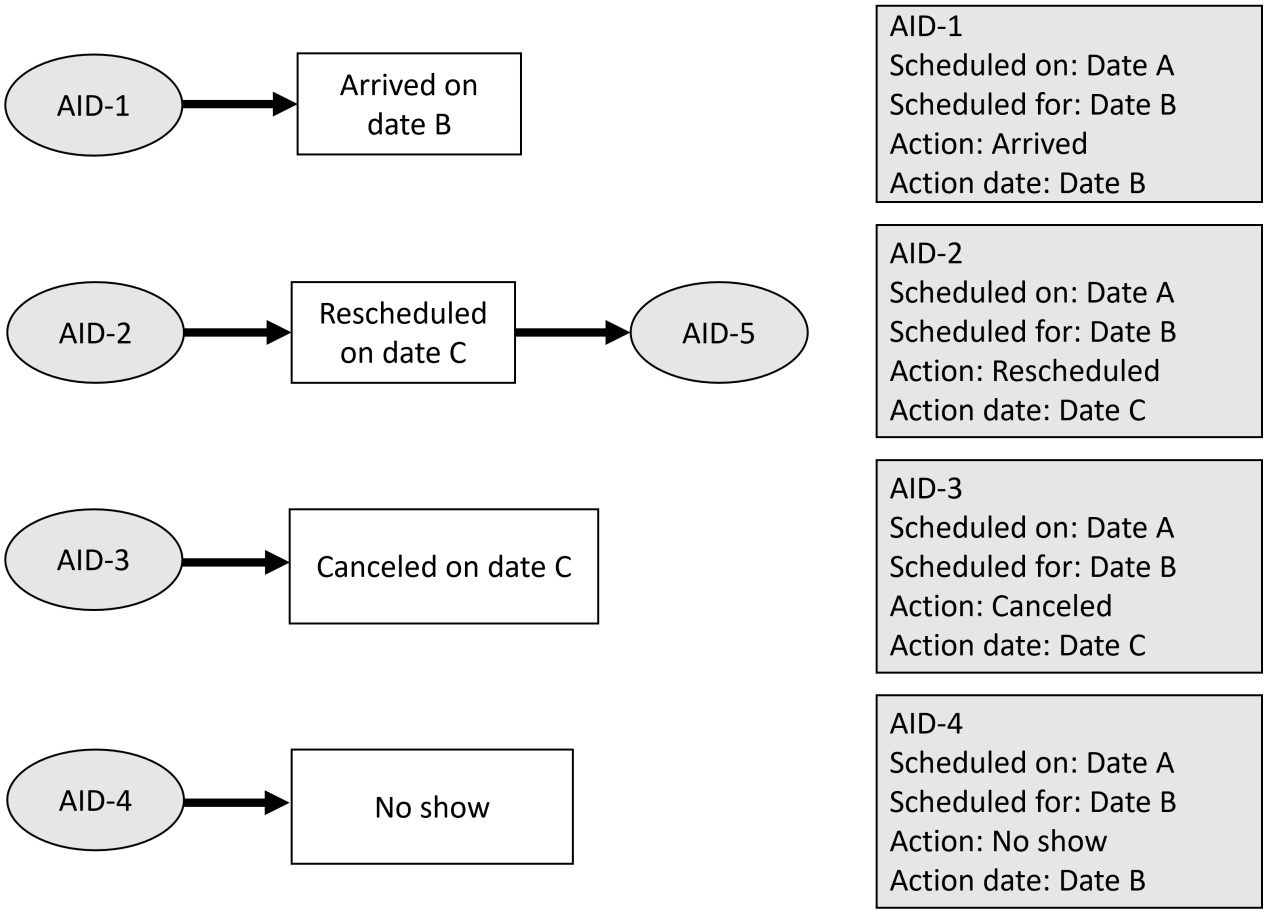
Appointment Action Outcomes

There are 4 possible action outcomes for an appointment: arrived, rescheduled, canceled, or no show as illustrated in Figure 2. Figure 2 illustrates 4 possible action outcomes for an appointment. Arrived occurs when the patient arrives on the scheduled appointment date. Rescheduled occurs when the appointment needs to be rescheduled for another date. This can be due to multiple reasons, such as patient's preference, medical necessity, financial or transportation issues, circumstances or system related factors, such as being bumped, unresolved insurance authorization, etc. Rescheduling an appointment will result in a new AID. An appointment can also be canceled by the patient or the hospital. For example, a provider could be unavailable due to illness or a scheduling conflict. Similarly, canceled appointments can be caused by a variety of patient or hospital system reasons. Finally, no show occurs when a patient doesn't arrive to an appointment and does not cancel the appointment.

Figure 2. The 4 possible action outcomes for an appointment. AID: appointment ID.



Sources for Scheduling Complexities

Sequence Complexity: Appointment Ordering Sequence

We define schedule sequence complexity as the degree to which appointments are scheduled and arrived to in a nonchronological order. While there are several ways to define temporal complexities, we choose a queuing approach as it most closely aligns with patient scheduling experience [25,26]. As such schedules with low sequence complexity are those where appointments are scheduled and arrived in chronical order. This follows the general queuing rule of first in-first out: appointments scheduled first are arrived to first which minimizes the number of outstanding appointments at any given time. Schedules with more sequence complexity are those where appointments are scheduled and arrived to in a nonchronological order. Using the illustration in Table 1, AID-1 and AID-3 are examples of appointments scheduled and arrived in chronical order. AID-1 is scheduled before AID-3 and AID-1 is arrived to before AID-3. AID-4 and AID-5 are examples of appointments scheduled and arrived in nonchronological order. AID-4 is scheduled before AID-5 but the patient arrived to AID-5 before AID-4. This complexity can be caused by many factors such as appointments scheduled for the far future, canceling and rescheduling of appointments, or emergent appointments. These factors can increase schedule challenges both for the patient and scheduling systems.

Resolution Complexity: Unresolved Appointments

No shows or canceled appointments without rescheduling or reason can increase scheduling complexity in a patient's care. Missing appointments leads to increase patient risk for cancer recurrence and mortality [27,28], and inefficiency for the health care system including lost revenue [29-31]. These unresolved appointments have no resolution, leaving uncertainty about potential delays in treatment and care. However, there are sometimes canceled appointments because of changes in treatment plans or no shows that are resolved through another action. Actions for these resolved appointments often co-occur with action dates for arrived or rescheduled appointments. Hence, we define resolution complexity as the number of no shows or canceled appointments on dates that do not co-occur with other action dates divided by the total number of no shows or canceled appointments.

Location Complexity: Appointments at Multiple Facilities

Having care at multiple facilities or locations can also increase scheduling complexities as this usually means more coordination and travel between facilities. Intuitively, a schedule with lower location complexity will have fewer facilities for care on the same day. A schedule with higher location complexity will more often require the patient to attend different facilities for care on the same day. Location complexity is calculated as the number of arrived dates involving 2 or more different locations divided by the total number of arrived dates.

Calculating Scheduling Complexity

The algorithm for calculating a schedule's scheduling complexity is described below (Textbox 1) . First, schedule data is separated into arrived and not arrived appointments, "ARRIVED" and "NONARRIVED" respectively. ARRIVED appointments are aggregated at the date level. For each AID in ARRIVED, if there exist other AIDs with scheduled on dates preceding the current AID's scheduled on date and these subsequent appointments were attended after the current AID's date, then the count of out-of-order occurrences is increased. Sequence complexity is calculated as the ratio of out-of-order counts to the total count of distinct arrived dates in ARRIVED. Next, for each AID in the NONARRIVED group, an action date is determined, representing the date when an appointment was either canceled, bumped, or scheduled but resulted in a no-show. If this action date does not appear in the dataset of ARRIVED appointments, then the count of unresolved cases is increased by 1. Resolution complexity is then computed as the ratio of unresolved counts to the total count of AIDs within the NONARRIVED group. Location complexity is calculated as the number of arrived dates in ARRIVED involving 2 or most different locations divided by the total number of arrived dates in ARRIVED. Finally, a composite metric scheduling complexity is the harmonic mean of sequence complexity, resolution complexity, and location complexity.

Textbox 1. ALGORITHM: Deriving scheduling complexity

ARRIVED, NONARRIVED ← Separate data into arrived and not arrived appointments

For each AID in **ARRIVED**:

If there are other AID date that was made before current AID date and arrived to after current AID date

Out of order count += 1

sequence complexity = out of order count / total count of unique arrived to dates in **ARRIVED**

For each AID in **NONARRIVED**:

Action date = canceled or bumped date or scheduled date for no-show

If Action date not in Arrived_data:

unresolved += 1

resolution complexity = unresolved count / total count of nonArrived AIDs

For each arrived date with multiple AIDs in **ARRIVED**

If AIDs are at different locations:

Location count += 1

location complexity = location count / total number of arrived dates with multiple AIDs in **ARRIVED**

scheduling complexity = 3 / (1/sequence complexity + 1/resolution complexity + 1/facility complexity)

Case Example and Study Background

To evaluate the use of scheduling complexity, we calculated the scheduling complexity for 38 patients with breast cancer who had hypertension or diabetes, as part of a larger health disparities project to support Black patients with cancer with comorbidities by mobile health and CHW support [24]. The 38 patients with breast cancer were enrolled in a 6-month comorbidity management intervention at an urban hospital in the Washington, DC area that serves low-income patients. This data was collected through the parent study whereby Black patients with breast and prostate cancer were recruited for a 6-month comorbidity management intervention. For tthis analysis, we focused on the association between scheduling patterns and social needs. Given significant differences in course of treatment by cancer site and time since diagnosis we limited the sample to those who had a diagnosis of breast cancer, all of whom had been diagnosed within the previous year. We further limited the sample to the 38 patients with breast cancer whom we had reliable appointment level data. The women in our sample were from an urban hospital in the Washington, DC area that primarily serves low-income patients. Black women with breast cancer in the DC area are a high priority sample, due to the increased mortality rate relative to White women [32].

CHW Call Logs

In addition, as part of the parent study, we conducted a qualitative context analysis of CHWs' call logs to identify social needs that arose throughout the study [33]. We used a deductive approach, first applying discrete categories from the health system screening tool focused on domains of food insecurity, housing instability, transportation, employment, financial strain, and utilities. Additional needs that were documented but did not fit into a predetermined category, such as access to wigs or special bras, were added as new codes using an inductive descriptive coding method to match social needs domain described by the Social Interventions Research and Evaluation Network (SIREN) [34].

Data Analysis

For this pilot evaluation, we use 1 year of scheduling data for each patient starting from their date of diagnosis. Furthermore, 1 year of scheduling data was chosen because the majority of patients completed curative treatment within the first year after diagnosis. Sequence complexity, resolution complexity, location

complexity, and scheduling complexity was calculated for each patient separately. In addition, we calculated count-based metrics: arrived ratio, rescheduled ratio, canceled ratio, and no-show ratio. We define an aggregated count-based adjustment metric as the harmonic mean of rescheduled ratio, canceled ratio, and no-show ratio. Count-based adjustments and scheduling complexities are stratified using quartiles and compared. We stratify patients into high, medium, and low complexities using the upper quartile, middle quartiles, or lower quartiles respectively. We used χ^2 test to compare our scheduling complexity metric to count-based adjustments because they are commonly used in first order analysis of scheduling data. All analysis was done in Python (version 3.0; Python Software Foundation).

Ethical Considerations

This research was approved by the Georgetown University Institutional Review Board (STUDY00003543). This study was registered with ClinicalTrials.gov (NCT04836221). Written informed consent was obtained before conducting all study procedures, which allowed for secondary analysis of participant data without additional consent. A Health Insurance Portability and Accountability Act waiver and access to medical record data was included in the signed informed consent. All data included in this manuscript are deidentified and reported in aggregate. Data obtained through the study adhere to data protection and institutional review board standards as determined by the governing institution. Participants were compensated US $50 at the completion of the study.

Results

Schedule Descriptives

A total of 38 female patients with breast cancer with an average age of 67.1 (SD 8.5), from 3 referring oncology providers had a median of 88 unique AID (IQR 60.3: first quartile [Q1]=59, third quartile [Q3]=119.3), 62 arrived appointments (IQR 47.8: Q1=38.7, Q3=86.5), 13 rescheduled appointments (IQR 13.5: Q1=7.5, Q3=21), 9 canceled appointments (IQR 10.0: Q1=3, Q3=13), and 1.5 missed appointments (IQR 5: Q1=0, Q3=5). The median nonarrived ratio was 0.304 (IQR 0.161: Q1=0.233, Q3=0.394). The median rescheduled ratio was 0.154 (IQR 0.080: Q1=0.127, Q3=0.207). The median canceled ratio was 0.098 (IQR 0.081: Q1=0.046, Q3=0.127) and the median no-show ratio was 0.019 (IQR 0.049: Q1=0, Q3=0.049). Figure 3 is a summary boxplot of nonarrived, rescheduled, canceled, and no-show ratios with nonarrived ratio being the largest. The median sequence complexity was 0.200 (IQR 0.100: Q1=0.140, Q3=0.240). Figure 4 is a summary boxplot of sequence, resolution, location, and scheduling complexities with location complexity being the largest. The median resolution complexity was 0.372 (IQR 0.398: Q1=0.188, Q3=0.586). The median location complexity was 0.464 (IQR 0.371: Q1=0.279, Q3=0.650). Finally, the median scheduling complexity was 0.239 (IQR 0.173: Q1=0.156, Q3=0.329).

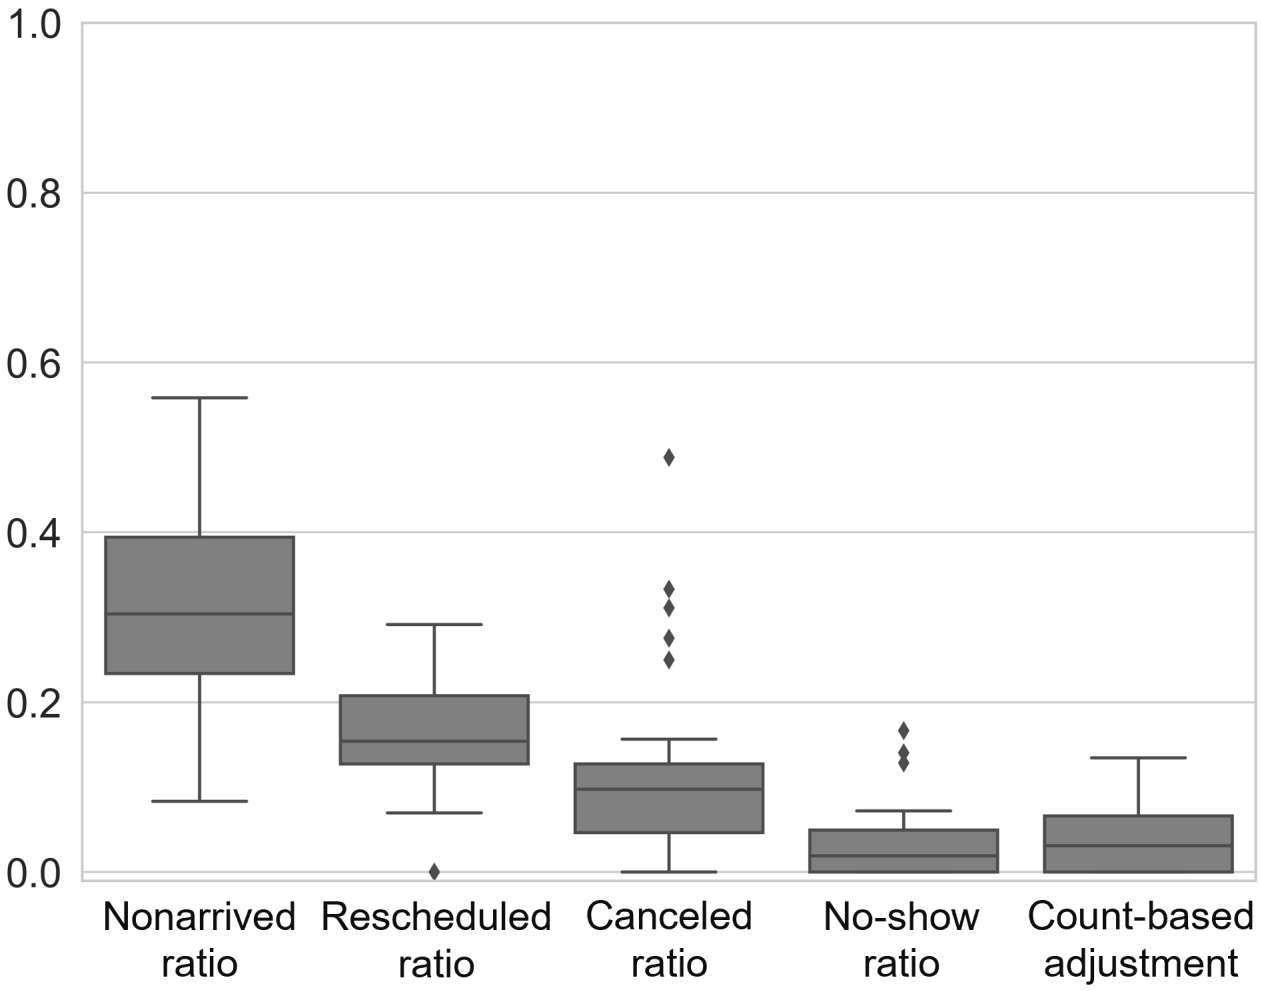

Figure 4. Summary boxplots of sequence complexity, resolution complexity, location complexity, and scheduling complexity.

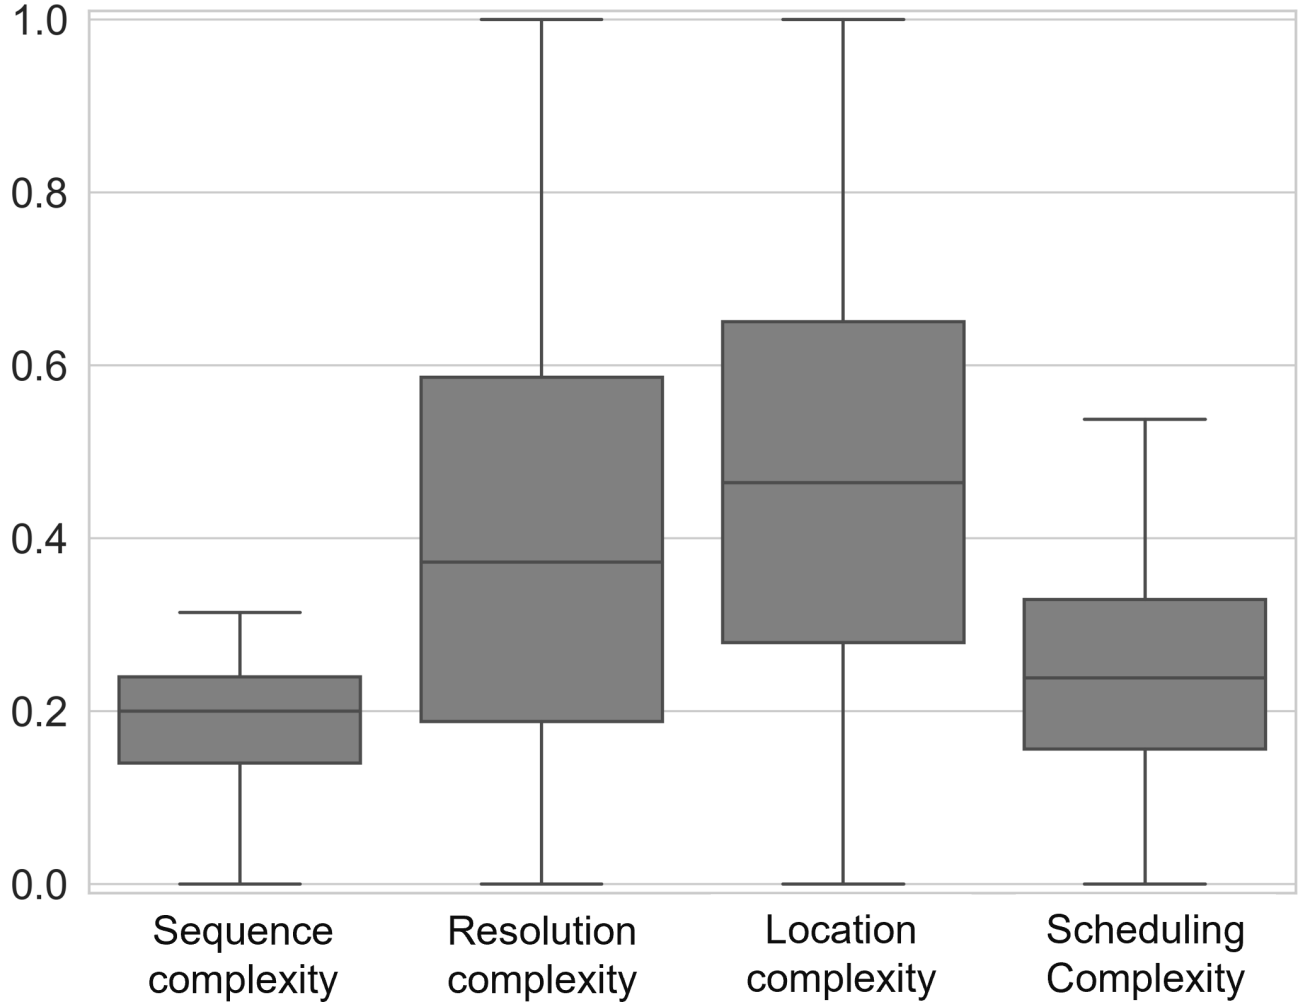

Comparison of Count-Based Adjustments With Scheduling Complexity

A total of 18 patients exhibited medium count-based complexities, 10 patients exhibited high count-based complexities, and 10 patients exhibited low count-based complexities. Similarity, 18 patients exhibited medium scheduling complexities, 10 patients exhibited high scheduling complexities, and 10 patients exhibited low scheduling complexities. There was no statistically significant difference in count-based adjustments and scheduling complexity bins (χ^2_4=6.296, P=.18). Table 2 shows the count-based and scheduling complexities were the same for 16 patients, 11 of which had both medium scheduling and count-based complexities. Furthermore, 5 patients exhibited high scheduling complexity with low count-based adjustments and 2 patients who exhibited high count-based adjustments with low scheduling complexity.

Table . Correlation of scheduling and count-based complexities binned by low, medium, and high.

Scheduling complexity	Count-based adjustments		
	Low	Medium	High
Low	3	5	2
Medium	2	11	5
High	5	2	3

In addition, Figure 5 gives examples of high scheduling complexity and low count-based adjustments, high count-based adjustments and low scheduling complexity, low scheduling complexity and low count-based adjustments, and high scheduling complexity and high count-based adjustments. Patient A had both low count-based adjustments and low scheduling complexity. Patient A's schedule is a good example of appointments following the first-in first-out pattern, that is appointments scheduled first will be arrived to first. In addition, Patient A only had 3 rescheduled appointments. Patient B had high count-based adjustments but low scheduling complexity; 40% (8/20) of Patient B's AID were rescheduling actions which likely contributing to a high count-based adjustments. However, Patient B had low scheduling complexity because these

rescheduling actions occurred only on 2 separate days and followed a first-in first-out sequence. Patient C had low count-based adjustments and high scheduling complexity. Although Patient C had few rescheduling actions (resulting in a low count-based adjustments), her appointments were largely scheduled and arrived to not in chronical order (resulting in a high scheduling complexity). Patient D had both high count-based adjustments and high scheduling complexity. In addition to nonchronical ordering of action, Patient D had 2 canceled and 1 no-show appointment action outcomes.

Figure 5. Examples of high scheduling complexity and low count-based adjustments, high count-based adjustments and low scheduling complexity, low scheduling complexity and low count-based adjustments, and high scheduling complexity and high count-based adjustments. Context From Call Logs: Transportation and Housing Needs

A total of 15 patients specifically indicated transportation or housing insecurity issues. Transportation concerns included "legally blind and worried about metro access," "[patient] feeling unsafe on metro," "transportation challenges to and from appointments," "extensive travel requirements," "making medical transportation rides," and "needing transportation assistance." Housing concerns included "help with finding affordable housing options," concerns related to advocating for tenant rights, home repair needs, "[patient] moving in with relative for a few months to save money," "having to find temporary housing while home is being repaired," "help finding rental assistance programs." Additional examples of identified social needs included a demanding work schedule, complexities with an eye surgery, and the additional responsibility of caring for an ill mother. Scheduling complexity was more sensitive to housing and transportation needs. 86.7% (13/15) of patients specifically indicated transportation or housing insecurity issues were identified as medium or high scheduling complexity compared with 65.2% (15/23) of patients who did not specifically indicate transportation or housing insecurity issues. On the other hand, 60% (9/15) of patients specifically indicated transportation or housing insecurity issues were identified as high with count-based adjustments compared with 82.6% (19/23) of patients who did not specifically indicate transportation or housing insecurity issues Table 3.

Table . Percentage of patients with medium or high complexities by transportation or housing insecurity needs.

Complexity type	Indicated transportation or housing needs (n=15), n (%)	Did not indicate transportation or housing needs (n=23), n (%)
Count-based adjustments	9 (60)	19 (82.6)
Scheduling complexity	13 (86.7)	15 (65.2)

Discussion

Principal Findings

Scheduling complexity stratification provides a novel lens to complement traditional count-based metrics for analyzing scheduling data. The results show that scheduling complexity can identify patients with complex but nonchronical scheduling behaviors missed by traditional count-based metrics. In addition, the study highlights that resolution and location complexity can also serve as an indicator for additional care requirements.

Comparison With Previous Work

This study shows a potential link between transportation and housing needs with schedule complexity. This study reinforces previous research relating social risk factors and schedule complexities [4,9]. Our results complement these findings as it relates to transportation and housing needs and highlights the potential use of the scheduling complexity algorithm to identify patients who might benefit from additional CHW support. Through earlier identification from CHWs, scheduling complexity could help narrow inequities in cancer-care which emerge from social needs. Future studies are needed to better understand temporal sensitivity of this approach, or how quickly in-need patients could be identified.

Support for CHW and Patient Navigators

By examining the temporal patterns of health care use, we gain a more comprehensive view of patients' experiences. Instead of relying solely on infrequent screeners, scheduling complexity can give CHWs and patient navigators a more "real-time" view of patients who might require more support in managing their health care journey, for example patients with changing, complex, and distributed care and changes in living conditions or social needs. In addition, scheduling complexity could also be used to identify care plans that might involve more complexity and preemptively identify patients that might need more support. This data-driven approach can help complement the often manual process for identifying patients who might benefit from additional assistance, potentially affording CHWs and patient navigators more time to directly care and help patients [13]. Additional research is needed to evaluate the utility of this algorithm in near "real-time" applications for CHWs.

Limitations and Future Directions

There are several limitations to consider in this pilot work. First, this research is constrained by its retrospective analysis design, relying on historical data and records. Second, a naïve weighting approach was taken in which sequence, resolution, and location complexity are weighted equally in the algorithm. These components might require different weights depending on circumstances. For example, for cancer care at integrated cancer centers, location complexity would probably be less important than sequence and resolution complexities. Third, the study exclusively focuses on the scheduling system of a single urban cancer institute. As such, the results only reflect the central tendencies given the specific conditions and scheduling pattern characteristics of our patient cohort. The generalizability this approach and interpretation of the metrics to other health care systems and patient conditions will need to be explored. Fourth, while this approach has provided insights, it does not fully capture the entirety of factors that contribute to scheduling intricacies, such as resource allocation, patient preferences, and staff availability. Further validation is needed beyond this case example, particularly with a larger patient sample to better capture variations in the scheduling complexity data. Nevertheless, this method could complement other approaches such as patient and scheduler interviews. This work should also be explored in a larger sample size to further explore our hypotheses generated about scheduling complexity.

Conclusion

Patients facing complex health care journeys often experience significant impacts on various aspects of their lives, including family dynamics and work commitments. While there was no

statistically significant difference in count-based adjustments and scheduling complexity bins, we showed that scheduling complexity can uniquely identify patients with complex and nonchronical schedule behaviors. We highlight the potential use of scheduling complexity in identifying patients who might need care coordination support especially as it relates to transportation and housing needs.

Abstract

Background: "Patient Voices" is a software developed to promote the systematic collection of electronic patient-reported outcome measures (ePROMs) in routine oncology clinical practice.

Objective: This study aimed to assess compliance with and feasibility of the Patient Voices ePROM system and analyze patient-related barriers in an Italian comprehensive cancer center.

Methods: Consecutive patients with cancer attending 3 outpatient clinics and 3 inpatient wards were screened for eligibility (adults, native speakers, and being able to fill in the ePROMs) and enrolled in a quantitative and qualitative multimethod study. Compliance, reasons for not administering the ePROMs, patients' interaction needs, and patient-perceived System Usability Scale (range 0-100) were collected; semistructured interviews were carried out in a subsample of patients.

Results: From June 2020 to September 2021, a total of 435 patients were screened, 421 (96.7%) were eligible, and 309 completed the ePROMs (309/421, 73.4%; 95% CI 69.8%-77.5%; mean age 63.3, SD 13.7 years). Organization problems and patient refusal were the main reasons for not administering the ePROMs (outpatients: 40/234, 17.1% and inpatients: 44/201, 21.9%). Help for

tablet use was needed by 27.8% (47/169) of outpatients and 10.7% (15/140) of inpatients, while the support received for item interpretation was similar in the 2 groups (outpatients: 36/169, 21.3% and inpatients: 26/140, 18.6%). Average System Usability Scale scores indicated high usability in both groups (outpatients: mean 86.8, SD 15.8 and inpatients: mean 83.9, SD 18.8). Overall, repeated measurement compliance was 76.9% (173/225; outpatients only). Interviewed patients showed positive attitudes toward ePROMs. However, there are barriers to implementation related to the time and cognitive effort required to complete the questionnaires. There is also skepticism about the usefulness of ePROMs in interactions with health care professionals.

Conclusions: This study provides useful information for future ePROM implementation strategies, aimed at effectively supporting the routine clinical management and care of patients with cancer. In addition, these findings may be relevant to other organizations willing to systematically collect PROMs or ePROMs in their clinical routines.

Trial Registration: ClinicalTrials.gov NCT03968718; https://clinicaltrials.gov/study/NCT03968718

Introduction

Patient-reported outcome measures (PROMs) are questionnaires for the self-assessment of patients' symptoms, well-being, and functional status associated with their health condition, without interpretation by a clinician or anyone else [1,2]. Well-validated PROMs are considered the gold standard for the collection of subjective health-related outcomes [3,4].

PROMs were initially developed to be used in research, but interest has been growing in integrating them into cancer clinical practice to facilitate personalized care management [5]. There is now a wealth of evidence indicating that PROMs may improve symptom control, communication, patient satisfaction, quality of life, and overall survival. In addition, consistent use of PROMs may contribute to reduce emergency room access and hospitalization rates [6-11].

Despite the generally positive effects and favorable attitudes reported by health care professionals (HCPs) [12-15], PROMs are not systematically implemented in routine oncology practice [16,17]. Potential facilitators to the routine use of PROMs have been highlighted, such as automatic scoring, immediate availability of above cut-off values, and time-trend visualization, along with automatic triggers and recommendations for clinical action. However, the barriers to PROM implementation act at many levels [18-20]. At the HCP and service level, major barriers include the workload associated with administering questionnaires, the lack of clear guidelines and confidence in routine use, difficulties in scoring and interpreting the results, and integration of PROMs into clinical workflows [17,19].

Electronic PROMs (ePROMs) have been proposed [21] to improve their applicability and acceptability by HCPs. Yet, inadequate IT infrastructures and ePROM systems that are not integrated with the electronic medical record (EMR) [22,23] emerged as critical issues. Relevant among these is the need for HCPs to connect to multiple systems, the increased risk of poor care coordination, inefficiencies in activating clinical pathways and referrals, and missed opportunities for care improvement [18,24].

Patient-related barriers also hinder the use of PROMs and include the negative perception of PROMs as time-consuming and burdensome to complete, difficulties in using electronic devices, lack of adequate explanations and support, and privacy concerns [19,22].

The Patient Voices project started in 2018 at the Fondazione IRCCS Istituto Nazionale dei Tumori (INT) in Milan (Italy), with the purpose of promoting the systematic collection of ePROMs in routine cancer care through a software system integrated into the hospital EMR that has not yet been implemented [25]. The system was designed in compliance with recommendations provided by the European Society for Medical Oncology clinical practice guideline on the role of PROMs in the continuum of cancer care [26]. The aim of the project was 2-fold: on the one hand, to explore the technical viability and the attitude of HCPs toward such an integrated ePROM system; on the other hand, to test its workability in a pilot implementation in routine oncology clinical practice in different settings of the hospital. This study aims at reporting on the assessment of compliance and feasibility of ePROM implementation as well as identifying patient-related implementation barriers.

Methods

Study Design

This study used a multimethod design based on concurrent quantitative and qualitative data collection. The aim was to increase the chances of getting varied and extensive research findings on the feasibility of the systematic use of ePROMs.

Data were collected and analyzed from the following substudies:

- Quantitative longitudinal substudy A: ePROMs were used for symptom screening and monitoring in patients with cancer who attended 3 outpatient clinics at INT, that is, palliative care, genitourinary oncology, and radiotherapy clinics.
- Quantitative cross-sectional substudy B: ePROMs were used to assess psychological distress among inpatients

admitted to urological surgery, medical oncology, and colorectal surgery wards.
- Qualitative feasibility substudy C: Semistructured interviews were carried out with a subgroup of patients involved in the previous quantitative substudies, with the aim to explore in depth the patient-related barriers to successful implementation.

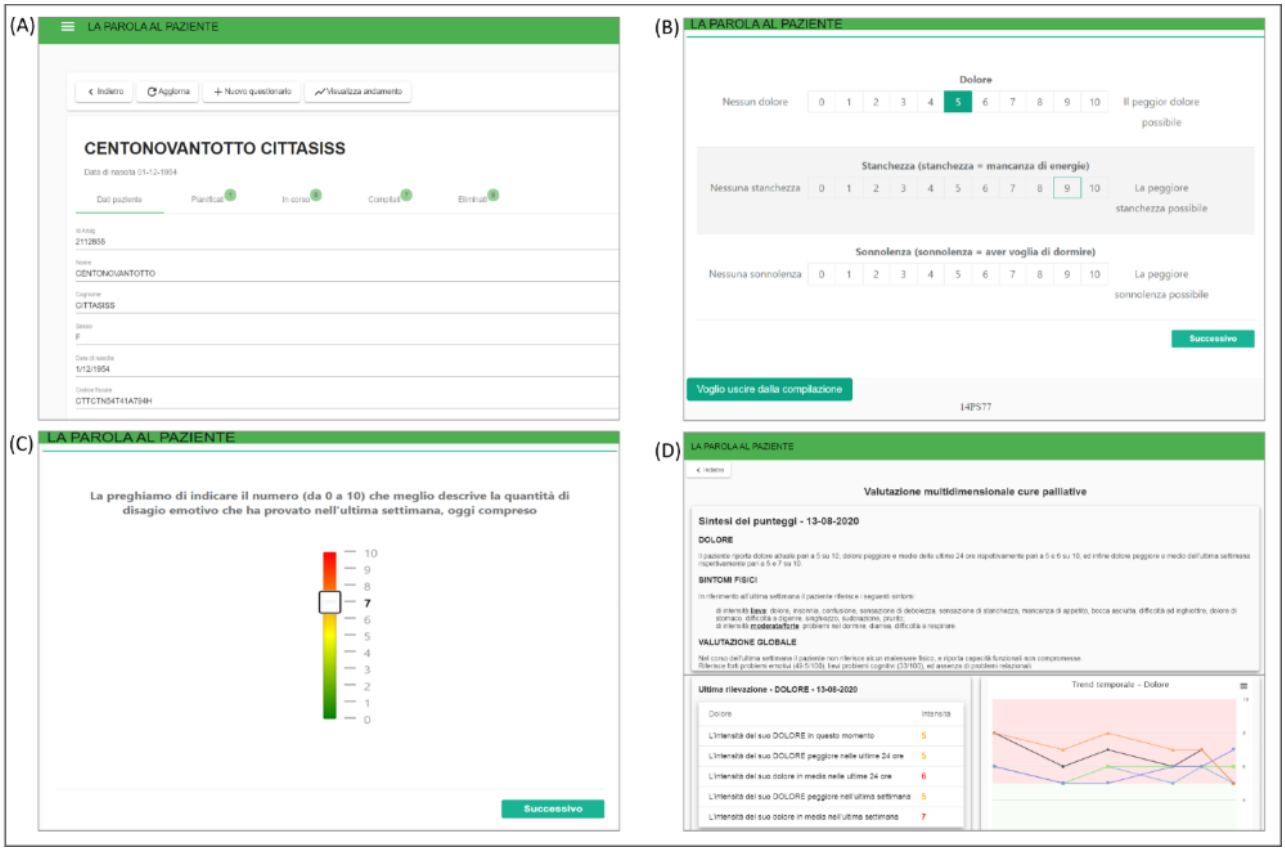
More methodological details are reported elsewhere [25].

Patient Voices ePROM System

The Patient Voices ePROM system was developed in 2020 at INT in collaboration with Politecnico of Milan (Italy). After a predevelopment phase, running an ad hoc analysis of technical and user requirements, the web-based application was integrated with the INT information system, including the EMR, and runs only under the hospital network. The system involves 4 kinds of users [25]: the administrator, who operates through a dedicated dashboard to authorize users to system access and to download PROM data for reports and research; the data collection coordinator (DCC), who registers patients and trains them to use the system; the patient, who completes the assigned questionnaires through a tablet provided by the hospital; and the clinician, who has access to real-time textual and graphical PROM data from the EMR.

Figure 1 shows sample screenshots from the Patient Voices ePROM system for the different users (fictional data).

Figure 1. Screenshots from the Patient Voices electronic patient-reported outcome measure system for the different users. (A) Patients' data registration by the data collection coordinator. (B) Edmonton Symptom Assessment Scale questionnaire compilation by the patient. (C) Distress Thermometer questionnaire compilation by the patient. (D) Visualization of Therapy Impact Questionnaire scores by the clinician.



Questionnaires (ePROMs)

The Patient Voices system was designed to allow for flexibility in the choice of questionnaires to be administered to patients. For the feasibility substudies A and B, the following questionnaires could be electronically administered:

- Edmonton Symptom Assessment Scale (ESAS) [27]: It requires the patient to rate a list of physical and psychological symptoms on a 0-10 numerical scale and was used in genitourinary cancer and radiotherapy clinics in substudy A.
- Therapy Impact Questionnaire (TIQ) [28]: It includes questions on physical symptoms (24 items), overall well-being (1 item), functional and emotional status (3 and 4 items, respectively), as well as cognitive and relational status (2 items each). The reference time is the previous week, and responses are collected on verbal rating scales (no or a little bit or quite a bit or very much). For this study, TIQ was complemented with five 0-10 numerical rating scales assessing pain intensity with different time referral. As this implementation project aimed to meet the needs of clinicians, the TIQ and the pain scales were chosen in place of the ESAS in the palliative care outpatient clinic, as these were the paper-and-pencil PROMs routinely used in that ward.
- Distress Thermometer (DT) [29]: It is a single 0-10 numerical scale on which participants rate their level of distress from any cause in the previous week. The DT is supplemented by a 35-item problem list, which prompts patients to identify their problems in practical,

family-related, emotional, spiritual or religious, and physical domains. Scores of 4 or higher suggest clinically significant distress. The DT was used with inpatients involved in substudy B.

All the above ePROMs are validated in the Italian language [28,30-32].

Quantitative Substudies

Study Participants

Consecutive adult patients with cancer (aged ≥18 years) attending one of the previously listed outpatient clinics and inpatient wards during pre-established days in the enrollment period (1 to 2 months for each ward or clinic) were potentially eligible to be enrolled in substudies A and B. Patients with inability to complete the questionnaires due to physical or cognitive impairment, psychological disturbances, or nonnative language issues were not eligible for the study. All participants attended as volunteers and gave their written informed consent to participate in the research.

Data Collection Procedures

A systematic screening of all patients attending inpatient wards and outpatient clinics was performed by a dedicated research nurse, who acted as the DCC. Reasons for not administering ePROMs were collected and classified as patient related (cognitive impairment, physical conditions, and language issues), institution related (organizational problems and patient already enrolled in another clinical trial), or patient refusal. After the eligibility screening and informed consent collection, the DCC provided basic training on how to use the tablet and explained how to fill in the questionnaire. Patients involved in substudy A filled in the ePROM at all subsequent visits during the data collection period, while patients involved in substudy B filled in the DT on admission only.

The DCC supported the patients while filling out the questionnaire, recording whether and how often the patient needed help in using the device or interpreting the questions. A specific DCC "structured form" was used for collecting such data, which were then analyzed using descriptive statistics. The time needed to complete the questionnaire by each patient was registered by the system.

After ePROM completion, patients were asked to fill in a paper-based questionnaire on their educational level and familiarity with electronic devices and internet use. Patients' demographic and clinical data (sex, date of birth, tumor site, year of cancer diagnosis, and visit or hospitalization reason) were extracted from the institutional data warehouse. Data collection was performed using REDCap (Research Electronic Data Capture; Vanderbilt University) electronic case report form [33,34]. Patients' perception and usability of the Patient Voices system were assessed, only for patients filling in the questionnaire, by the System Usability Scale (SUS), a standardized 10-item questionnaire with a final score ranging from 0 to 100 with higher values indicating higher usability [35].

Study End Points

The main end point of the study was compliance with the Patient Voices system, defined as the percentage of eligible patients completing the ePROMs assigned. Secondary end points were the percentage of screened patients who received the ePROMs; the average perceived system usability measured through SUS; the proportion of patients asking for interaction with the DCC to complete the tasks; the average time to fill in the questionnaire; and the successful administration of the questionnaire during subsequent visits (among patients attending outpatient clinics, at least twice during the follow-up period in substudy A).

Sample Size and Data Analysis

In the hypothesis that the compliance is 50% (hypothesis of maximum variability and then maximum imprecision), a sample size of 200 (in both in- and outpatient settings) allows the estimation of a 95% CI for the percentage of compliance with a precision (half-width) of 6.9% [36]. Basic descriptive statistics were applied to characterize the study sample. Point and interval estimates (95% CI) of proportion and averages described in the study end points were calculated for the whole sample and by inpatient ward or outpatient clinic. Cronbach α is used to measure the internal consistency of the SUS in this sample. Values above 0.70 indicate acceptable reliability [37]. The analyses were performed using the standard software packages Stata (StataCorp) and R (R Foundation for Statistical Computing).

Qualitative Substudy

Study Participants

Patients in the qualitative interview substudy were recruited among those who had completed at least 1 of the ePROMs administered in substudies A or B. Purposive sampling was undertaken to guarantee the inclusion of participants with a broad range of characteristics, such as disease site and stage, age, and sex.

Data Collection Methods and Procedures

A topic guide developed by the research team and based on a literature review [19,24,38,39] was used to structure the interviews with patients. This guide included questions on the feasibility and acceptability of the routine use of ePROMs, the difficulties encountered while completing the questionnaire, the information and help received about ePROMs, and the perception of the impact of these tools on clinical consultation. In addition, there was scope to digress from the guide if participants raised new and relevant topics.

After an initial training session, face-to-face interviews were conducted, audio recorded, and transcribed ad verbatim by volunteers from *Associazione Italiana Malati di Cancro* (AIMAC; Italian Association of Cancer Patients). The interviews were conducted between May and November 2021 and lasted an average of 28 (SD 11.02) minutes. The interviews (and participant involvement) were carried on until thematic saturation had been reached and no new insights could be drawn from additional participants [40].

Data Analysis

Interview transcripts were imported into NVivo (version 12; Lumivero) for data management, coding, and analysis [41]. Patients' names were transformed into textual and numeric strings to ensure data pseudoanonymization. Verbatim transcripts were analyzed using a thematic analysis approach, as described by Braun and Clarke [40]. Initial coding was done by 1 author (L Lombi), then supervised and verified by other 2 authors (C Brunelli and SA). Once the interviews had been initially coded, a finer analysis was conducted to identify themes, sample quotes, and interconnections between themes.

Some results of this qualitative study, particularly regarding participants' perspectives on the implications of using ePROMs for the clinical encounter, were discussed in Lombi et al [42]. In this work, we focused on findings concerning the perceived barriers to ePROM integration into oncological clinical routine.

Ethical Considerations

This study was approved by the institutional ethics committee of Fondazione IRCCS INT (Milan, Italy; INT 167/18) and complied with the Declaration of Helsinki. Participants provided written consent before the visit or during hospitalization. Participants were informed about (1) research purposes, (2) privacy, (3) use of the information obtained, (4) that participation was voluntary and unrewarded, and (5) that they could leave the research at any time without giving explanations. All the data were deidentified before data analysis and storage. There was no compensation for participation in the study.

Results

Quantitative Results

From June 2020 to September 2021, a total of 435 consecutive patients were screened, 421 (96.7%) were eligible, and 309 filled in the ePROMs, which indicates compliance of 73.4% (309/421; 95% CI 69.8%-77.5%). All patients who were administered the ePROM completed it, and no one stopped before completing the questionnaire.

Overall feasibility (percentage of patients, among those screened, who could be administered the ePROMs) was 71% (309/435; 95% CI 66.5%-75.2%). Table 1 shows comparable feasibilities by in- and outpatients; 69.6% (140/201; 95% CI 62.8%-75.2%) and 72.2% (169/234; 95% CI 66%-77.8%), respectively. Organization problems, such as pressure on time and difficult patient flow management, were the main reason for not administering ePROMs among outpatients (40/234, 17.1% vs inpatients: 5/201, 2.5%), whereas patient refusal was the main reason for inpatients (44/201, 21.9% vs outpatients: 10/234, 4.3%).

While the feasibility rates were similar in the 3 inpatient wards (colorectal surgery: 44/60, 73.3%; medical oncology: 48/70, 68.6%; and urological surgery: 48/71, 67.6%), higher heterogeneity was found in outpatient clinics, with the palliative care clinic showing the higher feasibility (59/65, 90.8%), followed by the radiotherapy clinic (42/54, 77.8%), and the genitourinary oncology clinic (68/115, 59.1%; Figure 2).

Table 2 reports demographic, disease characteristics, and the use of technological tools by patients who filled in the ePROMs.

Most of the responders stated that they regularly used smartphones (240/309, 77.7%) and the internet (203/309, 66%). About half of them (159/309, 51.5%) were quite familiar with computer, while tablet use was less common (65/309, 21%). In total, 24 (7.8%) patients reported they were not using any electronic devices or the internet.

Table 3 shows the interaction and help needed by patients during ePROM filling in. More help and interaction with the DCC to use the tablet was needed by outpatients (47/169, 27.8% vs 15/140, 10.7%), and overall, 244 (78.9%) out of 309 patients did not need help to use the tablet. Help received for the interpretation of questions was similar in the 2 settings (outpatients: 36/169, 21.3% and inpatients: 26/140, 18.6%). Of note, 216 (70%) out of 309 patients did not need any kind of interaction to fill in the ePROM (data not shown in table).

In a limited number of patients, although considered eligible for the study in the enrollment phase, the ePROM was filled in by the nurse upon patient interview (10/140, 7.1% vs 13/169, 7.7% in the inpatient and outpatient group, respectively) mainly because of physical issues (2/140, 1.4% of inpatients and 6/169, 3.6% of outpatients) and pain or asthenia (3/140, 2.1% of inpatients and 3/169, 1.8% of outpatients), which prevented them from being completely independent when filling in the questionnaire.

System usability, as measured by the SUS, was above 80 for both inpatient and outpatient groups (mean 86.8, SD 15.8 and mean 83.9, SD 8.9, respectively). Cronbach α was 0.84 (95% CI 0.77-0.88) in the overall sample. On average, the TIQ and DT required more time to be filled in (mean 6.63, SD 5.52 minutes and mean 6.25, SD 4.17 minutes, respectively) compared to the ESAS (mean 3.70, SD 2.79 minutes), as expected due to the different length of the questionnaires.

Figure 3 shows the repeated administration of ePROMs among outpatients who underwent at least 1 follow-up visit (n=225). The maximum number of completed questionnaires was 6 (including baseline ePROMs) of a total of maximum 7 visits recorded for this study, with 76.9% (n=173) of the overall follow-up ePROMs filled out.

Qualitative Results

Sociodemographic Characteristics of Participants

A total of 19 one-to-one interviews were conducted. Participants' age ranged from 35 to 78 (mean 57, SD 12.63) years, 10 (53%) were female, and 11 (58%) had completed secondary education. In total, 9 (47%) participants completed the DT, 8 (42%) completed the ESAS, and 4 (21%) completed the TIQ and pain scales. Some participants completed repeated ePROMs.

Attitude Toward ePROMs and Barriers to Successful Implementation

Participants were generally satisfied with ePROM administration and had positive attitudes toward their use in routine oncology practice. Many of their comments focused on the benefits of ePROMs, including improvement of quality and personalization of care through a holistic approach, increased chances of talking about their symptoms over time, increased awareness of both clinicians and patients about symptoms in real time, aid in rapidly detecting abnormal parameters, and perception to be engaged in scientific research.

Five key dimensions emerged from thematic analysis, relating to potential barriers to successful implementation of ePROMs in routine oncological care. The dimensions are reported in Table 4 alongside significant quotes from patients.

Table 4. Summary of dimensions identified from patient interviews (qualitative substudy C).

Barrier	Illustrative quotes
1. Skepticism toward ePROM[a] use during consultation with health care professional	• "...The way I see it, even the doctor or whoever is visiting you, that is, if he has to study your medical record, read your questionnaire, in one day he has so many patients, that is, it becomes a bit complicated to receive..." [Interview 18, male, 43 years old]. • "It doesn't help anybody. Because often it can happen, so we make a lot of papers, we put a lot of news...On the tablet, on the patient's health record...But if they are not read...They remain a dead letter, as they say, nobody needs them" [Interview 2, female, 74 years old].
2. Skepticism toward ePROMs as tools to examine symptoms	• "(The questionnaire is) very general...We should go into the specifics, everyone has different symptoms according to their history, their life, their way of living and everything...I mean...To their way of living" [Interview 10, female, 72 years old]. • "Definitely a self-limited questionnaire, in the sense, with specific questions, with closed answers, therefore it can be filled in...details should be provided, if necessary. If one feels compelled to write something else, related to each of these issues, the possibility of further compilation could be considered" [Interview 13, male, 38 years old].
3. Cognitive difficulties	• "In fact, the first time...I was wrong, because I went to the right, because...I gave 'No pain = 10', meaning I don't have any. And instead, she told me 'No, look, 10 is the worst'. Well, I hadn't looked closely, I had looked here...I hadn't understood, do you see?" [Interview 11, female, 61 years old]. • "I assumed that at first glance I would have said, probably because of the professional deformation I have...that 0 was the minimum and 10 the maximum. Instead, in some situations it is the opposite...That is, I didn't stop to think that no pain was zero and maximum pain was 10. I said, 'no pain, OK no pain, 10!'. Because I was fine, you know?" [Interview 1, female, 65 years old].
4. Technological issues	• "I'm bad with technology, so I'll tell you, sometimes I mess up so much with the phone that half is enough and so others always have to step in, but whatever." [Interview 4, female, 78 years old]. • "Paper for me is always better...a book for me is a paper book...when I feel paper...I like it! Then at home we have tablets, we have computers, we have everything...but...it's always nice to be able to write...I like it..." [Interview 3, male, 66 years old].
5. ePROMs as time-consuming tasks	• "Yes, it's counterproductive...And then it makes people feel less inclined because the person is there for the visit, not to fill out the form...The form is given to him, he fills it out, but if it takes half an hour to fill out the form when the visit was scheduled at two o'clock and he goes in at half past two he's upset...Because he's wasting time and because it's not correct in short" [Interview 6, male, 59 years old].

[a]ePROM: electronic patient-reported outcome measure.

The five key dimensions are as follows:

1. Skepticism toward ePROM use during consultation with HCPs: During the interviews, several participants complained that their ePROM results were not discussed or even mentioned during the clinical encounter. As a result, many patients doubted that clinicians had consulted their responses likely because of time pressure and work overload.
2. Skepticism toward ePROMs as tools to examine symptoms: Some patients criticized the use of a questionnaire based on close and structured questions to explore their health status and well-being, as these are dimensions that should be investigated through more flexible tools, that is, open questions also including descriptive comments.
3. Cognitive difficulties: Several participants, mostly among those who were asked to complete the TIQ and pain scale, mentioned problems to fill out the questionnaire due to the perceived complexity of the scales.
4. Technological issues: Patients, although older patients, generally stated that they had no difficulties using the tablets to fill out the ePROMs, with the only exception of 1 person who acknowledged limited digital skills and required direct support from the DCC. Two patients said they had no difficulties with the tablet, but they would have preferred to fill out the ePROMs in paper format.
5. ePROMs as time-consuming tasks: Mentioned by only 1 participant, the time required to complete the ePROMs was perceived as potentially lengthening the waiting time and delaying the visit.

Discussion

Principal Findings and Comparison With Prior Work

This study explored the compliance and feasibility of implementing an ePROM system integrated with the EMR in the clinical management of patients with cancer attending hospital wards or outpatient clinics. Potential patient-related barriers to the routine use of ePROMs were analyzed, collecting both reasons for not filling in and patients' views on the difficulties encountered while filling in the questionnaires.

The results showed good compliance and feasibility both by inpatients and outpatients. Most of them (244/309, 78.9%) were able to fill out the questionnaire without any help in using the device, which suggests that the electronic format was not a major barrier. In support of this, many participants stated that they regularly used smartphones, computers, and the internet, indicating a certain degree of familiarity with technology tools. Besides, system usability scores confirmed that the experience with the ePROM system was more than satisfactory by most of the patients in both clinical settings, and the qualitative results

also point in this direction. Indeed, in planning this project, we chose to use a system for ePROM collection that would facilitate the procedure from the patient's standpoint. Patients neither had to download any app or software nor register or log in via password; instead, they were provided with a tablet ready to fill out the questionnaire. Clearly, more proactivity by the patient would be needed in case of remote ePROM assessment on the patient's own personal devices. In any case, as already highlighted by several studies [19,22,43,44], basic IT literacy remains a prerequisite for electronic assessment, and addressing this issue, especially among older patients, is a priority.

The feasibility for outpatients at follow-up visits was also good: three-quarters of the total number of ePROMs administered after the baseline visit were completed, and more than half of the patients filled in the questionnaire at each consecutive visit, indicating an overall positive attitude toward regular use of health technologies. When interviewed, patients reported several benefits from ePROMs, including actively participating in their health care and improving patient-clinician communication.

Approximately 3 in 4 patients successfully filled in the questionnaire regardless of clinical setting. This is a very positive result considering that the administration of ePROMs took place in the context of a research study, which implies that data can be collected only after going through preliminary procedures concerning patient information, privacy, and consent to participation. If, as recommended, ePROMs were part of routine clinical practice, they would be administered to patients by default just like any other medical test or diagnostic noninvasive procedure.

Feasibility was similar in the 2 clinical settings, but the reasons for not filling in the ePROMs were different. In all 3 hospital wards, the main reason was patient refusal, which was 21.9% (44/201). Unfortunately, we could not collect any further information on refusal because patients were not specifically asked and did not spontaneously explain why they preferred not to participate in the study. Another important reason for not filling in was the language barrier for people not fluent in Italian (9/201, 5%), which, however, could be easily overcome by implementing different languages within the same ePROM to offer questionnaires also to nonnative speaking patients. In contrast to inpatient wards, outpatient clinics showed mainly institution-related reasons for not filling in, with organizational problems significantly affecting the feasibility rate. It is noteworthy that the palliative care outpatient clinic showed the highest feasibility (59/65, 90.8%), probably because in this clinical setting, both clinicians and patients are particularly well trained and accustomed to the use of paper-based PROMs that have been part of routine patient care for decades.

Similar studies exploring the compliance and feasibility of an ePROM system integrated into an existing clinical setting have reported good acceptance of both patients and HCPs [43,45-48], suggesting there is potential to use such instruments to improve the quality of information collected from patients by hospital systems. Yet, some challenges need to be addressed, including the patient-related barriers, which are also reported here (ie, time and cognitive burden upon patients to complete the questionnaires and skepticism toward ePROM use during a consultation with HCP) and are highly dependent on contextual factors. For example, a limitation of this study is that the 2 groups of patients were not administered the same ePROMs. This did not allow to distinguish the effect of the clinical setting (inpatient vs outpatient) from the effect of the type of questionnaires offered to inpatients (DT) and outpatients (ESAS and TIQ) on their different refusal rates. It can be assumed that patients awaiting surgery are less willing to take part in a research project than outpatients. On the other hand, filling in a questionnaire on psychological distress may be perceived as more burdensome than reporting about physical symptoms [49]. However, a combined effect of both these aspects on the higher inpatient refusal rate cannot be excluded.

Patients' perception that ePROMs are not valid tools to explore their own symptoms and well-being and share this information with clinicians has been reported by several studies [3,13,19,22,50]. Therefore, efforts should be made to ensure that patients receive adequate information about the questionnaire they are asked to complete and understand the value of PROM collection.

The time needed to fill out the PROMs and difficulties met in completing some items are also relevant barriers already reported in the literature [19,22,23,46]. Patients with cancer may perceive ePROMs as burdensome, as they see them as additional tests that negatively impact on the time already spent in visits, procedures, and treatments. For some patients, the questionnaire can also be difficult to complete without help, as our results showed, and this can be frustrating. Thus, selecting ePROMs that are both sufficiently informative and not overly burdensome for the patient is a critical aspect for their successful implementation.

Limitations and Future Work

This study has some limitations that should be considered. First, we acknowledge that this study was carried out in a single comprehensive cancer center, and this aspect may limit the generalizability of the results. However, existing evidence recommends that individual clinical settings independently examine local barriers in order to adopt ad hoc solutions [19,22,48,50,51].

Second, our results were obtained in the context of a research study. This implies that, on one side, compliance might be underestimated (patient refusal might be about the clinical study and not about filling in the ePROMs); on another side, feasibility might be overestimated, as data collection with a dedicated nurse might be difficult to replicate in real-world implementations due to lack of resources.

For ePROMs to supplement clinician-reported outcomes with useful information and help in patient's care, they should be efficient, effective, and satisfactory for stakeholders [21,52,53]. The European Society for Medical Oncology guideline recommends that PROMs evaluate outcomes that are clinically meaningful and actionable in the reference population and emphasizes that a single software system with PROM functionalities suitable for any stage of cancer disease would be the optimal solution, although technically challenging. However, evidence supporting the implementation of PROM

systems along the entire cancer trajectory is limited and largely based on studies under highly controlled conditions rather than on real-world data from routine clinical settings [26]. Based on these recommendations, this study contributes real-world evidence to support the integration of ePROMs into the hospital information system for their use in routine oncology practice.

Conclusions

At this feasibility stage, the patient-related barriers reported in this study provide useful information for improving future implementation strategies, which will be aimed to effectively support the routine clinical management and care of patients with cancer. In addition, these findings may be relevant to other organizations willing to implement a systematic use of PROMs or ePROMs in their clinical routines. Finally, current evidence suggests that the creation of a cultural infrastructure that values PROMs, that encourages and instructs HCPs to use these tools routinely, and that actively involves patients in their health care process is a key element in fostering the uptake of PROMs in real-world clinical settings [3,48,51].

Acknowledgments

The authors would like to thank Dr Michela Monfredini for her contribution to data collection. The Patient Voices study group includes GA, Marco Bellazzi, Filiberto Belli, C Borreani, C Brunelli, Giuseppi Capri, AC, Paolo Casali, Paolo Corradini, Filippo de Braud, Anna Maria Foschi, Secondo Folli, Marina Garassino, Lisa Licitra, NN, Chiara Pellegrini, MP, GP, AR, Roberto Salvioni, Pierangelo Spada, Riccardo Valdagni, and E Zito and Fondazione IRCCS Istituto Nazionale dei Tumori-Milano. Abstract

Background: Computer-aided detection and diagnosis (CAD) systems can enhance the objectivity of visual inspection with acetic acid (VIA), which is widely used in low- and middle-income countries (LMICs) for cervical cancer detection. VIA's reliance on subjective health care provider (HCP) interpretation introduces variability in diagnostic accuracy. CAD tools can address some limitations; nonetheless, understanding the contextual factors affecting CAD integration is essential for effective adoption and sustained use, particularly in resource-constrained settings.

Objective: This study investigated the barriers and facilitators perceived by HCPs in Western Cameroon regarding sustained CAD tool use for cervical cancer detection using VIA. The aim was to guide smooth technology adoption in similar settings by identifying specific barriers and facilitators and optimizing CAD's potential benefits while minimizing obstacles.

Methods: The perspectives of HCPs on adopting CAD for VIA were explored using a qualitative methodology. The study participants included 8 HCPs (6 midwives and 2 gynecologists) working in the Dschang district, Cameroon. Focus group discussions were conducted with midwives, while individual interviews were conducted with gynecologists to comprehend unique perspectives. Each interview was audio-recorded, transcribed, and independently coded by 2 researchers using the ATLAS.ti (Lumivero, LLC) software. The technology acceptance lifecycle framework guided the content analysis, focusing on the preadoption phases to examine the perceived acceptability and initial acceptance of the CAD tool in clinical workflows. The study findings were reported adhering to the COREQ (Consolidated Criteria for Reporting Qualitative Research) and SRQR (Standards for Reporting Qualitative Research) checklists.

Results: Key elements influencing the sustained use of CAD tools for VIA by HCPs were identified, primarily within the technology acceptance lifecycle's preadoption framework. Barriers included the system's ease of use, particularly challenges associated with image acquisition, concerns over confidentiality and data security, limited infrastructure and resources such as the internet and device quality, and potential workflow changes. Facilitators encompassed the perceived improved patient care, the potential for enhanced diagnostic accuracy, and the integration of CAD tools into routine clinical practices, provided that

infrastructure and training were adequate. The HCPs emphasized the importance of clinical validation, usability testing, and iterative feedback mechanisms to build trust in the CAD tool's accuracy and utility.

Conclusions: This study provides practical insights from HCPs in Western Cameroon regarding the adoption of CAD tools for VIA in clinical settings. CAD technology can aid diagnostic objectivity; however, data management, workflow adaptation, and infrastructure limitations must be addressed to avoid "pilotitis"—the failure of digital health tools to progress beyond the pilot phase. Effective implementation requires comprehensive technology management, including regulatory compliance, infrastructure support, and user-focused training. Involving end users can ensure that CAD tools are fully integrated and embraced in LMICs to aid cervical cancer screening.

(JMIR Cancer 2025;11:e50124) doi:10.2196/50124

Introduction

Background

In low- and middle-income countries (LMIC), visual inspection with acetic acid (VIA) is a common low-cost method for screening and triage. This method involves applying diluted acetic acid to the cervix during gynecological examination. This induces tissue whitening, which a trained observer assesses to guide the diagnosis. Despite VIA's cost-effectiveness and accessibility, a major limitation is its high subjectivity owing to variability in the training and experience of the observer [1].

With advancements in artificial intelligence (AI), its potential to assist in diagnosis has been extensively explored and investigated [2]. Tools that aid health care providers (HCPs) in detecting diseases and identifying abnormalities are clinical decision support (CDS) systems and, more specifically, computer-aided detection and diagnosis (CAD) systems [3]. In cervical cancer, CAD tools can mitigate the subjectivity inherent in VIA by providing standardized evidence for clinical decision-making [4].

Despite the promising potential of CAD systems, their implementation and sustained use in LMICs are limited, irrespective of the target disease. These barriers include the risk of workflow disruption, dependency on computer literacy, poor data quality, lack of transportability and interoperability (ie, system compatibility), and financial challenges [5]. In addition, frameworks exist to guide the implementation, evaluation, and regulation of these digital health tools [6-10]. However, the lack of harmonization across different entities compounds their development complexity. The technology may not progress beyond the pilot stage because of the previously mentioned reasons—a common phenomenon referred to as "pilotitis" [11].

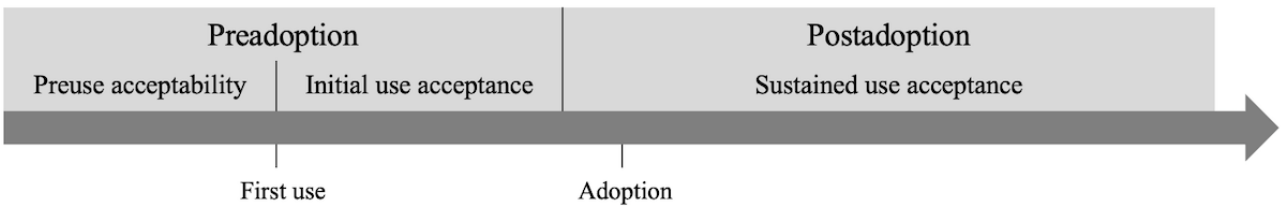
This study examines the barriers and facilitators to deploying a VIA CAD tool to enhance and standardize cervical cancer diagnosis using AI. User perspectives were collected to understand the challenges and enablers of implementing this technology. This study provides insights into deploying AI-enhanced diagnostic tools in LMICs to bridge the gap between technological development and real-world implementation.

Theoretical Framework

In the context of VIA CAD tools for LMICs, the following definitions are used throughout the paper: (1) acceptability: "the quality of being satisfactory and able to be agreed to or approved of," according to the Cambridge Dictionary [12]; (2) acceptance: "general agreement that something is satisfactory or right," as stated by the Cambridge Dictionary [13]; and (3) adoption: "a multiphase process starting with deciding to adopt [a technology] (selecting, purchasing, or committing to use it) and then achieving persistent use," provided by Carroll et al [14].

These 3 concepts are combined in successive steps in the technology acceptance lifecycle (TAL) proposed by Nadal et al [15]. The model (Figure 1) reveals that technology preadoption is a 2-stage process. First, acceptability before use is preuse acceptability, followed by initial use acceptance once the technology has been used for the first time. Postadoption is considered sustained use acceptance, implying that the device is fully adopted and sustainably used.

Figure 1. Technology acceptance lifecycle adapted from Nadal et al [15].



The TAL model was chosen because it captures key factors in the preadoption phase, which is crucial previous to integrating CAD tools in resource-constrained health care settings. Furthermore, the postadoption phase addresses specific barriers, such as infrastructure and data security, while simultaneously supporting sustained adoption and mitigating pilotitis risk.

Objective

This study focused on the challenges perceived by HCPs that would prevent the sustained use of CAD tools for VIA in clinical settings. The primary objective of this study was to identify the common barriers to adopting CAD tools for VIA, and facilitators were the secondary objective. Barriers and facilitators were studied within the framework of the TAL, especially in the preadoption phase. The study was conducted in Western Cameroon; however, the results are critically interpreted for generalizability to other geographical settings within sub-Saharan Africa or other LMICs.

Methods

Overview

This study is reported per the COREQ (Consolidated Criteria for Reporting Qualitative Research; Multimedia Appendix 1) and SRQR (Standards for Reporting Qualitative Research; Multimedia Appendix 2) checklists.

Study Settings and Recruitment

This study was conducted as part of a cervical cancer screening program in the Dschang district, Western Cameroon. A larger study, the 3T program (for test-triage-treatment), was initiated in 2018 at Dschang District Hospital with the support of the Ministry of Health and in collaboration with Geneva University Hospital [16]. This program includes patient recruitment through awareness campaigns in rural and urban areas, tests for HPV, followed by VIA triage (if the HPV test is positive), and treatment, if necessary. The cervical cancer screening was performed by midwives who welcomed the patients, explained the study, conducted the gynecological examination, and, if required, administered treatment. In the case of severe lesions, the patient was treated by a midwife and gynecologist. Within the scope of this program, images were collected during the colposcopy for peer review of the diagnoses and to develop a CAD tool for VIA. This technology relies on image processing and machine learning [17].

Participants were recruited from trained teams at the Dschang District Hospital and the Regional Hospital of Bafoussam, a second 3T program site approximately 60 km east of Dschang. Every HCP in the 3T program is Cameroonian, better to understand the local context and its specific culture. Participants were compensated for their transportation expenses and provided with refreshments during discussions.

Study Design and Procedure

A qualitative methodology was chosen to capture nuances in participants' views, experiences, and behaviors regarding technology and their environment [18]. Compared with a quantitative approach, a qualitative approach provides better insight into participants' perspectives and provides the flexibility required for participants to highlight information they may not have anticipated [19,20].

A mixed approach composed of individual interviews and mini–focus group discussions (mFGDs) was adopted. Individual interviews contributed to in-depth data collection [21], and mFGDs facilitated the exchange of participants' perspectives and the compilation of collective perceptions [20]. The term "mini" denotes the small group size of 3 participants, which was chosen because of the limited availability of individuals with relevant expertise and the sensitivity of the topic, which benefits from an intimate setting [22]. Due to the HCPs' various educational levels, training, and daily duties, the participants were grouped into homogeneous professional mFGDs. The aim was to create a climate of trust, enabling all participants to express themselves freely and reduce authority bias [23].

Therefore, 2 mFGDs, each with 3 midwives and 3 individual interviews with gynecologists, were conducted between March and May 2022. All discussions were moderated in French—the official language—by a female Cameroonian anthropologist who had worked on the 3T program for several years and had intimate knowledge and familiarity with the professional community. During focus group discussions, in which the perspectives of the HCPs were collected at the Dschang District Hospital, a second female Cameroonian anthropologist took notes to capture nonverbal cues and additional context. An individual interview was conducted via videoconferencing because the medical doctor was traveling. The remaining discussions occurred in clinical settings, either in a confidential conference room at the hospital or a private medical office.

Each interview began with an introduction to the CAD tools for VIA, and the procedure was described in detail. The slides supported the verbal explanation and clarified the following steps. During the gynecological examination, the HCP first applied diluted acetic acid to the cervix, corresponding to the routine VIA. Second, cervical images were recorded using a dedicated mobile app. Subsequently, the algorithm integrated into the mobile app processed the sequence of images and provided an analysis to the user. Finally, the HCP interpreted the results to determine whether treatment was necessary. The entire procedure can be conducted offline; nonetheless, internet-based synchronization with a server is also feasible, ensuring data backup and compliance with data privacy and confidentiality requirements.

A mobile app was specifically developed for the demonstration to concretize the concept for the participants. The mobile app allowed users to capture a series of pictures and generate simulated predictions of cervical cancer. The participants could manipulate the mobile app and take pictures of their surroundings to familiarize themselves with CAD tools for cervical cancer. A semistructured questionnaire was then used to (1) investigate HCPs' perceptions of smartphone use for medical applications, cervical cancer, and AI and (2) identify the challenges and facilitators for integrating CAD tools for VIA in clinical settings.

All interview guide questions were fully addressed, and the participants were given opportunities to ask questions. Finally, participants could share their thoughts and comments. All discussions were audio-recorded, transcribed, and anonymized. Triangulation was applied within and across sessions to enhance data reliability.

Data Processing and Analysis

A total of 4 audio recordings were transcribed verbatim in French, categorized, and coded using content analysis [24]. Therefore, coding was initially deductive based on a codebook, guided by the topics outlined in the interview guide, followed by the generation of inductive codes directly from the transcriptions. Around 2 female coresearchers (MJC and AMDM) independently coded transcripts using the computer-assisted qualitative data analysis software (ATLAS.ti, version 22.2.3) to support scientific rigor and reflexivity. The data were double-coded by a researcher from a different cultural context to address the potential reporting bias that could arise from the shared experience between the anthropologist and the HCPs. The coding was then compared, discussed when diverging, combined, and finally assessed for consistency following the open discussion method [25].

The coded data were analyzed to identify relationships between the categories and hierarchically ordered, with the TAL framework applied as a theoretical lens for interpreting the coded data. Data were analyzed with team members from diverse professional and cultural backgrounds. This combination of expertise and cultural insights strengthened the study design and analysis. Data saturation was confirmed through consistent responses across the mFGDs and interviews. Each mFGD was included, and all sessions were audio-recorded while maintaining confidentiality. Suppose quotations were selected for publication; in that case, they were translated from French into English.

Ethical Considerations

This study was approved by the Ethical Cantonal Board of Geneva, Switzerland (CCER, 2017-01110 and CER-amendment no. 4) and the Cameroonian National Ethics Committee for Human Health Research (2022/12/1518/CE/CNERSH/SP). The participants verbally consented after being informed of the study's purpose, topics, duration, benefits, and risks. Participants were compensated for their transportation expenses. All transcripts were anonymized and analyzed in a fully deidentified manner to ensure privacy and confidentiality. The achievement of data saturation, the presence of 2 researchers during the mFGDs, audio recordings, and triangulation of information attest to the rigor and trustworthiness of the data collection and analysis.

Results

Participants

The study involved all HCPs from both 3T program sites, encompassing 6 midwives and 2 gynecologists, of whom 5 were females and 3 were male participants aged 30-55 years. All participants specialized in cervical cancer, with experience between 6 months and over 10 years, providing insights for evaluating the technology across different stages of professional development. They all owned a smartphone, used it daily, and were familiar with smartphone apps in clinical settings through the 3T program. None of the participants dropped out of the study, and the discussion duration was 42-92 minutes.

Main Results

HCPs' perceptions of adopting a CAD tool for VIA were mainly positive. The HCP highlighted 8 facilitators and 5 barriers that should be addressed in the future.

The barriers were:

- Restriction of the HCP's movement due to the smartphone's position.
- Constraining requirements for the image quality.
- Confidentiality concerns for sensitive data, especially in case of data breach.
- Workflow changes may encourage HCPs to heavily depend on the technology.
- Limited access to internet connection and smartphones.

The facilitators were:

- Improved patient care through rapid and reliable diagnosis.
- Improved diagnosis.
- Reduced workload because of improved efficiency.
- Reinforcement of visual inspection with acetic acid (VIA) protocol.
- Clinical evaluation of the technology in conditions reflecting real-life conditions.
- Automated assessment of image quality.
- Training of the users.
- Provision of smartphones and tripods.

Barriers to CAD Tools for VIA

System Usability Challenges

The smartphone was positioned on a tripod between the gynecological chair and HCP to capture the images. This positioning restricted the movement of professionals during the examination.

> *When pipetting [acetic acid] and the whole cervix is not captured on the smartphone but the recording already started, then we need to twist and turn to finish. For those difficulties, we could pull the trip away, pipet to remove all the acetic acid well, and then position the device.* [P6]

In addition, image quality requirements entail acquisition conditions that are difficult to achieve. These quality assessment criteria can be affected by video movements, light changes, reflections, and the presence of blood or mucus. Furthermore, some HCPs raised concerns that the high-quality images required for an accurate diagnosis would be difficult to achieve, possibly leading to misdiagnosis.

> *[…] So that artificial intelligence provides an accurate result, one will need to fulfill all acquisition conditions. It means that if you make a small mistake in the process, the risk of a false positive or false negative will be high […]* [P2]

Confidentiality

Most HCPs expressed apprehension regarding the handling and storage of sensitive data. Their concerns revolved around potential breaches of medical data confidentiality and the unauthorized sharing of VIA images. Furthermore, they feared

the loss of images due to the misfunctioning or mishandling of smartphones.

> *[…] If I send a picture to someone, they can easily forward it to someone else without asking my permission. There were so many scandals in the field of medicine because someone took a picture with their smartphone, which was shared multiple times and leaked […]* [P8]

An HCP emphasized that framing the picture around the cervix alone can aid confidentiality concerns because it is anonymizing.

> *When using a smartphone to take photos of the cervix, it is beneficial as long as it preserves the woman's privacy by capturing solely the cervix. That way, the woman cannot feel frustrated about her face potentially being seen elsewhere.* [P2]

In addition, using a private mobile phone to take pictures during the gynecological examination was not allowed. The device should be dedicated to only clinical settings and not leave the screening area.

> *[…] the personal mobile phone is never fully private… when you drop it at home, kids may search into it and access the image […] Personally, I believe the mobile phone used needs to be professional only and to stay at the screening site, never reaching someone's home […]* [P8]

Workflow Changes

Several HCPs were concerned that the adaptation of the device might change the workflow, and users might heavily depend on CAD tools, neglecting their expertise. An HCP explained:

> *For me, and my colleagues, if this device is given to medical doctors, they might become lazy. They will not have to do their work fully. As soon as there is a case, they would take the smartphone and would not think about the diagnosis themselves.* [P1]

Therefore, their gynecological knowledge might be affected, possibly limiting patient care in complicated cases.

Limited Infrastructure and Resources

Another challenge regarding adopting the technology is the limited access to resources. Some HCPs were concerned about access to reliable internet connections and smartphones, along with their quality. The wear of the smartphone battery was also a concern.

> *[…] Everyone cannot access a smartphone, everyone cannot access the internet […]* [P8]

Facilitators of CAD Tools for VIA

Patient Care Improvement

Most HCPs agreed that the technology would improve patient care by providing a rapid and reliable diagnosis. According to them, accelerating the diagnosis speed benefited the patients and HCPs. First, patients would not return home with unanswered questions and directives to wait, which could induce stress and unnecessary worry.

> *They [patients] will accept the technology since when coming out of here [the hospital], they will know their diagnosis; they will think, 'They told me that I come back home with a clear head, not like before when I came and I had to wait for a phone call with the results […]* [P3]

Second, the technology could help HCPs provide a diagnosis or mitigate the lack of resources for conducting biopsies. Some professionals also believed that the workload could be reduced using technology that would enable the screening of more women for cervical cancer.

Furthermore, some HCPs mentioned that adopting a CAD tool for cervical cancer could enhance diagnosis by identifying lesions that are challenging to detect with the human eye. This can reduce the potential for human error.

> *If it is efficient, then it would be a very important tool because visual inspection is now very subjective. But if we manage to generate a diagnosis from a simple image, that would be a very good progress.* [P7]

This technology may also reinforce the protocol for performing appropriate VIA. For example, the predetermined duration of the recording constrains the user to wait until the recording is completed. Diagnosis improvements may also reduce the rate of overtreatment, which is currently considered crucial, as illustrated by one of the HCPs.

> *[…] in the approach to screen and treat, we are afraid, on the one hand, not to treat someone who should have, until the point it develops into a cancer. On the other hand, we may treat someone who did not need it, which is called overtreatment, but if we have this technology helping, then we will win in both cases […]* [P7]

Clinical Evaluation

Before this technology can be used in clinical settings, approval and validation by health care professionals is required. This implies comparing the technology's diagnosis in real conditions and that of HCPs, histopathology results, and a usability study regarding the tool's features and interface. The HCPs confirmed the need to validate the technology because they were concerned about its performance and their ability to distinguish accurate diagnoses from misdiagnoses.

Automated Assessment of Image Quality

Some HCPs apprehend that automating the technology would induce misdiagnosis and false-positive and false-negative predictions because of cervical abnormalities such as blood, mucus, and benign lesions. Therefore, an automated pipeline for assessing image quality was indicated as an essential technological feature preventing misdiagnosis by not allowing the application of the algorithm to images that are of extremely low quality or ineligible.

> *For instance, we could have a feature that gives us an ok when all acquisition criteria are fulfilled and that the analysis of the images can be conducted. Or, if criteria are not fulfilled, then there would be a*

message telling you not to launch the analysis and to, maybe, retake images. [P4]

Training and Resources Provision

The participants highlighted the importance of comprehensive training on properly using the CAD tool for its clinical adoption. In addition, resources such as smartphones and tripods are required for effective implementation.

[…] One needs to ensure that the user of the technology is well trained to create conditions allowing the capture of a good image because… bad acquisition conditions result in bad image quality. [P7]

Discussion

Principal Findings

This study identified 4 barriers and 4 facilitators each to adopting CAD tools for VIA during the preadaptation phase of the TAL model (Figure 1), either related to preuse acceptability or to initial use acceptance (Table 1). These included structural components such as limited infrastructure, confidentiality, data management, and personal factors such as workflow changes and user interaction with the CAD tool. HCPs emphasized the overall benefits, including improved patient care through better clinical evaluation, enhanced training, and technical advantages, such as ease of use of the system. The following section discusses the barriers and facilitators identified in both phases, contextualized within this literature, and highlights the barriers observed in previous studies but not encountered in this one.

Table 1. Synthesis of principal findings under the preadoption phases of the technology acceptance life cycle.

	Preuse acceptability	Initial use acceptance
Barriers	• Confidentiality and data management • Limited infrastructure and resources	• User interaction • Change in workflow
Facilitators	• Patient care improvement • Training	• Clinical evaluation • Ease of use

Barriers to Preuse Acceptability

Confidentiality and Data Management

Confidentiality concerns were highlighted as a significant factor affecting pre-use acceptability. HCPs expressed reservations about data loss and breaches and the acquisition of cervical images with smartphones. Patients also expressed concerns about the image frame. However, these concerns are not specific to the use of AI but are raised by the use of digital, sensitive images. Lodhia et al [26] observed that assuring patients of confidentiality was crucial to their mHealth intervention study for eye care in Kenya and recommended a robust data protection system. Prioritizing confidentiality, incorporating a secure data management system, and transparent communication about security measures are essential for alleviating privacy concerns and building trust among HCPs and patients. Practically, some HCPs have suggested showing the acquired data to patients to reassure them about the content of the images.

Limited Infrastructure and Resources

A lack of infrastructure and resources can affect the preuse acceptability of CAD tools for VIA in cervical cancer. Equipping HCPs with the necessary devices (such as smartphones and tripods) and ensuring regular maintenance of the devices is essential for limiting technical challenges and providing uninterrupted and effective health care services to patients.

Limited access to reliable internet connections, smartphone quality, and smartphone battery wear concerns during prolonged use have been highlighted as barriers by HCPs. These challenges align with findings from the existing literature in which infrastructure-related challenges have been identified in other health care settings. A study by Elahi et al [27] on a CAD tool for traumatic brain injury in Uganda emphasized the importance of internet connection and the associated costs. Spence et al [28] and Knoble and Bhusal [29] reported reliable electricity as a key challenge in the studies of childhood pneumonia diagnostic tools and electronic diagnostic algorithms.

A viable solution to overcome internet-related constraints is developing a CAD tool that can function offline. Internet access might be occasionally needed for maintenance, updates, and data sharing or backup; however, the device would provide CDS, irrespective of internet coverage and connectivity. In addition, ensuring access to electricity is essential to keep the smartphones charged. Therefore, adopting good practices, such as switching off the device at night or when it is not in use for several days, can help preserve battery life. Furthermore, optimizing the CDS algorithm to minimize smartphone power consumption can contribute to its ease of use without frequent recharging. By implementing these strategies, HCPs can confidently use CAD tools, even in remote areas with limited internet access and electricity.

Facilitators for Preuse Acceptability

Patient Care Improvement

CAD tools for VIA have diverse benefits that may contribute to improvements in cervical cancer screening and diagnosis [30]. A key advantage is rapid and reliable diagnosis, which reduces waiting time for patients who can receive test results and treatment in a single appointment. This point-of-care

approach can enhance patient satisfaction and positively impact mental health by providing a timely, near–real-time diagnosis [31]. In addition, this technology serves as a valuable supplementary test, assisting HCPs and making the diagnostic process less subjective. This technology limits cases of overtreatment and mitigates the risk of unnecessary treatment-related complications, such as pregnancy-related morbidity, by enhancing diagnosis accuracy [32].

Training

Comprehensive training is essential for users to understand and use the technology accurately. HCPs should not rely solely on the suggested diagnosis but use it as an assistive device that provides supplementary evidence to be considered in addition to their clinical knowledge and experience. Training must be tailored to the specific contexts of use and encompass geographical, cultural, and educational considerations [33]. The objective is to equip users with the ability to comprehend, interpret, and integrate recommendations from CAD tools into their decision-making processes.

Barriers to Initial Use Acceptance

User Interaction

The initial acceptance of the system can be hindered by difficulty in use. Demanding acquisition conditions are challenging for HCPs to comply with, potentially hindering technology adoption. The CDS algorithm requires adherence to specific acquisition conditions to address issues, such as movement, light, and mucus or blood in the cervix. The HCPs suggest that this could be facilitated by an automated quality assessment pipeline that assesses image quality in real time and provides immediate feedback to users, indicating whether the image quality is sufficient. Such a process could assess the visibility of the cervix, monitor movement, detect blurriness, or detect external objects (eg, pipettes).

Beyond the acquisition process, interaction with the device must be satisfactory to the HCPs. Knoble [29] conducted a comprehensive study on electronic diagnostic algorithms in Nepal and uncovered that HCPs found the device's size too small and the touchscreen sensitivity too low. This highlights the importance of considering all usability aspects while developing the technology and iteratively testing it with users.

Workflow Changes

Potential changes in the HCPs workflow also need to be assessed because they could hinder the initial acceptance of CAD tools for VIA [34]. Furthermore, a few HCPs expressed concerns about the risk of neglecting their expertise because of heavy reliance on the new technology. This observation is consistent with current literature. Despite the potential educational purposes of AI-driven CDS tools, the tendency to rely heavily on automation, described as automation bias, has been highlighted by Khera et al [35]. Furthermore, Jabbour et al [36] observed a decline in diagnostic performance when clinicians used AI support, even when visual explanations of AI-driven diagnoses were provided.

Introducing a novel technology can also increase the workload during the initial learning phase. Melas et al [37] observed that reduced time consumption was a vital factor influencing clinicians' intentions to adopt it. In contrast, Ellington et al [38] reported that HCPs need to practice using technology before using it with patients to improve efficiency. This preparatory practice would allow HCPs to become familiarized with the technology's functionalities and workflows, ensuring a smoother and more efficient integration of the technology into their clinical practice.

Facilitators for Initial Use Acceptance

Clinical Evaluation

The technology should undergo rigorous evaluation to assess its clinical and cost benefits to ensure initial use acceptance and foster sustained use acceptance [9]. The tool's performance can be evaluated using metrics such as sensitivity, specificity, accuracy, and false-positive rate. Evaluating the efficiency of the device and its integration into patient care contributes to assessing its clinical benefits. This involves examining the clinical utility of the technology, its compatibility with specific clinical settings, and its impact on patient outcomes. In addition, a user-centered design highlights the importance of user feedback for validating the technology, particularly its interface, features, and ease of use [39]. Cost benefits should also be assessed by estimating cost savings and implementation costs, including initial setup, training, and maintenance costs.

Laka et al [40] highlighted that evaluation frameworks should consider the dynamic nature of clinical settings and CDS (eg, through software updates). However, such devices need to be continuously monitored to ensure their safe and effective integration in clinical settings [41]. Papadopoulos et al [42] illustrated this challenge in a systematic literature review, revealing that only a few studies included "any form of evaluation," with often insufficient methodologies.

Ease of Use

In addition to facilitating the acquisition and quality assessment processes, simplicity in using CAD tools is crucial for their successful adoption in clinical settings [28]. Panicker et al [43] indicated that easy-to-use CAD tools save time because of their simple operation, fast access, effective recording, and information retrieval. These features contribute to the perceived usefulness and potential for extensive system adoption in clinical practice.

Comparison to Previous Studies

The barriers identified mostly align with those in the existing literature. However, these studies also reported barriers not mentioned by the participants of this study.

A common barrier highlighted in the literature is the limited resources to finance the technology, cope with increased diagnosis, and provide follow-up and treatment when necessary [26-28,44]. In the 3T program, external funding covers all costs, including salaries, clinical materials (gloves, speculum, acetic acid, etc), equipment (smartphone, tripod, etc), and patient travel cost compensation, eliminating immediate financial constraints.

Another barrier emerging from the literature, but not specifically addressed in this study, is the risk of mobile device theft [26].

This could be a relevant consideration in less controlled settings. Community and political support are also lacking in the literature [38,43]. The 3T program receives support from the Health Ministry, albeit financed through foreign grants.

The literature indicates a lack of user experience or skill (ie, phone literacy) as a potential barrier, even though the participants were comfortable handling smartphones [26,29,38,43]. This may result in misuse or an increased workload. In the 3T program, all HCPs follow comprehensive training, ensuring their proficiency in using the technology.

In summary, the absence of these barriers identified in the international scientific literature but not encountered in the 3T program might be attributed to the specific context and controlled environment provided by the program, as well as the active involvement of the study participants in it.

Further Recommendations

The World Health Organization (WHO) proposes 3 main solutions for barriers to the general use of medical devices [45]. First, the technology should be designed to fit the context of use. Second, the device system should be managed comprehensively, including its regulatory aspects, installation, maintenance, and monitoring. Finally, professionals need to be trained for proper use, maintenance, and presentation to patients. In alignment with the WHO recommendations to avoid pilotitis, this study identified barriers and facilitators to integrating CAD tools for VIA in cervical cancer diagnosis.

Addressing specific barriers to deploying CAD systems involves the fundamental element of trust. Patients and HCPs must trust the technology to ensure its successful implementation and sustained use. Trust might motivate HCPs to integrate CAD systems into their workflows and enhance patients' acceptance and comfort through a diagnostic process facilitated by CAD tools.

Trust can be built by involving users from the outset of technological development and integrating their feedback. Early engagement allows the understanding of their specific needs and ensures that the technology addresses relevant challenges. Involving various user profiles (eg, profession, degree, and working experience) from different clinical settings introduces a range of perspectives that can be leveraged to tailor the technology to diverse contexts.

In addition, providing evidence of the technology's trustworthiness is key to building trust [46]. Explainability, which makes the decision-making process of the technology transparent and understandable to users, builds confidence in its reliability. Traditionally, CDS are knowledge-based and rely on medical literature and conditional logic [47]. This approach tends to be more transparent than the current AI-leveraged CDS systems. Comprehensive training further reinforces trust for knowledge- and AI-based CDS by ensuring the appropriate use of the technology through stepwise instructions and presentation of its limitations.

The TAL framework provides valuable perspectives on the current stages of technological adoption. However, it should be considered as an iterative tool, acknowledging that perceptions and acceptance may evolve as the technology progresses. Continuous monitoring of these changes is essential to ensure the successful adoption and use of CAD tools for VIA in clinical practice.

Strengths and Limitations

To our knowledge, this is one of the first studies in sub-Saharan Africa that investigates the adoption of CAD tools for cervical cancer from the perspective of HCPs. The various professional backgrounds of the participants, years of experience in cervical cancer screening, and sex allowed us to gain in-depth insights into the barriers and facilitators present during the preadaptation phase.

The qualitative method allowed for collecting different perspectives; however, several limitations were observed. First, the study involved a limited number of nonrandom samples of participants familiar with the use of smartphones for cervical cancer diagnosis. In addition to potential selection bias and limited generalizability, mini–focus groups have been acknowledged in the scientific literature, especially among participants with intense experience with a topic, which was the case in our study, allowing for a more in-depth discussion [48]. The mFGDs were complemented by individual interviews to capture a wider range of perspectives and mitigate this bias. Second, the study was conducted in a controlled program in Western Cameroon, which may not reflect other settings with varying resources and infrastructure. Therefore, we recommend replicating the study in other contexts for broader validation. Third, this study focused on HCPs; however, patient perspectives, crucial for understanding technology adoption, were not included but addressed in a separate study [49]. Finally, barriers can be attributed to the use of CAD tools or smartphones. This study was conducted during the preadaptation phase; however, the technology and user attitudes have evolved. Iterative research is needed to determine whether factors can be attributed to specific digital tools and capture changing perceptions after implementing the CAD tool.

Some of the encountered barriers (such as workflow changes) might be addressed through adaptation and facilitator reinforcement (such as training); therefore, the findings of this study provide a crucial foundation for future work. In summary, further qualitative and quantitative studies should be conducted among HCPs with less smartphone experience and in various clinical settings to enhance the generalizability of findings and guide tailored strategies for implementing CAD tools in cervical cancer diagnosis.

Conclusions

Interviewing HCPs from various backgrounds with diverse working experience—midwives and gynecologists—was essential to better understand their concerns, perceptions, and expectations regarding a CAD tool for cervical cancer and to avoid "pilotitis."

Even if a CAD tool is designed to fit its context of use perfectly, understanding the barriers and facilitators is key to its successful implementation and use. In this study, the CAD tool was appreciated by the HCP for its ease of use and crucial role as an assistive device to improve patient care and support clinical

decisions. The barriers encountered (confidentiality and data management, limited infrastructure and resources, workflow changes, and user interaction) are specific to the study setting and might vary with the context. However, these challenges can be addressed in line with the WHO recommendations [40] by ensuring proper management of the technology (eg, regulation and maintenance) and involving the end user at every step of developing the solution. HCPs will help define the appropriate way of introducing new technology to patients and their peers, as well as how to train them for proper use. These measures aim to derisk the deployment of the technology and contribute to overcoming pilotitis.

Acknowledgments

The authors would like to thank all health care providers (HCPs) who dedicated some of their time to discussing with anthropologists from the project. This work was supported by the Swiss Federal Institute of Technology Lausanne through its Programme Tech4Dev.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to confidentiality and privacy concerns but from the corresponding author on reasonable request.

Authors' Contributions

All authors contributed to the conceptualization and design of the study. The methodology was developed collaboratively by AMDM, MJC, and NCS. For the investigation, AMDM conducted participant recruitment and data collection, while VFY attended the mini–focus group discussions and took notes. In terms of data curation, AMDM and VFY transcribed the audio recordings. The formal analysis and interpretation of the data were carried out by MJC, AMDM, and NCS. MJC wrote the original draft, while all authors contributed to reviewing and editing multiple versions of the paper.

Abstract

Background: Cancer is a life-threatening disease and a leading cause of death worldwide, with an estimated 611,000 deaths and over 2 million new cases in the United States in 2024. The rising incidence of major cancers, including among younger individuals, highlights the need for early screening and monitoring of risk factors to manage and decrease cancer risk.

Objective: This study aimed to leverage explainable machine learning models to identify and analyze the key risk factors associated with breast, colorectal, lung, and prostate cancers. By uncovering significant associations between risk factors and these major cancer types, we sought to enhance the understanding of cancer diagnosis risk profiles. Our goal was to facilitate more precise screening, early detection, and personalized prevention strategies, ultimately contributing to better patient outcomes and promoting health equity.

Methods: Deidentified electronic health record data from Medical Information Mart for Intensive Care (MIMIC)–III was used to identify patients with 4 types of cancer who had longitudinal hospital visits prior to their diagnosis presence. Their records were matched and combined with those of patients without cancer diagnoses using propensity scores based on demographic factors. Three advanced models, penalized logistic regression, random forest, and multilayer perceptron (MLP), were conducted to identify the rank of risk factors for each cancer type, with feature importance analysis for random forest and MLP models. The rank biased overlap was adopted to compare the similarity of ranked risk factors across cancer types.

Results: Our framework evaluated the prediction performance of explainable machine learning models, with the MLP model demonstrating the best performance. It achieved an area under the receiver operating characteristic curve of 0.78 for breast cancer (n=58), 0.76 for colorectal cancer (n=140), 0.84 for lung cancer (n=398), and 0.78 for prostate cancer (n=104), outperforming other baseline models (*P*<.001). In addition to demographic risk factors, the most prominent nontraditional risk factors overlapped across models and cancer types, including hyperlipidemia (odds ratio [OR] 1.14, 95% CI 1.11 - 1.17; *P*<.01), diabetes (OR 1.34, 95% CI 1.29 - 1.39; *P*<.01), depressive disorders (OR 1.11, 95% CI 1.06 - 1.16; *P*<.01), heart diseases (OR 1.42, 95% CI 1.32 - 1.52; *P*<.01), and anemia (OR 1.22, 95% CI 1.14 - 1.30; *P*<.01). The similarity analysis indicated the unique risk factor pattern for lung cancer from other cancer types.

Conclusions: The study's findings demonstrated the effectiveness of explainable ML models in assessing nontraditional risk factors for major cancers and highlighted the importance of considering unique risk profiles for different cancer types. Moreover, this research served as a hypothesis-generating foundation, providing preliminary results for future investigation into cancer diagnosis risk analysis and management. Furthermore, expanding collaboration with clinical experts for external validation would be essential to refine model outputs, integrate findings into practice, and enhance their impact on patient care and cancer prevention efforts.

Introduction

Cancer is a life-threatening disease and leading cause of death worldwide. In 2024, 611,000 people were estimated to have died from cancer in the United States, and the estimated new cancer cases will reach more than 2 million for the first time [1]. This surge includes rising incidence rates for major cancers, including breast, prostate, lung, and colorectal cancers, which display the trend of increasingly affecting younger individuals who have many more years of life expectancy [1]. The US Preventive Services Task Force modified the recommended age for colorectal cancer screening from 50 to 45 years for people at average risk in 2021 and adjusted the recommendation for breast cancer screening for all women to start at the age of 40 years in 2024 [2,3]. Similar upward trends in the incidence of early-onset cancers are observed in other high-income countries, suggesting shared risk factors and exposures across these regions. However, besides those uncontrollable risk factors, such as previous cancer diagnosis, family history of cancer, and genetics or inherited cancer syndrome, many cancer risk factors, including lifestyle factors, are modifiable and can be managed to decrease people's risk for cancer [4].

Extensive evidence highlights the potential benefits of early identification of individuals at high risk for cancer, which can contribute to improved prevention, more effective treatment, reduced cancer burden, and better long-term outcomes. However, demonstrating a clear survival advantage [5] from screening remains challenging, with notable exceptions such as cervical cancer [6]. It is essential to address biases like lead-time and length bias in screening, as they can overestimate its benefits, ensuring accurate evaluations [7]. In the context of breast cancer, it was estimated that early access to treatment services following breast cancer screening could have reduced breast cancer mortality by 25% - 40% [8]. Given the tremendous benefits of early identification of high-risk patients, an increasing number of cancer risk prediction models have been developed [9]. However, Traditional models used for cancer risk prediction, such as logistic regression (LR) and Cox regression, often demonstrate moderate discrimination accuracy, with an area under the receiver operating characteristic curve (AUC) ranging from 0.53 to 0.64 [10-13]. These models frequently emphasize family history and may have limited generalizability, potentially introducing biases when applied to specific subpopulations [14,15]. Furthermore, nontraditional risk factors, such as chronic diseases, are often overlooked, despite evidence suggesting that chronic conditions can elevate cancer risk similarly to lifestyle factors [16]. This highlights the need for more advanced methods to enhance cancer diagnosis risk prediction and support effective cancer prevention strategies.

Machine learning has shown promising potential in cancer prediction by leveraging electronic health record (EHR) data to identify risk factors [17]. Current applications range from developing predictive models for early cancer detection to personalized treatment recommendations and outcome predictions, based on various patient characteristics and biomarkers. Despite these advancements, several challenges remain in cancer prediction using machine learning [18]. A key issue is the need for a deeper understanding of risk factors within and across different cancer types [19]. As research progresses, explainable machine learning offers a meaningful step forward in improving the efficacy and transparency of predictive models [20-22]. These models not only enhance predictive accuracy but also provide interpretable insights into how predictions are made, fostering trust and facilitating clinical decision-making [23]. By systematically identifying and excluding irrelevant features, explainable approaches can reduce noise and streamline the prediction process. However, it is important to recognize that feature selection algorithms can be sensitive to dataset characteristics, where small changes in the data may lead to differing results [24]. This underscores the importance of carefully selecting features that are most relevant, contributing to a deeper understanding of cancer diagnosis risk factors and improving predictive performance.

Hence, this study presented comprehensive research aimed at uncovering the association between pivotal factors and the risks of 4 major cancer diagnoses (breast, prostate, lung, and colorectal) through the use of explainable machine learning techniques on penalized LR, random forest (RF), and multilayer perceptron (MLP). Our primary objective was to pinpoint the significant features that exert an influence on the risks associated with the diagnosis of these major cancers and to delineate the patterns of risk factors corresponding to each cancer type. Such insights can contribute to enhanced risk monitoring and patient stratification and provide valuable support for clinicians in their decision-making processes, ultimately improving the quality patient care. By elucidating these critical factors and their associated risk factor patterns, we provided clinicians valuable insights through rigorous analysis for enhancing risk monitoring and patient care across various cancer types.

Methods

Experimental Dataset

Our study was conducted using data from Medical Information Mart for Intensive Care (MIMIC)–III, a comprehensive, structured, longitudinal EHR dataset that is publicly available [25]. This dataset contains deidentified, detailed clinical data from intensive care unit (ICU) admissions between 2001 and 2012 at Beth Israel Deaconess Medical Center in Boston, Massachusetts, and is accessible to the global research community under a data use agreement. We used the most recent version (v2.0 released in January 2023) for this work which contains a broad spectrum of data, including information on individual patients' health and health care from various inpatient and outpatient visits, such as diagnoses, prescriptions, lab tests, and procedures. These visits include emergency room admissions and subsequent hospital transfers, where a patient's transfer to a ward or subsequent re-admission to the ICU within the same hospitalization period was considered a single visit. In total, this dataset contains 58,976 admissions of 46,520 patients.

Additionally, we investigated the health status and prevalence of a few common chronic diseases for the MIMIC-III dataset, compared with the prevalence of these chronic diseases in the US population. The MIMIC-III dataset shows that hypertension

affects 47.97% of ICU patients, while in the US population, prevalence ranges from 46.9% to 49.4% [26,27]. Diabetes mellitus is present in 21.20% of MIMIC-III patients, whereas it affects 11.6% of the US population and 14.7% of adults [28]. Hypercholesterolemia appears in 14.94% of ICU cases, with US estimates between 10% and 11.4% [29,30]. Congestive heart failure is recorded in 27.38% of MIMIC-III patients, while the lifetime risk in the US is 24% [31]. Esophageal reflux affects 15.33% of ICU patients and 20% of people in the US [32]. Pneumonia is diagnosed in 12.46% of ICU patients, while 24.9% of US adults have reported cases [33]. Anemia affects 14.02% of ICU patients, while 5.6% of the US population has the condition [34]. Acquired hypothyroidism is observed in 10.71% of MIMIC-III patients and 4.6% of US adults [35]. Tobacco use is recorded in 7.76% of ICU cases, while 19.8% of US adults report smoking [36]. Depressive disorders affect 8.17% of ICU patients, while 9.5% of American adults have been diagnosed [37]. Chronic airway obstruction is reported in 10.24% of MIMIC-III cases, while national estimates range from 6.0% to 6.1% [38].

Data Preprocessing

We included patients with 4 types of cancers (breast, colorectal, lung, and prostate) identified using *International Classification of Diseases, Ninth Revision* (*ICD-9*) codes associated with the diagnosis of each type of cancer (Table S1 in Multimedia Appendix 1).

We took a few steps to preprocess the experimental dataset, starting with the consolidation of 3 main tables from the MIMIC-III database. These included: (1) foundational patient information, capturing demographics and initial hospital admission data; (2) a reference table for *ICD-9* codes, detailing both codes and corresponding diagnostic labels; and (3) logs of patient visit sequences with associated *ICD-9* codes. This consolidation linked the records via patient IDs to construct a detailed longitudinal dataset. Figure 1 illustrates the data processing workflow of this study. Patients' ages were determined by deducting their date of birth from their initial hospital admission date, with the result rounded to the nearest year. Any patient records missing demographic details (such as ethnicity, marital status, or religion) were omitted, narrowing the dataset to a total of 21,372 unique individuals. Our study focused on patients who had multiple hospital visits prior to their cancer diagnosis presence in the record to identify potential risk factors. After a cancer diagnosis code was recognized, further visits were disregarded. These records were combined with those of patients without a cancer diagnosis. A label was created as 1 if a visit included an *ICD-9* code for a cancer diagnosis and 0 if not. To ensure a balanced dataset in terms of cancer diagnosis, the study matched patients diagnosed with cancer with those without cancer using propensity score matching based on demographic factors. Table 1 contains a detailed description of patient characteristics for 4 cancer types.

Feature Selection

Our experiment’s initial dataset comprised thousands of diagnosis codes intended for predicting cancer diagnosis risk. Aware of some features’ potential redundancy and less informative nature, we did a feature selection process. This involved assessing the relevance and importance of each feature in relation to 4 specific types of cancer. We performed a correlation-based feature selection process to identify a subset of features that were highly correlated with the target cancer outcomes. This was followed by a thorough review of relevant literature and consultation with experts to validate and refine the selected features.

Framework

In this work, we applied 3 advanced models, penalized LR, RF, and MLP, based on their demonstrated accuracy and robustness in handling high-dimensional datasets. RF and MLP excel at identifying complex, nonlinear interactions among variables without requiring predefined interaction terms. This capability is crucial for analyzing interactions between risk factors and cancer outcomes. Our choice of RF and MLP was determined by a desire to balance complexity with interpretability, as well as to ensure computational efficiency. Both methods are straightforward and offer high interpretability, which makes

them excellent foundational models for exploring how different features influence cancer diagnosis risk.

Since the task aimed at forecasting cancer diagnosis risk by considering important and relevant risk factors, we evaluated the efficacy of our methodologies by employing several critical performance metrics: AUC, accuracy, specificity, sensitivity, and the F_1-score for each model. We partitioned the dataset into 3 sections for model development: 70% for training, 10% for validation, and 20% for testing. The model that exhibited the best results on the validation set was further subjected to an in-depth analysis of the test set, using a 3-fold cross-validation technique to calculate its AUC precisely. To enhance our understanding of how our machine learning models contribute to cancer prevention, we also quantified the impact of each feature on the prediction of 4 cancer types. We then ranked these features according to their significance. All statistical analyses and model implementations were coded using Python, with the scikit-learn library serving as the foundation for our predictive framework [39]. To assess the generalizability of the model, we validated its performance using an independent ICU dataset from MIMIC-IV-ED ((Medical Information Mart for Intensive Care), which represents an extended patient population. For each cancer type, we randomly sampled 200 cases and 200 matched controls from MIMIC-IV-ED, ensuring no patient overlap with the MIMIC-III experimental dataset.

To investigate the similarity of features ranking by different cancer types, we applied rank biased overlap (RBO) [40], a similarity measure of 2 ranked lists. The RBO score ranges between 0 and 1, where a higher score indicates greater similarity between the lists. A score of 1 implies perfect overlap, meaning the 2 lists are identical in both order and content. On the other hand, a score of 0 suggests no overlap between the lists.

Mathematically, let xi be the high-dimensional feature input. Let yi∈ {0,1} be the corresponding label. yi=0 means not affected, and yi=1 means affected. Our goal is to learn a predictive function f that best classifies the data. We built 3 state-of-the-art models for 4 cancer types respectively in this study:

- Penalized LR: given M training instances, we considered L1 regularized LR by minimizing the following function: ∑i=1M−loglogp(x(i);θ)+β||θ||1.
- RF [41]: a robust ensemble learning method that constructs multiple decision trees during training to improve prediction accuracy and prevent overfitting, where f is the decision tree as base learners. The RF model was trained by iteratively selecting features from root to leaf nodes and aggregating multiple trees with the weights from a subset of the training instances. The nodes and the weights in the model reflect their importance to the final prediction.
- MLP [42]: a type of artificial neural network that consists of at least 3 layers of nodes: an input layer, one or more hidden layers, and an output layer. Each node, or artificial neuron, in one layer, connects with a certain weight to every node in the following layer, and nodes do not connect within the same layer. The nonlinear activation functions, such as the sigmoid, or Rectified Linear Unit, are applied to the weighted sum of inputs to a neuron, determining its output signal.

To rank the impact on predictive models of the features, relative to all 3 models, we used a permutation importance score to rank all features in the training models for MLP [43]. The scores were defined by the mean decrease in accuracy of the trained model when each feature was permuted.

Ethical Considerations

MIMIC-III data are the result of a collaboration between Beth Israel Deaconess Medical Center (BIDMC) and Massachusetts Institute of Technology. Data collected at BIDMC as part of routine clinical care are deidentified, transformed, and made available to researchers who have completed training in human research and signed a data use agreement. The Institutional Review Board (HUM00230096) at the BIDMC granted a waiver of informed consent and approved the sharing of the research resource. This study was determined to be exempt from further ethical review. The contributing author, XH, obtained the necessary authorization to access the anonymized dataset and oversaw the meticulous data extraction process.

Results

Feature Selection

We conducted a feature selection process to refine thousands of diagnosis codes for predicting cancer diagnosis risk, using correlation-based selection to identify the most relevant features for 4 cancer types. Through this rigorous analysis, we aimed to distill the dataset down to a more manageable and meaningful subset of features. Eventually, we identified 33 features (recategorized into 20 factors for further analysis, Table 2) that emerged as particularly crucial for accurately predicting cancer diagnosis risk. These features were meticulously curated, ensuring that only the most informative and pertinent variables were retained for our predictive models.

Table . Features selected for predicting cancer diagnosis risks.

Features	Factors
Acidosis	Acidosis
Acute kidney failure, unspecified	Acute kidney failure
Age	Age
Anemia, unspecified	Anemia
Acute posthemorrhagic anemia	Anemia
Depressive disorder, not elsewhere classified	Depressive disorder
Diabetes mellitus without mention of complication, type II or unspecified type, not stated as uncontrolled	Diabetes
Esophageal reflux	Esophageal reflux
Ethnicity	Ethnicity
Gender	Gender
Cardiac complications, not elsewhere classified	Heart disease
Aortocoronary bypass status	Heart disease
Coronary atherosclerosis of native coronary artery	Heart disease
Old myocardial infarction	Heart disease
Congestive heart failure, unspecified	Heart disease
Atrial fibrillation	Heart disease
Subendocardial infarction, initial episode of care	Heart disease
Pure hypercholesterolemia	Hyperlipidemia
Other and unspecified hyperlipidemia	Hyperlipidemia
Unspecified essential hypertension	Hypertension
Other iatrogenic hypotension	Hypotension
Unspecified acquired hypothyroidism	Hypothyroidism
Marital status	Marital status
Religion	Religion
Acute respiratory failure	Respiratory or pulmonary diseases
Unspecified pleural effusion	Respiratory or pulmonary diseases
Pneumonia, organism unspecified	Respiratory or pulmonary diseases
Pneumonitis due to inhalation of food or vomitus	Respiratory or pulmonary diseases
Pulmonary collapse	Respiratory or pulmonary diseases
Chronic airway obstruction, not elsewhere classified	Respiratory or pulmonary diseases
Unspecified septicemia	Sepsis
Personal history of tobacco use	Tobacco use
Urinary tract infection, site not specified	Urinary tract infection (UTI)

Model Performance

For each predicted cancer outcome, we carried out the experiment by predicting cancer using the entire diagnosis history of the patient by building LR, RF, and MLP models. Table 3 illustrates the accuracy, specificity, sensitivity, and F_1-score of these 3 models for breast, colorectal, lung, and prostate cancers. Figure 2 shows the receiver operating characteristic plots of 3 models for 4 types of cancer, respectively. Both Table 3 and Figure 2 show that within the 3 models, MLP performs the best, RF falls in the middle, and LR ranks last. It is worth noting that MLP achieved an AUC of 0.78 for breast cancer, 0.76 for colorectal cancer, 0.84 for lung cancer, and 0.78 for prostate cancer, demonstrating a higher AUC over traditional risk factor-based models and a statistically significant superiority over random chance. The underwhelming results from the LR model led us to investigate the complexity of risk factors for prediction. Compared with LR, MLP reveals the intricate, nonlinear associations between risk factors and the likelihood of cancer, offering meaningful insights into the

collective influence of these risk factors on cancer diagnosis risk.

Table . Comparison of model performance across 4 types of cancer on Medical Information Mart for Intensive Care (MIMIC)–III.

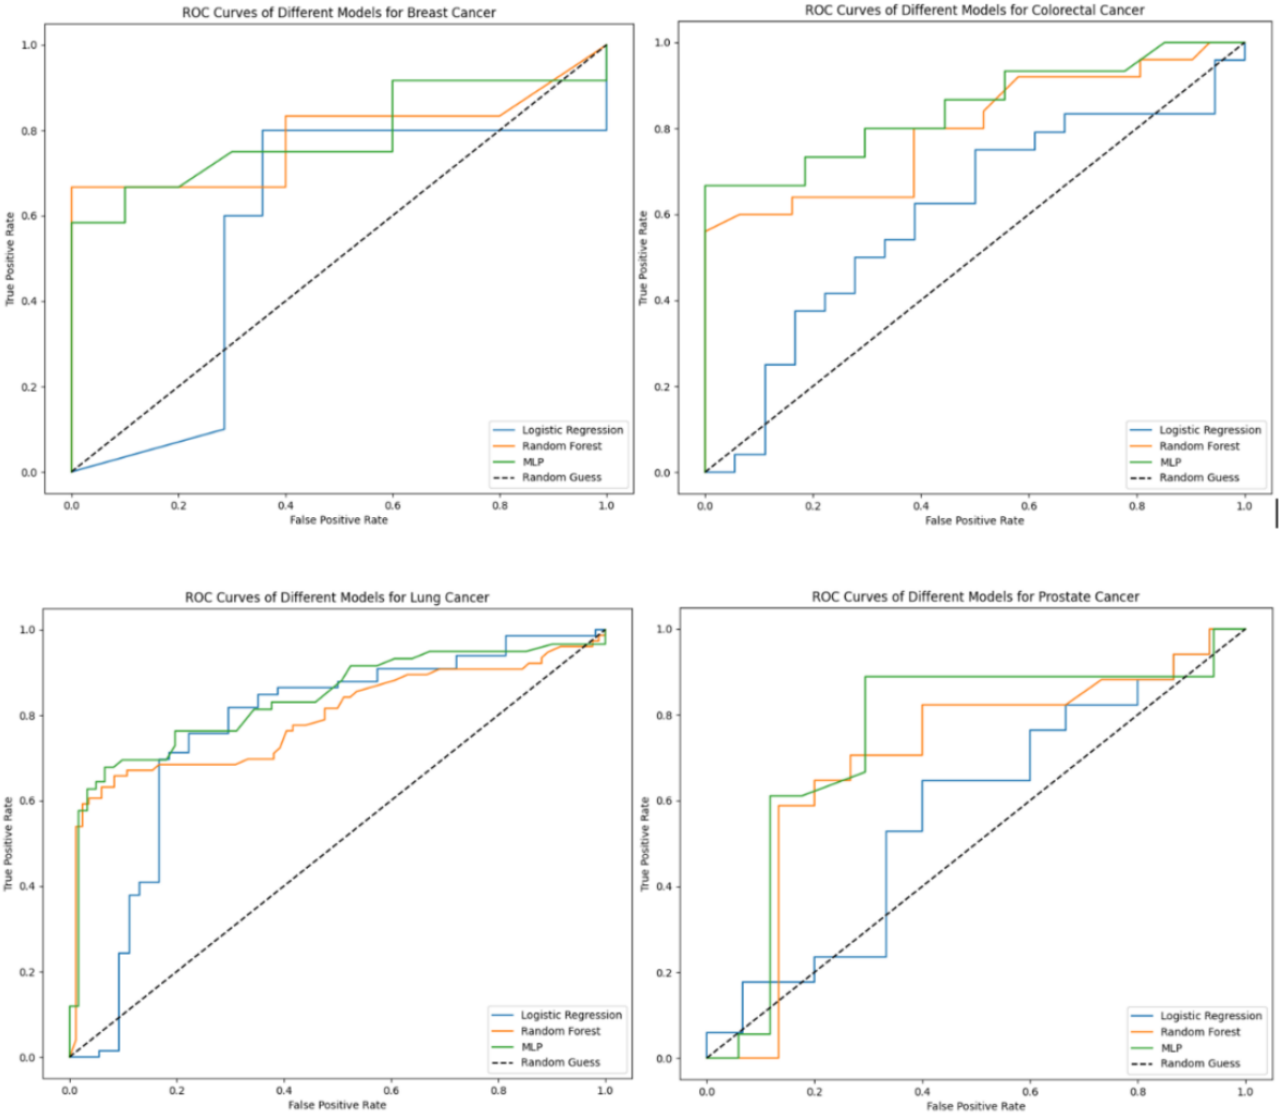
	Breast cancer			Colorectal cancer			Lung cancer			Prostate cancer		
	LR[a]	RF[b]	MLP[c]	LR	RF	MLP	LR	RF	MLP	LR	RF	MLP
Accuracy	0.56	0.73	0.78	0.60	0.70	0.76	0.74	0.80	0.83	0.59	0.72	0.78
Specificity	0.45	0.70	0.80	0.67	0.61	0.81	0.61	0.92	0.87	0.53	0.80	0.84
Sensitivity	0.71	0.75	0.75	0.54	0.80	0.73	0.85	0.68	0.80	0.65	0.65	0.72
F_1-score	0.56	0.75	0.75	0.60	0.70	0.79	0.78	0.78	0.84	0.63	0.71	0.76

[a]LR: logistic regression.

[b]RF: random forest.

[c]MLP: multilayer perceptron.

Figure 2. Area under the receiver operating characteristic curve (AUC) performance of the 3 binary classification models (logistic regression [LR], random forest [RF], and multilayer perceptron [MLP]). The figure shows AUC curves of breast cancer, colorectal cancer, lung cancer, and prostate cancer for LR, RF, and MLP, respectively.



Additionally, Table S2 in Multimedia Appendix 1 presents the AUC, accuracy, specificity, sensitivity, and F_1-score for the 3 models across breast, colorectal, lung, and prostate cancers. Among the models evaluated, MLP demonstrated the highest performance, achieving an AUC of 0.88 for breast cancer, 0.83

for colorectal cancer, 0.90 for lung cancer, and 0.85 for prostate cancer.

Feature Importance Analysis

We analyzed the feature importance for each cancer type further to investigate the potential impact of risk factors on cancer. Tables 4 and 5 present the feature importance analysis of RF and MLP, showcasing the top-ranked risk factors for each type of cancer. The ranks of these factors were relatively different by model and cancer type, although some consistency can be observed across cancer types. Age emerged as the top risk factor across all 4 types of cancer; race/ethnicity ranked among the top 10 factors for all cancers from all models except for the RF-based lung cancer and prostate cancer models; gender was ranked among the top 10 in MLP-based models but not in any RF-based models; marital status and religion were presented for some types of cancer in some of the models; and tobacco use as an important factor for patients with lung and prostate cancer exclusively. However, all these demographic risk factors were included in the top 20 factors for all cancer types (Table S3 in Multimedia Appendix 1). Similarly, RF-based models identified hypertension, heart diseases, respiratory/pulmonary diseases, and acute kidney failure as the common top risk factors for all types of cancers, while MLP-based models highlighted hyperlipidemia, diabetes, depressive disorder, and heart diseases. We calculated the odds ratio (OR) for each highlighted feature to assess its association with overall cancer diagnosis risk across 4 cancer types. The results indicated that hyperlipidemia had an OR of 1.14 (95% CI 1.11 - 1.17; P<.001), while diabetes showed a stronger association with an OR of 1.34 (95% CI 1.29 - 1.39; P<.01). Similarly, depressive disorders were linked to an OR of 1.11 (95% CI 1.06 - 1.16 P<.01), and heart diseases exhibited the highest association with an OR of 1.42 (95% CI 1.32 - 1.52; P<.01). Last, anemia was also significantly associated with cancer diagnosis risk, with an OR of 1.22 (95% CI 1.14 - 1.30; P<.01). These findings suggest a statistically significant relationship between these conditions and an increased risk of developing these 4 types of cancer. In MLP-based models, respiratory/pulmonary diseases and acute kidney failure were only presented as the top 10 for lung cancer. Both RF and MLP-based models pinpointed anemia as the top risk for breast cancer. Figure 3 shows the RBO similarity scores of risk factors for 4 types of cancer according to MLP-based models. Low similarity scores are presented between lung cancer and any other 3 cancer types, all around 0.58, suggesting distinct patterns of risk factors associated with lung cancer. Risk factors for breast and prostate cancers show the most similar ranking with an RBO similarity score of 0.76. A moderate similarity score between colorectal and breast cancers is about the same as the score between colorectal and prostate cancer, both around 0.70.

Table . Top-10 ranked features generated across 4 different cancer types in random forest.

Ranking	Breast cancer	Colorectal cancer	Lung cancer	Prostate cancer
1	Age	Age	Age	Age
2	Hypertension	Respiratory or pulmonary diseases[a]	Hypertension	Hypertension
3	Religion	Hypertension	Religion	Religion
4	Marital status	Acute kidney failure	Hyperlipidemia	Heart diseases[c]
5	Respiratory or pulmonary diseases	Diabetes	Heart diseases	Marital status
6	Heart diseases	Heart diseases	Acute kidney failure	UTI[c]
7	Race or ethnicity	Hyperlipidemia	UTI	Respiratory or pulmonary diseases
8	Depressive disorders	Race or ethnicity	Respiratory or pulmonary diseases	Anemia
9	Acute kidney failure	Religion	Marital status	Hyperthyroidism
10	Anemia	Acidosis	Anemia	Diabetes

[a]Respiratory or pulmonary diseases include pneumonia, acute respiratory failure, chronic airway obstruction, and other respiratory or pulmonary complications.

[b]Heart diseases include atrial fibrillation, myocardial infarction, congestive heart failure, coronary atherosclerosis, and other cardiac complications.

[c]UTI: urinary tract infection.

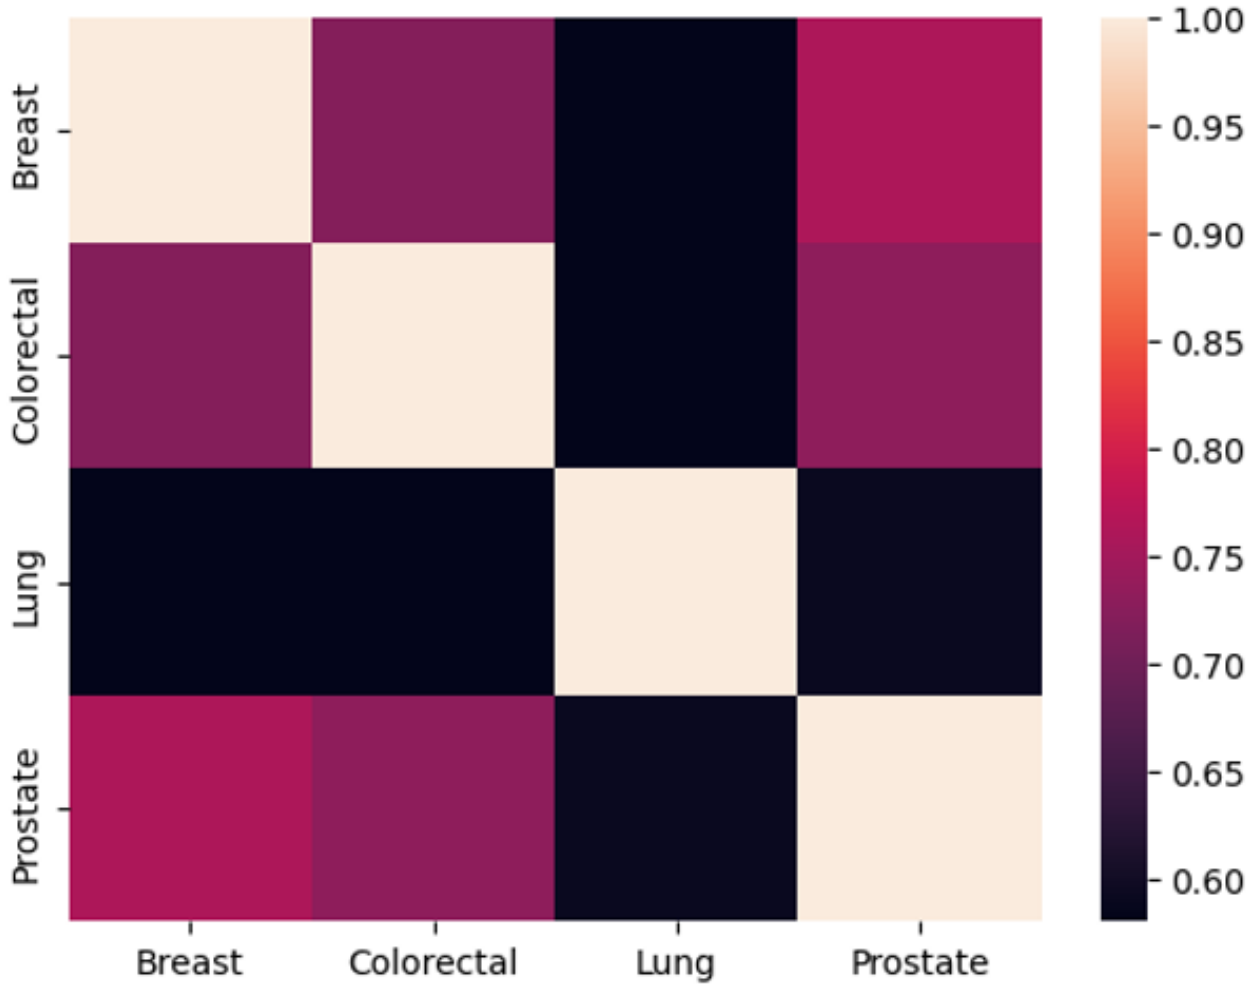
Table . Top-10 ranked features generated across 4 different cancer types in multilayer perceptron.

Ranking	Breast cancer	Colorectal cancer	Lung cancer	Prostate cancer
1	Age	Age	Tobacco use	Age
2	Gender	Diabetes	Age	Gender
3	Hyperlipidemia	Anemia	Respiratory or pulmonary diseases[a]	Race or ethnicity
4	Heart diseases[b]	Acidosis	Gender	Tobacco use
5	Race or ethnicity	Hyperlipidemia	Race or ethnicity	Diabetes
6	Marital status	Sepsis	Diabetes	Hyperlipidemia
7	Depressive disorder	Gender	Hyperlipidemia	Heart diseases
8	Religion	Race or ethnicity	Hypertension	Marital status
9	Anemia	Marital status	Heart diseases	Religion
10	Hypothyroidism	Depressive disorder	Acute kidney failure	Depressive disorder

[a]Respiratory or pulmonary diseases include pneumonia, acute respiratory failure, chronic airway obstruction, and other respiratory or pulmonary complications.

[b]Heart diseases include atrial fibrillation, myocardial infarction, congestive heart failure, coronary atherosclerosis, and other cardiac complications.

Figure 3. Rank biased overlap similarity score of risk factors for 4 cancer types. A high value represents high similarity, and a low value represents low similarity of risk factor ranks between 2 cancer types.



Discussion

Principal Findings

This study used comprehensive patient diagnosis histories to evaluate the association between key risk factors and cancer outcomes and identify risk factor patterns across different cancer types using penalized LR, RF, and MLP models. The analysis identified the top-ranking risk factors, including nontraditional risk factors such as the diagnosis of hyperlipidemia, diabetes, depressive disorders, heart diseases, and anemia, in addition to demographic factors such as age, sex, race/ethnicity, for the most prevalent 4 types of cancer, including breast, colorectal, lung, and prostate cancers. The model performance evaluation revealed the valuable potential of neural network-based models, especially MLPs, in oncology for predicting cancer diagnosis risks across cancer types. MLPs exhibit a strong capability to model complex, nonlinear interactions among diverse risk factors, making them potentially valuable tools for identifying patterns in cancer diagnosis risk and informing early detection strategies. However, their application in clinical interventions should be guided by a solid scientific rationale and supported by pathological models that explain the role of these risk factors in disease development. Additionally, validation across different cohorts and, ideally, prospective studies are necessary to ensure their reliability and clinical utility. This advantage is particularly important given the model's capacity to integrate and interpret the intricate relationships between clinical factors present in EHRs. In contrast to simpler models like LR, which struggle with the multidimensional nature of risk factors on cancer diagnosis in many cases, MLPs offer a more detailed and comprehensive analysis, enhancing our understanding of how these factors collectively impact cancer diagnosis risk and improving the precision of preventive strategies in clinical settings. Last, this study does not aim to establish causal inference but rather to examine significant overlapping risk factors that may contribute to cancer diagnosis risk, particularly those observed in patients with other medical conditions. While these diagnoses are not independent causal determinants of cancer, their presence may be associated with an increased risk. Careful consideration of these associations is essential for a comprehensive understanding of cancer risk factors and their potential interactions.

Comparison to Prior Work

Prior cancer risk prediction models usually focus on lifestyle factors like smoking, diet, alcohol consumption, physical activity, and sun exposure as key variables [44-46]. Some models have also incorporated genetic risk factors [47,48]. However, many of these models reported less optimal performance, such as a high specificity but low sensitivity [46] or a low AUC of around 0.65 [48]. Chronic diseases are often overlooked as risk factors for cancer, and they are not often targeted in cancer prevention strategies. The association between some of these diseases and cancers may partly be due to shared risk factors, such as aging, obesity, diet, and physical inactivity. However, they can also be independent risk factors for cancer. For example, diabetes mellitus has been identified as an independent risk factor for colon and rectal cancer in a meta-analysis of studies that either controlled for smoking and obesity, or smoking, obesity, and physical exercise [49]. As nontraditional risk factors, the influence of certain chronic conditions on cancer has been brought to researchers' attention in the past decade. A prospective cohort study with 405,878 participants followed for an average of 8.7 years demonstrated that 8 common chronic diseases accounted for more than 20% of cancer risk, which are comparable to 5 major lifestyle factors, such as smoking and lack of physical activity [16]. These 8 chronic diseases or markers included blood pressure, total cholesterol, heart rate, diabetes, proteinuria, glomerular filtration rate, pulmonary disease, and gouty arthritis marker [16]. However, as these diseases or markers were pre-selected by the researchers based on their disease burden worldwide, some other essential influential conditions might be missed. Our models confirmed most of these 8 diseases as the top-ranking risk factors. Additionally, some new conditions were revealed in our models among the top 10 factors for 4 types of cancer, such as depressive disorder, anemia, hypothyroidism, sepsis, urinary tract infection, and acidosis, which encourages further exploration. Certainly, some of these diagnoses may be directly related to the cancer itself. For example, anemia is a common symptom of metastatic breast cancer and a side effect of chemotherapy [50]. In addition, sepsis and colorectal cancer have demonstrated a complex relationship and may have shared pathophysiological traits and potential bacterial associations reported by the literature [51]. Notably, tobacco use and respiratory/pulmonary diseases emerged as pivotal risk factors, specifically for lung cancer, which is not surprising based on our knowledge in the field. Diabetes and anemia were highlighted as significant risk factors for colorectal cancer, which is congruent with the literature [52,53]. Iron deficiency has been recognized long-term as an independent predictor of colorectal cancer, which may be due to chronic blood loss from the gastrointestinal tract and the inflammation associated with malignancy [54,55]. These conditions could have shared risk factors with cancer. However, emerging evidence implies that they may have more complicated relationships, including shared pathophysiological mechanisms that need further exploration [56]. Moreover, cancer prevention strategies should consider the impact of comorbid conditions on the incidence of cancer and particularly their joint impact on cancer risks [53].

Understanding the relationships between various risk factors and cancer diagnosis risk is pivotal for the early detection and prevention of cancer. In this context, our feature importance analysis using RF and MLP models pinpointed critical risk factors for different cancer types and explored patterns of these risk factors across various cancers. Although the ranks of risk factors for cancers were slightly different by the RF and MLP-based models, similar patterns were presented among the top 10 factors (Tables 4 and 5), which are interpretable and supported by the literature. Both models highlighted age as the predominant risk factor across all 4 types of cancer, which is evident that as age increases, the incidence rates for cancer overall climb steadily, and alongside age, demographic variables such as gender, race/ethnicity, marital status, and religion emerged within the top 10 features [57]. Racial/ethnic disparities in cancer incidence and outcomes are well-known. Employing culturally tailored community awareness and education programs may increase cancer screening to improve early-stage

diagnoses and modify risk behaviors for cancer prevention [58]. Although there may not be existing evidence to confirm that marital status is an independent risk factor for cancer, observational studies demonstrate that married status is associated with reduced risk of cancer-specific and all-cause mortality [59,60]. Religion and spirituality are important in patient cancer care, and specifically, a systematic review suggests a positive association between religious attendance and cancer screening use [61]. Our models not only confirmed the significance of these risk factors for each cancer type but also our RF-based model facilitated an interpretable analysis, allowing us to clearly rank the significance of each risk factor, while the MLP-based model provided deeper insights into complex, nonlinear interactions among the risk factors. This approach enriches our understanding of how specific risk factors influence cancer diagnosis, enhancing the potential for developing tailored intervention strategies that address the unique risk profiles associated with different cancer types and potentially shared risk patterns across prevalent cancer types.

The analysis of the similarity among risk factors for the diagnosis of 4 types of cancer also revealed interesting findings. As breast and prostate cancer are both hormone-dependent cancers, it is understandable that their importance-ranked risk factors share a high level of similarity. However, lung cancer had more unique ranked risk factors than other types of cancer, which may be because lung cancer is more sensitive to environmental risk factor exposure. The findings from our analysis underscore the shared risk factors and heterogeneous nature of cancer and highlight the importance of considering unique risk profiles for different cancer types. This also urges us to address the fundamental mechanism of risk factors leading to cancers. Such insights are crucial for developing tailored prevention strategies, optimizing screening protocols, and informing personalized treatment approaches to mitigate the burden of lung cancer and improve patient outcomes.

Limitations

First, the use of the MIMIC-III dataset in this study on explainable machine learning for cancer risk prediction presents certain limitations that may impact the generalizability of the findings, Since the data are derived from ICU patient records, it primarily represents individuals with severe conditions, and the available *ICD* codes may not fully capture disease complexity, potentially leading to incomplete representations of patient conditions. Additionally, the limited sample size for patients with cancer may impact predictive performance and increase the risk of overfitting. Both limitations may affect the generalizability of the findings. To enhance the robustness of future research, integrating more recent and varied data sources and validating findings across different cohorts are essential steps. Second, one limitation comes from the application of explainable machine learning models for cancer risk prediction. Employing advanced techniques like penalized LR, RF, and MLP, this research seeks to optimize predictive accuracy. However, each model inherently embodies trade-offs: while more complex models, such as multi-layer perceptron, may enhance performance, they often compromise on interpretability. This presents significant challenges in clinical settings, where understanding the reasoning behind model predictions is crucial for acceptance and trust by medical practitioners. Third, another limitation of this study arises from the inherent nature of machine learning models, which are primarily designed to detect correlations in data and associations between features and the outcome rather than establish causal relationships. These models rely on the quality and comprehensiveness of the input data, and while they can reveal significant associative patterns, they do not focus on differentiating whether the associations observed are causal. Meanwhile, given the limited availability of patient lifestyle and socioeconomic information, additional factors related to social determinants of health, such as socioeconomic status, employment, and family size, can be considered as potential confounders within the model for future improvement. To address all the above, future work should integrate causal inference frameworks to validate the relationships suggested by the machine learning predictions and provide insights into underlying mechanisms.

Conclusions

In conclusion, our study established a predictive framework using EHR data to assess the association between risk factors and cancer outcomes using explainable ML models across major cancer types. We reported critical nontraditional chronic condition risk factors in addition to common demographic risk factors and outlined distinct patterns for each of the 4 cancer types studied. Additionally, we explored the similarities and differences in risk factor patterns across these cancers. These insights contribute to a better understanding of cancer risk profiles and benefit in improving cancer diagnosis and risk monitoring, offering supportive guidance for clinical decision-making.

Acknowledgments

The authors would like to thank the Beth Israel Deaconess Medical Center and the MIT Laboratory for Computational Physiology for making the Medical Information Mart for Intensive Care (MIMIC)–III database available to the research community. The authors would also acknowledge the support from the University of Michigan School of Nursing and the Yale School of Public Health throughout this study.

Data Availability

The datasets analyzed during this study are available on PhysioNet [62].

Authors' Contributions

XH and YJ conceived the study. XH and SR implemented the algorithm, conducted the experiments, and performed all the analyses. SR generated results visualization. XH and YJ supervised the study. XH, SR, EC, YH, and YJ wrote the manuscript. All authors provided feedback and approved the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: In low- and middle-income countries, cervical cancer remains a leading cause of death and morbidity for women. Early detection and treatment of precancerous lesions are critical in cervical cancer prevention, and colposcopy is a primary diagnostic tool for identifying cervical lesions and guiding biopsies. The transformation zone (TZ) is where a stratified squamous epithelium develops from the metaplasia of simple columnar epithelium and is the most common site of precancerous lesions. However, inexperienced colposcopists may find it challenging to accurately identify the type and location of the TZ during a colposcopy examination.

Objective: This study aims to present an artificial intelligence (AI) method for identifying the TZ to enhance colposcopy examination and evaluate its potential clinical application.

Methods: The study retrospectively collected data from 3616 women who underwent colposcopy at 6 tertiary hospitals in China between 2019 and 2021. A dataset from 4 hospitals was collected for model conduction. An independent dataset was collected from the other 2 geographic hospitals to validate model performance. There is no overlap between the training and validation datasets. Anonymized digital records, including each colposcopy image, baseline clinical characteristics, colposcopic findings, and pathological outcomes, were collected. The classification model was proposed as a lightweight neural network with multiscale feature enhancement capabilities and designed to classify the 3 types of TZ. The pretrained FastSAM model was first implemented to identify the location of the new squamocolumnar junction for segmenting the TZ. Overall accuracy, average precision, and recall were evaluated for the classification and segmentation models. The classification performance on the external validation was assessed by sensitivity and specificity.

Results: The optimal TZ classification model performed with 83.97% classification accuracy on the test set, which achieved average precision of 91.84%, 89.06%, and 95.62% for types 1, 2, and 3, respectively. The recall and mean average precision of the TZ segmentation model were 0.78 and 0.75, respectively. The proposed model demonstrated outstanding performance in predicting 3 types of the TZ, achieving the sensitivity with 95% CIs for TZ1, TZ2, and TZ3 of 0.78 (0.74-0.81), 0.81 (0.78-0.82), and 0.8 (0.74-0.87), respectively, with specificity with 95% CIs of 0.94 (0.92-0.96), 0.83 (0.81-0.86), and 0.91 (0.89-0.92), based on a comprehensive external dataset of 1335 cases from 2 of the 6 hospitals.

Conclusions: Our proposed AI-based identification system classified the type of cervical TZs and delineated their location on multicenter, colposcopic, high-resolution images. The findings of this study have shown its potential to predict TZ types and specific regions accurately. It was developed as a valuable assistant to encourage precise colposcopic examination in clinical practice.

artificial intelligence; AI; cervical cancer screening; transformation zone; diagnosis and early treatment; lightweight neural network

Introduction

Cervical cancer remains the fourth most prevalent cancer among women worldwide [1], and it continues to be a leading cause of morbidity and mortality threatening women's health. Since cervical precancerous lesions often progress to invasive cancer over an extended period, early detection is critical for cervical cancer prevention. Colposcopy serves as a crucial component of cervical cancer screening, providing a preliminary diagnosis for patients based on screening results, which then guides subsequent biopsy and treatment. Although it is a fundamental technique that health care providers can easily teach and implement, the strong subjective nature of colposcopy diagnosis makes it difficult for colposcopists with different qualifications to perform standardized diagnoses and make effective clinical decisions [2,3]. Artificial intelligence (AI) diagnostic technology could resolve the disparities in expertise among clinicians and enhance screening efficiency [4].

The transformation zone (TZ) is where a stratified squamous epithelium develops from the metaplasia of simple columnar epithelium and is the most common site of precancerous lesions. More than 90% of cervical cancers develop within the TZ [5], making it a critical region for cervical intraepithelial neoplasia (CIN) diagnosis and early treatment. According to the visibility of the squamocolumnar junction (SCJ), the TZ can be classified into three types: TZ1 (SCJ fully visible), TZ2 (SCJ fully visible under endocervical speculum), and TZ3 (SCJ partially visible or not visible) [6]. Accurately identifying the TZ is crucial for diagnosing and treating cervical precancerous lesions. As the TZ moves into the cervical canal with increasing age, endocervical curettage (ECC) is necessary for biopsy-guided pathology [7]. If TZ types are not classified, the importance of ECC for the canal may be neglected, leading to missed diagnosis of lesions during colposcopic examination. In addition, excision of the entire TZ is a standard treatment for cervical precancerous lesions. For excisional treatment, TZ types determine the length and depth of the cervix to be excised. In destructive treatments, a prerequisite is that the TZ must be either type 1 or type 2. Therefore, the type and location of the TZ are the determinants of treatment choices, and accurately assessing the TZ is essential for guiding more effective biopsies and precise treatment.

However, in underserved population, the skills of colposcopists are generally suboptimal, with colposcopic finding accuracy being significantly lower than desired [8,9]. AI-assisted technology could effectively enhance the competencies of colposcopists in these underserved areas. Current evaluation studies [10,11] have demonstrated that junior or less-experienced colposcopists can detect abnormal cervical lesions more effectively with AI assistance, which indicates its potential to help reduce missed diagnoses. However, the functions of AI cannot be limited. All colposcopic features were the indicators for assessing colposcopist performance. Among them, the accurate identification of TZ types is essential for implementing effective colposcopy diagnostics and treatment procedures, potentially reducing the number of missed diagnoses and unnecessary biopsy procedures. However, current AI-assisted colposcopy systems or developed AI diagnosis models do not include TZ or SCJ detection during model conduction. Therefore, it is essential to integrate important clinical features into AI model training to improve colposcopy diagnosis efficiency.

AI colposcopy diagnostic systems remain challenging to distinguish among benign, CIN1, CIN2, and CIN3+ cases during colposcopy examination [12-14], although they achieved over 80% accuracy in detecting high-grade squamous intraepithelial lesions. This difficulty is attributable to the lack of specificity in the CIN-related acetowhite staining characteristics. Typically, normal cervical features, such as immature squamous metaplasia, congenital TZ, inflammation, and epithelium regeneration, may exhibit mild acetowhite reactions similar to those associated with CIN. This similarity implies that relying solely on acetowhite area features can easily lead to misclassification either for AI or in less experienced colposcopist. In AI model training, standardized annotated images of different acetowhite morphologies or fine-grained lesion descriptions may help with a more precise assessment of acetowhite characteristics [15]. However, current AI-assisted colposcopy research is constrained by the lack of standardized annotated colposcopy images. From a clinical perspective, the colposcopy guidelines issued by the International Federation for Cervical Pathology and Colposcopy (IFCPC) emphasize that CIN-related acetowhite changes are most commonly found in the TZ, and near the new SCJ, with clear demarcation from the surrounding epithelium [6]. Therefore, the TZ region can be used as an indicator to identify lesion areas and can be developed as a learned feature for diagnostic model development, thereby resolving the problem of the lack of annotated colposcopy images. As a result, the multiclassification accuracy of AI-guided colposcopic diagnostic systems may be significantly improved. Therefore, in AI model development, accurately identifying TZ types and the SCJ is a crucial step toward improving AI diagnostic accuracy and guiding biopsies.

In this study, an AI method is developed and validated for the classification and delineation of the TZ. This method not only has the potential to guide clinical colposcopic examinations in resource-limited health care settings but also encourages the advancement of AI-guided digital colposcopic systems. By incorporating all colposcopic findings, such as TZ type and features of both minor and major lesions, AI-guided digital colposcopy could become a mature assistant for universal clinical colposcopy examinations.

Methods

Study Patients

This retrospective study included 3616 women who underwent colposcopy examinations across 6 multicenter hospitals in China between January 2019 and October 2021. These hospitals were

the Gansu Maternity and Child Healthcare Hospital, Second Hospital of Shanxi Medical University, Shenzhen Maternity and Child Healthcare Hospital, Jiangxi Maternity and Child Healthcare Hospital, The Affiliated Hospital of Qingdao University, and Chengdu Women's and Children's Central Hospital. The digital clinical records, including cytology, human papillomavirus infection status, colposcopy findings, and pathological results, were collected. All colposcopy images were captured using digital high-definition video colposcopes (Zonsun Healthcare Co Ltd, Edan Instruments). Colposcopy findings, including adequacy, SCJ visibility, TZ determination, and provisional diagnosis, were qualified by colposcopy experts from tertiary hospitals. The "ground truth" for TZ classification and SCJ visibility in this study was determined by an expert panel following IFCPC guidelines.

The inclusion criteria were as follows: (1) women with complete colposcopy findings and pathological diagnosis, (2) ages between 24 and 65 years, and (3) each record containing at least 5 satisfactory colposcopic images before and after acetic acid staining. The exclusion criteria were (1) all saline solution images (preacetic), since the TZ typically appears after acetic acid staining; (2) poor-quality images, such as overexposed images or those where the cervix was obscured or there was bleeding after the biopsy; (3) inadequacy colposcopic examination; and (4) records with missing TZ types or SCJ visibility. For external validation, an independent dataset was derived from The Affiliated Hospital of Qingdao University and Chengdu Women's and Children's Central Hospital. The training dataset was divided into training and test sets in an 8:2 ratio, with 10% of the training set used for validation during model tuning.

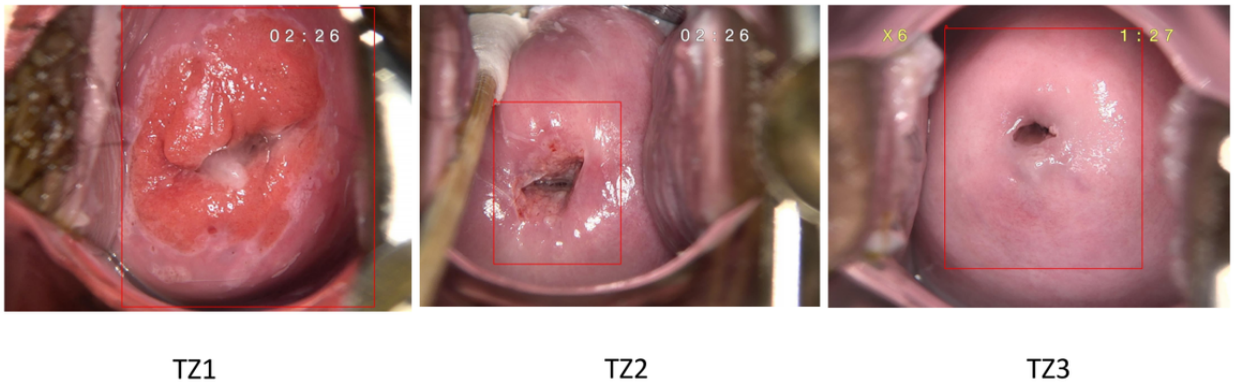
Transformation Zone

The colposcopy procedures adhered to the standard guidelines for *Colposcopy and Treatment of Cervical Precancer* [6]. Time-series images were captured for each case, including 1 original cervix image (saline solution) and at least 4 acetic acid–stained cervix images. The classification of TZ followed guideline criteria. TZ was classified as type 1 when it was entirely located on the ectocervix. In type 2, TZ was partially located within the endocervical canal, but its upper limit could be visualized using auxiliary instruments. Type 3 TZ lies partly or entirely inside the endocervical canal, with its upper limit being partially or completely invisible, even with the aid of auxiliary instruments.

Image Preprocessing

The colposcopy images were captured in high resolution. However, they contained irrelevant objects, such as the endocervical speculum, cotton swabs, or large regions of the vaginal wall, which could interfere with the classification model's ability to extract critical features of the cervix. To address this issue, we used the YOLOv5 network to detect the region of interest. Its single forward pass design enables real-time object detection with high efficiency and precision [16,17]. The integrated cervical region was automatically segmented and examined by a specialist (Figure 1). It divides an image into an S×S grid cell, predicting the bounding box locations and their associated categories. All segmented colposcopy images were resized to 224×224 pixels to align with the input specifications of the model.

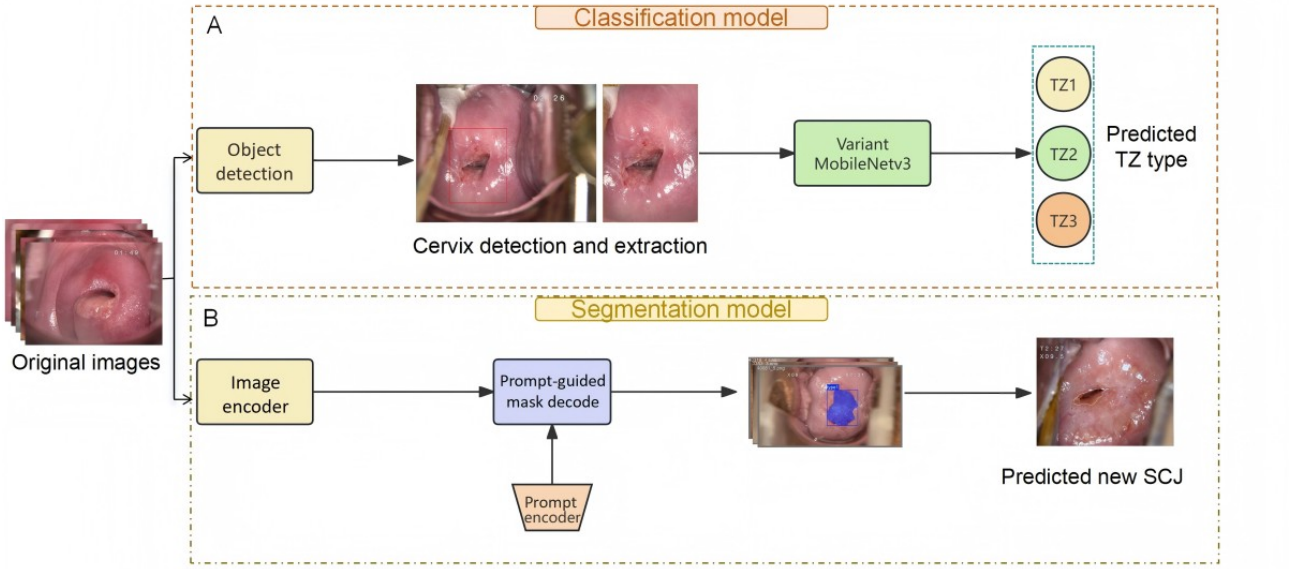
Figure 1. Cervix region of interest detection with bounding box examples in representative images. TZ: transformation zone.



Development of the TZ Classification Model

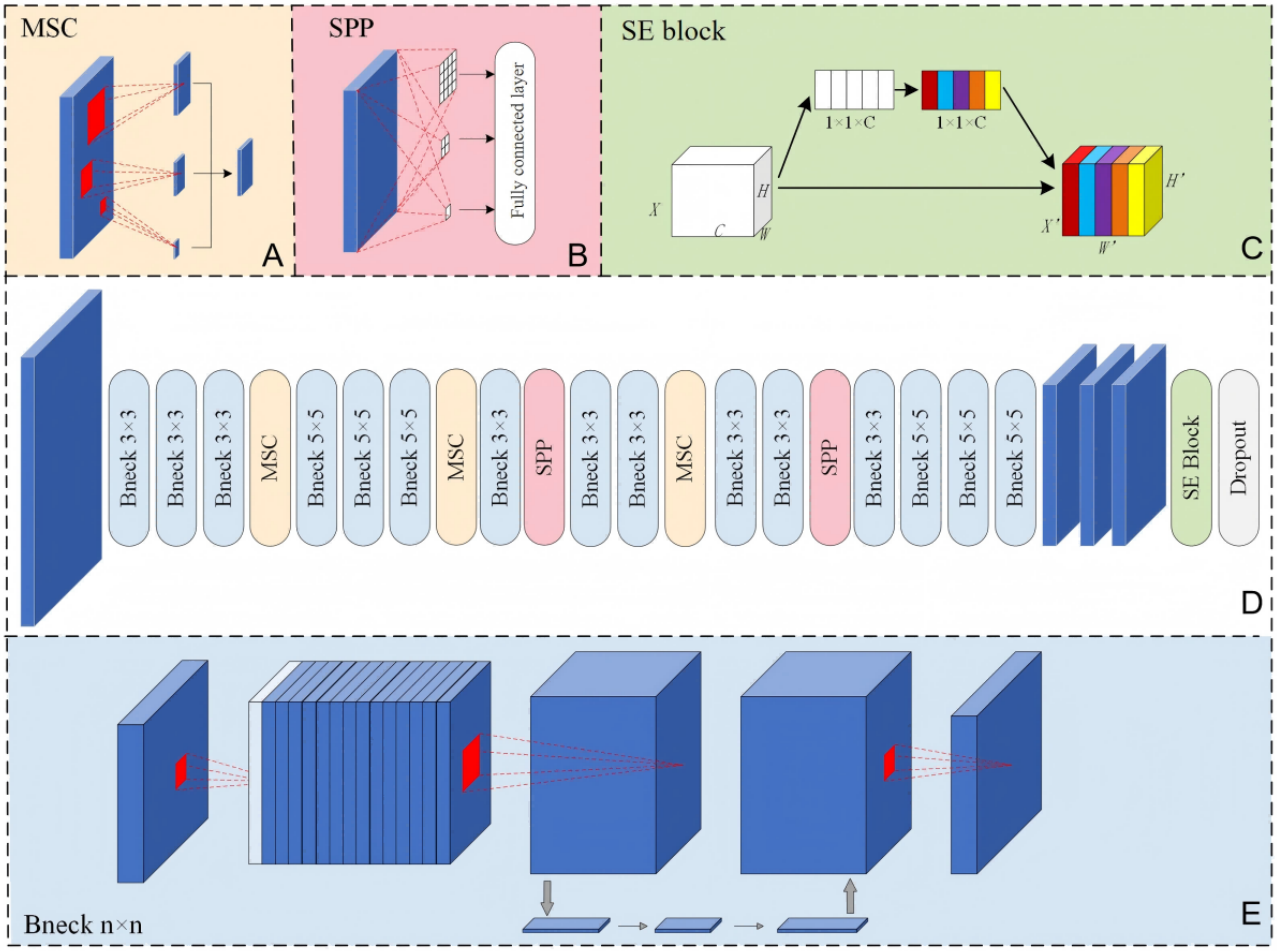
Initially, colposcopy images were input into a detection model to determine the cervical region, which was then preprocessed to enhance feature extraction. These data were then applied to a classification model to determine the types of TZ present (Figure 2A). In the second part of the method, the original images were annotated with new SCJ prompts to guide a general segmentation model in inferring the potential location of the TZ (Figure 2B).

Figure 2. The overall inference process of the TZ identification system consists of two stages: (A) detection and extraction of the entire cervical region from original images, followed by feature extraction using the variant MobileNetV3 and inference TZ1, TZ2, and TZ3 types; and (B) using the original images and images with polygon of the new SCJ as prompts to FastSAM, which then outputs the mask prediction of the out-of-TZ area to infer the new SCJ guidance line. SCJ: squamocolumnar junction; TZ: transformation zone.



We proposed a variant of the MobileNetV3 architecture for classifying TZ, a lightweight convolutional neural network (CNN) specifically designed for efficient operation on portable devices, which was particularly suitable for deployment in resource-limited settings. The overall model structure is presented in Figure 3. Our model retained the depthwise separable convolutions and the HardSwish (H-swish) activation function of MobileNetV3, which reduced computational demand and parameters without compromising accuracy. Multiscale convolution modules have been incorporated into the model to effectively extract features at multiple focal points (Figure 3A), from subtle acetowhite changes in the columnar epithelium to varying TZ-type scopes in the cervix. In addition, we introduced a spatial pyramid pooling module to address features at multiple scales while preserving spatial information in the input images to ensure the richness of feature representation (Figure 3B). The Squeeze-and-Excitation module is a lightweight attention mechanism designed to automatically prioritize the most diagnostically relevant visual patterns within the MobileNetV3 architecture (Figure 3C). In our model, the Squeeze-and-Excitation module was embedded to adjust global feature weights (Figure 3D), enhancing the overall effectiveness of feature extraction. It increased the sensitivity to important features, thereby improving classification performance [18].

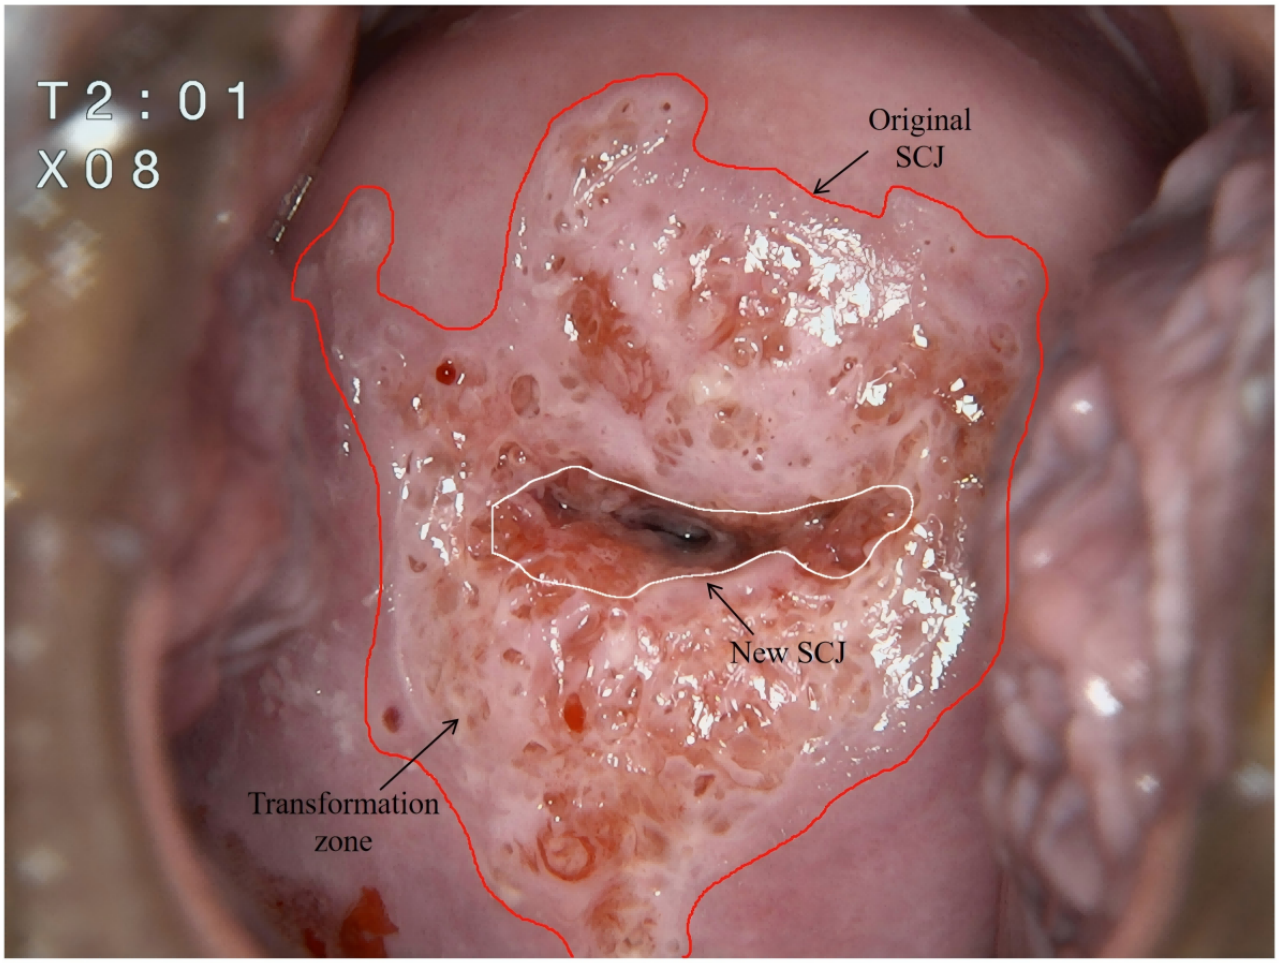
Figure 3. The overall architecture of the proposed model: (A) details of the multiscale convolution (MSC) module; (B) details of the Spatial Pyramid Pooling (SPP) module; (C) structure of the Squeeze-and-Excitation (SE) block module; (D) workflow of the model that included detailed layers of the network; and (E) structure of the inverted residuals module.



Development of the TZ Segmentation Model

The FastSAM model was used to segment the TZ from the entire cervix in colposcopy images (Figure 2B). FastSAM was fine-tuned for the specific dataset using a YOLO-based framework [19]. Colposcopic images were resized to 640×640 pixels, and the new SCJ was annotated using LabelMe (MIT CSAIL) [20]. By selectively freezing some of the backbone layers of the model, the deeper layers were fine-tuned to improve adaptation to the specific task, without compromising the extraction of general features. The model's performance was further enhanced by using coarse masks as spatial guides, which allowed the model to focus its attention on the most relevant image regions. The model was trained to delineate the new SCJ, thereby identifying possible TZ areas by this critical boundary. TZ is a dynamic region defined by the area between the original SCJ and the new SCJ. Typically, the original SCJ is considered a virtual line, and identifying the new SCJ is crucial for determining the location of the TZ (Figure 4).

Figure 4. Illustration of the squamocolumnar junction (SCJ) and the transformation zone.



Software and Hardware

The study was performed on a Windows 11 operating system with an NVIDIA GeForce RTX 3080 8GB graphics card. The models were implemented using Python (version 3.6.13; Python Software Foundation) and the PyTorch (Meta AI) Library (version 1.7.1).

Evaluation Metrics

Experiment performance of the cervical TZ classification model was evaluated using accuracy, precision, recall, F_1-score, and average precision, as defined in Equations 1-6.

Where TP, FP, and FN denote the true positive, false positive, and false negative predictions, respectively. $r(k)$ denotes the recall at threshold k. $p(k)$ denotes the precision at threshold k, and n denotes the number of thresholds. AP_i is the average precision for class i, and mAP denotes the mean average precision, where n is the number of classes.

Statistical Analysis

The performance of the classification model was evaluated by comparing it with selected state-of-the-art (SOTA) deep-learning models using metrics such as accuracy, precision, recall, and the area under the precision recall curve, represented by average precision. To evaluate the classification of TZ types, sensitivity, specificity, positive predictive value, and negative predictive value (NPV) were calculated, along with their corresponding 95% CIs. The evaluation metric was defined as the agreement with the expert-provided TZ classification. The demographic characteristics of the study participants were summarized using means and SDs for continuous variables and percentages for categorical variables. A P value of less than .05 (two-sided) was considered statistically significant. Statistical analyses were performed using SPSS (version 27.0; IBM Corp) and Python (version 3.7).

Ethical Considerations

This study was approved by the Institutional Review Board of the Chinese Academy of Medical Sciences and Peking Union Medical College (CAMS and PUMC-IEC-2022-022). Informed consent was not required due to the retrospective nature of the dataset, and all personal information and images were

completely anonymized. We commit that all research data will be used for academic research purposes.

Results

General Information of the Study Dataset

For the classification modeling, 8335 colposcopy images from 4 hospitals were selected for training and evaluation. These images included consisting of 2788 images of TZ1, 2663 images of TZ2, and 2884 images of TZ3. In the external validation study, 1335 cases were selected from 2 hospitals for model inference to predict the TZ types (Figure 5). The demographic characteristics of each participant, including age, colposcopic findings, and the distribution of each TZ type, are provided in Table 1. TZ types were found to be significantly associated with the participants' age group distribution (P<.001). The mean age of all participants at the time of colposcopy was 37.87 (SD 9.99) years, with the mean age of the TZ3 group being 45.04 (SD 11.69) years.

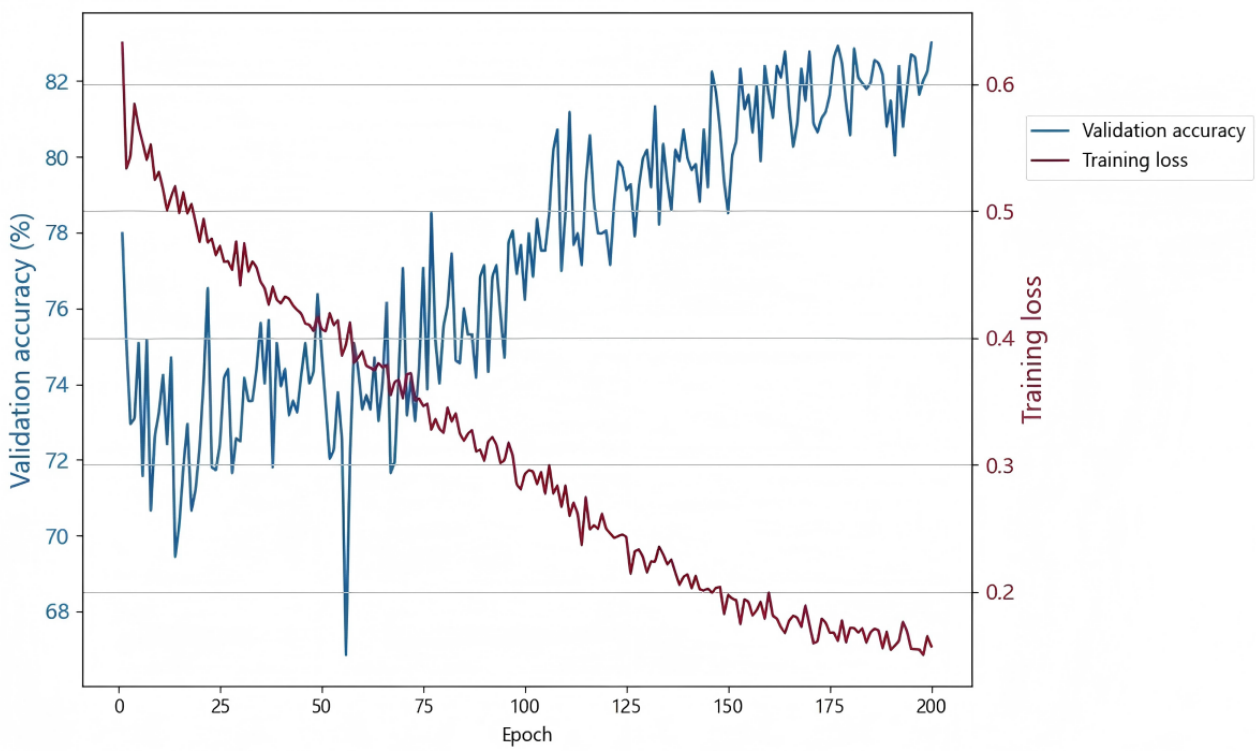
TZ Classification Results

Cervix detection with a bounding box was used for feature engineering. Proper cervix extraction improved classification accuracy. A total of 8335 cervix images were investigated and resized to 224×224 pixels before being input into the classification model. Out of these, 1663 images were used to evaluate the model's performance.

Around 80% of the images were randomly selected as the training set, with the optimal weight parameter model selected during training being used to classify the images in the test set. The validation accuracy of the model gradually improved as the number of epochs increased, as shown in the validation plot (Figure 6). After approximately 100 epochs, both validation accuracy and training loss stabilized, reaching a peak validation accuracy of 83% at the 200th epoch. The validation accuracy fluctuated significantly during the first 25 epochs, it showed a general upward trend, while training loss rapidly decreased, indicating active learning and adjustment of the model. The model reached an optimal balance point and performed well after the 75th epoch when validation accuracy stabilized and training loss continued to decrease but with minimal changes. Overall, the model demonstrated rapid convergence in the early stages of training, with steady performance improvements in the later stages.

Figure 6. Validation accuracy and training loss curve for the proposed classification model.



Our proposed model accurately classified cervical TZ types, as shown in Table 2. The highest classification accuracy of 83.97% and precision of 83.93% were achieved on the test set. For the 3 TZ types, the sensitivity was 84.74% for TZ1, 78.95% for TZ2, and 87.87% for TZ3, while the specificity was 89.99% for TZ1, 91.98% for TZ2, and 94.03% for TZ3. The detailed values for sensitivity, specificity, positive predictive value, and NPV are presented in Table 3. According to the classification performance of TZ types, the sensitivity and NPV for TZ2 were significantly lower.

Table 2. Comparative performance results of the proposed classification model with other state-of-the-art models.

Model	Accuracy (%)	Precision (%)	Recall (%)	F_1-score (%)	mAP[a] (%)
ResNet50	59.22	57.84	56.89	54.66	63.13
VGG16	70.33	69.76	69.21	69.19	74.64
ViT	59.46	57.64	57.39	56.49	63.76
EfficientNet	62.06	60.97	61.18	60.66	63.63

[c]NPV: negative predictive value.

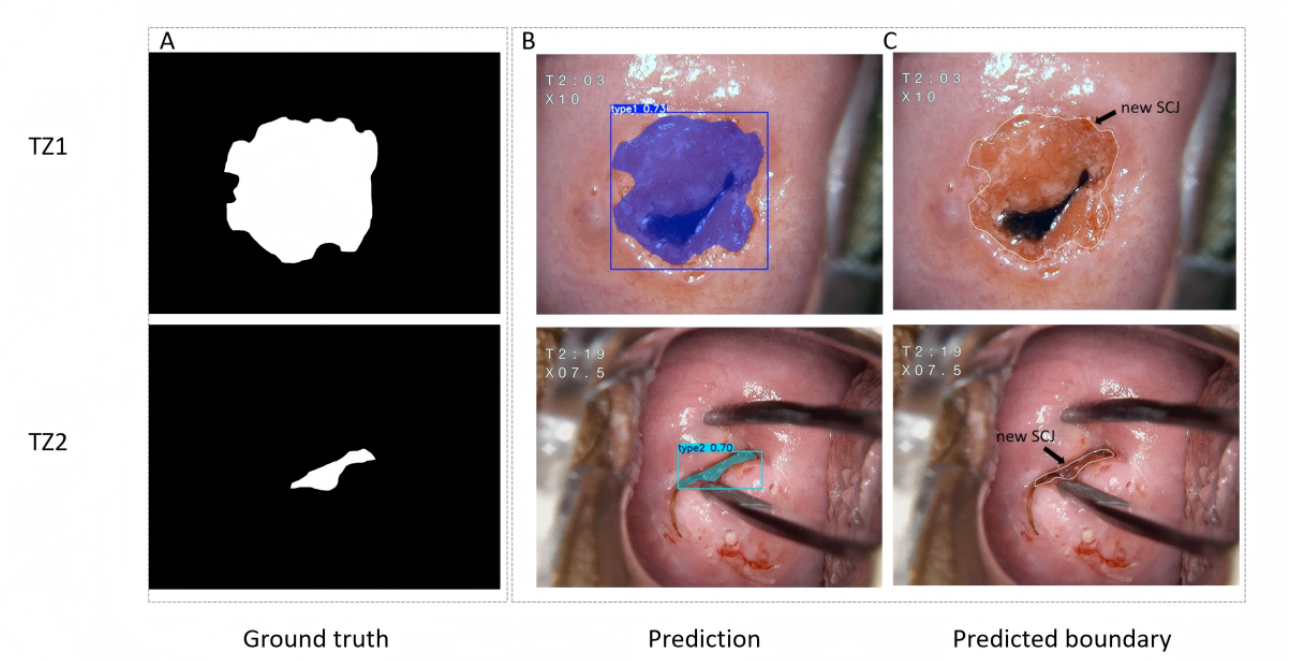
The SOTA deep-learning networks for interpreting colposcopy images were selected to train on our dataset for comparison with our model. Table 2 presents the experimental results of the test set based on various evaluation metrics. The traditional

ResNet50 and Vision Transformer models performed poorly in terms of accuracy and precision, achieving only 59.22% and 57.84%, and 59.46% and 57.64%, respectively. VGG16, with its relatively low-density network structure, performed better than ResNet50 in feature extraction. In addition, we selected 2 lightweight networks for comparison, EfficientNet and ShuffleNet, with higher accuracy of 62.06% and 74.47%. The proposed model achieved the highest accuracy of 83.97% among SOTA models.

TZ Segmentation Result

To enhance AI's clinical guidance, we used a pretrained FastSAM model to segment the TZ region by visualizing the new SCJ. A portion of the training data was used to annotate the new SCJ (Figure 7A), excluding TZ3, as the new SCJ is located in the endocervix. The segmentation model predicted the negative foreground region indicating the area outside the target TZ region (Figure 7B). The region boundary of the mask prediction was the predicted new SCJ (Figure 7C). In the test set, the overall recall and mAP50 (mean average precision at 50% Intersection over Union) of predicted mask were 0.78 and 0.75, respectively.

Figure 7. The segmentation model inference process. (A) Ground truth of the polygonal new SCJ outline. (B) Predictive segmentation of the out-of-TZ area. (C) Representative prediction of the new SCJ guidance line. SCJ: squamocolumnar junction; TZ: transformation zone.



Validation Results

An independent dataset of 1335 cases was used to evaluate the generalization of the TZ classification model, distributed as 594 cases of TZ1, 604 cases of TZ2, and 137 cases of TZ3. The overall classification accuracy was 79.33%. The model's predicted sensitivity for TZ1, TZ2, and TZ3 was 77.3% (95% CI 73.9%-80.6%), 81.1 (95% CI 78.0%-82.3%), and 80.3% (95% CI 73.7%-86.9%), respectively, while the specificity was 94.2% (95% CI 92.4%-95.8%), 83.3% (95% CI 80.6%-85.9%), and 90.7% (95% CI 89.1%-92.3%). The classification performance is presented in Figure 8 and Table 4.

Discussion

Principal Findings

In this study, we proposed a classification and identification model that facilitates clinical colposcopy examinations of cervical TZ. Our AI model achieved an accuracy of 79.33% in the task of classifying the three types of TZ in the external dataset. The sensitivity of TZ3 was 80.3%, and the specificity was 90.7%, which were satisfactory. TZ3 could be accurately differentiated, which further decreased the chance of missed diagnoses of high-grade lesions [21], and it was valuable for guiding ECC and recommending appropriate treatments. The AI model had increased sensitivity on TZ2 and lower sensitivity on TZ1 compared to the performance on the test set, which might be attributed to the similarity between TZ1 and TZ2. According to the standard terminology of the IFCPC, TZ1 and TZ2 were both visible either with or without the assistance of an endocervical speculum [22]. TZ2 was nearly entirely visible in some cases, while the SCJ was only visible at the endocervical canal's border. Therefore, it was difficult to differentiate it from TZ1, which frequently required expert evaluation in strict accordance with established guidelines. In clinical practice, the treatment management for TZ1 and TZ2 is generally similar [6]. Our AI model demonstrated noninferior performance in classifying them and could be used to assist less experienced or inexperienced colposcopists in the colposcopic examination process. The overall model accuracy from the validation study was similar to the performance during model training, indicating that it is capable of generalizing fairly well.

Comparison With Other Studies

In terms of AI techniques, we proposed a method based on the variant MobileNetV3 architecture for cervical TZ classification and FastSAM for segmenting TZ in colposcopy. Currently, only a few deep learning–based models have been developed to classify cervical TZ from colposcopy images. Dash et al [23] conducted a TZ segmentation and classification model based on colposcopy images from the IARC image bank. Similarly, Cao et al [24] developed a high-performance, deep learning model based on retrospective image data collected from one hospital [24]. Comparatively, our method was based on a multicenter study with a more diverse dataset of colposcopy images. While this diversity added to the challenge of feature extraction, the classification model showed better accuracy. Second, the proposed segmentation model could precisely annotate the new SCJ and indicate the approximate location of TZ, which could greatly assist junior colposcopists in selecting biopsy sites. Effective biopsy prioritization focused on the most severe lesions, particularly those within the TZ. Compared with the previous study [23], our method delineated a new SCJ rather than the original SCJ, which can provide more effective assistance and insights for colposcopic clinical examination and treatment. Furthermore, conducted external validation for the TZ classification model for the first time, and our model demonstrated strong stability and generalization performance.

Clinical Implications

In resource-limited settings, colposcopists demonstrated significantly lower clinical skills and performance than those observed in our study. The results of a study evaluating the colposcopic abilities of colposcopists in underserved Chinese communities indicated that colposcopists had a mere 22% accuracy specifically for TZ3 [8]. Similarly, in another study, colposcopists' clinical diagnostic abilities were assessed before and after intensive training [9]. It was found that junior colposcopists had only 49.1% accuracy in classifying TZs. Despite the notable improvement, their accuracy remained below optimal levels at 68.6% following training. In addition, a comparable study conducted in Europe demonstrated that junior colposcopists were only able to detect TZs with a 55% accuracy rate [25]. According to these findings, colposcopists at less-experienced levels generally exhibited inadequate colposcopic performance. However, AI might offer a promising solution to enhance colposcopic capabilities and clinical decision-making confidence. Compared to these studies, our TZ classification model demonstrated strong performance with a high accuracy of 83.97% in the test set and achieved much higher sensitivity in predicting three TZ types in the validation study. Based on the results of previous studies, our model was more effective at stand-alone classification than that of junior colposcopists. Therefore, the method presented in this study accurately identifies TZ in colposcopy images, providing a valuable reference for colposcopists when making clinical decisions. The findings from this study supported the potential of the proposed AI-based TZ identification method as a promising adjunct tool for colposcopic examinations, particularly when integrated with AI colposcopic diagnostic systems and digital colposcopes. Dynamic digital imaging with AI assistance enhances the objectivity of colposcopic examinations and might address the diagnostic subjectivity of less experienced colposcopists. When AI-guided digital colposcopists are deployed in resource-limited health care settings, colposcopists will be able to receive intuitive and accessible guidance on clinical features from AI during the colposcopic examination in real time, supporting less-experienced colposcopists in improving their overall colposcopy skills. Combining AI results with colposcopist assessments helps reduce diagnostic bias, improve colposcopic examination capability, and narrow the gap with resource-rich areas. It addresses the minimization of missed diagnoses, the facilitation of early detection of lesions, the reduction of the risk of CIN progression, and the reduction of the burden of cervical cancer [26]. The application of AI will be integral to improving the quality of colposcopy services in low-resource settings.

The development and application research of AI-guided colposcopy models has emphasized their auxiliary value in clinical practice [14,27]. With the advent of innovations in AI algorithms, these models rely predominantly on mainstream CNNs coupled with transfer learning, as a method of unsupervised learning for image feature learning [28,29]. In some AI models, object detection is used as a metric for identifying lesion areas; however, it remains limited to binary classification tasks. Nevertheless, the multiclassification of normal cervix, low-grade squamous intraepithelial lesion, and high-grade squamous intraepithelial lesion plus poses significant challenges to these models. A clinical perspective suggested that acetowhite changes within TZ have a higher likelihood of association with CIN lesions than those outside of TZ. While the lesion extends across the new SCJ, a biopsy should be taken within the TZ or at the new SCJ. Therefore, by incorporating the TZ-type information as a weight in the model, the AI could be able to perform a more effective feature engineering process within the TZ. It is anticipated that the AI model will markedly enhance the capability of lesion detection, thus eliminating the current limitation in which precise identification is confined to CIN2+ lesions. Our proposed AI system delineated the new SCJ on high-resolution colposcopy images, and it enabled the approximate location of the TZ to be visualized more intuitively, thereby guiding more effective colposcopy examination and biopsy procedures.

For applying AI techniques in limited-resource settings, we proposed a model based on the MobileNetV3 architecture for cervical TZ classification in colposcopy images. Since Google introduced MobileNet in 2017 [30] as a lightweight CNN architecture, it has gained significant attention for its efficiency and accuracy. A lightweight AI model is more energy efficient and requires significantly fewer computational resources than a large-scale AI model, aligning with sustainable AI practices. It has been designed to operate efficiently on battery-operated devices, making it especially suitable for deployment in remote regions with limited power availability and internet access. By minimizing the reliance on high-cost hardware and extensive cloud infrastructure, lightweight AI models enable resource optimization in low-resource settings and facilitate equitable access to AI. Our AI model achieved efficient computation and robust classification performance on portable devices and can be applied actively in a variety of clinical settings to validate its generalization ability. A further economic evaluation is required to support the decision to adopt novel technologies in screening strategies.

Limitations and Future Directions

There are several limitations to this study. First, the scale of the dataset we included was limited, which restricted the ability to support training deeper or more complex deep neural networks. However, the quality and standardization of image acquisition were assured, and the appropriate network depth was chosen to maximize feature extraction. It is necessary to obtain more high-quality colposcopy images with endocervix expansion by auxiliary instruments per case to train more complex networks that can extract additional features and potentially improve classification accuracy in TZ2 and TZ3. To address the suboptimal performance in TZ2 classification, expanding the dataset for TZ2 in future studies could enable the model to capture more distinct texture features that differentiate it from TZ1 and TZ3. The model could be further enhanced by applying edge detection techniques in regions where it is difficult to distinguish TZ2 from TZ3 and to highlight subtle morphological changes at the new SCJ. Second, the external validation was limited to evaluating the AI results alone. Further research is needed to assess the impact of AI-aided colposcopists in the classification of TZ. A prospective clinical trial is further needed

to investigate whether the method can be applied to real-world colposcopy clinics. In addition, although we collected the validation datasets from two different hospitals, the scale of the external validation dataset is relatively limited, particularly when it comes to representing clinical scenarios that involve different colposcope vendors and lighting conditions. Future studies will focus on expanding both the size and scope of the dataset, incorporating data from more regions for more comprehensive validation. Furthermore, transfer learning or domain adaptation techniques may be used to improve the model's robustness and adaptability to various imaging conditions. Finally, the TZ classification lacks an absolute subjective gold standard but is guided by colposcopic examination criteria and expert consensus. However, the colposcopy expert panel from tertiary hospitals conducted the "ground truth" categories for this study in accordance with established guidelines from IFCPC. In light of the subjectivity inherent in TZ classification, using only single-image modality data for model development is limited. Model optimization in the future may implement multimodal learning, which incorporates image data with associated clinical factors (eg, age, menstrual status, gravidity, and parity) to reduce the subjectivity of the model and enhance TZ feature discrimination. Furthermore, the construction of a knowledge graph based on existing consensus and colposcopic examination guidelines will help the model adhere to various rules or logic during the learning process.

Conclusion

In this study, an accurate AI-based method was developed and evaluated for automatically identifying cervical TZ using colposcopy images. The proposed method was the first application of a lightweight CNN for cervical feature extraction and applied a general segmentation model for TZ delineation among multicenter images, achieving commendable classification accuracy on TZ. The proposed approach has the potential to adapt to various colposcopy clinical environments and improve AI-guided colposcopy practice.

Acknowledgments

We acknowledge Haiyan Hu (Shenzhen Maternity and Child Healthcare Hospital), Zhilian Wang (Second Hospital of Shanxi Medical University), Jinfeng Liu (Gansu Maternity and Child Healthcare Hospital), and Jun Lei (Jiangxi Maternity and Child Healthcare Hospital) for assisting with colposcopy image collection and manual labeling. We thank Ms Qianling Dai (Chengdu Women's and Children's Central Hospital), and Ms Haiyan Hu for quality control. We also thank Ms Qianling Dai and Ms Mingyang Chen (Chinese Academy of Medical Sciences and Peking Union Medical College) for their comments on the original manuscript. Abstract

Background: Plain language summaries (PLSs) of Cochrane systematic reviews are a simple format for presenting medical information to the lay public. This is particularly important in oncology, where patients have a more active role in decision-making. However, current PLS formats often exceed the readability requirements for the general population. There is still a lack of cost-effective and more automated solutions to this problem.

Objective: This study assessed whether a large language model (eg, ChatGPT) can improve the readability and linguistic characteristics of Cochrane PLSs about oncology interventions, without changing evidence synthesis conclusions.

Methods: The dataset included 275 scientific abstracts and corresponding PLSs of Cochrane systematic reviews about oncology interventions. ChatGPT-4 was tasked to make each scientific abstract into a PLS using 3 prompts as follows: (1) rewrite this scientific abstract into a PLS to achieve a Simple Measure of Gobbledygook (SMOG) index of 6, (2) rewrite the PLS from prompt 1 so it is more emotional, and (3) rewrite this scientific abstract so it is easier to read and more appropriate for the lay audience. ChatGPT-generated PLSs were analyzed for word count, level of readability (SMOG index), and linguistic characteristics using Linguistic Inquiry and Word Count (LIWC) software and compared with the original PLSs. Two independent assessors reviewed the conclusiveness categories of ChatGPT-generated PLSs and compared them with original abstracts to evaluate consistency. The conclusion of each abstract about the efficacy and safety of the intervention was categorized as conclusive (positive/negative/equal), inconclusive, or unclear. Group comparisons were conducted using the Friedman nonparametric test.

Results: ChatGPT-generated PLSs using the first prompt (SMOG index 6) were the shortest and easiest to read, with a median SMOG score of 8.2 (95% CI 8 - 8.4), compared with the original PLSs (median SMOG score 13.1, 95% CI 12.9 - 13.4). These PLSs had a median word count of 240 (95% CI 232 - 248) compared with the original PLSs' median word count of 364 (95% CI 339 - 388). The second prompt (emotional tone) generated PLSs with a median SMOG score of 11.4 (95% CI 11.1 - 12), again lower than the original PLSs. PLSs produced with the third prompt (write simpler and easier) had a median SMOG score of 8.7 (95% CI 8.4 - 8.8). ChatGPT-generated PLSs across all prompts demonstrated reduced analytical tone and increased authenticity, clout, and emotional tone compared with the original PLSs. Importantly, the conclusiveness categorization of the original abstracts was unchanged in the ChatGPT-generated PLSs.

Conclusions: ChatGPT can be a valuable tool in simplifying PLSs as medically related formats for lay audiences. More research is needed, including oversight mechanisms to ensure that the information is accurate, reliable, and culturally relevant for different audiences.

Introduction

The significance of health literacy has been well established through numerous studies [1,2], demonstrating its importance not only for individual health care [3] but also within the public health system [4,5]. Various organizations, including the Center for Disease Control and Prevention and the National Institute of Health, have underscored the importance of using plain language in health communication to enhance understanding

of medical conditions and patients' engagement [6,7]. Health literacy is particularly important in oncology, where the advancement in cancer treatment beyond traditional methods has positioned patients and their families even more in the center of making care decisions [8]. Upon receiving a cancer diagnosis, patients often turn to various sources for more information, such as the internet, forums, social support groups, and literature [9,10]. Enhancing patients' understanding of their conditions has been shown to positively impact patient adherence and clinical outcomes in various chronic disease models by influencing patient behavior [11-13], whereas patients' struggle to understand complex medical information can adversely affect their adherence to medical advice [14]. However, nearly half of cancer patients struggle to understand the information about their treatment options from scientific literature [15]. Even though the official recommendation of the American Medical Association is that health information should be written at the reading level of the sixth grade in the US education system [16], the complexity of web-based cancer information often exceeds the reading and comprehension abilities of an average person, failing to meet the necessary standards for readability and understandability of health information [17].

To address the gap between the complexity of scientific evidence and the public, many organizations, including Cochrane, dedicate a lot of effort to enhancing the quality of health information available to the public [18]. Cochrane Database of Systematic Reviews is recognized as a highly reliable source for evaluating the effectiveness of health interventions [19]. Cochrane systematic reviews provide both a scientific abstract for professionals and a plain language summary (PLS) for the lay public [20]. Studies have consistently demonstrated that PLSs, which are authored by the same researchers who write the corresponding scientific abstracts, tend to exhibit readability levels that exceed those recommended for health information intended for a general audience [20-24]. In our previous study, we found that Cochrane PLSs for oncology interventions not only required a reading proficiency well above the average public level but also used language that lacked engagement, potentially reducing the reader's interest [21]. Additionally, the PLSs frequently contained ambiguous or insufficiently clear conclusions regarding the efficacy of the interventions assessed in the systematic review [21]. This lack of clarity can leave readers, especially patients and nonspecialists, uncertain about treatment benefits or outcomes, thus diminishing the utility of these summaries in supporting informed health decisions. In addition, we have to bear in mind that the language people use plays a vital role in processing and interpreting information in text, as well as in shaping psychological responses to information and influencing whether the reader will perceive the content as more relatable [25,26]. Given the significant challenges associated with the readability and clarity of PLSs, it is important to explore innovative solutions that can enhance the communication of health information to the lay public.

Artificial intelligence (AI) tools recently emerged as a tool to help generate textual outputs relevant to health care, with the potential to revolutionize the medical sector [27,28]. A standout example of AI in action is the Chat Generative Pretrained Transformer (ChatGPT), a chatbot that operates on the Generative Pretrained Transformer technology [29]. This technology is a type of large language model (LLM) with over 175 billion parameters, capable of understanding and generating text that mimics human conversation [30]. ChatGPT has been trained on a wide variety of internet content, such as books, articles, and websites [31,32]. Its fine-tuning process includes reinforcement learning from human feedback, enhancing its ability to grasp complex user intents and respond accurately to a wide array of tasks, including those related to medical inquiries [30,33]. The deployment of natural language processing models like ChatGPT in the health care field promises to significantly improve access to medical information for both professionals and patients [29,34,35].

Recognizing the challenge posed by the low readability of PLSs authored by researchers for Cochrane systematic reviews, particularly in the context of oncology interventions, we sought to investigate the potential of using AI LLMs, specifically ChatGPT as one of the most accessible tools today, to create PLSs that are more relatable to the public. Cochrane reviews are renowned for their rigorous methodologies and comprehensive analyses; however, this complexity often results in PLSs that may be difficult for a lay audience to understand [20,21]. By using ChatGPT, we aimed to improve the readability and the linguistic characteristics of these summaries, so that they effectively communicate critical findings, methodologies, and implications in a manner that is clear and engaging for nonexpert audiences.

Methods

Study Design and Data Sources

In this study, we analyzed the readability, linguistic characteristics, and conclusiveness of the PLSs generated by ChatGPT from corresponding scientific abstracts of Cochrane systematic reviews of oncology interventions. We then compared them to the readability and linguistic characteristics of the original PLSs, as well as with the conclusiveness of the corresponding scientific abstracts. The dataset included 275 PLSs and corresponding scientific abstracts of Cochrane systematic reviews about oncology interventions up to February 2019 from our previous study [21]. In that study, we assessed the language characteristics of PLSs of Cochrane systematic reviews of oncology interventions in comparison with corresponding Cochrane scientific abstracts. We used this dataset as it included the scientific abstracts for which the conclusiveness of the efficacy of interventions was already assessed, so that we could compare the conclusiveness of the AI-generated PLS with that of the original scientific abstracts from which it was created. Cochrane systematic reviews included in the dataset addressed came from Cochrane review groups focused solely on oncology: Breast Cancer; Childhood Cancer; Colorectal Cancer; Gynaecological, Neurooncology, and Orphan Cancer; Haematological Malignancies; and Lung Cancer. These groups served as representatives of different clinical cancer types. Systematic reviews that did not address intervention studies were excluded. Summaries from the dataset have been analyzed in terms of their Simple Measure of Gobbledygook (SMOG) index, linguistic characteristics (word

count and percentage of words related to different emotions), and the category of conclusiveness [21]. The full dataset is publicly accessible via the Open Science Framework [36].

We used the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist for reporting the results of this study.

Generation of PLSs by ChatGPT

We used a subscription chatbot, ChatGPT (version 4; Open AI) [37]. At the moment of our research, training data for ChatGPT included information up to April 2023.

We formed 3 prompts, and an author (JŠP) asked ChatGPT each prompt for each PLS separately. Before asking these questions, we asked ChatGPT to explain what a SMOG index is. ChatGPT correctly described the readability measure, its formula, and the interpretation of results, confirming that ChatGPT was adequately familiar with the SMOG index. We then used the following prompts (Figure 1):

1. Can you rewrite this Cochrane Scientific Abstract into a Cochrane Plain Language Summary so that your text has a SMOG index of 6?
2. Can you rewrite this Plain Language Summary so it is more emotional?
3. Can you rewrite this scientific abstract so it is simpler, easier to read, and more appropriate for the lay audience?

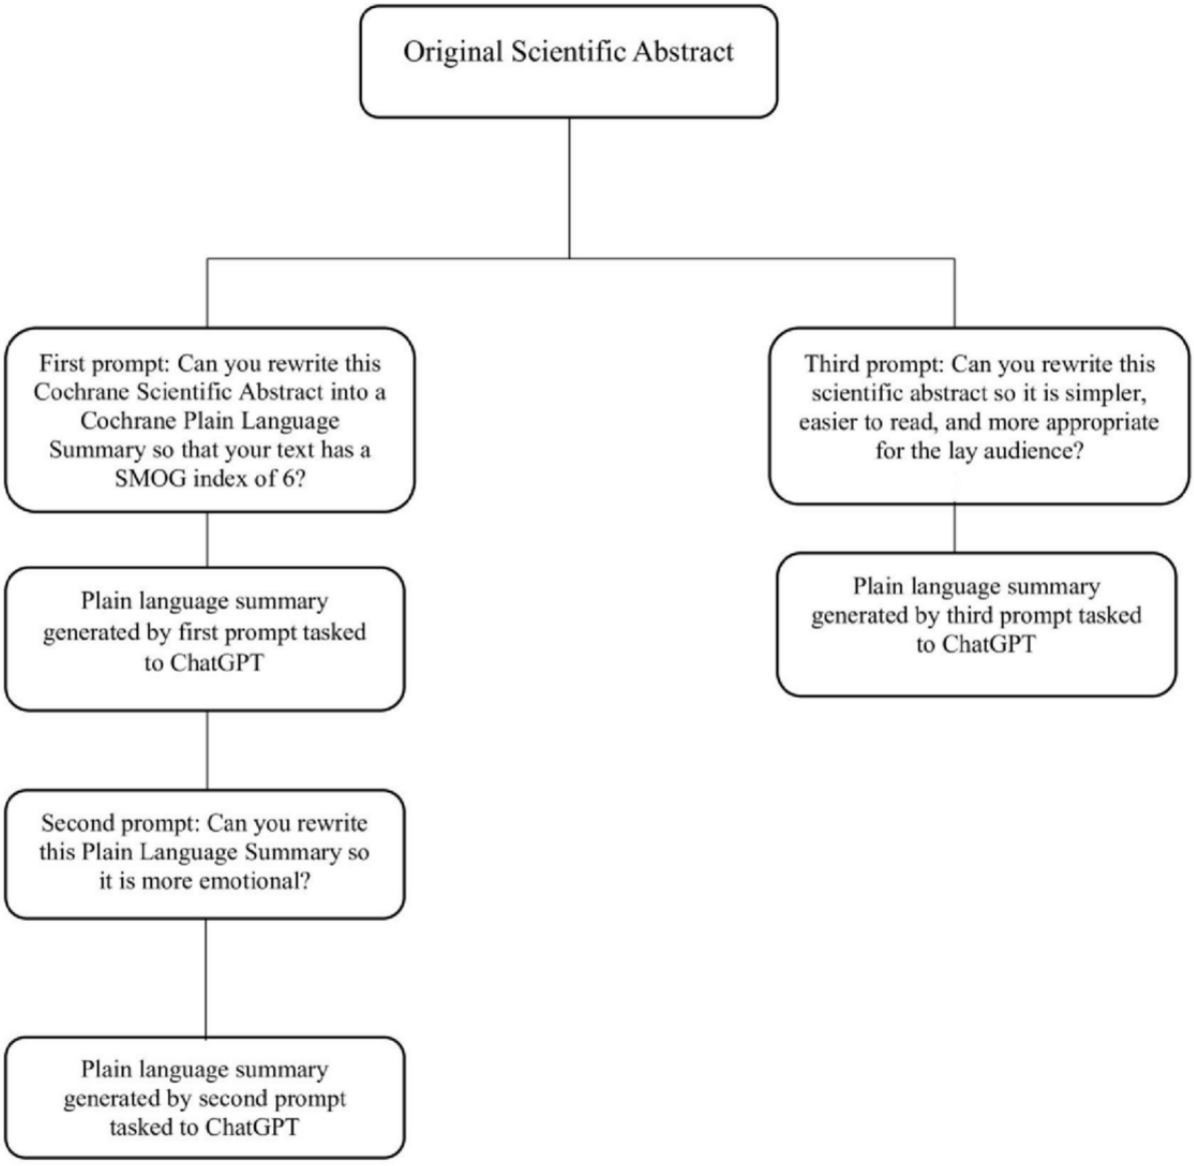
In the first prompt, we asked ChatGPT to rewrite the scientific abstract into PLS with a SMOG index of 6, because the official recommendation of the American Medical Association and National Health Institute is that the health information should be written at the reading level of the sixth grade in the US education system [16,38].

For the second prompt, we continued the conversation with ChatGPT that started in the first prompt. Since we found in our previous study that PLSs had language that was more emotional compared with the corresponding scientific abstracts and that PLSs that have a higher percentage of emotional tone have better readability [21], we used the PLS that was provided to ChatGPT in first prompt and asked ChatGPT to rewrite it again so that is more emotional, so this prompt was included to assess if adding emotional resonance could enhance reader engagement and relatability.

In prompt 3, similar to prompt 1, we asked ChatGPT to simplify the scientific abstract, but without defining the SMOG index. This prompt was designed to explore if using simpler language alone (without a specified readability index) would yield results with improved accessibility while retaining the essential information and nuance necessary for an accurate understanding of oncology topics. When tasking this prompt, we started a new chat with ChatGPT, so that it did not rely on the previous answer.

After that, for each PLS provided by ChatGPT, we measured its readability, expressed as SMOG index, and the following linguistic characteristics: word count and percentage of words related to authenticity, clout, emotional, and analytic tone. We analyzed only the first answers generated by ChatGPT for each of the 3 prompts and did not ask ChatGPT to revise the texts again. To be sure that the content of the PLS provided the same facts as the corresponding scientific abstract, we also checked the conclusiveness of each generated PLS, that is, checked whether there was any difference with the original conclusiveness category for the scientific abstract, determined in our previous study [21]. Multimedia Appendix 1 contains a supplementary table with examples of prompts.

Figure 1. Generation of Cochrane plain language summaries by ChatGPT. SMOG: Simple Measure of Gobbledygook.



SMOG Index

The readability of summary formats in English was assessed using the SMOG index [39]. SMOG index assesses the readability of certain content by counting polysyllabic words and the result is presented as the number of years of education required to understand a given text [39]. It is considered to be suitable for health information due to its consistent results, higher expected comprehension levels, application of recent validation criteria for estimating reading grade levels, and ease of use [39]. SMOG index for PLSs in English was calculated using a web-based tool "WebFX Readability Test Tool" [40]. The tool's reliability and accessibility made it a suitable choice for evaluating the readability of PLSs in our study. Regarding SMOG index interpretation, the official recommendation of the American Medical Association and National Health Institute is that health information should be written at the reading level of the sixth grade in the US education system [16,38].

Linguistic Characteristics

PLSs generated by ChatGPT were analyzed regarding their linguistic characteristics, using the Linguistic Inquiry and Word Count (LIWC) [41], a software tool designed to analyze a given text by comparing each word to its predefined dictionary. The tool categorizes text words into 4 main variables: analytical, clout, authenticity, and emotionality shared in the tone of the text, expressed as the percentage of words from the text in a particular category. The analytical thinking category is based on recognizing words associated with logic or connecting concepts and putting them into a relationship. Greater use of words related to analytical thinking is related to cognitive complexity and abstract thinking [26]. Clout speech is a variable that refers to the use of terms that denote self-confidence, leadership, or social status. A higher proportion of such words suggests that the author speaks from a position of expertise and certainty in what is stated, and a lower proportion suggests a style of presenting information that is humbler [42]. Authenticity is determined by the percentage of words related to personality,

such as the use of personal nouns in the first person (“I”, “my”, and “mine”), present tense, and relative adverbs (near, now). The use of these words is connected to writing that is more personal and honest [43]. Emotional share relates to how positive the tone is according to the words used. A score of 100 in emotional tone would mean the tone is maximally positive, while a score of 50 means an even balance of positive and negative emotion words [44].

Conclusiveness

The category of conclusiveness for each ChatGPT-generated PLS was analyzed by JŠP and checked by IB. Data extraction spreadsheet was tested by 2 authors (JŠP and IB). One author extracted the data, and the other one independently reviewed the data in a 10% random sample of PLSs and corresponding scientific abstracts. Then, it was checked whether the entry in the table was correct. Interobserver agreement was high (κ range 0.80 to 1.00, 95% CI 0.84 - 1.00). We resolved the differences in rating through the discussion with a third author (AM) before full data extraction.

The conclusiveness of statements about efficacy and safety was categorized into 3 categories [45]:

1. Conclusive: positive conclusive (there was moderate- or high-quality evidence indicating the effectiveness or safety of the intervention; ie, the drug was proven effective/safe); negative conclusive (there was moderate- or high-quality evidence indicating that the intervention is ineffective or harmful, or authors advised against the intervention/comparison or it is not recommended); or equal conclusive (the interventions analyzed were equally effective and safe).
2. Inconclusive: positive inconclusive (there was evidence suggesting effectiveness or safety, but it is of low quality or inconclusive, and the authors suggest that more research is needed); negative inconclusive (there was evidence of ineffectiveness or harm (evidence demonstrating that there was no effect or that the intervention was not safe) or authors urged against the intervention or comparison, or it is not recommended; however, the evidence is of low quality or inconclusive, or authors state that more research is needed); or equal inconclusive (the interventions appeared to be similarly effective and safe, but the evidence was of lower quality or inconclusive, and the authors suggest that more research is needed).
3. Unclear: no evidence (there was no evidence as the search did not retrieve any randomized controlled trials, ie, empty reviews); no opinion (the authors did not offer any opinion or judgment); and unclear (the authors did not give a clear conclusion or state that the more research is required).

Based on these criteria, we defined a category of conclusiveness for each of the derived PLS, and then the category of conclusiveness was compared with those from the original scientific abstracts to check whether they match and give the same conclusion about the effectiveness or safety of the intervention [21].

Statistical Analysis

Descriptive Statistics

The data on readability, word count, and linguistic characteristics were assessed as numeric variables. As the data deviated from normal distribution, the results were presented as medians and 95% CI and were presented on original PLS and across 3 prompt groups. The data on conclusiveness was assessed as frequencies and was presented on a bar chart across 3 different prompt groups.

Group Comparison

The results from the analysis of ChatGPT-generated PLSs were compared with the already published data for the original PLSs and scientific abstracts [21]. Since all versions were derived from the same PLS, the results were treated as within the subjects’ group under different conditions. Since the within-subjects ANOVA was not appropriate due to the deviations in the normality of data distribution, the comparison between groups was made using the Friedman nonparametric test for repeated measures, as nonparametric alternative and post hoc testing was made using the Conover post hoc test, since it is one of the recommended methods.

Statistical Software

Analyses were made using JASP (v.0.18.1.0; Jasp Team 2023) and R (v4.3.3; R core team, 2024) [46].

Ethical Considerations

The authors did not require ethical approval as the study is based solely on publicly available summaries of Cochrane systematic reviews. The research does not involve human participants or the use of animals. This is in accordance with the ethical code of the University of Split School of Medicine (April 2009).

Results

Overview

We generated a total of 275 PLSs for each of the 3 ChatGPT prompts. On average, all of them had statistically fewer words than the original PLSs (Table 1).

Table . Comparison of linguistic characteristics (median, 95% CI) between different plain language summary (PLS) groups.

Variable	Original[a], median (95% CI)	ChatGPT prompt, median (95% CI)			*P* value[b]
		First prompt: write from scientific abstract at SMOG[c] index 6	Second prompt: make PLS from first prompt more emotional	Third prompt: write simpler PLS from original PLS	
Word count	364 (339 - 388)	240 (232 - 248)	285 (278 - 292)	273 (266 - 278)	<.001
SMOG index[d]	13.1 (12.9 - 13.4)	8.2 (8.0 - 8.4)	11.4 (11.1 - 12)	8.7 (8.4 - 8.8)	<.001
Linguistic characteristics[e]					
Analytical tone	95.5 (95.0 - 95.8)	55.9 (53.6 - 57.9)[f]	85.7 (84.0 - 86.7)	60.9 (57.7 - 63.1)	<.001
Clout	50.0 (47.7 - 51.8)	67.2 (64.9 - 70.9)[f]	80.3 (77.8 - 83.6)	70.5 (68.0 - 72.8)	<.001
Authenticity	28.6 (26.2 - 31.3)	50.5 (47.0 - 53.5)[f]	38.0 (34.8 - 40.1)	49.4 (45.8 - 54.2)	<.001
Emotional tone	22.1 (18.5 - 26.2)	54.8 (51.3 - 58.7)[f,g]	63.9 (58.6 - 69.6)[f]	54.4 (51.9 - 56.4)	<.001

[a]The results for the original PLSs are from the previous study [21].

[b]Friedman nonparametric test. All post hoc differences were statistically significant except those labeled with symbols in superscript.

[c]SMOG: Simple Measure of Gobbledygook.

[d]Readability was measured as a SMOG index [39]. Higher scores indicated lower readability.

[e]Linguistic characteristics of the text were measured using dictionary-based text word categorizations by the Linguistic Inquiry and Word Count (LIWC) [26]. The variables are presented as the percentage of words from the text in a particular category.

[f]Not different from prompt 3.

[g]Not different from prompt 2.

SMOG Index and Linguistic Characteristics

PLSs generated by the first prompt (write at SMOG index 6) were the easiest to read, with the median SMOG index of 8.2 (95% CI 8 - 8.4), and the shortest. Regarding linguistic characteristics, these PLSs had less analytical tone and more authenticity, clout, and emotional tone when compared with the original PLSs written by authors (Table 1).

PLSs generated by the second prompt (make prompt 1 more emotional), had a median SMOG index of 11.4 (95% CI 11.1 - 12). Those PLSs also had more analytical tone and clout compared with the PLSs generated by the first prompt, but no difference in the emotional tone. They also used fewer words related to authenticity than the PLSs generated by the first prompt (Table 1).

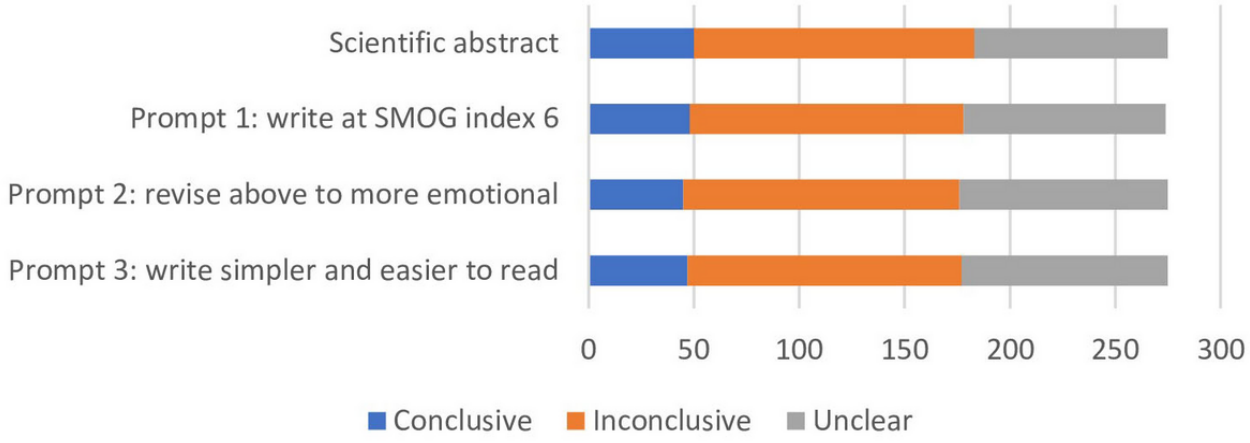
PLSs generated by the third prompt (write simpler PLS from original) had a median SMOG index of 8.7 (95% CI 8.4 - 8.8). Linguistic characteristics did not differ from the PLSs generated by the first prompt, but they had a less analytical and more authentic tone than the PLSs generated by the second prompt (Table 1).

Across the 3 GPT prompts, the results were consistent, without major outliers.

Conclusiveness

The category of conclusiveness of all 3 ChatGPT-generated PLSs did not differ from that of the original scientific abstract (Figure 2).

Figure 2. Distribution of plain language summaries according to the conclusiveness of the efficiency of interventions described in the systematic reviews across 4 different groups of writing prompts. SMOG: Simple Measure of Gobbledygook.



Discussion

Principal Findings

Our study investigated the potential of using an LLM-ChatGPT, to generate more readable and engaging PLSs for Cochrane systematic reviews in oncology. The results demonstrate that ChatGPT-generated PLSs were shorter and easier to read, as illustrated by the SMOG indices across different prompts. Across all prompts, ChatGPT-generated PLSs exhibited a decrease in analytical tone while showing higher levels of authenticity, clout, and emotional tone compared with the original PLSs. Notably, the categorization of conclusiveness in the original abstracts remained consistent in the ChatGPT-generated PLSs.

Specifically, PLSs created by the first prompt (targeting a SMOG index of 6) achieved the lowest SMOG index and the highest readability among the 3 approaches we used. The median SMOG index of the PLSs generated through prompt 1, while higher than the targeted level of 6, was still significantly lower than that of the original PLSs authored by researchers (median SMOG index 13.1).

The second prompt, which aimed to make the summaries contain text with more emotionally positive content, resulted in an increase in SMOG index and a notable shift toward analytical and clout tones, indicating that the addition of emotional language might inadvertently increase linguistic complexity. This observation is crucial because previous studies have shown that emotional resonance can improve reader engagement and comprehension [21], yet it must be balanced with readability to avoid overcomplicating the content.

The third prompt again managed to improve the readability of the summaries. Despite differences in readability and tone, the conclusiveness about the efficacy of the intervention in ChatGPT-generated PLSs remained consistent with that of the original scientific abstracts. This consistency is encouraging, as it suggests that ChatGPT can maintain the integrity of the original scientific conclusions while rephrasing content for a lay audience.

PLSs generated by ChatGPT had language characteristics more suitable for the lay population than the original PLSs from the published Cochrane systematic reviews [21]. They had fewer words and better readability—from the median of 8.2 to 11.2 compared with the original 13.1 SMOG index, bringing it closer to the recommended sixth-grade reading level for the health information intended for the lay public [16]. However, it is not clear whether we can expect at all for PLSs from oncology to be at the recommended reading level, as it is not sometimes possible to replace complex scientific expressions or names of the drugs (eg, trastuzumab-deruxtecan) without altering the meaning and jeopardizing the translation of the information to the reader in the correct way.

Regarding the linguistic content of the PLSs [16,42-44], those generated by ChatGPT had lower content with an analytical tone, meaning that they did not relate so much to abstract thinking or cognitive complexity as the original PLSs. They also had a higher positive emotional tone (a score over 50 for all ChatGPT-generated PLSs) than the original PLSs, which had a predominantly negative emotional tone (median of 22 out of maximum 100). ChatGPT-generated PLSs also had higher clout, meaning that the information came from the position of expertise and certainty, and they used more personal nouns, present tense, and relative adverbs, increasing authenticity tone, that is, making it more personal and honest. In this way, ChatGPT-generated PLSs could influence the subjective experience of people and their engagement in the given text when they process the information in the PLSs with respect to their opinion about the truthfulness of the information or their confidence in the information [25]. These cognitive processes are very important in reacting to health information, as it has been shown that patients adhere more to advice from doctors that contains more positive emotions [47].

Comparison to Prior Studies

ChatGPT-generated PLSs were closer in their characteristics to the press releases of Cochrane systematic reviews, written by professional writers. A study of Cochrane systematic reviews that had an official press release showed that these press releases were written in a more conversational and emotional language than the scientific abstracts or PLSs in different languages,

making them more engaging [22]. ChatGPT-generated PLSs had similar qualities, without losing the conclusiveness of the message, making them more suitable for health evidence translation to the patients and the general public.

Strength and Limitations

Regarding the strengths of the study, this study is among the first to evaluate the use of AI for generating PLSs in oncology, focusing on readability, linguistic characteristics, and consistency with original scientific conclusions. The use of multiple prompts provided a nuanced understanding of how prompt design influences AI-generated content.

These results must be considered in light of several limitations. First, we used PLSs from a single source, the Cochrane Library, and these PLSs were written by different authors. However, summaries from the Cochrane Library have the same format of presenting health information and specific guidance for writing PLSs [48], making them comparable. Second, we analyzed the PLSs in English only since it was the only common language for the summaries in oncology systematic reviews. The focus on English ensured uniformity in linguistic analysis, avoiding inconsistencies in translation processes. Third, a notable limitation of this study is that it required ChatGPT to generate PLSs from scientific abstracts and not from the complete texts of Cochrane systematic reviews. Typically, PLSs are derived from the full content of the reviews [48], which provides a more thorough understanding of the study's findings, methodologies, and contextual factors. Reliance only on scientific abstracts may lead to PLSs lacking depth and detail. Fourth, ChatGPT-4 was developed using a diverse dataset of publicly available information spanning multiple domains and at the time of our study, its information is limited to publicly available sources up to 2021 [49]. OpenAI does not specify the exact content of medical information included or the precise time frame of the dataset [49]. We used ChatGPT-4, the subscription version (unlike its predecessor ChatGPT-3.5), the most advanced and widely available version of ChatGPT during the study period, ensuring access to its latest capabilities, but it is available only to people willing to pay a monthly subscription. For the second prompt in our study, we relied on the answers from ChatGPT provided in the first prompt. For all 3 prompts, we did not ask the system to further rephrase the text but analyzed only the first output. Different AI models vary in training, algorithms, and capabilities, making the use and results of one model not universally applicable to others [50]. We did not use other AI tools such as Microsoft Bing AI, Bard, Jasper, or ChatSonic, which could have given different results. Microsoft Bing AI can only process up to 2000 characters [51], which is not suitable for summaries. Bard was not available in Croatia at the time of conducting the study [52], and Jasper and ChatSonic offered only paid subscriptions for which we did not have sufficient resources [53,54]. Additionally, we did not use specialized AI tools designed specifically for creating PLS, such as Sorcero's solution [55] or Putnam Associates' generative AI approach for PLSs [56]. Our decision not to use these specialized tools stemmed from a focus on general AI models that are more accessible to a wider range of users and our intent to evaluate the performance of widely available, nonspecialized AI for PLS generation. Fifth, it has to be kept in mind that, while our study assessed linguistic characteristics such as clout, analytical tone, authenticity, and emotional tone, it is equally important to consider the cultural and emotional sensitivities of the target audience [57]. AI models like ChatGPT-4 are trained on extensive datasets that may not fully capture the nuances of various cultural backgrounds. Consequently, the generated PLSs might lack the cultural relevance or sensitivity necessary to effectively communicate with all segments of the lay public. Further research should include PLSs from multiple sources to assess the generalizability of AI-generated PLSs across diverse formats and writing styles and explore the potential of AI tools in generating PLSs in languages other than English, to support Cochrane efforts to provide health information in 20 different languages [58].

Future Directions

What conclusions and recommendations can be drawn from our study? Our study is one of the first tests of AI language tools in creating health information from complex health evidence synthesis that is suitable for the lay public. The real-world implementation of medical AI interventions generally lacks high-quality evidence, as a recent systematic review identified 65 randomized controlled trials evaluating AI interventions, but only 7 with chatbots as an intervention [59]. We do not think that, at the current level of development, ChatGPT can replace evidence synthesis in real time, as it does not get updates in real time [60] and there is a potential for bias in the training data, which can result in biased or inaccurate responses [61]. In addition, text generated from the training data can have several other issues besides bias, such as plagiarism [62], lack of context, as well as underestimation of novelties in medicine that are important but may be less represented in web sources [63].

On the other hand, ChatGPT and other generative AI tools may be useful in ensuring the quality and appropriateness of the summary information for health evidence synthesis, such as Cochrane systematic reviews. Although Cochrane has clear guidance on writing PLSs [48], the evidence shows that they are not adequately implemented and published PLSs are not at the desired level of clarity and quality [64]. It seems that the authors of Cochrane systematic reviews have difficulties in translating their results into a language that is suitable for the lay public. This affects not only the usefulness of the PLSs but also their translations into a number of languages, where it is not clear whether there is a further loss to the clarity and understandability of the message to the lay public [22]. Readability metrics like the SMOG index provide an indication of text complexity but do not guarantee comprehension by the intended audience. This gap highlights the need for future research to evaluate the effectiveness of AI-generated PLSs in real-world settings and to determine their actual understandability among diverse patient populations.

Conclusions

Having all that in mind, ChatGPT may be a valuable tool in helping create content designed for the lay public. Cochrane should further explore the use of ChatGPT in generating PLSs, either as a tool for the authors or as an independent, systemic tool to generate high-quality, high-fidelity PLSs, also ensuring

that the main message of health information is unchanged and accurate.

Acknowledgments

This study was funded by the Croatian Science Foundation ("Professionalism in Health - Decision making in practice and research, ProDeM") under grant agreement number IP-2019-04-4882. The funder had no role in the design of this study, its execution, analyses, interpretation of the data, or decision to submit results.

Data Availability

The full summarized data generated or analyzed during this study are included in this published article and its supplementary information files. The datasets extraction sheets generated or analyzed during this study are available in the Open Science Framework repository [36].

Authors' Contributions

AM gave the idea for the study, and all authors contributed to the study plan. JŠP collected the data. IB analyzed the data and interpreted the results. JŠP wrote the first draft of the manuscript, and all authors critically revised the manuscript. All authors agreed to the version submitted for publication and take responsibility for the accountability of the study.

Conflicts of Interest

The authors declare no conflicts of interest, except for their membership in Cochrane.

Abstract

Background: Patients frequently resort to the internet to access information about cancer. However, these websites often lack content accuracy and readability. Recently, ChatGPT, an artificial intelligence–powered chatbot, has signified a potential paradigm shift in how patients with cancer can access vast amounts of medical information, including insights into radiotherapy. However, the quality of the information provided by ChatGPT remains unclear. This is particularly significant given the general public's limited knowledge of this treatment and concerns about its possible side effects. Furthermore, evaluating the quality of responses is crucial, as misinformation can foster a false sense of knowledge and security, lead to noncompliance, and result in delays in receiving appropriate treatment.

Objective: This study aims to evaluate the quality and reliability of ChatGPT's responses to common patient queries about radiotherapy, comparing the performance of ChatGPT's two versions: GPT-3.5 and GPT-4.

Methods: We selected 40 commonly asked radiotherapy questions and entered the queries in both versions of ChatGPT. Response quality and reliability were evaluated by 16 radiotherapy experts using the General Quality Score (GQS), a 5-point Likert scale, with the median GQS determined based on the experts' ratings. Consistency and similarity of responses were assessed using the cosine similarity score, which ranges from 0 (complete dissimilarity) to 1 (complete similarity). Readability was analyzed using the Flesch Reading Ease Score, ranging from 0 to 100, and the Flesch-Kincaid Grade Level, reflecting the average number of years of education required for comprehension. Statistical analyses were performed using the Mann-Whitney test and effect size, with results deemed significant at a 5% level (P=.05). To assess agreement between experts, Krippendorff α and Fleiss κ were used.

Results: GPT-4 demonstrated superior performance, with a higher GQS and a lower number of scores of 1 and 2, compared to GPT-3.5. The Mann-Whitney test revealed statistically significant differences in some questions, with GPT-4 generally receiving higher ratings. The median (IQR) cosine similarity score indicated substantial similarity (0.81, IQR 0.05) and consistency in the responses of both versions (GPT-3.5: 0.85, IQR 0.04; GPT-4: 0.83, IQR 0.04). Readability scores for both versions were considered college level, with GPT-4 scoring slightly better in the Flesch Reading Ease Score (34.61) and Flesch-Kincaid Grade Level (12.32) compared to GPT-3.5 (32.98 and 13.32, respectively). Responses by both versions were deemed challenging for the general public.

Conclusions: Both GPT-3.5 and GPT-4 demonstrated having the capability to address radiotherapy concepts, with GPT-4 showing superior performance. However, both models present readability challenges for the general population. Although ChatGPT demonstrates potential as a valuable resource for addressing common patient queries related to radiotherapy, it is imperative to acknowledge its limitations, including the risks of misinformation and readability issues. In addition, its implementation should be supported by strategies to enhance accessibility and readability.

Introduction

In an increasingly digitized society, patients frequently resort to the internet to access information about cancer [1-3]. However, despite being one of the most favored informational modalities, websites often require more content accuracy and better readability [1].

Recently, artificial intelligence (AI)–powered chatbots such as ChatGPT have signified a potential paradigm shift in how patients with cancer can access a vast amount of medical information [1,3,4]. The rise of these AI platforms, accessible to the general public, has escalated notably since OpenAI released version 3.5 of ChatGPT (GPT-3.5) on November 30, 2022 [4-13], which amassed over 1 billion users in March 2023 [4].

ChatGPT, a large language model (LLM) [6,14-17], uses natural language processing to offer varied responses to the same query considering the context of the conversation and individual user preferences [18]. Through text-to-text communication, ChatGPT can engage with humans [12] and aims to deliver responses resembling human interactions [6,14,18]. This model has undergone extensive training on a diverse corpus of text data encompassing a broad spectrum of sources, including books, scholarly articles, and web pages, enabling it to effectively comprehend and respond to natural language queries across a broad range of topics [19,20]. Moreover, the model's performance is enhanced through reinforcement learning from human feedback, which enables it to produce more coherent and contextually relevant responses [21]. Additionally, ChatGPT can compose emails, essays, and medical reports, as well as solve problems and provide clarification [10,13,22,23].

On March 14, 2023, OpenAI announced the release ChatGPT-4 (GPT-4), which became available through a subscription-based model [9,12,16]. This new version demonstrated outstanding performance across numerous academic and professional benchmarks, providing more refined and varied responses than GPT-3.5 [24].

In this context, ChatGPT has emerged as a contender for traditional search engines, such as Google, because of its capacity to filter vast quantities of data and provide easily comprehensible responses [4,6]. Consequently, ChatGPT is a potentially reliable source of medical information to both the public and patients with cancer, and it is capable of offering insights regarding radiotherapy [4,25]. This is particularly significant given the general public's limited knowledge of this treatment [15,26] and concerns regarding its possible side effects [27].

Radiotherapy is a well-established treatment that delivers targeted ionizing radiation with precision with the aim of destroying cancer cells while minimizing damage to healthy tissues. Approximately half of all patients diagnosed with cancer undergo radiotherapy as a part of their care. Advances in radiotherapy have increased its complexity, requiring greater preparation and support for patients who may face physical and psychological challenges [28]. Considering that approximately 80% of patients have limited knowledge regarding radiotherapy and associated expectations regarding treatment, many have significant misconceptions. These commonly include concerns about radiation burns or the possibility of becoming radioactive as a result of the treatment [29,30]. Such misunderstandings, coupled with the unfamiliarity of radiotherapy for most patients and the inherent invisibility of the treatment, further complicate their ability to fully comprehend the process [31,32]. Therefore, providing clear and accessible information is essential for reducing patients' fear of treatment [31]. Previous studies have explored radiotherapy educational resources, such as videos, and tested group education in radiotherapy settings. However, these studies did not specifically address individual patient education and support needs at key time points [33]. Alternatively, written documentation has proven effective for patients who may feel overwhelmed by excessive verbal information, as it allows them to process the material at their own pace and share it with family and friends [34]. Therefore, ChatGPT offers a convenient and accessible method for patients to obtain written information and support [19].

Given that patient education is particularly crucial for patients with cancer because of the complexity of their treatment pathways [20], providing them with comprehensive information about radiotherapy at appropriate stages may enhance adherence to the treatment plan, because inadequate information can lead to increased uncertainty, unnecessary anxiety, and distress among patients and their families [27,35,36]. Additionally, poorly informed patients are likely to be dissatisfied with their care, have difficulty coping [35], and have many follow-up questions regarding the treatment process. Moreover, patients with cancer often feel uncomfortable discussing their body image and sexual health with their clinicians. Consequently, patient communication with ChatGPT may lower these barriers [36].

However, given that ChatGPT was not explicitly trained for oncology-related inquiries, the quality of the information it provides remains unverified [7,14,36]. Evaluating the quality of responses is crucial, as misinformation can foster a false sense of knowledge and security, lead to noncompliance, and result in delays in receiving appropriate treatment [4,14,15]. Nevertheless, various limitations of ChatGPT have been identified. It has been observed to fall below the expected educational level [4], as health-related materials intended for patient consumption are typically recommended to have a reading level equivalent to fifth and sixth grades [4,37]. Furthermore, the training data for GPT-3.5 are outdated, limited to the information available up until September 2021, and lack access to newer knowledge beyond that date [5,38,39]. To address this constraint, GPT-4 introduces a novel feature that allows the use of external plug-ins [25]. However, this new version is available exclusively through paid subscription [9,12,16]. Additionally, ChatGPT tends to provide unreliable or inaccurate information, potentially generating incorrect or misleading responses [14,16]. This issue often arises from the dependence of models on their training data, which may not always be up-to-date or fully comprehensive [40].

To date, limited research has been conducted on the application of language models in the medical domain and the effectiveness of ChatGPT in patient education remains indeterminate [14].

Although the literature addressing ChatGPT's capabilities has proliferated in recent months, there remains a lack of data regarding the quality and reliability of the responses it provides [11,18]. This gap underscores the necessity for more comprehensive studies to evaluate the performance of language models, including ChatGPT, in the medical context. Ensuring that these models are equipped with the most current and comprehensive data is essential for their effective application in radiotherapy health care.

This study aimed to evaluate the quality and reliability of ChatGPT responses to common patient queries regarding radiotherapy to ascertain its potential as a reliable source of patient information. Additionally, it aimed to compare the performance of GPT-3.5 with GPT-4 in generating responses to the same radiotherapy queries.

Methods

Prompt Generation

To determine the most common patient queries regarding radiotherapy, an assessment was conducted using articles that addressed topics related to the most relevant patient concerns. These served as the foundation for the development of 128 questions, 90 of which were derived from the studies by Halkett et al [27,35,41] and Zeguers et al [32], whereas the remaining 38 were sourced from the National Cancer Institute [42]. The questions were then organized into a table to facilitate the identification of duplicates and the selection of the most pertinent ones. There were 36 questions identified as duplicates, and 43 were deemed specific to certain pathologies or specialized treatments, leaving a total of 49 questions. Four authors (AG, CM, MC-R, and MC) excluded 9 additional questions upon agreement, resulting in a final set of 40 queries to be input into ChatGPT. This exclusion aimed to ensure that the responses could be applied to all patients receiving radiotherapy, thereby reflecting their primary concerns and doubts. The questions were intentionally phrased in the first person to mirror the way patients might typically frame their queries when interacting with ChatGPT [43] and were structured to address the informational needs of patients at various stages of radiotherapy [27]. The final set of questions was categorized into three dimensions: general information (n=14), planning and treatment (n=16), and side effects (n=10) (Textbox 1). These dimensions were selected based on previous studies [27,31,32,44], which assessed the most critical information needs for patients receiving radiotherapy, and they were further chosen to evaluate the strengths and limitations of responses across various topics in radiotherapy.

Textbox 1. Common patient queries regarding radiotherapy by dimension inserted in ChatGPT.

General information

1. Why is radiotherapy recommended?
2. What does radiotherapy involve?
3. When should radiotherapy and chemotherapy be combined?
4. What's the cost of radiotherapy treatment?
5. Who will be providing my radiotherapy treatment?
6. How does the radiotherapy treatment machine work?
7. What impact will radiotherapy treatment have on my life?
8. What impact will radiotherapy treatment have on my health in the future?
9. During the period of radiotherapy, will I have to follow a particular diet?
10. Will radiotherapy make me radioactive?
11. What does radiotherapy do to healthy cells?
12. How long does radiotherapy take to work?
13. Can I be cured of my disease through radiotherapy treatments?
14. What will happen after the radiotherapy treatment is finished?

Planning and treatment

1. Can I maintain my daily routine and activities during radiotherapy?
2. Can I keep working while undergoing radiotherapy treatments?
3. Are complementary medicines recommended while undergoing radiotherapy treatments?
4. What's the planning appointment in radiotherapy and what does it involve?
5. Why is computed tomography (CT) planning necessary in radiotherapy?
6. Why are tattoos useful in radiotherapy CT planning?
7. What happens on the first day of radiotherapy treatment?
8. Will the radiotherapy treatment schedule be adjusted to my availability?
9. What am I expected to do during the radiotherapy treatment?
10. Does the radiotherapy machine make noise?
11. How close is the radiotherapy treatment machine going to get?
12. What happens during radiotherapy treatment?
13. Is there a possibility of experiencing pain due to the radiotherapy treatment?
14. How long does a radiotherapy session last?
15. What should I wear for radiotherapy treatment?
16. Will there be follow-up after the end of radiotherapy treatments?

Side effects

1. What are the side effects of radiotherapy?
2. What skin care should I have during and after radiotherapy?
3. Am I going to feel tired after the radiotherapy treatments?
4. What hygiene care should be taken after radiotherapy treatments?
5. Which steps should be taken to reduce radiotherapy side effects?
6. Will the radiotherapy treatment be interrupted if I experience adverse side effects?
7. Who can I go to if the radiotherapy side effects become too burdensome?
8. Will radiotherapy affect my fertility?
9. Will radiotherapy cause hair loss?
10. Will radiotherapy cause permanent damage?

Data Collection

Responses were collected from ChatGPT between April 6, 2024 and April 9, 2024. Each question was queried on both versions of ChatGPT in English. Each query was entered separately using the "New Chat" function, acknowledging that ChatGPT considers the context of the conversation, which can influence responses. Therefore, the memory retention option was disabled when the questions were introduced into ChatGPT to ensure independence of the responses. The queries were then regenerated in each version of ChatGPT, and both responses were documented to analyze consistency.

Various methods were then used, as described in later sections, to assess the quality and reliability of the response content, response consistency, response readability, and similarity between responses from GPT-3.5 and GPT-4.

Outcomes

Quality and Reliability

To evaluate the quality and reliability of the information provided by ChatGPT, we used a 5-point Likert scale, known as the General Quality Score (GQS), which has been used in previous studies [14,45]. The assessment criteria included accuracy, lay-language use, information flow, usefulness, and empathy. The 5-point Likert scale was defined as follows: (1) inaccurate information, poorly organized text, missing important details, and not helpful for patients; (2) limited accuracy, some relevant information is present, but still not easily understandable for patients; (3) adequately accurate information and some important details are explained in plain language; (4) accurate information, well-organized text, and most relevant details are presented in a patient-friendly manner; and (5) extremely accurate information, well-structured text, and all relevant details are presented in a compassionate and patient-friendly manner [14].

The median GQS was calculated by averaging the ratings provided by 16 independent radiotherapy experts with substantial experience in managing oncology patients undergoing radiotherapy. The experts were randomly assigned to evaluate either GPT-3.5 or GPT-4, assuring that each expert evaluated only the responses from one of ChatGPT's versions to reduce potential bias during the evaluation process, thereby decreasing the likelihood of altering assessments and enhancing their credibility [46]. All the experts received detailed instructions on the evaluation guidelines to promote a uniform understanding of the assessment process. Furthermore, the responses from ChatGPT were provided to the experts in paper format, and their evaluation was conducted in real time without internet access and without knowledge of which version the responses corresponded to, thereby ensuring a blinding effect. Moreover, the authors (CM and MC-R) who analyzed the obtained results were unaware of the identity of the radiotherapy experts.

Consistency and Similarity

The consistency and similarity of the responses were evaluated using the cosine similarity score. This method involves transforming the text information provided by ChatGPT into vectors, then calculating the cosine of the angle between the two vectors, indicating how similar the responses are to each other. Scores were calculated using an online tool. The cosine similarity score ranges from 0 to 1, where a score of 0 indicates complete dissimilarity between the texts, and a score of 1 indicates complete similarity [14,36].

To assess the similarity between the responses generated by GPT-3.5 and GPT-4, the initial responses to the same question provided by both versions were inserted into the web-based tool to determine the cosine similarity score between them.

The consistency of the responses generated by ChatGPT was assessed by entering the same question into both versions and calculating the cosine similarity score between the two responses to the same question. By regenerating the same question, we aim to assess whether ChatGPT can provide consistent information or if its responses vary widely.

Readability

To evaluate readability, responses from both versions were assessed using a web-based Flesch Reading Ease Score (FRES) calculator. This calculator determined the responses' readability using two different indices: the FRES and the Flesch-Kincaid Grade Level (FKGL). These readability tests use mathematical formulas that consider factors such as sentence length and word count. The FRES is a numerical score ranging from 0 to 100, with higher numbers indicating better readability, meaning the content is easier to read and understand [8,47,48] and corresponds to a lower grade level [4,47,48] (Multimedia Appendix 1). The FKGL score indicates the average number of years of education needed to comprehend a text, with lower scores suggesting better readability [8,47,48] and correlating to the equivalent school level [4,47] (Multimedia Appendix 2).

Statistical Analysis

The data were analyzed using SPSS statistical software (version 29.0; IBM Corp). The results were considered statistically significant at the 5% level (P=.05). Exploratory data analysis was carried out using frequency analysis (n, %) for categorical variables and median and interquartile range (IQR = $Q_3 - Q_1$) for continuous variables. To test the normality of the data, the Shapiro-Wilk test was used. The Mann-Whitney test (since the normality assumption was not verified) and effect size were used to compare the evaluations between the 2 versions of ChatGPT. To analyze the question evaluations, scores were calculated for each question, considering the 8 experts assigned to each version. Krippendorff α and Fleiss κ were used to assess the agreement between experts. For this analysis, the experts' assessments were considered for all questions in each dimension in each version of ChatGPT.

Ethical Considerations

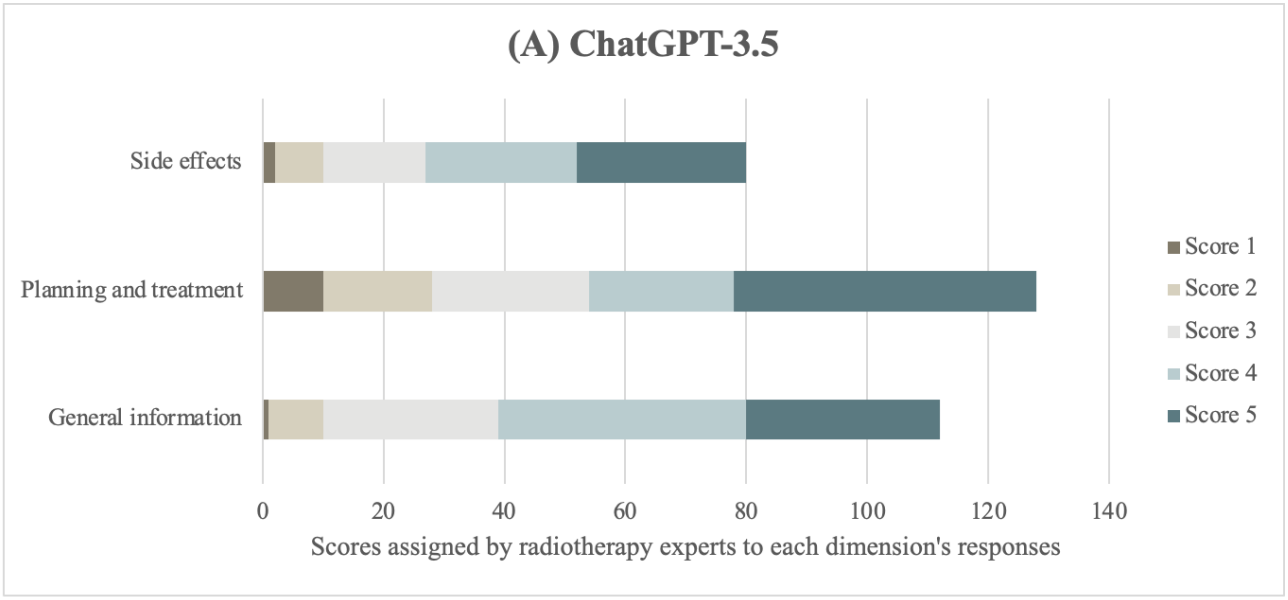
This study did not qualify as human subjects research due to the lack of patient involvement and identifying data for the health professionals involved; therefore, it was deemed exempt from institutional review board approval. Additionally, the use of ChatGPT, a public platform accessible to all, meant no permission was required to use the information generated in this study.

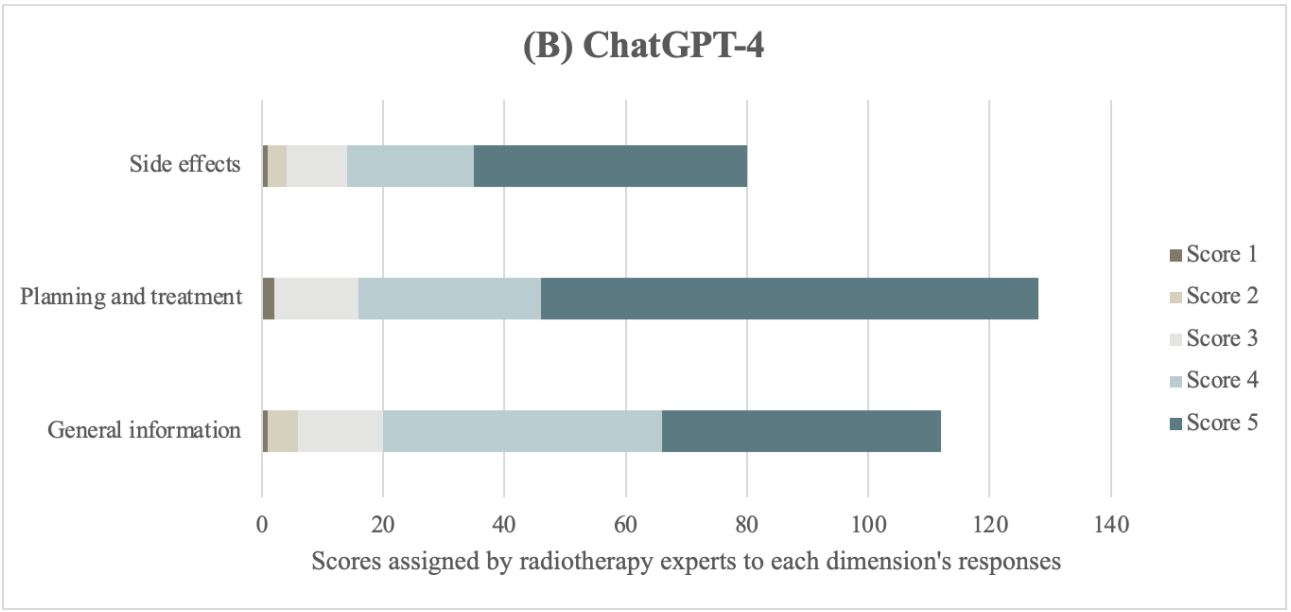
Results

Quality and Reliability

GPT-3.5 received primarily midrange scores, with most evaluations at levels 3 (n=72) and 4 (n=90), indicating generally accurate and comprehensible responses. Notably, many responses had the highest rating of 5 (n=110), providing extremely accurate and well-structured information. However, they also received low scores of 1 (n=13) and 2 (n=35), suggesting inaccurate or limited information, respectively. Conversely, GPT-4 received the highest score of 5 (n=173), indicating a superior ability to provide accurate and well-structured information. A significant number of responses were assigned a score of 4 (n=97), while a smaller proportion received a score of 3 (n=38), demonstrating that it consistently provided responses that were accurate, well-organized, and accessible to patients. Remarkably, GPT-4 exhibited a lower number of low scores of 1 (n=4) and 2 (n=8) than GPT-3.5. The score breakdown by the question dimension is shown in Figure 1.

Figure 1. Number of scores assigned by radiotherapy experts to the total number of responses in each dimension from (**A**) ChatGPT-3.5 and (**B**) ChatGPT-4. The Likert scale was defined as follows: score 1=inaccurate information; score 2=limited accuracy; score 3=adequately accurate information; score 4=accurate information; and score 5=extremely accurate information.





Considering the general information dimension, statistically significant differences were detected between the 2 versions of ChatGPT regarding questions 3 (P=.03, effect size=0.6) and 10 (P=.04, effect size=0.5). Regarding planning and treatment, statistically significant differences were detected for questions 5 (P=.046, effect size=0.5), 7 (P=.002, effect size=0.8), 9

(*P*=.003, effect size=0.7), and 11 (*P*=.02, effect size=0.6). Finally, regarding side effects, statistically significant differences were detected for question 9 (*P*=.04, effect size=0.5). In either situation, GPT-4 showed higher ratings (Table 1). The high effect size values revealed a weak overlap in the response distributions between the 2 versions of ChatGPT. However, in the results of the comparison of the evaluation of the 2 versions of ChatGPT, for the other questions, the effect size was low, revealing overlapping distributions of responses, which is why no statistically significant differences were detected. It can also be seen that, although not significant, version 4 of ChatGPT presents higher evaluation scores.

Table . Comparison of responses to questions about general information; planning and treatment; and side effects between the 2 versions of ChatGPT, with Mann-Whitney test and effect size results.

Dimension and questions	Number	Mean rank		*P* value	Effect size

Based on the analysis of Krippendorff α and Fleiss κ coefficients across the 3 dimensions (general information; planning and treatment; and side effects), the results indicated a low level of agreement in the classification of questions for both GPT-3.5 and GPT-4. This trend of weak agreement was consistent across the overall set of queries in Multimedia Appendix 3.

Consistency and Similarity

Regarding similarity and consistency, a cosine similarity score ranging from 0 to 1 was calculated, as previously described. Concerning similarity, the median (IQR) cosine similarity between GPT-3.5 and GPT-4 responses was 0.81 (IQR 0.05), indicating a reasonably good similarity between the 2 versions of ChatGPT. Notably, question 11 in the planning and treatment

dimension exhibited the lowest similarity, with a value of 0.68. With respect to consistency, the cosine similarity median (IQR) for GPT-3.5 and GPT-4 responses were 0.85 (IQR 0.04) and 0.83 (IQR 0.04), respectively. In both versions, consistency was demonstrated to be good or very good, with values ranging between 0.74 and 0.92.

Readability

The word count, sentence count, FRES, and FKGL score for both versions are summarized in Table 2. A relevant disparity was observed in the median (IQR) word count between GPT-3.5 and GPT-4 (299.00, IQR 176.5 versus 344.50, IQR 74.75). Additionally, the sentence count was higher in GPT-4 compared to GPT-3.5 (20.00, IQR 10.5 versus 18.00, IQR 17).

Table . Word count, sentence count, Flesch Reading Ease Score, and Flesch-Kincaid grade level score of responses from GPT-3.5 and GPT-4.

Q7	298	21	45.09	10.50	371	27	38.28	11.33

Dimension and questions[a]	GPT-3.5				GPT-4			
	Word count	Sentence count	FRES[b]	FKGL[c]	Word count	Sentence count	FRES	FKGL
Q8	164	8	23.53	15.07	277	10	17.15	17.75
Q9	108	5	43.91	12.50	214	15	57.94	8.72
Q10	212	10	29.29	14.44	330	12	26.13	16.45

[a]Please refer to Table 1 for the full questions.

[b]FRES: Flesch Reading Ease Score.

[c]FKGL: Flesch-Kincaid Grade Level.

The FRES median (IQR) for GPT-3.5 and GPT-4 responses were 32.98 (15.59) and 34.61 (16.07), respectively. This indicates that the responses generated by the two versions were considered college-level and difficult to read. The FKGL median (IQR) for GPT-3.5 and GPT-4 responses were 13.32 (3.79) and 12.32 (3.32), respectively. This suggests that at least 13 years of education (college-level) are required to understand the responses generated by GPT-3.5, whereas the responses from GPT-4 require at least of 12 years of education (college-level) for comprehension.

Discussion

Principal Findings

The power and utility of AI platforms in health care, such as ChatGPT, are rapidly evolving and improving and have the potential to significantly improve patient education [5,49]. This study sought to assess the quality and reliability of ChatGPT responses to common patient queries regarding radiotherapy with the aim of determining its potential as a reliable source of information for patients. We also aimed to compare the performances of GPT-3.5 and GPT-4 in generating responses to the same radiotherapy-related queries.

Although most responses were correct or close to correct, upon comparing the accuracy of responses between GPT-4 and GPT-3.5 in the 3 dimensions, it became evident that GPT-4 consistently offered improved elucidation of specific concepts relevant to radiotherapy treatment. In question 10 of the general information dimension, GPT-4 specifically delineated that patients are nonradioactive and may safely interact with others posttreatment (“You can safely be around others, including children and pregnant women, without any risk of exposing them to radiation”). However, this aspect was not as clearly articulated in GPT-3.5, which failed to mention that patients may come into contact with others after treatment. Additionally, within the side effects dimension, in questions 2 and 3, GPT-4 emphasized that the intended creams to use throughout radiotherapy treatment should only be those recommended by the health care provider (“Apply a fragrance-free moisturizer recommended by your healthcare provider”) and specified strategies to mitigate fatigue, a treatment-related side effect. However, this advice was not as detailed in the responses from GPT-3.5. Within the planning and treatment dimensions, GPT-3.5 demonstrated a propensity to diverge from directly addressing the queried issue in certain responses in contrast to GPT-4. In question 7, the response did not describe the first day of treatment but rather outlined the entire course of the patient’s radiotherapy. Question 11 failed to specify the distance between the equipment and the patient, a detail that was thoroughly addressed by GPT-4. In response to question 12, GPT-3.5 did not describe what occurs during treatment, instead reiterating the patient’s overall course. This indicates that GPT-3.5 exhibits reduced accuracy when responding to queries related to planning and treatment, as Valentini et al demonstrated [50].

However, in GPT-4’s response to the 13th planning and treatment question, specific information was inaccurately presented as it erroneously stated that radiotherapy induces direct pain (“Direct Pain from Treatment Site: Radiotherapy can cause localized pain at the site of treatment”). This error may have occurred because not all web-based sources are reliable, and because the model is trained on a diverse array of internet texts, it may incorporate biased or outdated information. Consequently, misinformation regarding cancer continues to pose a significant concern in online communication, which could result in responses or recommendations that do not consider the most current, evidence-based medical practices [21].

Moreover, there were a few occasions in both versions in which a lack of information was demonstrated. For instance, in question 7 of the side effects dimension, neither version mentioned that radiation therapists, who are team members that assist the patient daily throughout their treatment [31], could serve as advisers for patients experiencing severe side effects.

In summary, both GPT-3.5 and GPT-4 demonstrated the ability to address concepts related to radiotherapy. However, GPT-4 provided more targeted and detailed responses, thereby exhibiting superior performance compared to GPT-3.5, as corroborated by several studies [9,24,25,43,47]. The reduced number of scores of 1 and 2 assigned by radiotherapy experts to GPT-4 responses indicated a substantial improvement in response quality and reliability.

Comparison With Prior Work

In most responses, ChatGPT used a typical structure characterized by a succinct introductory paragraph, followed by 5 or 6 bullet points delineating the responses, culminating in a short concluding paragraph. Additionally, in a fair number of responses generated by GPT-3.5 (n=25) and GPT-4 (n=28), a statement was included advising that the information provided should always be discussed with health care providers, consistent with prior studies [43,51,52]. This recommendation is significant because the use of ChatGPT in health care must be carefully

monitored and should not be viewed as a substitute for human judgment. Its performance, safety, and associated risks require thorough evaluation by experts before integration into mainstream practice [53]. Moreover, it is essential that the model be trained on a substantial dataset validated by experts. This rigorous validation process could enhance the reliability and trustworthiness of ChatGPT responses, ultimately benefiting patient care [54].

The cosine similarity score indicated a reasonably substantial similarity and consistency, and while subtle changes in sentence structure were noted, most answers remained consistent, implying accuracy [3].

A key feature influencing consistency is the temperature parameter, a value ranging from 0 to 2, which adjusts the randomness of each subsequent word in the chat output. A value of 0 results in minimal variability, whereas values approaching 1 introduce greater randomness and creativity into the responses. Creativity is a powerful tool in communication, as it simplifies complex concepts, fosters critical thinking, and enhances the accessibility of intricate information, making it especially valuable for developing patient education materials. However, using ChatGPT with high creativity settings in clinical contexts may present challenges. By lowering the creativity level, we ensure that the summarized information remains faithful to the training data, thereby prioritizing accuracy and reliability over creative expression. Although this feature is not currently available for modification in ChatGPT, it may be included in future iterations of the tool's web interface [55].

Therefore, ensuring high reliability in ChatGPT's outputs is essential for users to trust its data-driven conclusions. Although advances in ChatGPT's performance can be attributed to key developments in its underlying technology, it is crucial that patients approach the information provided by AI tools such as ChatGPT with caution [56]. This is especially important given that ChatGPT does not disclose the bibliography used to generate responses [7,21,22]. This issue was observed during our study, as the bibliography was not disclosed in either version, indicating ChatGPT's inability to inform users of the contentious nature of certain information [7,10,21,22]. This lack of transparency is particularly significant, given the ethical concerns that arise regarding its application in patient care. Its implementation may lead to unintended or undesirable issues such as risks of bias and transparency, challenges related to interpretability, and generation of inaccurate content, all of which can have serious negative consequences for patient health [53].

Moreover, patient accessibility to AI technology varies significantly according to socioeconomic status, education, age, and geography. Individuals in higher socioeconomic groups or urban areas have better access to the necessary infrastructure, whereas those in lower socioeconomic conditions or rural regions face significant barriers. The effective use of AI also requires digital literacy and computational skills, making the understanding of technology crucial [57]. Although AI can revolutionize education and research, GPT-4 may widen the gap between the wealthy and poor [58]. Conversely, the free availability of GPT-3.5 helps reduce socioeconomic inequalities in cancer treatment by providing fast medical information to all, regardless of financial circumstances [21].

Concerning readability, all responses were considered more difficult to read than the sixth grade reading level recommended for patient consumption, a concern highlighted in prior studies [4,37]. This finding suggests that although the content was predominantly accurate, it was presented at a level too advanced for the public, particularly for individuals with lower health literacy [37,59]. Health literacy, defined as a patient's ability to read and understand health care information and make effective decisions, is crucial for quality patient engagement in health care options. An important aspect of health literacy is readability, which measures the ease with which text can be read and understood and is particularly relevant in radiotherapy due to the complexity of the field and its evolving nature. Patients with lower health literacy may have limited knowledge of radiotherapy; struggle to understand their conditions, treatments, and potential side effects; and often confuse different treatment modalities [60]. Owing to the heightened challenges faced by these patients, this bears particular significance [36].

Various studies have been conducted to assess ChatGPT's ability to enhance readability and simplify responses [36,61-63], considering that, when providing patient education in a written form, it is important to ensure that it is tailored to the reading level of the target population [62]. To address this issue, it was suggested that direct prompts such as "Explain this to me like I am in fifth grade" could assist in generating simplified responses [36,61-63]. This indicates the potential of ChatGPT to tailor responses to varying literacy levels and customize them based on an individual's educational background [61].

Strengths and Limitations

This investigation revealed that both GPT-3.5 and GPT-4 demonstrated proficiency in addressing radiotherapy-related concepts, with GPT-4 exhibiting notably higher performance. Although GPT-4 achieved marginally better readability scores, the content generated by both models remains complex for a general audience. Therefore, their use should be complemented by strategies to improve their accessibility and readability. Moreover, ChatGPT holds significant potential in promoting health behavior changes among patients with cancer by enhancing health literacy and supporting the self-management of radiotherapy-related conditions [64]. However, ChatGPT's responses must be validated by experts before they are integrated into a health care system to serve as a reliable source of information [53,54]. Therefore, ChatGPT shows promise in providing clinical guidance, suggesting treatment options, and serving as a valuable resource for medical education, facilitating a more effective shared decision-making process [6,47,59,65]. Hence, it can potentially serve as an alternative to current web-based resources [36].

This study had some limitations. First, the formulation and phrasing of queries in both versions may have influenced the performance of ChatGPT. Second, the queries were exclusively written in English, which restricted the responses to a single language. Third, although the total number of questions was comparable to other studies [1,8,11,18,47,50], the optimal number of queries needed to effectively evaluate the model

remains undetermined, and the sample may not capture the full diversity of patient concerns about radiotherapy. Fourth, the scoring process inherently involves subjectivity, particularly with the GQS, as different raters may interpret and prioritize quality aspects differently. Fifth, the potential bias introduced by using a 5-point Likert scale may lead to a central tendency bias, as respondents tend to avoid extreme options and cluster their answers around the midpoint, which can limit the granularity of the evaluations and distort the data [66,67]. Sixth, this study was conducted within a specific time frame (April 2024), and ChatGPT is expected to improve continuously over time. Repeating this study at a later time could improve response quality.

Another limitation of our study was the limitations of ChatGPT itself. First, it should be noted that the information provided by GPT-3.5 is available only up to September 2021. Second, GPT-4 has a limited number of questions that can be posed within a specific time frame and it is exclusively accessible through paid subscriptions, potentially constraining the public's access to more accurate information. Finally, ChatGPT is one of the many AI models available, making it uncertain whether the responses obtained represent the general characteristics of all LLMs.

Future Directions

Further research is essential to fully comprehend ChatGPT's role in patient education, including comparative studies with other AI models or traditional information sources, to better contextualize the findings. Additionally, future work should incorporate patient feedback into their understanding and satisfaction, providing valuable insights into the effectiveness of ChatGPT as an educational tool in real-world settings.

Conclusions

Both GPT-3.5 and GPT-4 demonstrated the ability to address concepts related to radiotherapy, with GPT-4 exhibiting superior performance. Although GPT-4 achieved slightly better readability scores, the content produced by both versions remains challenging for the general public. This highlights the need for caution regarding potential misinformation and readability. Furthermore, the paid subscription model for GPT-4 could exacerbate existing health care disparities by limiting access to certain patient populations. Despite these limitations, ChatGPT shows promise as a valuable tool for addressing common patient queries regarding radiotherapy. However, its use should be complemented by strategies to improve accessibility and readability.

Acknowledgments

This work received Portuguese national funding from FCT – Fundação para a Ciência e a Tecnologia, IP, through the Research Center for Psychological Science of the Faculty of Psychology, University of Lisbon (UID/04527). The funding source was not involved in the study design, analyses, or interpretation of the data; writing of the report; or decision to submit the paper for publication. The authors used AI to assist in rephrasing sentences and enhancing their clarity and effectiveness. After using the tool, the authors reviewed and edited the content as necessary and take full responsibility for the final publication.

Data Availability

The datasets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

AG and MC contributed to the conceptualization, methodology, writing/review and editing, supervision, and project administration. CM and MC-R were responsible for the conceptualization, methodology, investigation, resources, data curation, and writing the original draft. EC conducted the statistical analysis. All authors approved the final version of the manuscript and had full responsibility for the decision to submit for publication.

Abstract

Background: National guidelines recommend germline genetic testing (GT) for all patients with early-onset colorectal cancer. With recent advances in targeted therapies and GT, these guidelines are expected to expand to include broader groups of patients with colorectal cancer. However, there is a shortage of genetic professionals to provide the necessary education and support for informed consent. As such, there is a pressing need to identify alternative approaches to facilitate and expedite access to GT.

Objective: This study describes the development of a pretest education intervention, Nest-CRC, to facilitate the uptake of germline GT among patients with early-onset colorectal cancer. Patients with early-onset colorectal cancer and health care providers reviewed Nest-CRC, and their reactions and recommendations were captured using a nested mixed methods approach.

Methods: Using the learner verification approach, we conducted 2 sequential phases of surveys and interviews with English- and Spanish-speaking patients with early-onset colorectal cancer and health care providers. The surveys assessed participants' experiences with genetic services and provided immediate feedback on the Nest-CRC genetic education modules. Semistructured interviews evaluated participants' perceptions of self-efficacy, attraction, comprehension, cultural acceptability, and usability of Nest-CRC. Survey data were analyzed using descriptive statistics (mean, median, and proportions), while interview data were analyzed through line-by-line coding of the transcribed interviews. After each phase, Nest-CRC was refined based on participants' recommendations.

Results: A total of 52 participants, including 39 patients with early-onset colorectal cancer and 13 providers, participated in the study. Of these, 19 patients and 6 providers participated in phase 1 (N=25), and 20 patients and 7 providers participated in phase 2 (N=27). Most participants (phase 1: 23/25, 92%, to 25/25, 100%; phase 2: 24/27, 89%, to 27/27, 100%) agreed that each of the 5 education modules was easy to understand and helpful; 13 patients reported no history of GT, with 11 (85%) expressing interest in GT and 2 (15%) remaining unsure after completing Nest-CRC. Participants reported that Nest-CRC provided sufficient information to help them decide about GT. The tool was deemed acceptable by individuals from diverse backgrounds, and participants found it visually attractive, easy to comprehend, and user-friendly.

Conclusions: The findings revealed that Nest-CRC is a promising strategy for facilitating pretest education and promoting GT. Nest-CRC has been refined based on participant recommendations and will be re-evaluated.

KEYWORDS

genetic education; genetic testing; genetic counseling; digital health; early-onset colorectal cancer

Introduction

Colorectal cancer (CRC) is the third most common cause of cancer incidence and mortality among men and women in the United States [1]. By 2030, it is projected to become the leading cause of death among patients diagnosed with early-onset cancer (under the age of 50 years) [2]. Approximately 14%-25% of early-onset CRCs are linked to hereditary factors, irrespective of family history [3,4]. Identifying germline variants in patients with CRC can help reduce morbidity and mortality by enabling guided treatment decisions, risk management to prevent and detect new primary cancers early, and cascade testing for at-risk relatives [5-9]. The National Comprehensive Cancer Network (NCCN) Guidelines recommend multigene panel testing (MGPT) for *all* individuals diagnosed with CRC before the age of 50 years and consider its use for all individuals diagnosed with CRC [10]. MGPT is recommended because it can simultaneously identify gene variants associated with various cancers and simplifies referrals for genetic testing (GT), as neither family history nor patient tumor characteristics are required.

Genetic services heavily depend on clinicians to identify and refer high-risk patients for genetic counseling (GC) and GT. However, approximately 40% of patients with early-onset CRC are not referred for GC [11,12]. Additionally, racial and ethnic disparities exist in germline studies and access to genetic services [11,13]. A study conducted between 2009 and 2017, involving patients with early-onset CRC treated at a tertiary-care referral center and a safety-net health system, found that Black patients were less likely to attend GC compared with Hispanic and non–Hispanic White patients [11]. Another retrospective study, using data from 2012 to 2016 across 4 academic medical centers, found that Black and Hispanic patients with CRC were referred to genetic specialists less often than non–Hispanic White patients [13]. However, among those referred, no racial or ethnic differences were observed in GC attendance [13], highlighting a missed opportunity for guideline-concordant genetic care. Therefore, systematic strategies are necessary to ensure GT services are offered to all patients with early-onset CRC.

With the expanding indications for genetic services, there is a shortage of genetic counselors and qualified genetic professionals [14,15], which can result in delays in GT. Although oncologists and other health care providers can order GT for at-risk patients, most lack the expertise or time to provide adequate genetic education [16,17]. Consequently, the American Society of Clinical Oncology (ASCO) acknowledges GC as the standard of care but also advocates for alternative approaches to delivering genetic services [18]. Studies examining the uptake of genetic services among patients with early-onset CRC have identified cost, limited availability of services, and racial and ethnic referral disparities as key barriers [11,19]. To address these known barriers to GT, the National Institute of Health Clinical Genome Resource's Consent and Disclosure Recommendations Working Group suggested reserving traditional, provider-delivered pre- and posttest GC for patients with greater clinical and genetic complexity, such as those with conditions lacking well-established testing and risk management criteria [20]. Alternative approaches to genetic education are needed to facilitate, expedite, and expand access to GT for patients at risk of cancer without overburdening GC resources [21]. To address this, we developed a digital health tool designed for patients with early-onset CRC from diverse racial and ethnic backgrounds. This tool systematically delivers pretest education and triages patients to GC and GT.

Previous studies involving patients with cancer suggest that digital genetic education is well-accepted and effective in improving knowledge, decisional satisfaction, and reducing decisional conflict [22-24]. However, most educational interventions addressing germline testing have focused on patients with breast cancer [25-27]. To our knowledge, only 2 studies have evaluated alternative strategies for genetic education in patients with CRC. These studies were not specific to patients with early-onset CRC, and their educational content focused on tumor testing [28] or GC [29]. Therefore, in this study, we propose a digital health tool designed for patients with early-onset CRC to promote autonomy by allowing them to access relevant germline information at their convenience, make informed decisions about GT, and opt-in to pretest GC if desired. This study outlines patient and provider feedback on the digital pretest genetic education tool and provides recommendations for its implementation, using a mixed methods approach.

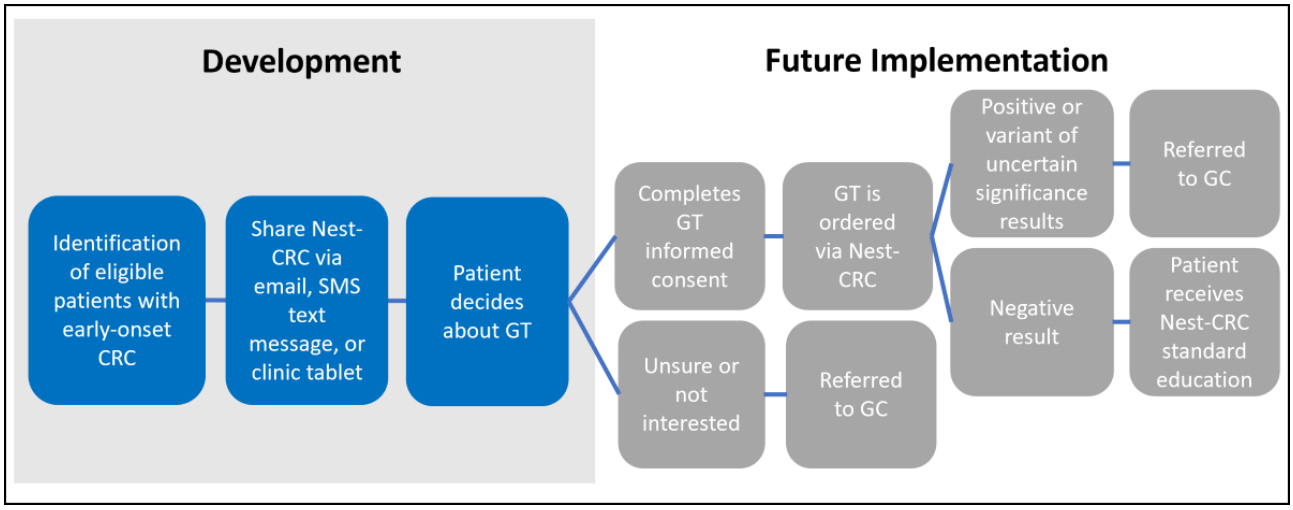
Methods

Intervention

Nest Genomics is a software company specializing in developing tools that help patients and providers scale the delivery and long-term implementation of genomic information. The Nest platform is a comprehensive, Health Insurance Portability and Accountability Act (HIPAA)–compliant solution designed to launch, implement, and scale longitudinal genomic programs, supporting both patients and clinicians throughout the care continuum—from patient identification and education to test ordering, result integration, and long-term management. Within Nest, our research team developed the Nest-CRC, a digital health tool designed to provide pretest genetic education for patients with early-onset CRC from diverse racial and ethnic groups (Figure 1). Nest-CRC is not publicly available at this time. The tool is divided into 5 brief modules. The modules

included in the first version of Nest-CRC are (1) hereditary CRC, (2) GT, (3) benefits and risks, (4) care recommendations, and (5) implications for family members. Nest-CRC takes approximately 10 minutes to complete. The information covered in Nest-CRC is supported by ASCO content recommendations for pretest genetic education [18], standard informed consent for GT, and feedback from genetic counselors and experts on the study team. Nest-CRC delivers education through text and images and is accessible on any personal device with internet access [30]. It includes images that are representative of different ages and races, with written content at a 5th-grade reading level in both English and Spanish.

Figure 1. Development and future implementation of the Nest-CRC tool. CRC: colorectal cancer; GC: genetic counseling; GT: genetic testing.

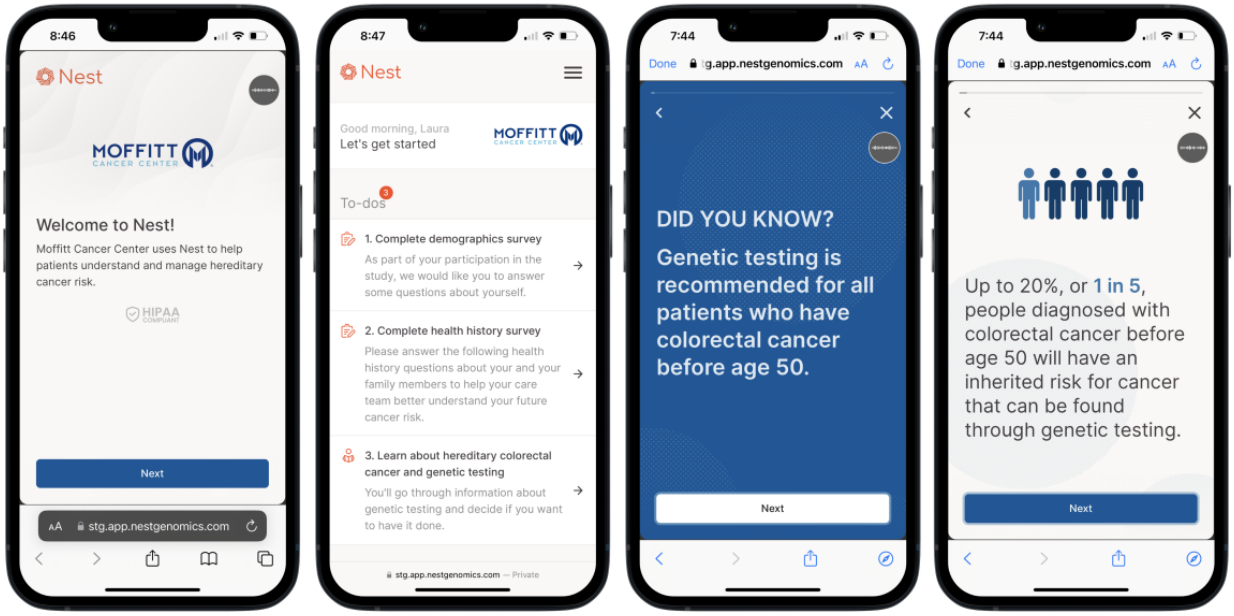


Procedure

We conducted a nested mixed methods study to develop and refine Nest-CRC for patients with early-onset CRC. Following the learner verification approach [31], we carried out 2 sequential phases of patient and provider surveys and interviews about Nest-CRC. Learner verification, which is useful for formative research, uses semistructured individual interviews to assess the appropriateness of materials for a target population. The quantitative data collected in each phase were used to describe the demographic characteristics of our sample population, their experiences with genetic services, and to obtain immediate feedback on their experience navigating each of the genetic education modules.

During phase 1, participants were emailed a link to a brief survey covering demographics, clinical characteristics, and experiences with genetic services, as well as the Nest-CRC educational modules, which included integrated questions about each module. Participants completed a semistructured interview after finishing the survey and Nest-CRC education. Patients could complete the survey and Nest-CRC on their personal device or a clinic tablet. After phase 1, we refined Nest-CRC based on participant recommendations (Figure 2). The revised version of Nest-CRC was then re-evaluated in phase 2 using the same procedure as in phase 1. However, in phase 2, participants also had the option to receive the link via SMS text message. Each version of Nest-CRC was reviewed by the entire study team for final edits.

Figure 2. Example of Nest-CRC for phase 2.



Ethical Considerations

This study was reviewed and approved by the Moffitt Cancer Center's Scientific Research Committee and Institutional Review Board (approval number 22176) on November 15, 2022. Before enrollment, all participants were provided with a copy of the informed consent form. All patients gave verbal informed consent in person or over the phone, and all providers consented to participate via email. Participants who agreed to take part in the study received a link to the survey and Nest-CRC education. The interviewer reviewed the informed consent form again with each participant before beginning the interview. All data collected for this study were deidentified using a unique ID number. Participants received US $25 upon completion of the interview.

Recruitment

From February to August 2023, English- and Spanish-speaking adult patients with early-onset CRC with upcoming medical appointments at the Moffitt Cancer Center Gastroenterology clinic were contacted in the clinic or by phone and invited to participate in the study. Recruitment flyers in both English and Spanish were posted in various waiting areas at Moffitt Cancer Center and distributed to community partners for sharing on their social media platforms (eg, Facebook). Interested potential participants responded to flyers and internet advertisements by calling or emailing the study team. The study team then contacted these individuals to screen them, obtain informed consent, and schedule their interview.

We purposely recruited at least 20% (n=4) Spanish-speaking and 20% (n=4) Black patients for each phase. These groups were specifically targeted because a lower proportion of Spanish-speaking and Black patients seen at the oncology clinic were eligible for the study. Gastroenterologists, oncologists, nurse practitioners, and genetic counselors with at least 2 years of experience working with patients with CRC were recruited from Moffitt Cancer Center (phases 1 and 2), MedStar Health (phase 2 only), and through referrals (phases 1 and 2). Different individuals participated in each phase.

Survey Measures

Before reviewing Nest-CRC, participants were asked to complete a brief survey capturing relevant sociodemographic, clinical, and epidemiologic characteristics adapted from the Health Information National Trends Survey (HINTS) 5 [32]. Patients were asked about their age, gender, race, ethnicity, country of birth, marital status, education level, employment status, household income, and insurance, while providers were asked about their age, gender, marital status, race, ethnicity, and professional degree. Additional information collected from patients included self-reported technology literacy (using the 3-item Digital Health Care Literacy Scale [33]), health literacy (using the 3-item Short Literacy Survey [34]), clinical details about their cancer diagnosis (including the type of CRC, cancer stage, age of diagnosis, and treatment history), family history of early-onset CRC, Ashkenazi Jewish ancestry (due to the known genetic risk for CRC and other cancers in this population), awareness of genetic services (ie, GC, GT, hereditary cancers, and Lynch syndrome), and history of genetic services (ie, referrals to genetic services, GC, and GT). We also evaluated patients' perceived importance of GT for cancer prevention and early detection (adapted from HINTS 5) [32]. Providers' self-reported practice characteristics included the frequency of communication with patients about genetic risk, referrals to GT, working with patients with early-onset CRC, and working with ethnic/racial minority patients. At the end of each module (n=5), participants were asked 2 questions: whether the information was easy to understand and whether it was helpful, using a 5-point Likert scale ranging from 1=strongly disagree to 5=strongly agree. Responses of strongly agree and agree were recoded as agreed, while neither agree nor disagree, disagree, and strongly disagree were recoded as did not agree.

Upon completing Nest-CRC, participants were asked if they were interested in GT, with response options of yes, no, or unsure.

Interview Process

Interview guides were based on key elements of learner verification. Patients and providers gave feedback on the Nest-CRC tool's attractiveness, comprehension, self-efficacy, cultural acceptability, and usability (Table 1). The development of these questions was informed by prior studies using the learner verification approach [31,35,36] and refined by the study team. All interviews were recorded, and audio files were transcribed verbatim. Interviews conducted in Spanish were translated into English [37]. JRR conducted all English and Spanish interviews via Zoom (Zoom Communications/Qumu Corporation; phase 1: mean 26.96 minutes, range 17.26-37.36 minutes; phase 2: mean 26.04 minutes, range 15.07-36.02 minutes).

Table 1. Sample questions included in the interviews.

Key elements	Example of questions
Attractiveness	• What was the first thing that came to your mind when using the Nest-CRC tool? • How do you feel after going through this tool? • What attracted you or did not attract you about Nest-CRC?
Comprehension	• Overall, did you find the tool easy to understand?/Overall, did you find the tool easy to understand for patients that you typically see in the clinic?[a] • While completing Nest-CRC, can you describe any words, phrases, or sections that were difficult to understand? • What information do you think might be missing from the genetic education?
Self-efficacy	• Do you think this tool provides enough information to make an informed decision about getting or not genetic testing? • After completing the Nest-CRC tool, can you give me some examples of what happens after genetic testing?/After completing the Nest-CRC tool, would the patients have enough information for getting genetic testing?[a]
Cultural acceptability	• What are your thoughts about Nest-CRC being appealing to people from different backgrounds? • Were there any sections of the genetic education that made you feel uncomfortable?/Were there any sections of the genetic education that made you feel uncomfortable, or do you think patients might feel uncomfortable?[a]
Usability	• Overall, did you have any challenges using the tool? • Would you recommend this tool to other patients with colorectal cancer?/Would you recommend this tool to patients with early-onset colorectal cancer?[a] • If your health care provider had referred you to this tool, would you have completed it?/Would you think your patients will complete this tool?[a] • What do you think is the best way to share this tool with other patients with colorectal cancer diagnosed before the age of 50 years? • How should this tool be used in the clinic?[a]

[a]Provider-specific questions.

Data Analysis

Descriptive statistics (mean, median, and proportions) were calculated using IBM SPSS software (version 28). All qualitative data were transcribed into English and reviewed by team members. The research team met to develop the initial codebook, using deductive codes derived from the key elements of the interview guides. The themes and codebook, along with operational definitions for each code, were subsequently refined during the intercoder reliability process. Three research team members (CG, MLM, and HF) coded the transcripts using a direct content analysis approach. Intercoder reliability was assessed until Cohen κ reached 0.80, indicating substantial agreement [38]. Qualitative analysts performed line-by-line coding of all interview data using NVivo 12 software (Lumivero).

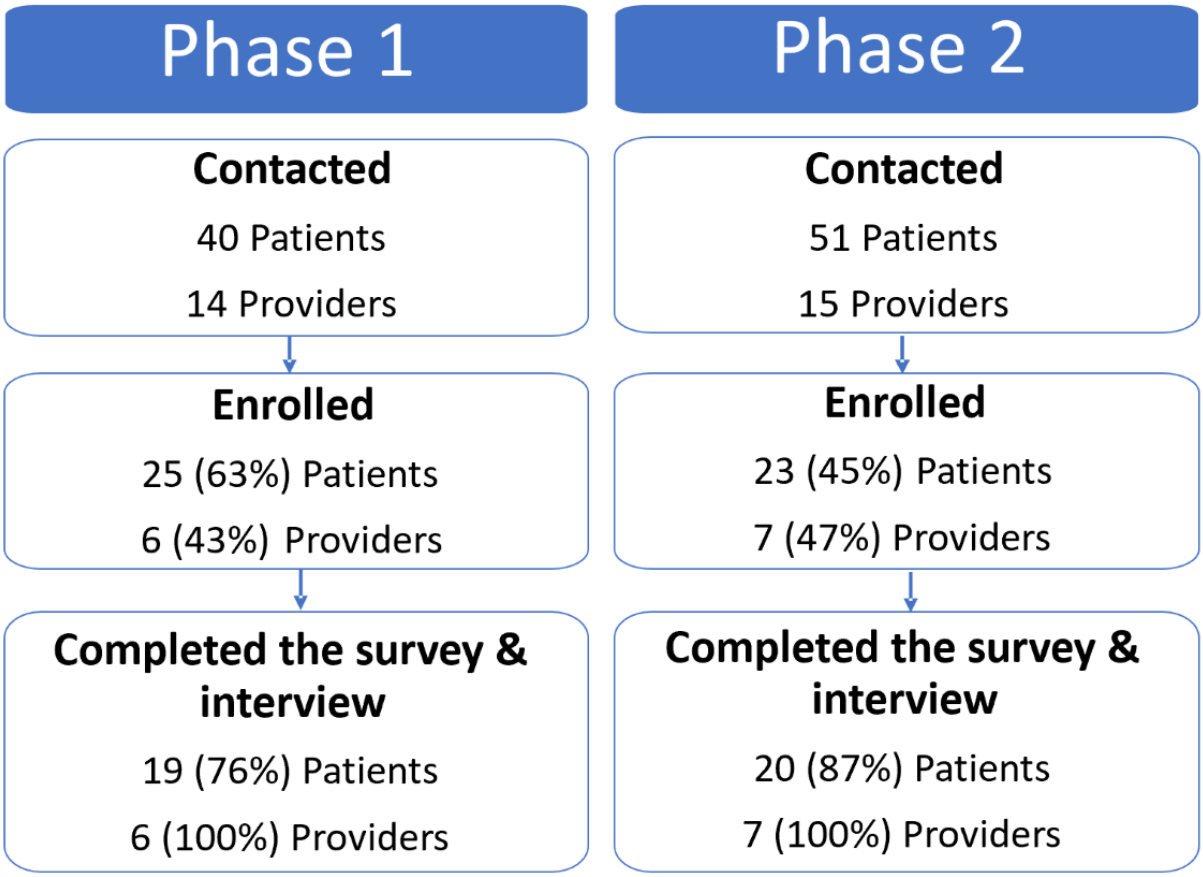
Results

Demographics and Clinical Characteristics

Phase 1

We contacted a total of 40 patients with early-onset CRC and 14 providers, of whom 19 patients and 6 providers completed the survey and interview (Figure 3). The most common reasons patients did not participate were a lack of interest or unsuitable timing due to their recent diagnosis and treatment. Providers generally declined participation passively.

Figure 3. Recruitment study flow for phases 1 and 2.



The median age of patients was 43 (range 27-51) years (Tables 2 and 3), with 10 out of 19 (53%) being female, 2 (11%) identifying as Black, 6 (32%) of Hispanic ethnicity, and 4 (21%) preferring Spanish (Table 1). About half (n=10) had at least some college education, and most were employed (n=11). One-third of the patients had stage 4 cancer (n=7), and half were undergoing active treatment (n=9). Most patients reported adequate health literacy (median 4, range 1-4) and technology literacy (median 4, range 1.6-4). Before completing Nest-CRC, 18 of the 19 (95%) patients indicated that GT was very important for cancer prevention and early detection, though only 10 (53%) and 15 (79%) reported awareness of GC and GT, respectively.

The median age of providers was 39 (range 31-46) years (Table 4). Half of the providers were female, all identified as White, and 1 was Hispanic and preferred Spanish. Two-thirds were medical or surgical oncologists, and 2 were genetic counselors. All providers had at least 2 years of experience with patients with CRC (median 11 years, range 2-13) and discussed genetic risk with patients at least 50% of the time.

Table 2. Patients' demographic characteristics by phase.

Demographic	Phase 1 (n=19)	Phase 2 (n=20)
Age (years), median (range)	43 (27-51)	47 (36-59)
Gender, n (%)

Phase 2

We contacted a total of 51 patients with early-onset CRC and 15 providers, of whom 20 patients and 7 providers completed the survey and interview (Figure 3). The most common reasons for nonparticipation were the same as in phase 1. The median age of phase 2 patients was 47 (range 36-59) years, with about half being female, 4 out of 20 (20%) identifying as Black, 7 (35%) as Hispanic, and 4 (20%) as Spanish-preferring (Tables 2 and 3). Most patients had at least some college education (n=18), were employed (n=13), and had health insurance (n=18). Patients also reported adequate health literacy (median 3.7, range 1-4) and technology literacy (median 3.7, range 2-4). Similar to phase 1, before completing Nest-CRC, 15 (75%) and 18 (90%) patients indicated that GT was very important for cancer prevention and early detection, respectively. However, only 9 (45%) and 17 (85%) reported awareness of GC and GT, respectively.

Nest-CRC Findings and Recommendations

Nest-CRC Quantitative Data

In phase 1, 9 patients reported no history of GT, and after completing the education, 7 (78%) were interested in GT, while 2 (22%) were unsure; none of the participants reported having no interest in GT. In phase 2, 4 patients reported no history of GT, and all of them indicated interest in GT after completing Nest-CRC. Across both phases, most participants reported that each of the Nest-CRC modules was useful and easy to use (phase 1: 23/25, 92%, to 25/25, 100%; phase 2: 24/27, 89%, to 27/27, 100%; Table 5). The average completion time for patients in phase 2 was 11 (range 5-26) minutes.

Table 5. Comprehension and usefulness of each Nest-CRC module.

Modules	Phase 1, n (%)		Phase 2, n (%)

Qualitative Interviews

Attraction/Visual Appeal

Participants in both phases reported finding Nest-CRC visually appealing and well-suited to its goals. The layout was described by phase 1 participants as “straightforward,” “concise,” and “clean” (Table 6). Phase 1 participants appreciated how each slide presented information in “bite-sized” amounts, making it “easy to digest and read” and helping to prevent feelings of being overwhelmed, which echoed the quantitative findings. Recommendations for improvement included enhancing the “dark mode” to increase readability and incorporating more visual elements (eg, photos, animations, and diagrams) to maintain attention and simplify complex concepts.

Table 6. Interview excerpts by study phase.

Theme	Phase 1	Changes implemented for phase 2	Phase 2
Attraction/Visual Appeal	• "I really think it's concise. I think you'll lose people if you make them read through too much information even when it's important, so I thought it was – it was a good capture of the important information." [Participant #1219, patient] • "Maybe having something graphic might make it a little bit better. Because it's a lot of text. So, I don't know if maybe having either, like, a little video or animation, at least just for the introduction, that explains what genes are – and mutations or variants – are. That might be helpful." [Participant #1301, provider]	• Included more images and graphics • Simplified complex concepts • Used colors and font size to highlight important information • Improved readability for dark mode	• "Yes, I had an 8-year-old child at the time I was making that decision and wanted to know what would impact him the most [...] I thought it was pretty comprehensive [...] I found that very useful, especially having a child that I feel like, anything I needed – I wanted to know everything I could know." [Participant #2206, patient] • "I thought the technology was good, simple, you click, next, go to the next one, and when you finish number 1 it takes you to number 2. My question is, is that going to be the format you are going to use? Is it going to be that shape and color? It's a little bit boring." [Participant #2304, Spanish-speaking patient]
Comprehension	• "Yes, because I guess it said that you could be discriminated against. Obviously, that's a huge red flag in my opinion. So, that would be the only thing. It didn't really say much about it. So, that would be the only thing to deter me from getting it because, obviously, I'd have cancer. So, it's hard to get insurance period. So, if that makes it even harder to get insurance or my children hard to get insurance, then I wouldn't wanna get it. Or I would need it explained to me a little bit more so that I would know it's not really that big of a deal or it is a big deal." [Participant #1202, patient]	• Included introduction with summary information about the importance and benefits of GT[a], what to expect from the education, and the next steps for GT • Added more information about sporadic, familial, and hereditary cancer, GT versus somatic/tumor testing, incidental findings from GT, and insurance discrimination • Simplified information and provided examples about GT, patients who are at greater risk/in need of testing, and treatment recommendations based on results • Included additional optional information about genes, most common types of hereditary colorectal cancer syndromes, GC[b], and insurance discrimination • Added word definitions • Explained that cancer-causing gene variants are also known as gene mutations and referred to them as mutations throughout. • Added at the end a summary of the information covered	• "I thought that the explanations were really easy to understand for people like myself not in the medical field [...] So, it was really easy to understand. And I think kinda gave us a lot of information but not make it overwhelming." [Participant #2203, patient] • "I wanna suggest if there's any data about how minorities are hit pretty hard with colon cancer. If you could possibly put something like that in there because I know sometimes myself – I'm an African American – sometimes minorities feel a little bit afraid about doing the GT [...]" [Participant #2215, patient]
Cultural Acceptability	• "We know that this population [cancer patients under 50], they have different needs about treatment and other things and this is something that would be very helpful for this population." [Participant #1106, provider] • "I think the text was short enough that it was easy to read through, but I guess maybe having audio in case people, I don't know, can't read well." [Participant #1102, provider]	• Added voice-over feature	• "I think the language is quite basic, and concise, but very appropriate. I don't think some words are difficult to understand for a person from Peru or Venezuelan or Argentinean. The vocabulary is easy to understand. I didn't see any questionable vocabulary." [Participant #2304, Spanish-Speaking patient] • "[A language option] would be easier for [my mother and grandmother]. [...] Maybe having that little option might be better for them and more comfortable for them to participate." [Participant #2218, patient]

Theme	Phase 1	Changes implemented for phase 2	Phase 2
Self-Efficacy	• "It is easy to use, easy to navigate, bite-sized bits of information, which is completely different from all the other information you're getting in this process, quick, structured well, and it does take you towards the information you need to make a decision." [Participant #1213, patient] • "I think another reason I have felt more comfortable about it is because my provider had mentioned it to me and kinda talked about it, so I kind of understood it. So, it was just basically like an extra confirmation." [Participant #1215, patient] • "Well, I guess that's one comment then. That wasn't clear to me. [...] I don't remember seeing like if you don't have questions and want to proceed with testing, we can do it today versus seeing a counselor. And like, and then you see a counselor if you have any positives, or you could just see a counselor before testing because that wasn't clear to me. [...]" [Participant #1102, provider]	• Added information about GT cost, data security, GT/GC process and wait time, and behavioral and environmental cancer risk factors • Added and simplified information about genetic test results and care implications • Reordered the content so personal and family benefits will be presented before the risks • Insurance discrimination information was simplified	• "I mean, honestly overall it's a thing of – it's a positive thing overall. It's just – it's simple to be done and there's not – there won't be repercussions for finding out information [...] 'Cause that's what something that people worry about is – so, if I find out this is a hereditary thing are my kids gonna be denied whatever, insurance or whatever down the road because I did this now [...] So, you know – I think between that and how simple the test – knowing that there won't be those repercussions and knowing how simple the testing is I think that was a good message for me." [Participant #2208, patient] • "And that's the tricky part. If somebody gets diagnosed with colon cancer, the first they are thinking is am I going to live? Am I going to not live? And what's the treatment? They're not truly thinking about genetics. So, maybe once they met with the surgeon and oncologist and have had a treatment plan. At that time maybe a good way to bring in that. We have universal protocol anyways for colon cancer. Every colon cancer should be tested. So, it has to be brought up at some point. [...]" [Participant #2101, provider]
Usability/Utility	• "I think the app is pretty simple to navigate... I think overall, this does a pretty good job of making sure that somebody at 50 that doesn't have a whole lot of experience with technology and somebody at 20 who basically that's all he does is technology are able to use it. Again, I think it's pretty good across the board, but you're still gonna have some outliers." [Participant #1210, patient] • "Yes, because it was difficult for me because I needed my daughter's help and when my daughter wasn't there, I couldn't enter because I would copy the information and I would go to a link, and it wouldn't let me enter. Yes, it was difficult to me... Oh, that [being sent a text with a direct link] would be easier for those of us who don't know that much about technology. It would be easier where there is just a link, and you click on it and it takes you to the information." [Participant #1306, Spanish-speaking patient]	• The education was sent via SMS text message, and a direct link was provided via email or SMS text message • An audio option was implemented • Added an option to obtain additional information	• "I did like that it allows for audio and visual learning. That was kinda one of my favorite parts because a lot of times, essentially, some patients can hear what you have to say, but the ability to be able to kinda pause and listen or go back and listen again, I think that was a very smart use of the learning modality. I thought that the information was very clear and concise, and it wasn't very cumbersome. It wasn't just a lot of information on each slide." [Participant #2105, provider] • "A circle that came out there? I could see it moving but I didn't know what it was to read it for me. I thought they were listening to me. I kept reading and doing the up and down but I didn't use it to listen." [Participant #2301, Spanish-speaking patient] • "But I guess maybe what might be helpful is – I don't know how to say this. Sorta like an outline or something. You know what I mean? So that you can skip forward or skip back [...]." [Participant #2203, patient]

[a]GT: genetic testing.

[b]GC: genetic counseling.

The main factors most patients and providers emphasized in phase 2 were a desire to protect family members and trust in science and medical providers. Patients stated that a recommendation from a provider to review the education would influence their interest in it. The information provided in the education, along with its ease of use, was highlighted in phase 2 as the primary factor that attracted participants.

For the most part, participants did not have strong opinions about the visuals of the tool. Most described it as "clean" and "easy to navigate" and reported that the text was clear and easy to read. One participant found the aesthetic dull and "boring" and felt it needed more color. Another participant mentioned that the lack of personal interaction decreased their interest, preferring to speak with a person instead.

Comprehension

Participants in both phases found the information easy to comprehend and described the intervention as "straightforward," "simple," "succinct," "understandable for a layperson," and "super easy to understand."

Nearly all phase 1 patients stated that they understood GT could be used to determine genetic predisposition for their CRC and that learning whether they carry a particular gene could be helpful for family members. The most commonly cited point of confusion in phase 1 was the possibility of discrimination based on their GT results. This was surprising to many participants, with some requesting links or resources for further information. Other recommendations from phase 1 participants included adding information on the most common types of hereditary CRC syndromes (eg, Lynch syndrome, familial adenomatous polyposis), clarifying which patients are most at risk or in need of testing, distinguishing between GT and somatic/tumor testing, addressing incidental findings from GT (eg, beyond CRC, such as BRCA1), defining specific gene associations, discussing treatment options based on variants, reducing redundancies in "informed consent," and communicating clearly to lay audiences (eg, clarifying language and providing examples). When suggested by the interviewer, patients agreed that a dictionary tool to define unfamiliar terms would be useful.

Phase 2 participants felt the intervention provided just the right amount of information: educational, yet not overwhelming for a new patient. Most phase 2 providers found the intervention easy to understand, free of jargon, and containing an appropriate level of detail.

Although participants were overall very satisfied, they suggested some additional educational topics. One of the most commonly requested topics by both patients and providers was information on what other cancer and health condition risks can be detected via GT. The general consensus was that most patients would want GT to detect different cancers if it were covered by insurance or affordable. Some participants raised privacy concerns regarding who can access their results and what can be done with their DNA and results in the future. Many providers suggested that it could be beneficial to outline privacy policies within the intervention. Participants were also interested in the impact and next steps for family members based on their GT results. One participant requested more data on cancer prevalence by race/ethnicity.

Some participants wanted more information (eg, the likelihood of having Lynch syndrome, more details about specific genes, and variants of uncertain significance), while others felt the level of information provided was sufficient and that additional details should be discussed with a genetic counselor. In both phases 1 and 2, there was disagreement regarding the preferred term "variant" versus "mutation" and when to use each.

Cultural Acceptability

All participants in phase 1 and phase 2 indicated that they felt the information was acceptable to a wide audience of varied backgrounds. None reported concerns that the content of Nest-CRC was offensive or inappropriate for any groups. Instead, participants described the material as "neutral," "broad," and believed "it can help anyone."

Most of the concerns regarding the acceptability of Nest-CRC in phase 1 were related to accessibility. English-preferring participants inquired whether the education was available in Spanish and emphasized the need for patient-friendly language. Participants found the online delivery to be appropriate, given that the target audience is under 50 years of age, but recommended reevaluation if Nest-CRC is expanded to older patients. Participants also suggested adding an audio voice-over option or videos within Nest-CRC to improve accessibility for blind people/those with visual impairment, those not fully literate in English, or those who prefer listening over reading.

One phase 2 participant appreciated that the materials were inclusive of adopted patients who may be unaware of their family history. Phase 2 participants were also appreciative of the audio voice-over option.

Self-Efficacy

Both phase 1 and phase 2 participants described Nest-CRC as "very informative" and "comprehensive," and most felt that the intervention provided enough information to help them decide if they wanted GT without being overwhelming. Most patients had already undergone GT or were interested in it, evaluating Nest-CRC as a helpful way to be "proactive," with some wishing it had been available when they were first diagnosed.

Trust in their care team's recommendations was a major facilitator for using Nest-CRC. Participants responded positively when asked if they would complete the intervention if their provider recommended it, including patients who were undecided about GT. A few participants did not fully understand the benefits of GT (eg, therapeutic decision-making, risk management recommendations, and cascade testing), given that they already had cancer, with one commenting that it would be "pointless" now. Other potential barriers to GT included cost, information sharing/data security, and fear and anxiety around test results. Some participants also described fear of insurance discrimination as a potential barrier and felt this risk should be better clarified.

Self-efficacy for phase 2 participants was bolstered by their greater satisfaction with the information provided about insurance, costs, and the risks of discrimination, as well as the

available legal protections. Participants identified information on screenings and sample collection modalities (saliva vs blood) as important topics to support GT decision-making. Many providers and patients noted an assumption that GT was more invasive or complicated than it is and felt that providing information about the minimally invasive process could increase interest. The option for saliva testing was highlighted as important to make GT more appealing to patients afraid of blood and needles and more manageable for those undergoing multiple treatments or procedures for cancer care.

For phase 2, the remaining barriers to GT decision-making included unresolved concerns about discrimination and the ability to afford GT. Despite being informed that most insurance plans cover GT, participants remained concerned that their results could be positive and that cascade testing could be recommended for uninsured family members. One patient, who had previously experienced mishandling and misuse of medical results, expressed distrust in the efficacy of policies and institutions despite education about protections. Some newly diagnosed younger patients stated that being diagnosed with cancer was overwhelming and found it difficult to process information and make decisions, even with the necessary resources. With this in mind, some participants recommended that providers bring up or offer Nest-CRC again during the second or third visit to allow patients time to check insurance coverage for GC and GT.

Usability/Utility

Participants in both phase 1 and phase 2 described using the Nest-CRC tool as “user-friendly,” “very easy to use,” and “seamless.” They found the tool logically structured and easy to navigate, and appreciated that it is accessible on both desktop and mobile devices.

Phase 1 participants encountered minor technical issues, such as difficulty getting the link to work and not being able to return to where they left off. Participants felt usability could be improved by providing a direct link (rather than requiring copying and pasting into a browser), adding an audio option, allowing easier navigation of content out of sequence, and offering access to Nest-CRC via tablet in the clinic waiting room.

Phase 2 participants who noticed the audio option rated it positively, even if they preferred to read. However, this feature was not apparent to all users. For users with their phone set to “silent,” the audio option was also silenced, even if the phone volume was turned up. This led to confusion among many participants who were unable to hear the audio. One patient even thought the tool was recording audio because they could not hear it and noticed the sound wave animation within the audio button.

Summary and Next Steps

Most participants found each of the modules easy to understand and helpful. In general, patients described the content as straightforward, easy to comprehend, beneficial to anyone, informative, and useful for making decisions about GT. Following phase 1, usability was improved by providing participants with a direct link to Nest-CRC, sending links via SMS text message, and adding an audio option. The educational modules were also reordered to highlight the benefits first and end with the risks. Several additions were made to the educational content, including optional pathways and links for more detail on specific topics (eg, Lynch syndrome), definitions of key terms (eg, genes), graphs, images, and clarifying information about GT cost, insurance discrimination, and the GT process.

For the next phase, the audio voice-over will be improved, and additional optional pathways (eg, genes commonly tested in MGPT) will be incorporated. The revision will include more information about variants of uncertain significance, as well as content explaining the difference between GT and somatic testing, and addressing GT privacy concerns. Patients will also have the option to select their preferred language. Navigation within Nest-CRC will be simplified to allow easier return to core educational content from optional paths and modules.

Discussion

Principal Findings

Nest-CRC was developed as a user-friendly, scalable digital health tool designed to improve access to GT by facilitating pretest education at a lower cost. Findings indicated strong attraction, comprehension, cultural acceptability, self-efficacy, and usability of Nest-CRC in both phases. Endorsement of Nest-CRC was high, with participants recommending it be offered routinely and repeatedly to patients at different stages of the cancer journey, as some patients may prioritize GT immediately, while others may postpone it until survivorship care. Nest-CRC was also described as an acceptable alternative for empowering patients with information about GT and supporting their decision-making. Therefore, it was identified as a viable strategy for streamlining patients with early-onset CRC toward GT.

Comparison With Prior Work

NCCN guidelines recommend MGPT for all patients with early-onset CRC [10], but referrals to genetic services for these patients are inconsistent [11,12]. A prior study from 2 Texas health systems, evaluating data from 2009 to 2017, revealed that 58% of patients with early-onset CRC were referred for GC, and only 37% completed GT [11]. A more recent study, examining retrospective data from 2010 to 2019 at Cleveland Clinic, found that 62% of patients with early-onset CRC were referred to GC, 49% completed GC, and 48% completed GT [12]. In our study, less than half of the patients reported a history of GC, while two-thirds reported a history of GT. The proportion of patients reporting GT in our study was higher than previously reported rates for patients with early-onset CRC. However, interviews revealed that some patients were confusing their experiences with somatic testing and germline testing, which may have contributed to the elevated reporting of GT. Among those patients with early-onset CRC who denied GT at baseline, most expressed interest in GT after completing Nest-CRC. Additionally, the few patients who were unsure about GT showed interest in GC. This suggests that Nest-CRC can be used to streamline the triage of patients with early-onset CRC

for GT, while complex patients needing more support can be prioritized to maximize the efficiency of limited GC resources.

Prior studies examining barriers to genetic services among patients with early-onset CRC have identified cost, a shortage of qualified genetic professionals, and racial/ethnic referral disparities [11,19]. In our study, patients expressed concerns about the cost of GT, insurance coverage and discrimination, and the potential misuse of their DNA. While the cost of GT remains a concern, it has decreased substantially, making it more affordable for many individuals without health insurance. In the United States, patients who meet insurance criteria for GT typically pay between US $0 and US $100 out of pocket, while those without insurance may pay around US $300. Additionally, some laboratories offer financial assistance. Furthermore, the United States has federal and state laws that protect patients from insurance discrimination. For example, the Genetic Information Nondiscrimination Act (GINA) prevents nonmilitary employers and health insurance companies from using GT results against patients [39]. However, GINA does not apply to life, disability, or long-term insurance companies. Some states, like Florida, have enacted laws that protect patients from life, disability, or long-term insurance companies using GT results against individuals residing in the state [40,41]. Therefore, patients' commonly reported concerns about GT could be alleviated through education about existing resources and federal and state protections.

To address barriers to accessing GT information and services, the Clinical Genome Resource's Consent and Disclosure Recommendations working group recommended a brief pretest genetic education approach for more straightforward cases, reserving traditional GC for patients with greater clinical and genetic complexities or those without well-established testing recommendations [20]. Automated educational tools, such as videos and written materials, have proven effective in delivering genetic education, particularly for patients with high-risk cancer [21,22,25,42]. For example, a study involving patients with pancreatic cancer found that when oncology providers used an educational video to obtain GT informed consent, the rate of GT increased 6.5 times compared with previous years, when traditional GC referrals were used [21]. However, these advances still rely on clinic staff and providers to obtain informed consent and order GT.

Nest-CRC provides an alternative for GT education that can further alleviate the burden on patients, clinic staff, and institutions. Like other patient-driven digital tools [42,43], Nest-CRC can be completed conveniently from home, enhancing accessibility without incurring out-of-pocket costs for the patient. For institutions, the annual cost of using Nest-CRC can be tailored to the specific functionalities required, averaging a few thousand dollars per month—less than the cost of an entry-level GC assistant. Unlike a single assistant, Nest-CRC can scale the volume and capabilities of genetic services without being impacted by patient load, staff turnover, or the need for ongoing training. By automating workflows for education, consent, test ordering, and results return, tools such as Nest-CRC can significantly enhance clinic efficiency. While this study focuses on the perceived benefits of pretest genetic education, implementing a platform such as Nest has the potential to generate substantial cost savings and operational efficiencies across other routine tasks, such as family history collection, patient tracking, risk model calculations, and care plan management. As the demand for genetic services continues to grow, digital health tools such as Nest-CRC could be leveraged to identify high-risk patients and promote GT across various health care settings, such as primary care, oncology clinics, and even the general public. In this way, Nest-CRC offers an acceptable alternative strategy to expand equitable access to GT among high-risk patients.

Strengths and Limitations

The primary goal of this study was to evaluate the reactions and recommendations of English- and Spanish-speaking patients and providers to Nest-CRC, with preliminary data on patients' interest in GT as a secondary aim. This study is innovative in providing valuable insights from a diverse group of patients and providers, highlighting key considerations for developing pretest genetic education for patients with early-onset CRC. However, due to the small sample size, quantitative data were limited to descriptive purposes and were used primarily to describe the study sample and support the qualitative findings by incorporating patients' immediate feedback on the educational content. While we intentionally recruited Black and Spanish-speaking patients to ensure diverse representation, the findings should not be generalized to all patients with early-onset CRC. It is also important to note that during interviews, some participants expressed uncertainty about their GT history; therefore, the self-reported GT data should be interpreted with caution. This uncertainty underscores the potential benefit of a comprehensive digital health platform where GT history and related lifelong care recommendations can be easily accessed and shared with patients' clinicians and family members as needed.

Conclusions and Future Directions

Adults with early-onset CRC are at higher risk for having a hereditary cancer syndrome. GT to identify the causative variant can facilitate screening and risk reduction measures for both patients and their relatives. Despite GT being recommended for all patients with early-onset CRC, racial disparities persist in referrals for GT, access to GC, and uptake of both GC and GT. These issues are further compounded by a shortage of qualified genetic professionals and patients' concerns about the cost of genetic services. Our findings suggest that Nest-CRC is a promising strategy to scale genetic services by augmenting pretest genetic education and promoting GT uptake among patients with early-onset CRC from diverse racial and ethnic backgrounds. Future studies should implement digital GT platforms in clinical settings to evaluate their feasibility and acceptability among high-risk patients and their relatives from diverse racial and ethnic backgrounds, as well as assess their impact on lifelong care recommendations and survival outcomes.

Acknowledgments

This project was funded by the Society of Behavioral Medicine Bridging the Gap Research Award and the National Cancer Institute (grant T32 CA090314; principal investigators: Thomas Brandon and SV). We also want to acknowledge the support of Stefania Alastre Arcusa, MSPH, LCGC, for reviewing and providing feedback on the Nest-CRC education in Spanish for phases 1 and 2.

Data Availability

Deidentified data generated and analyzed during this study will be made available (as allowable according to institutional review board standards) by emailing the corresponding author.

Authors' Contributions

JRR wrote the first draft of the manuscript. JRR and M Sholeh were involved in data collection, data curation, and quantitative data analysis. MLM, CG, and HF conducted qualitative data analysis and wrote the first draft of the qualitative results. JRR and SV conceptualized the study and were responsible for funding acquisition, project administration, and supervision of the study team. M Snir, ES, and TS implemented Nest-CRC. JRR, M Snir, ES, TS, M Sholeh, LB, BDG, JP, and SV contributed to the development and revisions of Nest-CRC. All authors reviewed and edited the manuscript.

Conflicts of Interest

M Snir is the CEO of Nest Genomics, and ES and TS are employees of Nest Genomics. The remaining authors declare no potential conflicts of interest.

Abstract

Background: Breast cancer survivors have increased cardiovascular risk compared to those without cancer history. Cardiovascular disease is the most common cause of death in breast cancer survivors. Cardiovascular risk in breast cancer survivors is impacted by both cancer treatment–associated effects and in risk factors for breast cancer and cardiovascular disease overlap. Strategies to improve screening for and management of cardiovascular disease in breast cancer survivors are needed to improve the delivery of survivorship care.

Objective: This study aims to assess current cardiovascular risk counseling practices and perceived cardiovascular risk in breast cancer survivors.

Methods: Semistructured interviews were conducted from May to December 2021 with breast cancer survivors identified as having a primary care clinician within an academic family medicine center in Charleston, South Carolina. The interview guide and content were developed using the Health Belief Model with a focus on cardiovascular risk behaviors, risk perception, and barriers to risk reduction. Analysis of categorical data was conducted by frequency and quantitative variables by mean and SD. Template analysis was performed for qualitative analysis. Outcome measures included self-reported history of cardiovascular disease, risk perception, and risk behaviors.

Results: The average age of participants (n=19) was 54 (SD 7) years; 68% (13/19) were White and 32% (6/19) were Black or African American. Of the interviewed women, 90% (17/19) reported a personal history and 90% (17/19) reported a family history of cardiovascular disease. Only 53% (10/19) had previously reported receipt of cardiovascular counseling. Primary care most commonly provided counseling, followed by oncology. Among breast cancer survivors, 32% (6/19) reported being at increased cardiovascular risk, and 47% (9/19) were unsure of their relative cardiovascular risk. Factors affecting perceived cardiovascular risk included family history, cancer treatments, cardiovascular diagnoses, and lifestyle factors. Video (15/19, 79%) and SMS text messaging (13/19, 68%) were the most highly reported mechanisms through which breast cancer survivors requested to receive additional information and counseling on cardiovascular risk and risk reduction. Commonly reported barriers to risk reduction such as physical activity included time for meal planning and exercise, resources to support dietary and exercise changes, physical limitations, and competing responsibilities. Barriers specific to survivorship status included concerns for immune status during the COVID-19 pandemic, physical limitations associated with cancer treatment, and psychosocial aspects of cancer survivorship.

Conclusions: Breast cancer survivors identified that factors associated with their cancer diagnosis and treatment both impacted their cardiovascular risk and introduced additional barriers to risk reduction. Potential strategies to improve counseling and awareness around cardiovascular risk include video and messaging platforms. Further risk reduction strategies should consider the unique challenges of cancer survivorship in delivery and implementation.

KEYWORDS

cardiovascular health; cancer survivorship; lifestyle counseling; breast cancer; cancer survivors

Introduction

Breast cancer survivors are at increased risk of cardiovascular disease in part due to pre-existing comorbidities and cardiotoxicity associated with treatment [1]. Breast cancer survivorship has increased significantly, with over 3 million current breast cancer survivors. Breast cancer survivors are at increased risk of cardiovascular disease including heart failure, myocardial infarction, coronary artery disease, and vascular disease compared to those without a history of malignancy [2]. The etiology of the increased risk includes common risk factors, pre-existing comorbidities, and cardiotoxicity associated with breast cancer treatment. The likelihood of morbidity and mortality from cardiovascular disease exceeds that of breast cancer for many older women and those who have a personal history of cardiovascular disease [3-5]. In breast cancer survivors

older than 50 years of age, 35% of nonbreast cancer–associated mortality was attributed to cardiovascular disease [6]. In one cross-sectional study, over 60% of breast cancer survivors were diagnosed with hypertension, over 50% with hyperlipidemia, and 5% - 6% had a reported history of heart failure or stroke [7]. Cardiovascular comorbidity is common in breast cancer with significant implications for morbidity and mortality requiring screening, counseling, and management with a multidisciplinary health care team including primary care.

Comorbid risk factors for breast cancer include increasing age, alcohol consumption, dietary patterns, family history of cardiovascular disease, elevated BMI, and physical inactivity [2]. Breast cancer treatments can increase the risk of cardiovascular disease, including chemotherapy, endocrine therapy, and radiation therapy, although the specific cardiovascular risk profiles vary based on treatment history [2,8]. Management of comorbid medical conditions has also been shown to be suboptimal during active cancer treatment. Cancer disease processes themselves may cause subclinical myocardial damage [9]. Current strategies for risk factor reduction in breast cancer survivors include aggressive management of comorbid conditions, including hypertension, diabetes, and hyperlipidemia, and promotion of lifestyle factors such as smoking cessation, maintaining an appropriate body weight, and increased physical activity [1,10-12]. Survivorship guidelines for breast cancer recommend screening and management of cardiovascular risk among patients with breast cancer; however, current screening practices and management are inadequate [3,13]. Lifestyle interventions including nutrition, physical activity, and weight management are essential components to integrate into survivorship care to reduce cardiovascular risk [14].

When considering cardiovascular disease and breast cancer risk, it is advised to weigh factors both of breast cancer reoccurrence and cardiovascular disease risk [15]. However, previous studies have identified that women at increased risk of cardiovascular disease also have an increased risk of cancer reoccurrence [16]. Interventions targeting cardiovascular risk reduction also have the potential to impact breast cancer outcomes. Despite this, limited qualitative and interventional studies have evaluated strategies and interventions for cardiovascular risk reduction in breast cancer survivors. Observational studies have demonstrated that increasing physical activity and dietary changes improve all-cause survival and improve cardiovascular risk in breast cancer survivors [17,18]. Pilot studies using exercise-based interventions have been demonstrated to improve cardiovascular fitness in breast cancer survivors. A randomized trial by Lee et al [19] demonstrated an improved cardiovascular risk profile following participation in a 16-week exercise program [20]. Cardiovascular risk reduction consistent with guidelines and evidence-based interventions focuses on smoking cessation, increased physical activity, and dietary changes, although the specific dietary recommendations vary based on guidelines and interventions studied [21]. The purpose of this project is to identify multilevel barriers and facilitators to cardiovascular risk reduction among breast cancer survivors to best advise breast cancer survivors and to support the development of interventions focused on the unique demands of breast cancer survivors following treatment.

Methods

Qualitative analysis using semistructured interviews informed by the Health Belief Model was conducted to evaluate cardiovascular counseling and perceived risk in breast cancer survivors.

Inclusion Criteria

Inclusion criteria included female breast cancer survivors aged 40 - 65 years without metastatic disease seen by primary care at the Medical University of South Carolina in Charleston. The clinic population at the time of study initiation was predominately White and approximately 30% Black or African American. A majority of clinic patients were insured with either public or commercial insurance. For the purposes of this study, survivorship was defined as women who had completed their primary treatment for breast cancer. However, ongoing maintenance therapy, including endocrine therapy, was not considered an exclusion criterion.

Interviews

Participants were contacted using MyChart messaging within the electronic health record. Potentially eligible participants were identified through an electronic health record data inquiry based on the history of breast cancer and primary care appointments at the academic medical center within the last 3 years. Only individuals who had opted into a system-wide query about research contact were included in outreach. Of the individuals contacted, 11% (19/170) participated in the study. Outreach was stratified by age (<50 years old and >50 years old) and race (White, Black, or African American) with outreach equally to these groups to promote representation consistent with clinic demographics. A total of 19 semistructured interviews were conducted on Teams (Microsoft Corp) using audio recording only by a trained female, master-level study coordinator. The interview duration ranged from 11 to 17 minutes. Interviews were conducted until saturation of depth and diversity of themes occurred. Neither the interviewer nor the study team had previous interactions with the participants. Study objectives were provided to interview participants prior to informed consent. Interviews were transcribed and reviewed for accuracy. Participants were not contacted following the initial interview. Participants were provided with contact information for the study team with an opportunity to reach out about any additional questions or study results. Our research team is composed of primary care clinicians and public health researchers involved in primary care research, including researchers with expertise in onco-primary care. Our team values patient self-efficacy and the importance of interdisciplinary coordination of care guided by a patient-centered approach to care. To reduce potential bias, the study team member completing the interviews was not involved in data coding. Coding was completed independently and reviewed by consensus.

Conceptual Framework

The study was grounded in the Health Belief Model as a conceptual framework [22]. The Health Belief Model was selected based on its capacity to understand how individuals respond to communication of health-related information and their subsequent engagement in health-related behaviors. The Health Belief Model has been extensively used to assess cardiovascular risk perception, barriers to behavior change, and the development of interventions to address these [23-27]. More specifically, in this study, the focus on communication of information about cardiovascular risk in breast cancer survivors was predicted to inform and desire to and engagement in health behaviors to reduce cardiovascular risk. The interview guide was developed by the primary author after a review of previous literature, with revision following feedback from the research study team. Training was provided in the interview guide. Key constructs evaluated included perceived susceptibility to cardiovascular disease, perceived severity, self-efficacy, perceived barriers, and cues to action for engaging in cardiovascular risk reduction behaviors. Perceived susceptibility provides essential information on the participant's assessment of the probability of cardiovascular disease. Perceived severity focused on the understanding of the potential severity of health impacts of cardiovascular disease and its relation to breast cancer survivorship status. Participants identified their perceived barriers to engaging in health behaviors to promote improved cardiovascular health. Self-efficacy was assessed based on the patient's reported belief in their capacity to engage in health behaviors to reduce cardiovascular risk. Cues to action included experiences or actions within the participant's environment that prompted the decision to engage in cardiovascular risk reduction behaviors. Interview questions also included questions about adherence to cancer survivorship guidelines.

Template Analysis

Template analysis was conducted using an interview guide and codebook developed using the Health Belief Model [22,28-31]. Template analysis uses a structured template while still permitting a flexible coding process for the analysis of qualitative data. Since the interview guides in this study were based on the Health Belief Model framework, template analysis allowed researchers to use an initial template developed based on the constructs of the Health Belief Model framework, while also allowing codes to be updated in the coding process [30]. Coding was conducted by 3 independent coders with previous experience with qualitative analysis who each independently coded all transcripts. Following initial limited interview coding, further coding continued by consensus of themes which remained consistent across all coders. Nvivo (Lumivero) was used to assist in coding. Saturation of themes was reached after 19 interviews.

Ethical Considerations

The study was deemed by the Medical University of South Carolina institutional review board as exempt (Pro00073820) with a waiver for written informed consent. All participants provided verbal consent for participation. Participants self-reported current exercise participation, consumption of fruits and vegetables, and current cardiovascular health conditions. Interview transcripts were deidentified prior to coding and analysis. Interview participants received a US $35 gift card as compensation for their time for participation.

Statistical Analysis

Descriptive statistics including mean and SD were calculated for continuous variables and frequency data for qualitative variables.

Results

Participants

A total of 19 participants were enrolled in and completed interviews. The average participant age was 54 (SD 7; range 43 - 66) years. Participants averaged 3 primary care and 3 oncology visits annually. Over half (10/19, 52%) of participants reported receiving counseling on cardiovascular risk. Counseling was provided by primary care (8/10, 80%) and oncology (3/10, 30%). Demographic information is provided in Table 1. Themes and illustrative quotes identified are displayed in Table 2. Themes were consistent across participants based on age and race.

Table . Demographic information of participants (n=19).

Characteristics	Participants, n (%)
Race	
Black	6 (31)
White	13 (68)
Education	
High school or less	2 (10)
Some college	5 (26)
Bachelor's program	7 (37)
Master's program or graduate school	5 (26)
Employment	
Full time	13 (68)
Part time	2 (11)
No current employment	4 (21)
Marital status	
Married	11 (58)
Not currently married	8 (42)
Treatment history	
Surgery	19 (100)
Chemotherapy	12 (63)
Radiation	14 (74)
Endocrine therapy	14 (74)
General health (participant report)	
Poor	2 (11)
Fair or good	12 (63)
Very good or excellent	5 (26)
Adherence to survivorship guidelines	
>150 minutes exercise weekly	6 (32)
>5 servings fruits or vegetables daily	3 (16)
History of personal cardiovascular disease	17 (90)
Current cardiac medications	10 (50)
Family history of cardiovascular disease	17 (90)

Table . Health Belief Model themes.

	Quotation example	Theme
Perceived barriers	• "I'm almost 100 percent sure [my exercise limitations are] due to breast cancer treatment because I have some lung involvement. And so, you know, I've had issues with having a pleural effusion where it builds up the liquid in your lung." [INT7]	• General barriers identified included fatigue, limited time, and medications • Treatment-associated barriers included physical limitations and associated anxiety and stress
Overcoming barriers	• "But when I'm on the road, it's hard to find foods that fall in those categories ... When I know ahead of time that I'm going to have a pick up at a certain time. I'll make sure I either eat before I leave or I pack a lunch. But lots of times ... I only got like a 30 minute window to get them to pick it up." [INT17] • "So I think making the time about prioritizing ... prioritizing the time to exercise, and to shop appropriately, to eat healthy, so making the right decisions." [INT2] • "I think the main thing affecting me was I was kind of feeling because of what I went through, I was suffering a lot with PTSD and anxiety and all that. And I think because of that, I wasn't focusing too much on my health. I was stress eating and gained 20 pounds because I was like so stressed out from what happened and being on the hormonal meds and shot every month, it just really messed with my I guess, my whole, like, energy level and motivation." [INT4]	• Discussions with clinicians identified as factors promoting change • Scheduling considerations impact exercise and nutrition and mechanisms to prioritize change • Individual motivation important determinant for cardiovascular risk reduction
Perceived susceptibility	• "Genetics. On my father's side, everyone has died of heart disease, and I apparently got his genes." [INT3] • "I would say it's pretty high and I say that basically because when I had my radiation, they told me my tumor happened to be on my left side, so my radiation happened to be my heart. And so they told me that I was a high risk for congestive heart failure in the future." [INT12] • "I've never correlated the breast cancer to heart disease. I'm gonna need to think a little bit more about that. But I've never done that. So I would say no, because I just never thought about it in that way." [INT2]	• Individual factors impacting perceived risk include current personal cardiovascular disease, family history of cardiovascular disease, and lifestyle factors • Cancer and treatment-associated factors impact perceived risk of breast cancer in some individuals although there was uncertainty in others
Communication regarding cardiovascular risk and cancer	• "Possibly in the beginning ... My oncologist may have [discussed cardiovascular risk], but at that point, I think I was so overwhelmed with everything else that I probably didn't listen that well." [INT6] • "So, like, if I am at risk as being a breast cancer patient for heart issues, then that's something that I would want to stay on top of and have more information and have my primary care doctor or my oncologist talk to me about in ways that I could get on top of that before anything crazy happens." [INT7]	• Timing important factor in communication between health care team and patients about cardiovascular risk • Communication limited about cardiovascular risk and breast cancer.

	Quotation example	Theme
Self-efficacy	• "I stopped smoking was one [way I took control of my health]. Because the reality of possibly having cancer in another location or not healing from the procedure. I never realized that they actually kept you from healing. And diet improved. Everything had to improve." [INT5] • "I'm a survivor, thank God. And I think it has a lot to do with my healthy choices. But if you don't, if you're not educated on that stuff, most people don't know, you know. So it's important to talk to professionals and see what's the best thing for you to do." [INT8]	• Motivation to change and resources to support effective behavior change both reported as necessary by participants
Cues to action	• "You know, there's a publication that the [health system] puts out. I want to say four times a year ... There's a lot of just good little health tips, reminders that just kind of keep things at the forefront when you're starting to get busy." [INT1]	• Weight change and perception of body image motivation for lifestyle change • New diagnoses of cardiovascular disease in an individual or relative impacted motivation to seek care • Health promotion materials influence motivation for cardiovascular risk reduction

Perceived Barriers

Perceived barriers included both factors unrelated to cancer, as well as those associated with the late and long-term effects of breast cancer and treatment. Commonly reported barriers included fatigue, time limitations to participation in exercise or meal planning, motivation to change, and available resources to support behavioral changes to support cardiovascular risk reduction. Cancer-specific barriers included physical limitations, including those from previous cancer treatments that impacted the capacity for exercise. Anxiety and stress, especially associated with changes in health status associated secondary to cancer and cancer treatment, were reported and identified as a barrier to behavior changes in exercise and nutrition. Medication side effects following treatment were cited by one participant as a limitation to participation in exercise.

Overcoming Barriers

Engagement of the health care team and individual motivation for change were identified as factors promoting cardiovascular risk reduction behaviors. Participants reported that treatment of mental health conditions improved their capacity for behavior change. Participants highlighted the need for time management for meal preparation and exercise. The availability of group classes and discussions with clinicians in the health care team increased motivation for behavioral change.

Perceived Susceptibility

Participants identified breast cancer treatment–associated factors including radiation and chemotherapy as contributing to cardiovascular risk. Others expressed uncertainty about the potential impact of cancer treatment on their cardiovascular risk but desired more information on this from their health care team. Individual factors associated with risk perception included current diagnosis of cardiovascular disease or history of a cardiovascular event. A family history of cardiovascular disease was reported as increasing an individual's perceived personal risk of cardiovascular disease. Perceived protective factors included participant engagement in diet modification, regular exercise, and medication management of cardiovascular conditions.

Communication Regarding Cardiovascular Risk and Cancer

Participants reported limited communication regarding cardiovascular risk specifically related to their cancer history. However, they desired to receive information on cardiovascular risk. Timing of communication about cardiovascular risk further removed from the time of initial diagnosis and treatment was preferred.

Self-Efficacy

Participants identified self-efficacy as important in facilitating care and risk reduction. The ability to cook and resources for healthy food were identified as factors to support cardiovascular health. Motivation for change was identified as a necessary prerequisite for change.

Cues to Action

Participants reported inciting stimuli to engage in risk reduction behaviors as a new diagnosis of cardiovascular health conditions either in themselves or in family members or friends. Individuals who were experiencing symptoms reported a stronger motivation to seek medical care and engage in risk-reduction behaviors. Participants valued outreach from trusted organizations, including health care organizations, about behaviors to improve health and reduce cardiovascular risk as important in keeping their desire for change at the forefront of their priorities.

Sources of Information

The majority of individuals valued information from their health care team or other medical resources designed for patients. Specific sources of information on cardiovascular risk included clinicians, medical publications, and both medical and

nonmedical internet sites. The timing of communication impacted the reception of the discussion regarding risk. Some participants reported the initial stages of treatment as overwhelming in the amount of information delivered and reported being more treatment-focused at that time. Participants did desire to receive information about their cardiovascular risk both from their oncologists, as well as their primary care clinician. Desired mechanisms of delivery of information on cardiovascular risk in survivors of breast cancer included video (n=15, 79%), SMS text messaging (n=13, 68%), telephone (n=11, 58%), and mobile apps (n=10, 53%).

Summary

Based on the use of the Health Behavior Model, themes that promoted engagement in cardiovascular risk reduction were identified in each of the constructs assessed. Perceived barriers included both traditional barriers to cardiovascular risk reduction, as well as treatment-associated barriers derived from both mental and physical health. Factors promoting overcoming these barriers included clinician engagement with patients about cardiovascular risk reduction and the need for individual motivation for change to accomplish this. Although clinician communication was essential in promoting change, the timing of communication was identified as important. Immediately after diagnosis, breast cancer survivors preferred to focus discussion on treatment options. The availability of both financial resources and accessible resources supported the self-efficacy of participants with video and SMS text messaging as the preferred mediums for health information. Cues to action included changes in family and individual health. These interviews and themes have the capacity to inform further counseling and the development of interventions to support cardiovascular risk reduction both in breast cancer survivors and other cancer survivor populations.

Discussion

Principal Findings

Breast cancer survivors face additional cardiovascular risk following treatment, which impacts both overall and breast cancer–specific survival. Survivorship guidelines recommend screening and management strategies to reduce cardiovascular risk. Limited information is available on the barriers and facilitators of engaging breast cancer survivors in cardiovascular risk reduction behaviors. This qualitative study using semistructured interviews sought to evaluate facilitators and barriers to cardiovascular risk reduction in breast cancer survivors. Consistent with previous literature, uptake of survivorship guidelines including participating in physical activity and regular consumption of fruits and vegetables was limited [4]. The participants in the study overall received multiple treatment modalities that had the potential to increase individual cardiovascular risk.

The primary findings of the study included that there were opportunities to improve communication about cardiovascular risk in breast cancer survivors both within primary care and oncology. Breast cancer survivors valued communication about cardiovascular risk reduction, while also identifying the timing of delivering this information as important in engagement with subsequent risk reduction behaviors. Specifically, participants noted the importance of cardiovascular risk counseling as they progressed through treatment and into survivorship, rather than just at diagnosis. Many participants reported that they did not receive information on cardiovascular risk and were interested in learning more about their individual risks and the impact of their treatment on cardiovascular risk. These findings are in alignment with previous studies on both cancer survivors and health care professionals who identified that there was a knowledge gap among breast cancer survivors about cardiovascular risk. Cancer survivors consistently identified interest in discussions about heart disease and risk factors [32-34]. Although health care providers are generally aware of the increased cardiovascular risk in cancer survivors, system-based barriers include a lack of training, competing demands, and time limitations that limit the capacity for counseling and screening [34]. Furthermore, patient-level factors including socioeconomic factors and having a fatalistic outlook have been reported by health care clinicians as barriers to adopting risk reduction strategies [32,33]. In this study, the need for resources to promote self-efficacy was similarly identified by multiple participants even in a population with access to primary care [35].

Participants identified previously known barriers and facilitators to cardiovascular risk reduction, including motivation, time limitations, and resources to support efforts for change. Participants simultaneously identified breast cancer–specific factors as both significant components of their risk perception and as limitations to participation in risk-reducing behaviors. These same barriers were identified in previous formative research for intervention development, with the identification of cancer and other health conditions limiting the ability to increase physical activity. These studies simultaneously identified the need for individual motivation to facilitate change [34]. Participants in this study identified the need for multimodal changes, which aligns with previous literature supporting the greater efficacy of interventions that address factors beyond physical activity alone [30,31,34].

Breast cancer survivors desired additional communication about cancer-specific cardiovascular risk factors, preferably delivered after initial diagnosis and treatment have been established. Cardiovascular risk reduction strategies, including physical activity, have been demonstrated to reduce cardiovascular risk and improve quality of life, and therefore increased attention to cardiovascular risk reduction is essential to promoting improved survivorship care of breast cancer survivors [36,37]. Therefore, additional interventions that promote cardiovascular risk reduction and consider the elevated risks and unique barriers faced by breast cancer survivors are essential.

This study supports and aligns with existing literature regarding the need to support self-efficacy and consider the physical limitations of breast cancer survivors following treatment. Previous research identifies the critical role of clinicians in identifying and communicating the cumulative role of risk factors in cancer survivorship on cardiovascular risk and the importance of patient-clinician communication [38]. Engagement in communication about cardiovascular risk is limited and especially important in cancer survivors at increased

risk, including those with existing cardiovascular disease and obesity. Primary care clinicians can serve an important role in screening for cardiovascular risk, promoting risk reduction, and pharmacologic management when indicated [39]. Based on this study, primary care clinicians often initiate this discussion and have an opportunity to improve communication about risk and promotion of health behaviors. When primary care clinicians were surveyed about barriers and enablers of care, system-level barriers including lack of time and training were critical to address to promote improved cardiovascular survivorship care [32]. Clinical risk assessment and management tools have been identified as strategies to improve the delivery of cardiovascular disease care to reduce morbidity and mortality. This study identifies the need to consider mental health support and treatment in facilitating cardiovascular risk reduction. In addition, it identifies the importance of timing in the delivery of cardiovascular risk-reducing education during the breast cancer treatment-survivorship continuum in order to optimize the uptake of risk-reducing measures.

Strengths and Limitations

The proposed study is novel in its evaluation of breast cancer survivors–specific perceived risks and susceptibility to breast cancer, as well as potential survivorship-associated barriers to engagement in risk reduction. However, the study has a number of limitations. First, the study focuses on participants from a single academic medical center, which may limit its transferability. Further studies should include participants from a diversity of geographical locations and practice settings. A stratified recruitment approach was used to broaden the perspectives obtained as part of the interview process. Second, participants were selected based on having an existing primary care clinician, as the study included the role of primary care clinicians in survivorship. Future work would benefit from the inclusion of individuals with reduced access to care. Third, study findings may have been impacted by participation bias, where either the desire to engage in cardiovascular risk reduction behaviors or existing cardiovascular disease may have impacted the decision to participate. There are elevated rates of cardiovascular disease in breast cancer survivors, and this perspective is proportionally represented in this study. Another limitation is that the interview guide was not pretested before implementation. The interview guide was based strongly on the constructs of the Health Belief Model, which have been extensively studied. Future investigations could ensure the validity of the interview guide as related to capturing Health Belief Model constructs as related to cardiovascular risk in breast cancer survivors. Finally, the study is limited by the small sample size. This study focused on a limited number of individuals in order to obtain more breadth of information. While the achievement of theme saturation strengthens the study findings, future quantitative studies are needed to further evaluate the identified themes using a larger sample size to promote the development of interventions that improve communication between health care team members and breast cancer survivors about cardiovascular risk and engagement with risk reduction behaviors.

Conclusions

Breast cancer survivors face unique cardiovascular risks influenced by their diagnosis and treatment, which introduce barriers to effective risk reduction. Participants in this study expressed a desire for enhanced counseling on cardiovascular health, highlighting a significant knowledge gap regarding their risks and the impact of cancer treatments. Many reported insufficient communication from health care providers about cardiovascular risks, particularly after the initial treatment phases. To address these issues, health care systems should leverage electronic communication methods, such as video and SMS text messaging, to deliver tailored cardiovascular risk information. Interventions must consider the specific challenges of survivorship, including physical limitations and mental health concerns, to effectively engage survivors in risk-reducing behaviors. This study highlights the importance of improving adherence to guideline-based care for breast cancer survivors and emphasizes the need for further research to develop comprehensive strategies that facilitate cardiovascular health in this population. By prioritizing timely and accessible information, we can enhance self-efficacy and support better health outcomes for breast cancer survivors.

Acknowledgments

The authors would like to acknowledge Suzanne Perkins for her contributions to recruitment, data collection, and interviews. The authors would additionally like to thank Dr Emily Ramsayer for her contributions to data analysis and Nekia Robinson for her role in manuscript revision. This study was funded by pilot funding through the Cancer Control Group at Hollings Cancer Center at the Medical University of South Carolina. Generative artificial intelligence was not used in manuscript writing.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

STM contributed to conceptualization, formal analysis, funding acquisition, methodology, and writing including the original draft and review and editing. VD contributed to conceptualization, methodology, supervision, and writing including the original draft and review and editing. NS contributed to formal analysis, methodology, and writing in all stages of development.

Abstract

Background: Despite the known benefits of physical activity, cancer survivors remain insufficiently active. Prior trials have adopted digital health methods, although several have been pedometer-based and enrolled mainly female, non-Hispanic White, and more highly educated survivors of breast cancer.

Objective: The objective of this study was to test a previously developed mobile health system consisting of a Fitbit activity tracker and the MyDataHelps smartphone app for feasibility in a diverse group of cancer survivors, with the goal of refining the program and setting the stage for a larger future trial.

Methods: Participants were identified from one academic medical center's electronic health records, referred by a clinician, or self-referred to participate in the study. Participants were screened for eligibility, enrolled, provided a Fitbit activity tracker, and instructed to download the Fitbit: Health & Wellness and MyDataHelps apps. They completed usability surveys at 1 and 3 months. Interviews were conducted at the end of the 3-month intervention with participants and cancer care clinicians to assess the acceptability of the intervention and the implementation of the intervention into clinical practice, respectively. Descriptive statistics were calculated for demographics, usability surveys, and Fitbit adherence and step counts. Rapid qualitative analysis was used to identify key findings from interview transcriptions.

Results: Of the 100 patients screened for eligibility, 31 were enrolled in the trial (mean age 64.8, SD 11.1 years; female patients=17/31, 55%; Hispanic or Latino=7/31, 23%; non-White=11/31, 35%; less than a bachelor's degree=14/31, 45%; and household income <US $75,000=11/31, 35%). The mean (SD) years since diagnosis was 7.1 (8.2), and the two most frequent cancer diagnoses were prostate (9/31, 29%) and breast (4/31, 13%) cancer. Participants provided positive feedback on the MyDataHelps app usability; the overall app quality received a mean score of 3.79 (SD 0.82) on a 5-point Likert scale (1=worst, 5=best). Interviews with 10 patients yielded four themes: (1) Fitbit and app setup was easy but the research team provided assistance, when needed, which was helpful, (2) motivational messages within the app were not memorable, (3) step counts and Fitbit notifications were motivating, and (4) medical professionals viewing their data were acceptable. Interviews with 5 cancer care clinicians yielded four themes: (1) some patients used wearables but rarely discussed data with clinicians; (2) activity trackers can be helpful to motivate patients and keep them accountable; (3) objective activity measures—similar to BMI, weight, and blood pressure— that they can track over time and refer to afterward were preferred; and (4) training and systematic processes to view these data as part of active workflow were desired.

Conclusions: Implementing a remotely delivered, light-intensity physical activity program was feasible and acceptable in a sample of diverse cancer survivors. Future studies should consider registry-based methods and work with clinicians to engage hard-to-reach survivor populations who have low physical activity levels and disproportionately high adverse health outcomes.

Trial Registration: ClinicalTrials.gov NCT05417438; https://clinicaltrials.gov/study/NCT05417438

Introduction

The health benefits of physical activity for cancer survivors are widely known. Yet, few survivors are active during (<10%) and after cancer treatment (20% - 30%) [1,2]. Per the American Heart Association recommendation, cancer care clinicians should provide phsyical activity referrals to prevent cardiovascular disease in survivors [3]; however, clinicians do not always suggest these referrals [4]. Notably, acknowledging an individual's unique perspective and offering choices rather than referrals to one singular program have been shown to increase effectiveness [5,6].

There has been a recent increase in the number of physical activity programs that exist for survivors. Virtual group programs have appeared as an option that is preferred by some survivors, allowing them the social support they seek in a group format with the convenience of participating in a program from one's own home [7,8]. In a previous study, clinic-based referrals to group in-person and group virtual programs were acceptable to cancer survivors, but some also expressed a desire for a nongroup digital program option [8]. In cancer survivors, digital health programs can be effective in promoting physical activity and reducing participation barriers [9]. However, engaging diverse groups of survivors in digital programs continues to be a challenge [10], along with sustainably integrating digital programs into clinical survivorship care [11]. Ninety percent of US adults own a smartphone and 40% - 60% a wearable device [12,13]. As digital health programs are becoming increasingly more accessible, more strategies are needed to increase the reach of these programs, particularly as the number of cancer survivors grows annually [14].

This pilot study differs from past research in several ways. First, most prior digital health trials used pedometer-based interventions as opposed to Fitbit-based interventions [15], and many of these studies incorporated counseling and other forms of support in their interventions [15]. Additionally, the majority of trials using wearable physical activity trackers with cancer survivors have been done in homogenous populations, such as White, college-educated [10], and survivors of breast cancer [10,15]. Past evidence on the optimal frequency and timing of SMS text messages in this context is lacking and what evidence there is has been inconclusive [10]. Finally, very few studies have focused on older adults, who comprise the majority of cancer survivors in the United States [10].

Thus, the purpose of this study was to test a previously developed mobile health system in a diverse group of cancer survivors with the goal of refining the program and setting the stage for a larger future trial [16,17]. We tested the feasibility of using a wrist-based wearable activity tracker (Fitbit) and smartphone app dyad with survivors, including seeking feedback on survey data collection and message prompts within the app. We also sought feedback from our clinical partners to better understand the implementation of referrals to a digital health program and perspectives on accessing patient-generated health data from these programs.

Methods

Ethical Considerations

This study took place at the University of Massachusetts Chan Medical School with remote recruitment, allowing participants to partake in study activities outside of the institution. Procedures were approved by the University of Massachusetts Chan Medical School Institutional Review Board (#H00023545) and informed consent was obtained from each participant. All participant data were deidentified and study data were kept anonymous. Participants received US $25 compensation for participation in the pilot and US $25 for participation in a follow-up interview. The study was registered at ClinicalTrials.gov (NCT05417438).

Study Design

This study used a longitudinal, nonrandomized, multilevel mixed methods approach, involving both quantitative and qualitative data collection (explanatory sequential design) from enrolled patients and cancer care clinicians between January 2023 and July 2023. Cancer survivors were enrolled in a 3-month Fitbit or smartphone app intervention. The convenience sample size was not calculated, as this was a feasibility pilot study. Outcome data for the intervention included Fitbit adherence and step counts over 3 months, usability ratings of the MyDataHelps app at 1 month, and follow-up interviews. No data were collected regarding the usability of the Fitbit: Health & Wellness app, as the app was primarily used to continuously synchronize Fitbit data with the MyDataHelps app. Clinician semistructured interviews were conducted following the data collection period for the intervention (June-July 2023).

Recruitment

Eligibility criteria for the pilot study included having a past cancer diagnosis, owning a smartphone with internet access, and being deemed appropriate to participate by a medical professional as necessary. Recruitment was first conducted using paper flyers posted throughout clinics in the UMass Memorial Health network. The flyer provided interested participants with the study team's email address and telephone number to call and SMS text message to discuss the study further. Potential participants were additionally identified by extracting data directly from the electronic health record (EHR) data hosted in the UMass Chan Data Lake. Next, potential participants were sent a letter containing information about the study and instructions to call to opt out of further contact. Two weeks after being mailed, potential participants who did not opt out were called and asked if they were interested in joining the study. Potential participants who expressed interest were screened over the phone. Approval to participate in the study was sought from clinicians for potential participants based on responses in the Physical Activity Readiness Questionnaire (PAR-Q), a 7-step questionnaire screening for evidence of risk factors during moderate physical activity and reviewing for family history and disease severity [18]. Potential participants were then sent a secure email through REDCap containing a link directing them to an electronic consent form. After going through the electronic consent form with the study team over

the phone, eligible potential participants who were interested consented using their electronic signature.

Statistical Analysis

Healthy History, Demographics, and Physical Activity Readiness

Participants self-reported their age, sex, education level, race, ethnicity, date of last cancer diagnosis, and type of cancer via a telephone screening process with the study team. Physical activity readiness was assessed using the PAR-Q. Any "yes" response prompted approval to be sought from the participant's primary care provider or cancer care clinician. Once enrolled, patients completed additional health history baseline questionnaires through surveys delivered in the MyDataHelps app.

Fitbit Adherence and Step Count

Physical activity data were adjusted for a number of valid wear days. Consistent with prior studies [19-21], valid wear days were defined as those with a daily step count of 1500 or greater as measured by the Fitbit activity tracker.

App Usability

The Mobile App Rating Scale (MARS) was used to assess the acceptability of the MyDataHelps smartphone app at 1 month through a survey delivered in the MyDataHelps app. Specific assessments of app functionality and aesthetics included ease of use, navigation, visual appeal, performance, graphics, and layout, as well as overall app quality [22]. Items were rated by participants using a 5-point Likert scale from 1=inadequate to 5=excellent. Sample questions included "how easy is it to learn how to use the app?" and "how clear are the menu labels or icons and instructions?" The MARS was scored using a mean for each category. The MARS has demonstrated internal consistency (α=.9) and interrater reliability (intraclass coefficient=0.79) [22,23].

Participant and Clinician Acceptability

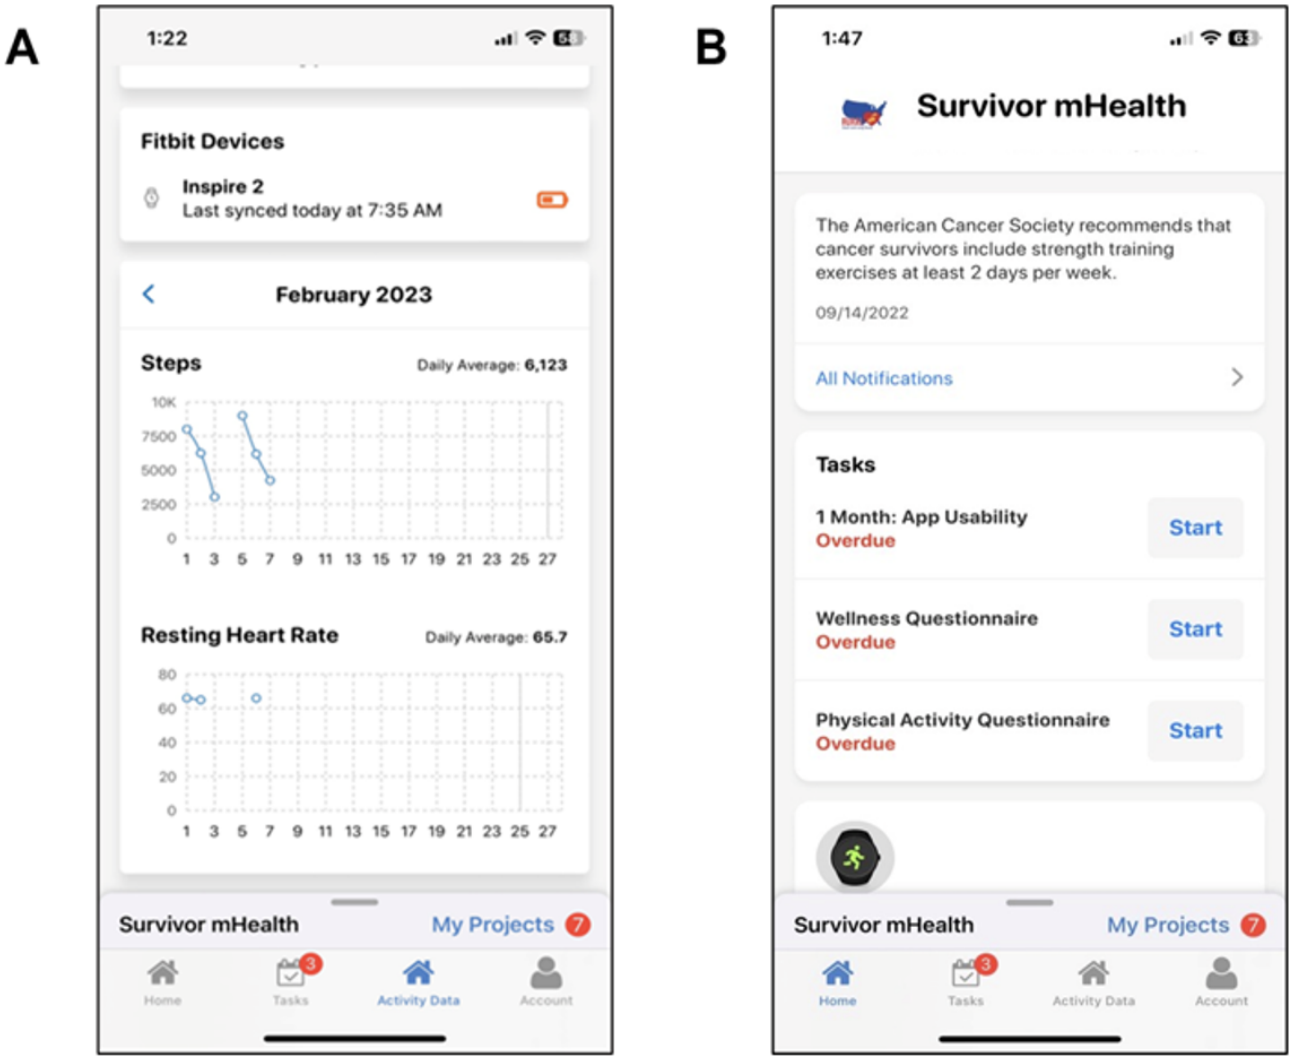
Enrolled participants completed semistructured interviews (Multimedia Appendix 1) after the 12-week intervention to assess their experiences during the study, including areas of improvement. Health care clinicians' perceptions on integrating this program into clinical practice were also assessed through semistructured interviews.

Protocol for Intervention

The intervention protocol, including the MyDataHelps app, was previously user-tested in a healthy cohort [24]. All participants received a Fitbit Charge device (versions 2 and 5) to keep as part of their compensation for participating. Following consent, participants were mailed their Fitbit along with paper instructions for device and app setup (including a unique study identifier) and were provided technical support over the phone by the study team. Study participants downloaded 2 apps onto their phones: Fitbit: Health & Fitness and MyDataHelps. Upon enrollment, participants were instructed that the standard goal steps/day set by Fitbit is 10,000 steps. They were told they could modify their step-count goal based on what their current activity level was and what they felt was achievable. Participants were instructed to wear their Fitbit for a total of 3 months, during which time they received standard Fitbit: Health & Fitness push notifications to their Fitbit devices, such as alerting them of achievement of goal steps per day, time spent in active heart rate zone minutes (if participants enter a high-intensity workout zone), and movement reminders (to get up and move if inactive for a period). These messages are preset by Fitbit to be delivered to participants based on their individual data.

Participants' smartphones also received push notifications from MyDataHelps to promote adherence to the study surveys, along with weekly push notifications of motivational messages (Figure 1). These messages were templated messages to inform participants about the benefits of exercise and strategies to incorporate exercise into their day, derived from the American Cancer Society (eg, "Research has shown that exercise is not only safe and possible during cancer treatment, but it can improve how well you function physically and your quality of life" and "End your exercise session with stretching or flexibility exercises. Hold a stretch for about 15 to 30 seconds and relax. Examples of stretching are reaching overhead, deep breathing, and bending over to touch your toes so that you relax all the muscle groups") [25].

Figure 1. MyDataHelps app displaying Fitbit data (A) and message notifications and survey tasks (B).



Participants who experienced technical challenges or difficulties adhering to study protocols (eg, syncing Fitbit, completing surveys) were contacted by phone to troubleshoot issues. Through the MyDataHelps app, participants completed surveys 24 hours, 1 month, and 3 months after enrollment. Participants also received push notifications alerting them that the surveys were available within the app (Figure 1). Participants' Fitbit devices were synced to the MyDataHelps app. Once participants registered for MyDataHelps and synced their Fitbit: Health & Wellness account, data collection from the Fitbit activity tracker began. The study team viewed activity and survey completion data weekly and conducted outreach to participants with missing data. We continued to reach out to participants, including giving them an opportunity to complete their 3-month survey. Those who did not complete their 3-month survey were considered lost to follow-up. After participants completed all the tasks required for the study, they were allowed to keep their Fitbit and were provided a US $25 Amazon gift card.

Protocol for Qualitative Feedback From Participants and Cancer Care Clinicians

Upon completion of the study tasks, participants were offered the option to take part in a 30-minute semistructured Zoom interview. Participants who took part were compensated with a US $25 Amazon gift card (in addition to the gift card provided for the completion of study tasks). Interview guides were developed by the study team using an iterative process of pretesting. The interview guide consisted of questions asking their perceptions of the program overall, as well as asking them ways to improve the current list of messages they received within the app (Multimedia Appendix 2). These guides were revisited after interviews to determine if any additional questions needed to be added, removed, or probed further. Cancer care clinicians, specifically advanced practice providers, were recruited via pre-existing relationships with the study team and through the survivorship coordinator. The survivorship coordinator emailed cancer care clinicians involved in survivorship care information about the study and about participating in interviews. Participating clinicians were asked to complete a 30-minute Zoom interview using a structured interview guide. The guide was designed to discuss implementing physical activity referrals to digital health programs into clinical workflow, along with preferences for reviewing those data. Again, the interview guide was revisited after each interview for revisions. The survivorship coordinator also provided feedback on the interview guides throughout the process. Zoom interviews were conducted by a trained member of the research team in conjunction with the study principal

investigator and recorded and transcribed electronically using an institutional review board–approved software.

Data Analysis

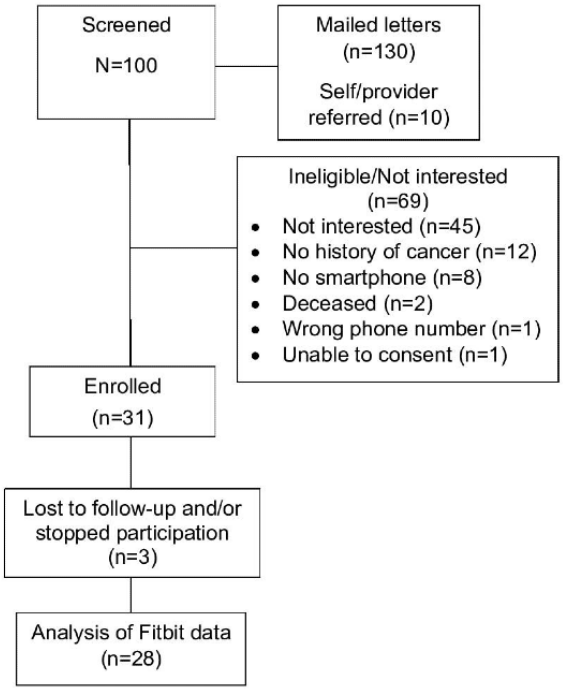
Quantitative analyses for demographics, usability surveys, and Fitbit data were completed using R 4.3.2 (The R Foundation) and Microsoft Excel. Analysis of Fitbit step count data (mean and SD of steps per day each week) was done on valid days, in which valid days were defined as those with a step count of 1500 or greater [20-22]. As such, the first valid day of Fitbit use was the first day the participant walked 1500 or more steps while wearing Fitbit, and data collection from Fitbit concluded 90 days following the first valid day. Any days with fewer than 1500 steps within the 90-day time frame of study participation were considered missing. Qualitative data were analyzed using rapid qualitative analysis [26]. This was done by first creating a matrix in Excel after the participants' interviews were completed. The matrix had a row for each participant and columns for each domain that corresponded with the interview guide. Domains included "experiences with patients and wearables devices," "when to integrate program into clinical practice," "preferences to clinical team viewing data," and "support needed for clinicians (eg, EHR staff) or patients." The study team (JMF, RN, AK, and ZD) then met to code the interview transcripts for 2 participants in each group, and then individually coded the remainder on their own. The study team met regularly to conduct data and coding checks and resolve any discrepancies in coding or domain assignment. The team noted the common themes between the participants' responses to each domain and identified key findings of the qualitative interviews. Each key finding discusses the main common themes within the qualitative interviews that align with the domains.

Results

Overall Results

Figure 2 presents the flow of participants from contact to the conclusion of the 12-week intervention. The study team mailed letters to 130 potential participants and had 10 potential participants either self-refer or were referred by their clinician. Of the 100 potential participants who were screened, 31 participants enrolled in the trial, achieving a response rate of 31%.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flow diagram.



Among the 31 participants enrolled in the intervention, the mean age was 64.8 (SD 11.1) years, 17 (55%) identified as female, 14 (45%) had less than a bachelor's degree level of education, 7 (23%) identified as Hispanic or Latino, and 11 (35%) identified as non-White (Table 1). The top two cancer diagnoses were prostate (9/31, 29%) and breast (4/31, 13%), and the mean years since diagnosis was 7.1 (SD 8.2).

Table . Enrolled patient baseline demographics (N=31).

Variables		Values
Age (years), mean (SD)		64.7 (11.1)
Sex, n (%)		
	Male	14 (45)
	Female	17 (55)
Education level, n (%)		
	High school or less	7 (23)
	Some college	7 (23)
	Bachelor's degree	6 (19)
	Advanced college degree	11(35)
Race, n (%)		
	White	20 (65)
	Black or African American	10 (32)
	Other	1 (3)
Ethnicity, n (%)		
	Hispanic or Latino	7 (23)
	Not Hispanic or Latino	24 (77)
Household income in US$, n (%) [a]		
	>75,000	18 (62)
	50,001-75,000	4 (14)
	25,000-50,000	5 (17)
	<25,000	2 (7)
Cancer type, n (%)[b]		
	Gynecologic	2 (6)

	Blood	2 (6)
	Don't know	2 (6)
Years since diagnosis, mean (SD)		7.1 (8.2)

[a]Due to missing responses, n=29.

[b]Due to missing responses, n=27.

Fitbit Adherence and Activity

Physical activity adherence during the 12-week intervention was assessed using Fitbit data (Table 2). Based on this measure, the mean daily step count was 7219 (SD 4418) at baseline and 6687 (SD 3183) at 12 weeks.

Table . Mean (SD) number of valid days of adherence to wearing the Fitbit activity tracker and mean (SD) steps/day during the 12-week intervention period among cancer survivors (n=28).

Intervention week	Number of valid days/week, mean (SD)	Steps/day, mean (SD)
1	1.93 (2.61)	7218.61 (4417.71)
2	4.78 (2.83)	6447.97 (3405.71)
3	5.30 (2.52)	6200.9 (3382.68)
4	5.22 (2.61)	6645.24 (3607.05)
5	5.04 (2.89)	6782.65 (3901.27)
6	4.85 (2.74)	6639.79 (4072.6)
7	5.11 (2.53)	6570.96 (3950.37)
8	5.07 (2.89)	6628.75 (3745.22)
9	4.70 (3.01)	6871.6 (4134.65)
10	4.69 (3.17)	6598.36 (3481.8)
11	4.77 (2.96)	7384.56 (4157.78)
12	4.08 (2.62)	6686.95 (3183.27)

Mobile App Rating Scale

At 1 month, 25 participants completed the MARS usability scale responding to questions about the MyDataHelps app functionality, appearance, and overall rating on a scale of 1 to 5 (1=worst and 5=best; Table 3). The highest-rated category was “performance” with a mean score of 4.36 (SD 1.02), and the lowest-rated category was “ease of use” with a mean score of 3.79 (SD 1.22). The overall app quality received a mean score of 3.79 (SD 0.82).

Table . MARS (Mobile App Rating Scale) usability scores of the MyDataHelps smartphone app; ratings range from 1=worst to 5=best.

Variable and question	Values, mean (SD)
Performance: How accurately/fast do the app features (functions) and components (buttons/menus) work?	4.36 (1.02)
Ease of use: How easy is it to learn how to use the app? How clear are the menu labels/icons and instructions?	3.79 (1.22)
Navigation: Is moving between screens logical/accurate/appropriate/uninterrupted? Are all necessary screen links present?	4.21 (1.22)
Interactions: Are interactions (taps/swipes/pinches/scrolls) consistent and intuitive across all components/screens?	4.13 (1.05)
Layout: Is the arrangement and size of buttons/icons/menus/content on the screen appropriate or zoomable if needed?	4.04 (1.02)
Graphics: How high is the quality/resolution of graphics used for buttons/icons/menus/content?	3.80 (0.85)
Visual appeal: How good does the app look?	3.84 (0.78)
Overall rating: What is your overall star rating of the app?	3.79 (0.82)

Qualitative Feedback

Ten participants completed 3-month follow-up interviews assessing their overall experiences in the program. Four themes were identified from our analyses, and illustrative quotes can be seen in Table 4. Overall, participants felt the Fitbit activity tracker and the MyDataHelps app were easy to use but also benefited from the assistance of the research team. The weekly motivational messages within MyDataHelps were not very memorable and were often confused with the daily push notifications sent directly to the Fitbit activity tracker. For example, when asked about the content of the MyDataHelps weekly messages, a participant responded, “I didn’t pay a whole lot of attention to them. I know I got ‘em maybe daily or every other day.” However, participants noted overall that the messages and notifications motivated them to be more active and accrue additional steps. Lastly, most participants were comfortable with and liked the idea of sharing their physical activity data with their clinicians.

Table . Enrolled patient feedback from qualitative interviews.

Theme	Illustrative quotes
Fitbit and app setup were easy and assistance from the research team was helpful.	• "I didn't find it [Fitbit and MyDataHelps setup and navigation] to be a problem at all once you walked me through it." "The information provided was pretty self-explanatory, even though I'm not very computer-savvy and never had a Fitbit."
Motivational messages within the app were not memorable.	• "They weren't sent often. Not, not particularly unless I set it up wrong. I think if I had gotten something on a weekly or even a daily [basis], it would motivate me." "Well, the messages, if any, were, I believe...I forget how I was able to access them...I'm trying to think of a specific message."
The step counts and Fitbit notifications to be active were motivating.	• "Tracking my steps was helpful, especially given how I've changed my lifestyle from working full-time to finally being home most of the time. And I had to make sure I put some time into taking steps or helping my health progress." • "Before, I never actually paid attention to like, 'Okay, I'm gonna do this many steps today, or I'm gonna do this.' And that was pretty cool that it gave that option to keep track of all that. And if I beat my goal from the day before, it would let me know. It would tell me, 'Congratulations!' which was kind of cool."
Patients were comfortable with and liked the idea of medical professionals seeing their data.	• "I did tell my oncologist that I was doing this study and I also spoke with my pulmonologist...And I told my primary care, and she said, "Well, that's interesting." I said, "You know the thing is, you never know what [information] is going to come along that might be helpful to you in the long run." • "I would like that because it's able to connect some of the dots, right? They're only seeing, you know, the medical side of it, but they can't see your everyday activity."

Five advanced practice providers specializing in oncology completed interviews to assess their perceptions of the digital health program and workflow integration. All 5 clinicians were female, had been practicing in their clinic for >1 year, and treated either disease-specific patients (breast, gastrointestinal, or genitourinary) or patients of all diagnoses. Clinicians were from one academic hospital (n=4) and one community hospital (n=1). Four themes were identified with illustrative quotes represented in Table 5. Clinicians noted some patients use wearables but rarely bring them up during their clinic visits. They also expressed that goal setting may be helpful for their patients and thought it may be helpful to have objective metrics of physical activity to track over time in lieu of standard weight and BMI clinical measures. Most clinicians wanted more education and training on physical activity and wearable device programs and better standard operating procedures integrated into their workflows.

Table . Clinician feedback from qualitative interviews.

Theme	Illustrative quotes
Some patients use wearables but rarely discuss data with clinicians.	"I don't know that it comes up all that often. Things have changed since Covid. I used to have tons of patients who would do this kind of thing like the Silver Sneakers-type program...Not too much beyond the generic, like, 'I shoot for X number of steps a day and I usually [get] X.'"
Activity trackers can be helpful to motivate patients and keep them accountable.	"Some people are motivated by their internal motivations. And I think Fitbit still gives you that accountability and that trackability. I've had patients that have used pedometer-esque, Fitbit-like, applications, whether it's their iPhone or something like that, and they'll say, 'Okay, I got this many steps.' And I think that it does motivate them to be more active."
Clinicians prefer objective measures similar to BMI, weight, and blood pressure that they can track over time and refer to afterward (eg, vital signs).	"Typically, what I use is their BMI...to say, 'Oh, congratulations! Your BMI last visit was this and look what it is now. I can see that you have better energy, and your wellbeing seems to be improved as well.' It could be helpful for that sort of reinforcing and motivating and monitoring portion."
Clinicians want more training and systematic processes to view these data as part of active workflow.	"With training and guidance, if that was considered part of our scope, if we felt like patients were benefiting...yeah, absolutely...if it's something that would help patients and is clinically appropriate depending on whatever training we got."

Discussion

Principal Results

Our study found that deploying a Fitbit or app dyad remotely was feasible and acceptable in this convenience sample of diverse participants with histories of several types of cancers. Participant engagement, as indicated by mean valid wear days and mean daily steps each week, was highly consistent over the course of the 12-week intervention. This finding was similar to those of past trials in cancer survivors [27-29]. The main exception to this was that on average, participants had fewer valid wear days in the first week of the intervention, which, similar to other trials, can be attributed to an initial adjustment period to wearing a Fitbit daily [30]. Though engagement was high, step counts remained relatively unchanged from baseline to 12 weeks. Lastly, several cancer care clinicians were interested in the ability to deploy such an intervention into their clinical practice for physical activity surveillance and interventions for their patients with cancer histories.

The MARS app ratings were similar to other physical activity monitoring app studies in that functionality components were rated higher than aesthetic components [24,31]. The high functionality ratings were supported in our qualitative feedback, with participants specifically noting the app being easy to use even if they themselves were not very tech-savvy. This is critical in the cancer survivor population, as 67% of US cancer survivors are over the age of 65, and this proportion is expected to grow to 74% by 2040. There are noted disparities in the use of digital health tools in advanced age [32]. However, participant qualitative feedback revealed the messages sent within the app were not very memorable. This may have been due to the message content, or possibly that they did not know where to view the messages on the MyDataHelps app dashboard. Several participants made more mention of the daily Fitbit device notifications being helpful. As motivational messaging has been shown to be effective in promoting physical activity [33,34] and was memorable to our participants on the Fitbit device, it is possible the notifications, along with vibrations, going directly to a patient's device on their wrist are more noticeable than having to open an app to see the message. Despite notifications being reported as helpful, changes in step count over time were minimal. Though consistent with prior feasibility studies in this population [27,35], it will be critical to explore the effect of intervention components on step count over time in a large randomized trial. This includes exploring the addition of social support, a feature in Fitbit, and a feasible and acceptable intervention method for cancer survivors [35].

Qualitative feedback from participants yielded several important implications of recruiting, enrolling, and retaining patients throughout the study. The first important implication was that the MyDataHelps and Fitbit: Health and Wellness apps setup was straightforward and easy to follow. Some participants noted they were not tech-savvy, but they did not find it to be an issue. Participants also appreciated the help from the study team during the initial setup and to troubleshoot any issues that arose. To provide technical support, our study team used multiple methods to meet the needs of the participants. For most, this only entailed troubleshooting issues over the phone or SMS text message. Six participants additionally required videoconferencing and screen sharing to troubleshoot technical difficulties with a visual aid. Of the 6 participants, 4 chose to come in person for the study team to troubleshoot their issues. With additional assistance by video call or in person, these participants were also able to complete the study tasks quickly. Overall, the team found that participants greatly appreciated having options to connect and talk with them. The final theme from participants indicated they were comfortable sharing data with health care clinicians. Health care professionals can be critical in helping survivors engage in physical activity. Survivors reported a lack of physical activity guidance, prescriptions, and referrals from their care team as barriers to activity [36].

Clinicians revealed that patients rarely discuss wearable devices or data with them during their clinic visits. Oncology nurses have reported that patients lack interest in discussing physical activity with them. However, clinicians liked the notion of having long-term activity monitoring as a topic to discuss with patients in lieu of discussing weight or BMI. Physical activity independent of weight loss can improve health outcomes in individuals with obesity [37], and sedentary time, which is inversely correlated with physical activity levels, is an independent risk factor of cancer incidence [38]. Using a more neutral objective measure of physical activity rather than a more sensitive metric like weight or BMI may be more acceptable to discuss with patients who have weight concerns. To do this, clinicians expressed wanting more education and training on integrating physical activity digital health tools into their workflow as options for their patients. Lack of provider knowledge has been one of the most commonly reported barriers to the provision of physical activity promotion by cancer care clinicians to survivors [39]. Additionally, integrating wearable devices and subsequent data directly into clinicians' workflow poses challenges. Prior studies have identified barriers to integrating devices into the EHR, maintaining privacy and confidentiality of patient data, lack of system interoperability and connectivity of wearable devices and health systems, and patient information or data overload [40].

Limitations

This study has limitations to note. The small sample size is a statistical limitation. Similar to most studies done in the past, this study was limited to 3 months in duration; thus, there still remains little research regarding long-term outcomes from Fitbit-based interventions, including health outcomes [11,16]. As trials longer than 6 months have noted greater dropout rates over time [16], it will be important to explore this timeframe in future trials. Another limitation regarding the study design was the lack of a control group. Although this design has been used in similar feasibility trials, the lack of a control group limits the inferences we can make pertaining to the internal validity of the intervention. Though participant step counts were fairly consistent during the trial, this consistency could be attributed to having a highly motivated sample of individuals or to the Hawthorne effect and its impact on motivation and behavior. With regard to app usability, some participants reported confusing the SMS text messages delivered by the MyDataHelps app with push notifications sent by the Fitbit: Health & Wellness

app, which may have affected their MARS usability score evaluation. Additionally, familiarity and comfort with navigating smartphone apps associated with wearable technology were not assessed. Notably, we relied on recruiting patients from an EHR patient registry list. This method may have allowed us to capture patients who would not otherwise have reached out to join the study, but also may have introduced selection bias and is less pragmatic than a program that is implemented within routine clinical workflow. While we examined step counts only, it should be noted that Fitbit tracks additional metrics of minutes and intensity of activity and time spent being sedentary that should be considered. Lastly, we ascertained that most of the clinicians wanted training, guidance, or knowledge of how to integrate these into their workflow. Given the busy workload of clinicians, it is possible that in practice they would prefer better reports and objective data to be provided, rather than actively taking part in new tasks added into their workflow. This should be examined in future trials.

Conclusions

This study showed that a remotely delivered light-intensity physical activity program was feasible and acceptable in a sample of diverse cancer survivors. Future studies should consider registry-based methods and other strategies to engage hard-to-reach cancer survivor populations who are known to experience disproportionately high adverse health outcomes and low physical activity levels. These strategies should also be directed toward making improvements to recruit and engage larger numbers of participants from diverse sociodemographic backgrounds with consideration to technology access and use. On an individual scale, since some participants may have been more intrinsically motivated than others, future trials will benefit from assessing the underpinnings of participant motivation. Lastly, future trials should place emphasis on clinic implementation, including the quality of and method of delivery for reports, given the noted importance and use of the wearable device and app integration by cancer care clinicians for their survivors to be motivated to engage in and sustain physical activity.

Acknowledgments

This work was supported by the National Cancer Institute (5P50CA244693) and the National Heart, Lung, and Blood Institute (K01HL163254). The funders did not play a role in the design of the study; the collection, analysis, and interpretation of the data; the writing of the manuscript; and the decision to submit the manuscript for publication.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Older adults (aged >65 years) are disproportionately affected by cancer at a time when Canadians are surviving cancer in an unprecedented fashion. Contrary to persistent ageist assumptions, not only do the majority of older adult cancer survivors use digital health technologies (DHTs) regularly, such technologies also serve as important sources of their health information. Although older adults' transition to cancer survivorship is connected to the availability and provision of relevant and reliable information, little evidence exists as to how they use DHTs to supplement their understanding of their unique situation to manage, and make decisions about, their ongoing cancer-related concerns.

Objective: This pilot study, which examined older adult cancer survivors' use of DHTs, was conducted to support a larger study designed to explore how digital health literacy dimensions might affect the management of cancer survivorship sequelae. Understanding DHT use is also an important consideration for digital health literacy. Thus, we sought to investigate older adult cancer survivors' perceptions of DHTs in the context of accessing information about their health, health care systems, and health care providers.

Methods: A qualitative pilot study, which involved semistructured interviews with older adult cancer survivors (N=5), was conducted to explore how participants interacted with, accessed, and searched for information, as well as how DHT use related to their cancer survivorship. Institutional ethics approval (#21 - 0421) was obtained. Interpretive description inquiry—a practice-based approach suitable for generating applied knowledge—supported exploration of the research question. Thematic analysis was used to examine the transcripts for patterns of meaning (themes).

Results: Assessing the credibility of digital information remains challenging for older adult cancer survivors. Identified benefits of DHTs included improved access to meet health information needs, older adult cancer survivors feeling empowered to make informed decisions regarding their health trajectory, and the ability to connect with interdisciplinary teams for care continuity. Additionally, participants described feeling disconnected when DHTs seemed to be used as substitutes for human interaction. The results of this pilot study were used to create 12 additional questions to supplement a digital health literacy survey, through which we will seek a more fulsome account of the relationship between digital health literacy and DHTs for older adult cancer survivors.

Conclusions: Overall, this pilot study confirmed the utility of DHTs in enhancing the connection of older adult cancer survivors to their health care needs. Importantly, this connection exists on a continuum, and providing greater access to technologies, in combination with human support, leads to feelings of empowerment. DHTs are an important aspect of contemporary health care; yet, these technologies must be seen as complementary and not as replacements for human interaction. Otherwise, we risk dehumanizing patients and disconnecting them from the care that they need and deserve.

(JMIR Cancer 2025;11:e59391) doi:10.2196/59391

KEYWORDS

older adults; cancer survivors; digital health literacy; digital health technologies; aging; qualitative; pilot study; semistructured interview

Introduction

Older adults (aged >65 years) are the fastest-growing segment of the Canadian population with unprecedented cancer survivorship [1]. Technology has become increasingly important, with older adult cancer survivors reporting that a significant proportion of their health care information is gathered from digital sources [2]. Despite such availability, finding and accessing information during transitions to survivorship are challenging [3]. Access to information plays a vital role in improving cancer survivors' health outcomes and quality of

life. Although older adult cancer survivors may have unique needs, there is little research examining the extent of digital health technology (DHT) use to support their health. DHTs "use computing platforms, connectivity, software, and sensors for health care and related uses" and include telemedicine, wearable devices, educational resources, remote patient monitoring, etc [4].

With the increasing reliance on DHTs [5], a consistent concern for older adult cancer survivors is interacting with health care systems digitally [6]. Contrary to persistent ageist assumptions, not only do 95% of this group use DHTs regularly, DHTs are substantial sources of their health information [7]. Understanding DHT use is also an important consideration for digital health literacy (DHL). DHL is the capacity "to acquire, process, communicate, and understand health information and services, make effective health decisions, and promote and improve individual and collective health in the context of the use of digital information and technologies" [7]. This pilot study, which examined older adult cancer survivors' use of DHTs, was conducted to support a larger study designed to explore how DHL dimensions might affect the management of cancer survivorship sequelae.

Methods

Ethical Considerations

The pilot study reporting was guided by the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Checklist 1) [8]. Institutional ethics approval (#21 - 0421) was obtained from the University of Victoria, and informed consent was secured in advance of conducting interviews. Confidentiality was maintained throughout the research process, and all transcripts were deidentified prior to analysis, with data stored in password-protected files. Participants were given a CAD $25 (US $17.53) gift card.

Recruitment

Participants were recruited through the social media platforms of local eldercare and retirement groups, and recruitment consisted of 3 recruitment posters that were posted weekly in attempts to elicit diverse responses. As only 2 participants responded to those efforts, an additional 3 participants were recruited, using the snowball method by way of the initial 2 participants' social networks. The inclusion criteria included being aged 65 years or older, speaking English, having completed cancer treatment within the past 5 years, and being a resident of British Columbia, Canada.

Data Collection

Semistructured, 90-minute, individual interviews were conducted over a secure videoconferencing platform. Interview questions investigated how participants interacted with, accessed, and searched for information, as well as DHT use related to their cancer survivorship (Textbox 1). The audio-recorded interviews were transcribed and deidentified by the research associate (CF), with two researchers (LN and HM) reviewing for accuracy, prior to analysis. Participants were offered an opportunity to review their transcript for accuracy.

Textbox 1. Interview questions. Research questions asked to the participants aimed to identify how older adults use digital health tools to interact with, access, and search for information related to their health care and cancer survivorship.

Interview questions

1. What information resource(s) did you use most often?
2. How did you manage multiple information resources?
3. How did you determine the information was credible?
4. Knowing what you know now, what information do you wish you had access to?
5. What questions did you have around your transition from treatment to survivorship?
6. What questions were the most difficult to find answers to?
7. What have you found difficult to understand about this transition?
8. What do you like/dislike about using digital health tools?
9. What makes it easy/difficult for you to use digital health tools?
10. Now that you have completed the eHealth literacy survey, and after thinking about the questions already asked, is there anything else you would like to tell us?

Reflexivity, Interpretive Description, and Thematic Analysis

All interviews were conducted by 2 PhD-prepared assistant professors (LN and HM) and an undergraduate student, who was included as a research associate (CF). The lead authors have experience with qualitative research; are from the Global North; and identify as cisgender, White, female individuals who endeavor to be reflexive on positionality and perspectives throughout the research process. Interpretive description inquiry—a practice-based approach suitable for generating applied knowledge—supported exploration of the research question [9]. Thematic analysis was used to examine the transcripts for patterns of meaning (themes) [10]. The researchers convened after independently reviewing the first transcript to ensure congruence. As the researchers became familiar with the data and generated initial codes, themes were reviewed together. Finally, the researchers agreed that the themes accurately reflected participants' responses.

Results

Participants

A total of 5 older adult cancer survivors (4 women and 1 man), with an average age of 69 (SD 2.06) years, completed interviews. All 5 had postsecondary education and stated that they accessed DHTs daily. All participants had completed cancer treatment within the past 5 years and represented different geographic areas of the province. Participants were not known to the researchers prior to the interviews; however, researcher information and an overview of the research project were included in the informed consent process. Time and an opportunity for participants to ask questions were provided prior to the interviews. Additionally, during the informed consent process, participants were assured that their data were private and were not to be shared publicly. Thus, supporting data are not available publicly.

Themes

Thematic analysis [10] highlighted the following three main themes: access, empowerment, and connection.

Access

All participants agreed that access to DHTs is crucial for health care purposes and for facilitating health care needs with minimal disruption to routines. Distinguishing between access and accessibility is essential; despite owning digital devices and feeling comfortable with using them, 3 participants had no interest in or did not enjoy using digital devices for health care. However, 1 participant expressed how DHTs "were very helpful" and that they "used them for follow up with therapists and counselors." Such access allowed health care needs, such as education and remote connection to health care professionals (HCPs), to be addressed conveniently.

Empowerment

All participants associated DHT with feelings of empowerment, that is, being involved in their health decisions and being in control of their information (including access). All participants discussed the autonomy provided by DHTs. Participants explained feeling empowered by being in control, by accessing education, and by the ability to book appointment times. One participant said, "You can get all the information you need…I never cease to be amazed at what technology can do." Another participant expressed their satisfaction with DHTs, stating "I don't have to track it down; everything is just right there." As such, participants found that independently booking appointments, retrieving educational materials, and reviewing available medical records (eg, laboratory results) improved their sense of empowerment.

Connection

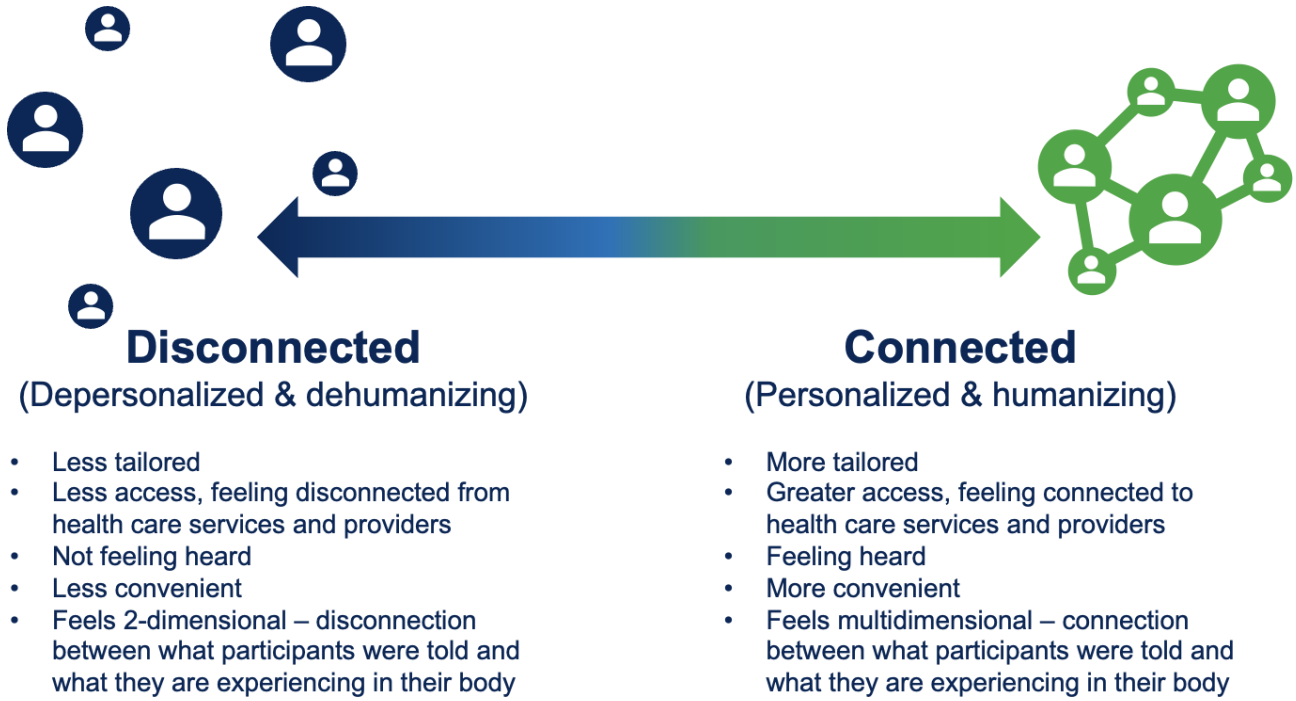
Participants described how DHTs enhanced connection. One participant stated that DHTs "allow for discussion that healthcare professionals wouldn't [otherwise] have time [to start]." A second participant echoed this, saying "When I was really sick, my doctor called me every day." This web-based connection was especially important in instances when participants were too ill to commute but not ill enough to be admitted to a hospital. In other cases, participants discovered community support through online groups. For example, one participant found videoconferencing with a survivorship group very helpful. Another participant stated, "I remember [medication] affected emotions; nothing could prepare you for that…My doctor and counselor didn't really talk about it...going online and finding that other people are having the same impact was very comforting." In this case, the patient found a sense of community through shared experiences on the web.

Paradoxically, participants also described experiences where human connection was absent. One participant shared an example of when an HCP noticed and addressed a physical concern as they were leaving an in-person appointment. This participant felt that this would never have been noticed in a web-based meeting. Another key observation was how intonation of voice, facial expressions, and body language of HCPs were difficult to discern and negatively impacted the participants' interpretations of interpersonal communication. One participant expressed frustration with "stereotypes placed on older people." Another stated, "People tend to treat everyone over the age of 65 like they are homogenous." Participants expressed annoyance with HCPs often overexplaining technology or assuming a lack of understanding of how to access DHTs when the participants felt that they could complete the task independently. The participants also pointed out instances in which HCPs lacked knowledge about the DHTs they expected patients to use.

Key Learnings to Inform Future Work

Participants reported that DHTs can facilitate access and empowerment. Participants' experiences also pointed to how DHTs can either foster connection or create barriers to human connection. That is, they described their feelings of connection as along a continuum from feeling disconnected from health care services to feeling connected with health care services (Figure 1). Participants outlined items that contribute to disconnection, such as the feeling of not being heard, services that are less tailored to their situation, and less accessibility. In contrast, participants further described feelings of greater connection with items such as greater access, the feeling of being heard by HCPs, and congruence between information received and what they are experiencing in their body. The results of this pilot study were used to create 12 additional questions to supplement a DHL questionnaire (Textbox 2) for the next phase of the project [11], in which we will seek a more fulsome account of the relationship between DHL and DHTs for older adult cancer survivors.

Figure 1. Connection continuum.



Textbox 2. Questions to be included in the eHealth literacy survey. After completing the interviews, the following questions, based on the insights from pilot study participants, were created to address additional areas of importance in the digital health literacy survey.

Questions to be included in the eHealth literacy survey

1. To support your survivorship, what information did you get using digital health tools?
2. Has the COVID-19 pandemic changed the way you think about digital health tools?
3. What digital health tools (apps, websites, wearables) did you use to support health and survivorship and how useful were they?
4. Did you join any support groups for people who have finished cancer treatment?
5. How often do you use digital health tools?
6. Is there anything you like about using digital health tools?
7. Is there anything you dislike about using digital health tools?
8. Is there anything you dislike about digital health tools as a part of health care?
9. If you are frustrated using digital health tools, how did you get through this frustration?
10. Where do you go if you need help with digital health tools?
11. In the past year, have you connected with a health care professional digitally?
12. What recommendations do you have about digital health tools for health professionals and organizations?

Discussion

Principal Findings

The participants in this pilot study confirmed some of the benefits of using DHTs for older adults' cancer survivorship; they can learn about their condition, connect with interdisciplinary teams for continuity of care, find connections and community support, and make educated and informed decisions regarding their health trajectory in survivorship. These findings are congruent with other studies, in which older adult cancer survivors expressed preferences for in-person visits and personalized telehealth visits [12], described how using DHTs could provide a sense of autonomy (ie, by allowing them to be actively involved with their health care) [2], and appreciated access to technology while maintaining a strong preference to be listened to with basic respect [13]. However, the propensity of health care systems to use DHTs as substitutes for human interactions to increase cost-effectiveness and efficiency can counteract those benefits. Indeed, given the existing structural ageism inherent in contemporary health care, there is a real danger of amplifying ageist processes, which can result in care that does not account for the intersection of normal aging and cancer survivorship [13]. Further, with the current lack of accounting for the burdens of navigating challenging cancer care systems, DHTs can either escalate feelings of disconnection or provide opportunities for connection and reconnection. Re-establishing the patient at the center of care and leveraging the humanity possible in DHTs are crucial; to continue to do

otherwise will ultimately lead to a sense of disengagement. DHTs are an important aspect of contemporary health care; yet, these technologies cannot replace HCP contact, or we risk dehumanizing patients and disconnecting them from the care that they need and deserve. By using DHTs compassionately and strategically for the ongoing care of older adult cancer survivors, HCPs can support this group along a continuum from feeling disconnected from health care services to feeling connected with health care services. Thus, it is imperative to determine the conditions under which DHTs complement health care and enhance rather than impair connection.

Limitations

Despite providing insights to augment the future survey, having only 5 participants inherently limits the scope and transferability of these findings. Further, although the participants represented geographic diversity, all identified as White, spoke English, and had postsecondary education; thus, this small, nonrepresentative sample may have reduced the richness of the data and the ability to achieve data saturation. Questions regarding diversity will also be added to the upcoming survey.

Conclusion

Overall, this pilot study confirmed the utility of DHTs in enhancing the connection of older adult cancer survivors to health care. Importantly, this connection exists on a continuum, and providing greater access to DHTs, in combination with human support, leads to feelings of empowerment. We are confident that applying these findings to further research will illuminate best practices for supporting older adult cancer survivors to optimize their cancer-free years.

Abstract

Background: Though telehealth has been a promising avenue for engaging cancer survivors with health care and lifestyle programming, older and rural-dwelling cancer survivors may have additional challenges in accessing digital devices and tools that have not yet been described. This study aimed to use a robust, nationally representative sample collected in 2022 to provide an updated view of digital technology use and the use of technology for health in this population.

Objective: This study aimed to examine the prevalence of digital technology use for health-related activities among older cancer survivors in both rural and urban settings. The primary outcomes of interest included (1) internet access and use for health-related activities, (2) digital device ownership and use as a tool for health behaviors, (3) use of social media for health, and (4) use of telehealth.

Methods: A cross-sectional analysis of the National Cancer Institute's Health Information National Trends Survey Cycle 6 (HINTS 6) was completed to examine the prevalence of digital technology use among older cancer survivors. For analysis, the sample was restricted to cancer survivors over the age of 60 years (n=710). Unadjusted and adjusted logistic regression models were used to test the association between rurality and digital health tool use.

Results: Overall, 17% (125/710) of the sample lived in a rural area of the United States and the mean sample age was 73 (SD 8.2) years. Older cancer survivors, regardless of rural-urban status, reported a high prevalence of internet usage (n=553, 79.9%), digital device ownership (n=676, 94.9%), and social media use (n=448, 66.6%). In unadjusted models, rural survivors were less likely than urban survivors to report that they had used a health or wellness application in the previous year (odds ratio [OR] 0.56, 95% CI 0.32-0.97; *P*=.04). In adjusted models, rural survivors were more likely to report that they had shared personal health information on social media (OR 2.64, 95% CI 1.13-6.19; *P*=.03). There were no differences in the proportion of rural and urban respondents who reported receiving health services through telehealth in the previous year.

Conclusions: Regardless of the residential status, older cancer survivors report high internet and technology use for health-related activities. These results show promise for the feasibility of using digital technologies to implement supportive care and wellness programming with older cancer survivors.

KEYWORDS

cancer; non-metropolitan; disparities; digital divide; health research; aging; rural-urban; digital health technology; cross-sectional; health behaviors; mobile phone

Introduction

Improvement in cancer treatments and increasing life expectancy have led to a greater proportion of older, long-term survivors of cancer. As of 2022, 67% of cancer survivors in the United States were above the age of 65 years [1]. Though there are over 12 million older cancer survivors in the United States, their perspectives regarding survivorship and long-term care needs are not well described [1-4]. There are noted cancer care disparities among rural populations where the population tends to be older and to face a higher incidence and mortality rate from cancer than younger survivors. This is likely driven by barriers to accessing state-of-the-art cancer prevention, treatment, and survivorship services that support cancer-preventive behaviors [5-9].

Telehealth and other digital health tools offer an opportunity to bridge the gaps in care between rural and urban cancer survivors. Digital tools, such as the internet, electronic wearable devices, and social media, offer ways to disseminate health promotion materials and education remotely. Given the barriers that rural residents face in accessing in-person health behavior programming and resources, remote delivery with digital health tools is one strategy for delivering this information. In fact, a systematic review of lifestyle behavior change interventions for rural cancer survivors found that programming predominately relied on delivery using a hybrid or remote format by the use of digital technology, though the evidence of effectiveness was limited [10]. Remotely delivered programming to support psychosocial well-being and lifestyle behavior change has been shown to be effective for survivorship more generally, but the evidence of acceptability and usability for survivors living in rural areas is lacking [10]. While digital literacy and access disparities have long existed between rural and urban communities, commonly known as the digital divide [11-13], the COVID-19 pandemic has provided a push to address some of these barriers and has led to greater adoption of telehealth and other digital health tools [14-16]. For example, during the pandemic, providers pushed for the use of telehealth visits to complete routine check-ups with patients, especially immunocompromised cancer patients undergoing treatment. By providing information and instructions on how to complete telehealth visits remotely, many patients became familiar with how to access digital technology. Whether additional modifications in telemedicine and digital health delivery are needed to meet the supportive care needs of older survivors is not known. To address this gap in the literature, additional work is needed to understand the access and use of digital technology in this population.

Digital health technology is a promising tool to support lifestyle behavior change programming, but the acceptability and usability of digital technology for rural cancer survivor populations, particularly older survivors, has not been fully explored. This study aimed to use a robust survey-based dataset to (1) describe the use of digital technology among cancer survivors, (2) assess the use of telehealth and other digital technology to support health, and (3) examine the association between rurality and digital health tool use and access among older (>60 y) cancer survivors who responded to this nationally representative survey in 2022.

Methods

Study Design and Population

This cross-sectional analysis was derived from the National Cancer Institute (NCI) Health Information National Trends Survey (HINTS), a nationally representative sample of the adult, noninstitutionalized population in the United States. NCI has been collecting HINTS data every few years since 2003 to evaluate trends in health information access and attitudes toward digital health technology [17,18]. Detailed information about the methodology and publicly available deidentified datasets can be found on the NCI HINTS website [19]. This analysis was deemed exempt by the University of Arizona Institutional Review Board.

This analysis uses data from HINTS 6, which was collected between March and November 2022. As this was the first full HINTS survey completed after the beginning of the COVID-19 pandemic wherein telehealth use increased appreciably [15,20], this iteration was selected to best reflect the current prevalence of digital technology use. HINTS 6 is also the first to include stratification for residential status in the sampling strategy to ensure better representation of rural participants [21]. Out of the 6252 total respondents (response rate 28.1%), those without a history of cancer (n=4982), those under the age of 60 years (n=174), or those with missing data for cancer diagnosis or age (n=119) were excluded from analyses. Cancer diagnosis was determined with a self-report question asking if the respondent had ever been diagnosed with cancer. A cutoff of 60 years of age was used to define an “older cancer survivor” to maximize the analysis sample size and realizing that cancer survivors experience accelerated aging, meaning a 60-year-old cancer survivor may be more like a 65-year-old noncancer survivor. The final analytical sample included 710 cancer survivors 60 years of age or older. Most participants completed HINTS 6 using a mailed paper copy of the survey (435/710, 61.3%) compared with a web-based version of the survey (275/710, 38.7%).

Ethical Considerations

The HINTS 6 general population survey was designated “exempt research” and approved by the Westat Institutional Review Board (IRB) (Project # 6632.03.51). HINTS 6 was designated as “Not Human Subjects Research” from the National Institutes of Health Office of IRB Operations (iRIS reference number: 562715).

Outcome Variables

The primary measures of interest pertained to (1) internet access and use for health-related activities, (2) digital device ownership and use as a tool for health behaviors, (3) use of social media for health, and (4) use of telehealth.

Internet

Internet use was assessed with the question, “Do you ever go on-line to access the internet or World Wide Web, or to send and receive email?” Respondents who indicated “yes” were

then provided a follow-up question asking how they have used the internet for health-related needs in the previous 12 months with 4 statements to consider: "Look for health or medical information," "Send a message to a health care provider or a health care provider's office," "View medical test results," and "Make an appointment with a health care provider." Respondents answered each statement with a "yes" or "no" response. Those who reported using the internet were also asked about their level of satisfaction with their home internet connection using a 5-point scale ranging from "extremely satisfied" to "not at all satisfied."

Digital Devices

Survey respondents were asked if they own any of the following digital devices: tablet computer (eg, Apple iPad, Samsung Galaxy, or Kindle Fire), a smartphone (eg, Apple iPhone, Blackberry, or Android), or a basic mobile phone. These responses were then categorized to describe participants who owned these devices, those who owned multiple devices, and those who owned no digital devices. Those who indicated they own a tablet or smart phone were asked, "In the past 12 months, have you used a health or wellness app on your tablet or smartphone?" Ownership and use of wearable devices (eg, Fitbit, Apple Watch, or Garmin Vivofit) was assessed with the question, "In the past 12 months, have you used an electronic wearable device to monitor or track your health or activity?" To assess how respondents have used digital devices to support their health, participants were asked if they had shared any health information from either their wearable device or smartphone with a health professional in the previous year.

Social Media

Social media use was assessed with the question, "In the past 12 months, how often did you do the following?" The 5 statements included: "Visited a social media site," "Shared personal health information on social media," "Shared general health information on social media," "Interacted with people who have similar health or medical issues on social media or online forums," and "Watched a health-related video on a social media site (eg, YouTube)." The response options for each included 5 categorical frequency of use options ranging from "Never" to "Almost every day." These response types were dichotomized to capture if the respondent had used social media for the purpose at all in the last 12 months or not at all.

Telehealth

Telehealth use was assessed with the question, "In the past 12 months, did you receive care from a doctor or health professional using telehealth?" Those who indicated they had not used telehealth were then asked if telehealth had been offered by their provider if they had tried to schedule medical care. Those who did choose to use telehealth in the previous year were prompted with a set of statements and asked to indicate if they agreed that the statement reflected a reason they participated in a telehealth visit.

Exposure Variables

The exposure of interest for this analysis was residential status. This variable was dichotomized into rural and urban residency using the 2013 Rural-Urban Continuum (RUC) Codes set by the US Department of Agriculture Economic Research Service [22]. This code includes 9-values and is derived along a continuum based on population size and adjacency to a metropolitan area. Based on previous analyses, urban residencies were defined as RUC codes 1 - 3, while rural residencies were defined as RUC codes of 4 - 9 [11,23,24].

Sample Characteristics

The sociodemographic characteristics included in this analysis were age, sex, race and ethnicity, occupational status, annual household income, household size, marital status, education, and census region. To ensure adequate cell sample size for analysis, the race and ethnicity variable was condensed into non-Hispanic White, non-Hispanic Black or African American, Hispanic, and non-Hispanic other. Occupational status was organized into 4 categories including employed, retired, disabled, and other (ie, unemployed, homemaker, and student). Related to cancer history, the age of diagnosis, years since diagnosis, and cancer type were included in the summary of the sample.

Statistical Analysis

This is a cross-sectional analysis of the use of digital health tools and telehealth in older cancer survivors who completed the HINTS 6 survey collected in 2022. Provided survey weights were applied using the Jackknife repeated replication method for population level estimates.

Sociodemographic characteristics, health behaviors, and cancer history were stratified by residential status (rural vs urban) and differences were assessed using Wald design-based chi-square tests of independence or *t* tests. Rurality and associations with using digital health tools and telehealth were individually assessed using both unadjusted and adjusted multiple logistic regression models. Models were adjusted for age, race and ethnicity, annual household income, and education. Sex and marital status were not found to be confounders or effect modifiers and were thus not included in the adjusted model. An α level of .05 was considered statistically significant. A post hoc sensitivity analysis was conducted excluding respondents who reported diagnosis with nonmelanoma skin cancer as this is a population of people with a cancer diagnosis that experience very different treatment and survival outcomes from the general survivor population. All analyses were completed using STATA 17 (StataCorp LLC).

Results

Demographics

Out of the 710 older cancer survivors included in this analysis, 17% (n=125) were living in rural areas (see Table 1 for detailed sample characteristics). The average age of the respondents was 73 (SD 8.2) years. While most demographic characteristics did not differ between rural and urban survivors, rural cancer survivors were more likely to identify as non-Hispanic White (93% [n=95] vs 84% [n=415]; *P*=.007) and reported a lower annual household income (*P*=.01). When considering the US census region, a greater percentage of Midwest participants were living in rural areas compared to urban areas (37.3% vs 14.4%), while a lower percentage of participants in the West

and Northeast regions were living in rural areas compared to urban areas (*P*<.001). Most respondents were retired (n=497, 71.7%) and married or living with a romantic partner (n=356, 64.7%). Though there were no differences in age at diagnosis or years since diagnosis between groups, nonmelanoma skin cancer was the most prevalent cancer type (n=149, 31.2%); rural participants reported greater prevalence of breast and gynecological cancer than urban residents (*P*=.03). There were no differences in the survey form version completed between rural and urban residents, with 59.9% (n=350) of urban respondents and 68% (n=85) of rural respondents using a paper version of the survey (*P*=.09).

Table . Sociodemographic characteristics of cancer survivors participating in Health Information National Trends Survey 6 (HINTS 6) by residential status. Missing data <10%.

Characteristics	Total	Rural	Urban	*P* value

There were no differences in internet use or mode of access, digital device ownership, or social media use in the previous 12 months between older rural and urban survivors (Table 2). Overall, most older survivors were using the internet (n=553, 79.9%) and predominately used a high-speed service to connect (n=486, 89.8%). Though they shared the same prevalence of internet use, rural cancer survivors were more likely to report a lack of satisfaction with their internet connection than urban survivors (8.7%, n=7, rural vs 0.4%, n=3, urban; *P*<.001). Regardless of residential status, older survivors reported high rate of smartphone ownership (n=544, 78.5%) and only 5% (n=31) reported not owning any digital devices. About half of older survivors owned more than 1 digital device (n=345, 51.7%).

Table . Weighted prevalence of internet use, digital device ownership, and social media access in the past 12 months by residential status.

	Total, %	Rural, %	Urban, %	*P* value
Used the internet at all	79.9	78.1	80.1	.67
Mode of accessing the internet [a]				
Dial-up or telephone line	1.9	2	1.9	.95
High-speed service	89.8	84.7	90.8	.29
Cellular network	69.5	74.1	68.5	.45
Internet connection satisfaction				.006

Internet

In both unadjusted and adjusted logistic regression models, the use of the internet to support health did not differ between older rural and older urban cancer survivors. Regardless of residential status, most respondents who used the internet within the past 12 months indicated that they have used the internet to look for health information (n=463, 86.5%), they have sent a message

to their health care provider (n=362, 67.5%), and they have viewed their medical test results (n=405, 78.9%; Table 3).

Table . Association of rural versus urban residence and use of digital health tools in the previous 12 months.

Digital health tools	Weighted percent, %		Unadjusted OR (95% CI)	*P* value	Adjusted OR[a] (95% CI)	*P* value
	Rural	Urban				
Internet						
Used the internet to look for health or medical information	78.7	88.1	0.50 (0.22-1.11)	.09	0.73 (0.33-1.62)	.44
Used the internet to send a message to a health care provider or health care providers office	63.6	68.4	0.81 (0.40-1.61)	.54	0.80 (0.33-1.95)	.62
Used the internet to view medical test results	69.5	80.8	0.54 (0.26-1.11)	.1	0.63 (0.28-1.44)	.27
Used the internet to make an appointment with a health care provider	42.7	58.4	0.53 (0.27-1.07)	.07	0.52 (0.22-1.21)	.13
Digital devices						
Used a health or wellness app on a tablet or smartphone	36.9	51.3	0.56 (0.32-0.97)	.04	0.85 (0.47-1.53)	.58
Used an electronic wearable device to monitor or track health or activity	19.8	28	0.64 (0.33-.21)	.17	0.81 (0.38-1.73)	.58
Shared health information from an electronic monitoring device or smartphone with a health professional	21.8	24.4	0.87 (0.46-.63)	.65	1.25 (0.56-2.78)	.58
Social media						
Shared personal health information on social media	19	10.9	1.92 (0.82-4.51)	.13	2.64 (1.13- 6.19)	.03
Shared general health-related information on social media (ie, news article)	21.9	26.3	0.79 (0.35-1.79)	.56	0.55 (0.24-1.23)	.14
Interacted with people with similar health or medical issues on social media or online forums	19.7	16.5	1.24 (0.50-3.07)	.63	1.08 (0.46-2.58)	.85
Watched a health-related video on a social media site	40.2	42.3	0.91 (0.48-1.72)	.78	0.76 (0.37-1.55)	.44

[a]Logistic regression models were adjusted for age, race and ethnicity, annual household income, and level of education.

Digital Devices

Compared with urban survivors, rural respondents who owned a smartphone or tablet were less likely to report that they had used a health or wellness application in the previous year (36.9%, n=36, rural vs 51.3%, n=234, urban; unadjusted OR 0.56, 95% CI 0.32-0.97; *P*=.04). This difference was no longer significant in adjusted logistic regression models when age, annual household income, education, and race and ethnicity were considered (adjusted OR 0.85, 95% CI 0.47-1.53; *P*=.58). There were no differences in the use of wearable devices to track activity or to share health information with a health care provider. Overall, 26.5% (n=165) of older survivors reported using a wearable device to track their health or activity. While only 23.9% (n=166) of older survivors indicated they have shared data from a smartphone or wearable device with a health professional in the previous year, 81.3% (n=135) indicated that they would be willing to do so in the future.

Social Media

Two-thirds of older adults (n=448, 66.6%) visited a social media site in the previous year. Though social media use was similar for both urban and rural survivors, older cancer survivors living in rural areas were twice as likely to report that they had shared personal health information on social media in the previous year (adjusted OR 2.64, 95% CI 1.13-6.19; *P*=.03). Less than 20% (n=115) of older cancer survivors reported having used social media or a chat forum to interact with people who have similar health issues and 25.5% (n=173) indicated that they had shared general health information on social media in the previous year.

Telehealth

There were no differences in the proportion of rural and urban respondents who indicated they had received care from their health care provider using telehealth in the previous 12 months (Table 4). Rural and urban cancer survivors were equally likely to have been offered the option to have a telehealth visit by their providers. For respondents who indicated they received care using telehealth, the primary reason for choosing to participate in a telehealth visit was provider recommendation or requirement (n=215, 81.1%). A total of 54% (n=136) of older cancer survivors indicated that they chose to participate in telehealth because it was more convenient than going to a health care office. Compared with older urban survivors, rural survivors were less likely to indicate that one of their reasons for choosing telehealth was to seek advice about whether in-person care was needed (adjusted OR 0.21, 95% CI 0.05-0.94; *P*=.04).

Table . Association of rural versus urban residence with use and reasons for use of telehealth in the previous 12 months.

Statement	Weighted percent (%)		Unadjusted OR (95% CI)	*P* value	Adjusted OR[a] (95% CI)	*P* value
	Rural	Urban				
Received care from a doctor or health professional using telehealth	33.5	42.6	0.68 (0.40-1.15)	.15	0.79 (0.41-1.54)	.49
Offered the option to have a telehealth visit for any medical care	40.6	48.2	0.74 (0.36-1.49)	.39	0.87 (0.41-1.86)	.71
Reported technical problems with the telehealth visits	37.1	26.3	1.65 (0.64-4.24)	.29	1.80 (0.52-6.23)	.35
Reasons for choosing to participate in telehealth						
Health care provider recommended or required the visit use telehealth	74.6	82.1	0.64 (0.18-2.32)	.49	0.86 (0.12-6.07)	.87
Wanted advice about whether in-person medical care was needed	10.8	26.4	0.34 (0.12-1.00)	.05	0.21 (0.05-0.94)	.04
Wanted to avoid possible infection at the doctor's office or hospital	30.4	48.9	0.46 (0.19-1.10)	.08	0.43 (0.13-1.46)	.17
More convenient than going to the doctor	59.9	53.4	1.31 (0.52-3.29)	.56	1.94 (0.63-5.94)	.24
Could include family or other caregivers in the appointment	19.1	23.2	0.78 (0.31-1.98)	.59	0.44 (0.10-1.90)	.26

[a]Logistic regression models were adjusted for age, race and ethnicity, annual household income, and level of education.

Sensitivity Analysis

Exclusion of the 149 respondents diagnosed with nonmelanoma skin cancer did not materially change the study results (see Table S1 and S2 in Multimedia Appendix 1 and Multimedia Appendix 2, respectively). In general, no associations were identified between residential status and digital tool use in this smaller sample. There were significant differences in digital device ownership, with rural survivors being less likely to own a tablet computer (37.9%, n=37 vs 56.7%, n=265; *P*=.02) and to own multiple digital devices (28.7%, n=28 vs 51.5%, n=233; *P*=.003; Table S1 in Multimedia Appendix 1).

Discussion

Principal Findings

This study is among the first to examine the use of technology among older cancer survivors with a specific focus on the use of technology that became more common overall after the start of the COVID-19 pandemic. While findings from iterations of HINTS completed before the start of the pandemic indicated that rural survivors were less likely to access the internet than urban survivors [25-27], digital health tool access and use were similar between groups in this post–COVID-19 analysis. Regardless of residential status, older survivors of cancer reported a high prevalence of internet use (n=553, 79.9%), digital device ownership (n=676, 94.9%), and social media use (n=448, 66.6%). These post–COVID-19 pandemic prevalence results are similar to those found in an analysis of older cancer survivors who responded to the National Health and Aging Trends Study. In that analysis, a rise in digital health technology use was seen after the pandemic (52% in 2021), compared with before (45% in 2019), though they did not compare rural and urban populations [28]. As this is the first analysis to compare digital technology use between rural and urban older survivors after the pandemic, our results indicate that the pandemic may have enhanced uptake of digital technology across residential areas, potentially reducing the digital divide between rural and urban survivors.

Comparison With Previous Work

One of the differences noted between groups in this sample was that rural survivors, as compared with urban survivors, were

more likely to report that they had shared personal health information on social media in the previous year. There are several hypotheses for why this difference may arise. First, rural survivors experience greater barriers to accessing in-person social support, such as travel distance and access to transportation [5,29,30], which may leave phone or computer-based support as the more feasible option. Second, rural survivors tend to experience greater symptoms of anxiety and depression and poorer health-related quality of life than urban survivors, yet have limited access to mental health professionals [5,8,31,32]. Sharing on social media may be an avenue to garner support, elicit shared experience, or share positive outcomes. There is limited information available on rural cancer survivorship and social media use. As follow-up information was not collected in the HINTS survey about what type of personal health information was shared or who it was shared with, future research should explore how rural survivors use social media and how it is used as a tool for social support or information gathering.

The access and usability results from this study show promise for remote treatment and care for older cancer survivors, particularly those living in rural areas. However, adoption of wearable devices was modest (n=165, 26.5%) and there remains a lack of evidence exploring the barriers to digital technology adoption for those who do not access these tools [33,34]. Wearable devices are one tool to promote self-monitoring of healthy lifestyle behaviors that may be especially beneficial for rural survivors who have do not have access to in-person health coaching. With only 1 in 4 older cancer survivors using a wearable device, additional work is justified to explore the acceptability of wearable devices and to classify the barriers to use. In addition, while these results show promise for increasing acceptability and usability of telemedicine for health care, there is still a question of whether remote delivery of survivorship care and lifestyle behavior change programming is acceptable, feasible, and efficacious for older, rural cancer survivors [10,35]. A recently completed pilot trial examined this question using implementation of a remotely delivered, evidence-based group exercise program for older cancer survivors living in rural areas. This trial, the tele-EnhanceFitness program, incorporated remotely monitored Zoom (Zoom Video Communications) fitness classes 3 days a week for 16 weeks and found low attrition (5%) and high class attendance rate (87%) [36]. Additional research has identified that rural survivors are interested in the incorporation of remote lifestyle programs to their care, but additional study is needed to assess the efficacy of remote programming and barriers to implementation [10,35,37,38].

Strengths and Limitations

A strength of this study is the use of the HINTS dataset. HINTS is a nationally representative survey, which includes rigorous probability sampling of the US population. The HINTS 6 sampling strategy also introduced stratification for residential status to ensure better representation of rural participants [21]. In addition, the jackknife weighting strategy used for HINTS data analysis allows for population-level comparisons and estimates. Participants used a paper copy to complete the HINTS 6 survey regardless of rural-urban status, limiting potential bias that may have arisen from digital collection of the survey. As with all cross-sectional studies, a limitation of this analysis is the inability to determine cause and effect relationship. The sample size included for analysis was small given the exclusion of any respondents without a cancer history and relied on self-report, which may be affected by recall or response bias. It also lacked diversity reflecting the larger population of cancer survivors, limiting the ability to stratify analysis by race and ethnicity. To maximize sample size and to report results for the overall survivor population, cancer survivors of nonmelanoma skin cancer were included in analysis. This may have introduced confounding by favorable diagnosis, as survivors of nonmelanoma skin cancer generally do not receive chemotherapy or radiation. Another limitation is that the questions regarding digital health technology were general with limited follow-up about satisfaction with the technology or desire for future use. Finally, all data were self-reported, although bias related to reporting of social media use has not been previously reported.

Future Directions

While digital technology use was found to be similar between older urban and rural survivors, additional research is needed to explore the barriers and facilitators to digital technology adoption for this population and the acceptability of using digital tools for remote intervention delivery. Quantitative work is warranted to examine patterns of digital technology use over time to determine any trends that have emerged since the COVID-19 pandemic. Future work should aim to expand the generalizability by recruiting a diverse sample that better reflects the overall population of cancer survivors living in rural areas.

Conclusion

These findings provide valuable insight into the acceptability and usability of digital health technology for older cancer survivors. Regardless of rural-urban status, digital health technology use was found to be high among cancer survivors. This is the first analysis of digital health technology use among rural and urban residents after the start of the pandemic, indicating the digital divide may be narrowing as use and access to technology changes over time. For cancer survivors, these results indicate digital technology is a feasible method for delivering health information. Implementation of digital technology-based survivorship and lifestyle programming shows promise as a feasible solution to overcome barriers to high-quality cancer care for older and rural-dwelling survivors, yet additional work in this area is needed.

Abstract

Background: Patients with melanoma receiving immunotherapy with immune-checkpoint inhibitors often experience immune-related adverse events, cancer-related fatigue, and emotional distress, affecting health-related quality of life (HRQoL) and clinical outcome to immunotherapy. eHealth tools can aid patients with cancer in addressing issues, such as adverse events and psychosocial well-being, from various perspectives.

Objective: This study aimed to explore the effect of the Cancer Patients Better Life Experience (CAPABLE) system, accessed through a mobile app, on HRQoL compared with a matched historical control group receiving standard care. CAPABLE is an extensively tested eHealth app, including educational material, remote symptom monitoring, and well-being interventions.

Methods: This prospective pilot study compared an exploratory cohort that received the CAPABLE smartphone app and a multisensory smartwatch for 6 months (intervention) to a 2:1 individually matched historical prospective control group. HRQoL data were measured with the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire-Core

30 at baseline (T0), 3 months (T1), and 6 months (T2) after start of treatment. Mixed effects linear regression models were used to compare HRQoL between the 2 groups over time.

Results: From the 59 eligible patients for the CAPABLE intervention, 31 (53%) signed informed consent to participate. Baseline HRQoL was on average 10 points higher in the intervention group compared with controls, although equally matched on baseline and clinical characteristics. When correcting for sex, age, disease stage, and baseline scores, an adjusted difference in fatigue of −5.09 (95% CI −15.20 to 5.02, *P*=.32) at month 3 was found. No significant nor clinically relevant adjusted differences on other HRQoL domains over time were found. However, information satisfaction was significantly higher in the CAPABLE group (β=8.71, 95% CI 1.54 - 15.88, *P*=.02).

Conclusions: The intervention showed a limited effect on HRQoL, although there was a small improvement in fatigue at 3 months, as well as information satisfaction. When aiming at personalized patient and survivorship care, further optimization and prospective investigation of eHealth tools is warranted.

Introduction

Immunotherapy with immune-checkpoint inhibitors (ICIs) and targeted therapies with BRAF/MEK inhibitors have significantly improved clinical outcomes for patients with melanoma and have become standard treatment for patients with high-risk and advanced disease [1-6]. Nevertheless, these novel systemic treatments are associated with short- and long-term (immune-related) adverse events (AEs) [7-10]. Furthermore, these AEs have shown to affect physical and psychosocial well-being of patients with melanoma [10-13]. Most prevalent in patients with melanoma undergoing immunotherapy with ICIs are cancer-related fatigue (CRF) and emotional distress, affecting both health-related quality of life (HRQoL) and clinical outcome to immunotherapy [8,14-16]. Efforts to address CRF include exercise recommendation, psychosocial support, mindfulness-based interventions, and yoga, showing positive effects on fatigue, emotional distress, and HRQoL [14,15,17-23].

Insufficient monitoring and reporting of AEs can exacerbate side effects, possibly leading to more frequent hospital visits and admissions [24-26]. Electronic symptom monitoring has shown to be associated with improved clinical outcomes such as survival and HRQoL in patients with cancer undergoing chemotherapy [27-30]. One way to improve patient care in immunotherapy could therefore involve regularly gathering patient-reported outcomes (PROs), such as symptom information, using patient-reported outcome measures (PROMs) through eHealth tools [31-34]. Furthermore, using biometric sensors could potentially detect symptoms and track physical activity in outpatient oncology settings [35,36]. To date, evidence of the effect of eHealth tools monitoring patients with melanoma on treatment with ICIs is scarce. One study showed that an electronic PROMs tool could not reduce the number of severe AEs, although it did increase HRQoL [34,37].

Health apps have also the potential to fulfill patients' requirements for information and support, especially concerning symptom control and supportive services [38,39]. Furthermore, web-based programs and eHealth apps have incorporated nonpharmacological well-being interventions, such as promoting physical exercise, providing psychoeducation, mindfulness-based interventions, and yoga, to address CRF, showing encouraging outcomes [40,41]. By providing a combination of remote symptom monitoring, nonpharmacological well-being interventions, and information provision through an eHealth tool, patients believe this will positively affect their HRQoL and symptom burden [39].

Based on these insights, we previously developed a Cancer Patients Better Life Experience (CAPABLE) mobile app. CAPABLE is an extensively tested eHealth app as part of the EU Horizon 2020 program, designed to offer educational material, supportive care, remote symptom monitoring, and well-being interventions [42], initially for patients during and after ICIs, but open to treatment changes to targeted therapies. Development involved a user (patient)-centered design process in order to improve system usability and user acceptance [43]. The aim of this study was to explore the effect of CAPABLE on patient-reported outcomes, specifically fatigue and other HRQoL domains, compared with a matched historical control group receiving standard care [44].

Methods

Setting

The CAPABLE study was a prospective, exploratory, pilot study in which a cohort that received the CAPABLE smartphone app and a multisensory smartwatch (intervention) was compared with a historical prospective cohort that did not receive the CAPABLE app and smartwatch (control group). CAPABLE was registered as a medical device trial according to the Medical Device Regulation, article 62. A detailed description of the design of the pilot study and the design and development of the CAPABLE app was published previously [44]. Development and content was frozen during the trial. The CAPABLE app

was used in its final operational state for the first time in a trial setting during this study, although preliminary prototype testing was done during system development. Briefly, participants included in the study were provided with the CAPABLE mobile app and a multisensorial smartwatch (ASUS VivoWatch 5 HC-B0) during the first 6 months of treatment with ICIs. The mobile app consisted of 3 main components; first, facilitating symptom and mental well-being monitoring, second, providing educational material, and finally, providing well-being interventions through goal setting and demonstrating the well-being intervention activity through a video or text and figures. The symptom monitoring functionality was used "as needed." When a patient experienced a symptom, they were able to enter this into the CAPABLE app, upon which the decision support system managed the symptom [44]. No regular or static symptom monitoring was prompted by the app; however, the health care professional (HCP) monitored the symptom input coming from the patients on a daily basis and the information was included and discussed in clinical encounters. The well-being interventions could be executed from the home environment, and include a 30-minute walk, deep breathing practice, imagery training, physical activity of stretching, and strengthening exercises, Hatha Yoga or Nidra Yoga videos, or Tai Chi practice videos. The smartwatch collected data on heart rate, sleep (stages, hours, and performance), and physical activity, although data from the smartwatch were treated as ancillary data and not used for real-time symptom monitoring, decision support, or diagnosis. Over the course of the pilot study, participants were asked to complete PROMs at 3 time points. Results of the intervention (CAPABLE) group were compared with participants of 2 previously collected control groups (patient-reported outcomes in high risk and advanced melanoma patients cohort [PRO-MEL]; NL75996.031.20 and PROMs collected in clinical practice), which were 2 similar prospectively collected cohorts with the same inclusion criteria, but treated following standard of care and following the same follow-up schedule. PROMs in clinical practice were collected starting August 2024 and is still ongoing at the time of study. In addition, the PRO-MEL cohort was a prospective cohort that started inclusion in May 2021 and collected additional PROMs, as also collected in the CAPABLE cohort.

Ethical Considerations

The Medical Ethical Committee NedMec (Amsterdam, the Netherlands) granted ethical approval (reference 22 - 981/NL81970.000.22). The trial was prospectively registered at ClinicalTrials.gov (NCT05827289). Ethical approval also included the (secondary) use of data collected in the PRO-MEL and PROMs in clinical practice cohorts. Privacy and confidentiality protection was covered in the Medical Ethical Committee approval by a large data protection impact assessment. The study has not been amended during the course of the trial. Compensation to participants was not provided, except for the temporarily use of the smartphone and smartwatch used in the study.

Recruitment

During a 6-month inclusion period, from April to October 2023, participants were recruited through their treating HCP and the CAPABLE research team recruited in an oncology-specialized center in Amsterdam, the Netherlands. The target sample for feasibility end points of this pilot was to include 36 patients, corresponding to 60 eligible patients and a 60% inclusion and compliance rate in the inclusion period [44]. Eligible participants had histologically confirmed stage III or IV melanoma and planned to start treatment with ICIs (anti–programmed-death 1 with or without anti–cytotoxic T-lymphocyte associated protein 4) according to standard clinical practice. Furthermore, participants had to be >18 years of age, had a sufficient understanding of the Dutch language, and were able to use a smartphone.

Data Collection

Included patients were asked to use the CAPABLE app and smartwatch for a minimum period of 3 months and a maximum period of 6 months after start of treatment with ICIs. CAPABLE installation on mobile phones and baseline measurements took place after signing informed consent and before or during first ICI infusion. Research data were collected at baseline (T0), 3 months (T1), and 6 months (T2) after start of treatment by providing the participants a set of questionnaires. Clinical data (eg, staging, treatment details, and demographics) were extracted from the medical record during the study. PROMs data were stored and managed in ALEA (FormVision) [45]. Data generated through the CAPABLE app were stored on an internal secured drive.

To investigate the primary end point of this study, fatigue, the European Organization for Research and Treatment of Cancer (EORTC) Quality of Life Questionnaire-Core 30 (QLQ-C30) was used [46], a questionnaire developed to assess the quality of life of patients with cancer. Responses to this questionnaire range from 1 (not at all) to 4 (very much) and are linearly transformed into a functioning or symptom scale ranging from 0 to 100, with higher scores representing more experienced symptoms or a higher functioning, respectively. Primarily, the changes in fatigue over time in the intervention cohort were compared with the changes in fatigue over time in the control cohort. The validated fatigue scale of the QLQ-C30 is constructed out of 3 questions in the QLQ-C30 questionnaire, "Did you need to rest?", "Have you felt weak?", and "Were you tired?". To explore secondary outcomes of this study, other domains of the EORTC QLQ-C30 were investigated (functioning and other symptom scales), as well as changes between the CAPABLE and (matched) control group when looking at the EuroQol 5D (EQ-5D-5L) [47], Functional Assessment of Cancer Therapy-Melanoma (FACT-M) [48], and EORTC Quality of Life Questionnaire-Information 25 (QLQ-INFO25) [49].

Feasibility outcomes were investigated throughout the course of this pilot study by exploring the inclusion and compliance rate of the CAPABLE app users. Recruitment rate was calculated as the percentage of patients included in the study out of the patients screened for eligibility. Patient compliance was calculated as the percentage of patients completing the

questionnaires per follow-up moment. Finally, patient retention was calculated as the percentage of patients adhering to the CAPABLE mobile app for 6 months (ie, ≥1 interaction with any of the functionalities within the follow-up period). Patient engagement with the app was presented by descriptive data on the use of the symptom reporting and well-being intervention functionalities. Extensive data collection methods and corresponding figures and tables are described in the previously published study protocol [44].

Data Analysis

Patients that completed at least 1 PROM over the course of the study were included in the final analysis. Because of low inclusion in the (control cohort) PRO-MEL study, matching was done on a control group composed of patients from both the PRO-MEL and PROMs in clinical practice cohort who filled in the EORTC QLQ-C30, FACT-M, and EQ-5D-5L according to the same follow-up schedule. Patients in the CAPABLE cohort were individually matched 1:2 with patients in the control cohorts based on sex, age, and tumor staging. To compare information needs (QLQ-INFO25) between the CAPABLE cohort and controls, no matching was performed, and comparison consisted of the entire PRO-MEL cohort to increase statistical power and be able to interpret results.

Descriptive statistics were calculated to provide information about the patient population, feasibility, and engagement with the CAPABLE app. For the purpose of this study, mean scores for fatigue and other QLQ-C30 domains were calculated and presented according to current guidelines [50]. To compare the mean fatigue scores and other HRQoL outcomes between the group receiving the CAPABLE intervention and the control group at each individual time point, independent sample *t* tests were used. To analyze the differences in all outcomes on different time points between the CAPABLE cohort and matched controls over time, linear mixed effects models were used. Statistical models were adjusted for age, sex, tumor stage, time, and baseline scores (with an interaction term between time and cohort). A 2-tailed *P* value<.05 was considered statistically significant, although *P* values in this pilot setting were not powered to provide much information due to the small sample size. Therefore, this study mostly focused on clinically relevant differences according to Cocks et al [51]. Similar methods were used for analyzing the EQ-5D-5L, FACT-M, and QLQ-INFO25.

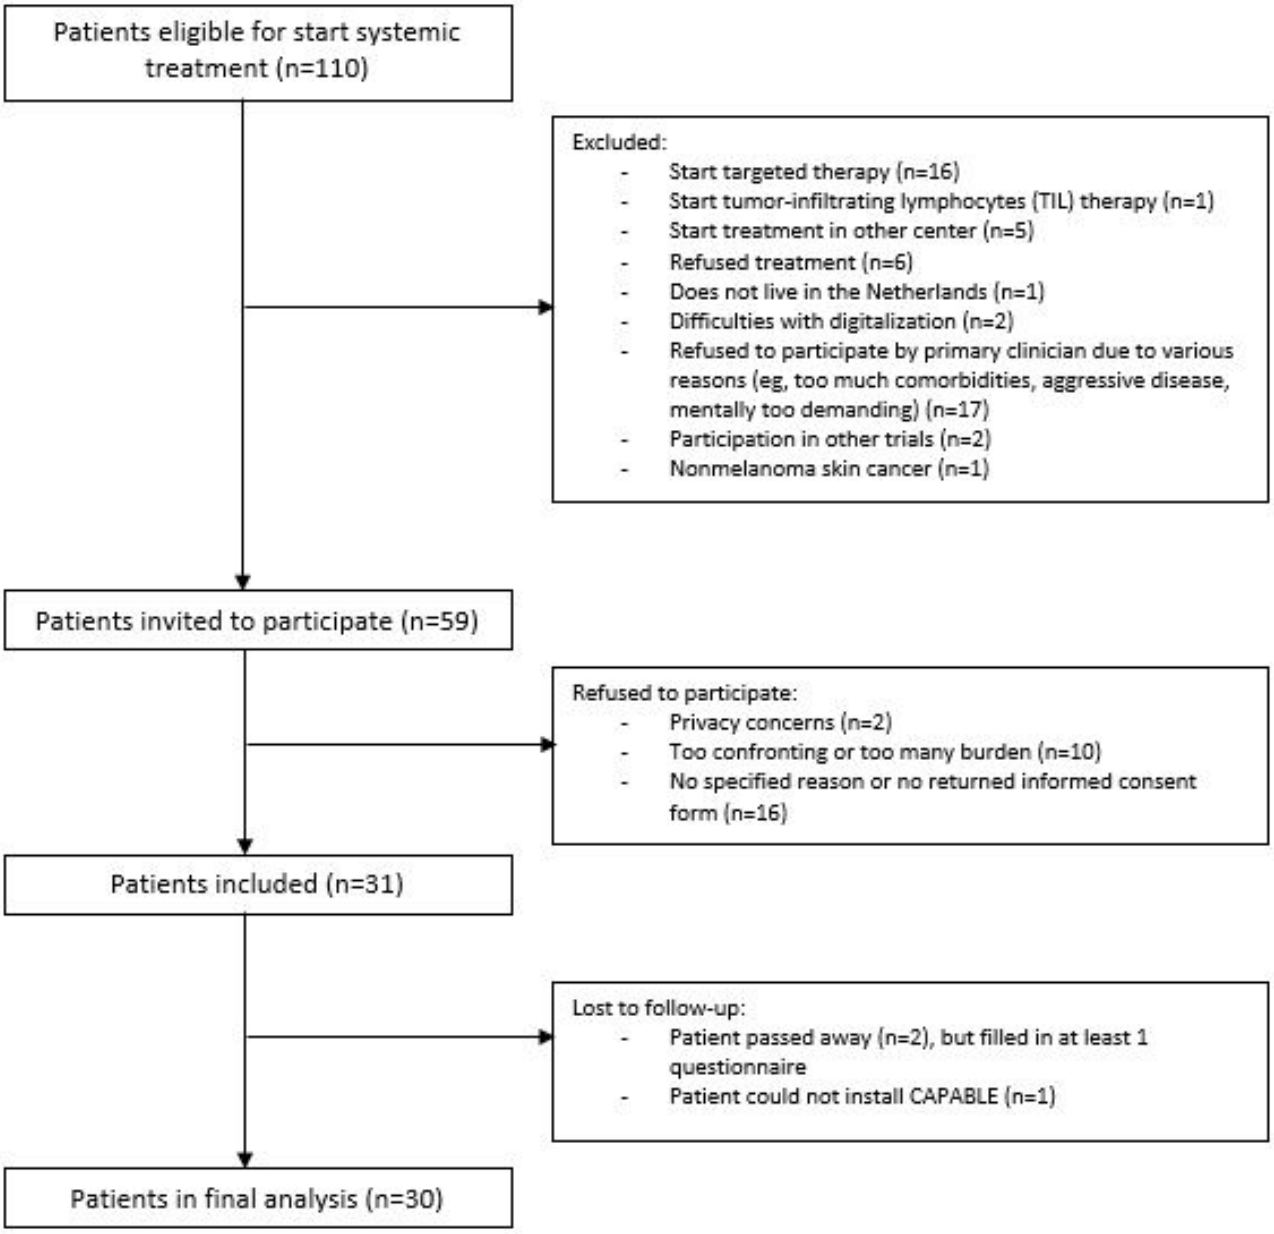
Missing items from the questionnaires were imputed according to corresponding EORTC guidelines [50]. The scale scores of the EORTC QLQ-C30 were set to missing if fewer than half of the items on a given scale were answered. Where at least 50% of the relevant scale scores were present, the missing values were replaced by the mean of the present values. We applied the same strategy to the other questionnaires as no other guidelines are available for those. Statistical analyses and matching procedures were done using Stata version 15 (StataCorp) [52].

Results

Overview

In total, 110 patients were screened for eligibility for the CAPABLE trial in the 6-month inclusion period (Figure 1). Main reasons for noneligibility were the start of targeted therapy instead of ICIs (n=16) or the patient not being invited for inclusion by the treating physician's decision (eg, aggressive disease, comorbidities, symptomatic brain metastasis, low health literacy, and mentally too demanding; n=17). Eventually, 59 out of 110 (54%) patients were contacted to participate. Most of the contacted patients who did not return a consent form did not specify a reason (n=16). Reasons specified for not participating in the pilot study included privacy concerns (n=2) and the expectation that the burden would be too high (n=10). Of the 31 included patients, 1 did not manage to install the CAPABLE app before T1. A total of 30 patients were taken into consideration for the statistical analysis, although 2 patients died due to progressive disease before reaching T2. In total, 297 patients (70 from the PRO-MEL cohort and 227 from the PROMs in clinical practice cohort) were eligible for individual matching. This yielded 56 patients that were matched 2:1 to the CAPABLE cohort. Thus, a group of 86 patients was included in the analysis of the EORTC QLQ-C30, FACT-M, and EQ-5D-5L. Since data on the EORTC QLQ-INFO25 were only available in the PRO-MEL cohort, the entire PRO-MEL cohort (n=70) was used in the comparison with the CAPABLE group (n=30) for these secondary end points.

Figure 1. Cancer Patients Better Life Experience (CAPABLE) study inclusion flowchart.



Both cohorts were equally balanced in terms of age, sex, and tumor stage, due to matching (Table 1). Median age of the CAPABLE cohort was 65 (IQR 55 - 72) years. Females represented 61% (19/31) of the included participants, and approximately half the participants had stage IV disease (17/31, 55%). Most patients received anti-PD1 monotherapy in the CAPABLE and matched control group (19/31, 61% and 37/56, 66%, respectively). In the matched control group, 21% (12/56) of patients received targeted therapy after therapy switch, compared with 7% (2/31) in the CAPABLE group, but this difference was not statistically significant (P=.07).

Table . Participants' clinical characteristics. Not all percentages add up to 100% as multiple patients received multiple treatments. Missing data were not taken into consideration when calculating the *P* values.

Characteristic		CAPABLE[a] cohort (n=31)	Control cohort (n=56)	*P* value[b]
Sex, n (%)				.96
	Male	12 (39)	22 (39)	
	Female	19 (61)	34 (61)	
Age (years), median (IQR)		65 (55-72)	64 (56-71)	.99
Tumor stage, n (%)				.96
	III	14 (45)	25 (45)	
	IV	17 (55)	31 (55)

[a]CAPABLE: Cancer Patients Better Life Experience

[b]*P* values are based on χ^2 tests for group variables and Mann-Whitney test for age.

[c]PD-1: programmed-death 1.

[d]CTLA-4: cytotoxic T-lymphocyte associated protein 4.

[e]ICI: immune-checkpoint inhibitor.

Fatigue

The trend in unadjusted fatigue over time was similar between the CAPABLE group and the matched controls although fatigue seems to increase less in the CAPABLE cohort (Figure S1 in Multimedia Appendix 1). A 5-point difference was shown in baseline fatigue. The CAPABLE group had lower fatigue score on baseline compared with the matched controls (mean 18.4, SD 21.7) compared with the matched controls (mean 23.4, SD 19.4; *P*=.28), increasing to a difference of 8.2 points at month 3 (mean 23.0, SD 25.2 vs mean 31.2, SD 24.1; *P*=.17) (Table S1 in Multimedia Appendix 1). When correcting for sex, age, stage, time, and baseline scores, an adjusted difference in fatigue of −5.09 (95% CI −15.20 to 5.02; *P*=.32) for the CAPABLE group at month 3 was observed (Table 2). Although this result was not statistically significant, this difference was considered a small, clinically relevant difference. At month 6, a nonsignificant and nonclinically relevant difference was shown between the 2 groups (β=−2.32, 95% CI −12.81 to 8.16; *P*=.66).

Table . Adjusted mixed effects linear regression analysis on fatigue as measured by the Quality of Life Questionnaire-Core 30 (QLQ-C30) between Cancer Patients Better Life Experience (CAPABLE) group and matched controls over time.

Fatigue		β (95% CI)	*P* value	Clinical relevance

[a]Not applicable.

Health-Related and Melanoma-Specific Quality of Life

A significant difference in baseline scores was observed between the 2 cohorts for most of the HRQoL domains measured by the EORTC QLQ-C30 (Table S1 in Multimedia Appendix 1). On all functioning scales except cognitive functioning, the CAPABLE group reported better function in terms of both statistical significance and clinical relevance, with mean baseline differences ranging from 8.5 in social functioning (*P*=.11) to 12.0 in role functioning (*P*=.07) (Table S1 in Multimedia Appendix 1). After adjusting for covariates in multivariable regression analysis, no statistically significant nor clinically relevant changes on any of the HRQoL domains were observed between the CAPABLE group and matched controls at either month 3 or month 6 follow-up (Table 3).

Table . Adjusted mixed effects linear regression analyses on different health-related quality of life (HRQoL) outcomes as measured by the European Organization for Research and Treatment of Cancer (EORTC) Quality of Life Questionnaire-Core 30 (QLQ-C30) between Cancer Patients Better Life Experience (CAPABLE) group and matched controls over time. Analyses are adjusted for age, sex, stage, and baseline scores.

HRQoL subscales		β (95% CI)[a]	*P* value	Clinical relevance
Physical functioning				
	CAPABLE × month 3	−4.45 (−11.93 to 3.03)	.24	Trivial
	CAPABLE × month 6	−6.31 (−14.09 to 1.47)	.11	Small
Role functioning				
	CAPABLE × month 3	0.55 (−11.88 to 12.99)	.93	Trivial
	CAPABLE × month 6	−3.82 (−16.74 to 9.10)	.56	Trivial
Emotional functioning				
	CAPABLE × month 3	−5.77 (−14.71 to 3.16)	.21	—[b]
	CAPABLE × month 6	−8.41 (−17.63 to 0.80)	.07	—
Social functioning				
	CAPABLE × month 3	−1.89 (−12.54 to 8.77)	.73	Trivial
	CAPABLE × month 6	1.09 (−9.95 to 12.13)	.85	Trivial
Cognitive functioning				
	CAPABLE × month 3	0.30 (−7.16 to 7.77)	.94	Trivial
	CAPABLE × month 6	1.06 (−6.64 to 8.77)	.79	Trivial
Insomnia				
	CAPABLE × month 3	3.65 (−1.68 to 13.93)	.58	Trivial
	CAPABLE × month 6	0.88 (−12.57 to 14.33)	.90	Trivial
Financial difficulties				
	CAPABLE × month 3	4.93 (−0.33 to 10.20)	.07	Small
	CAPABLE × month 6	7.47 (1.99 to 12.95)	.01	Small
Summary score				
	CAPABLE × month 3	−3.37 (−8.78 to 2.04)	.22	—
	CAPABLE × month 6	1.19 (−4.40 to 6.80)	.68	—

[a]Results presented are adjusted βs coming from interaction between cohort and time. Matched controls at baseline are reference group.

[b]Not applicable.

Similar baseline differences were observed in melanoma-specific quality of life as measured by the melanoma subscale (MS) and melanoma surgery subscale (MSS) of the FACT-M. Melanoma-specific quality of life showed a significant baseline difference between the CAPABLE group and matched controls when looking at both the MS (mean 57.5, SD 5.3 vs mean 50.4, SD 8.3; *P*<.001) and the MSS (mean 28.1, SD 4.4 vs mean 22.4, SD 6.3; *P*<.001). Mean scores did not change much over time in both cohorts (Table S3 in Multimedia Appendix 1). When adjusted for sex, age, tumor stage, time, and baseline scores, there were also no significant changes in melanoma-specific quality of life between both cohorts over time (Table 4). Utility scores of the EQ-5D-5L yielded similar results in terms of mean scores, and when adjusted for all covariates, no effect of CAPABLE was seen compared with matched controls (Table S3 in Multimedia Appendix 1; Table 4). However, HRQoL as measured by the visual analog scale, was significantly higher for the CAPABLE cohort compared with the matched controls on month 3 and month 6 when corrected for sex, age, and stage of disease (B=10.28, 95% CI 1.45 - 19.11, *P*=.02 and B=11.50, 95% CI 2.08 - 20.92, *P*=.017, respectively).

Table . Adjusted univariable mixed effects linear regression analyses on different patient reported outcome measures between CAPABLE group and matched controls. Analyses are adjusted for age, sex, stage, and baseline scores.

HRQoL[a] subscales			β (95% CI)[b]	*P* value
FACT-M[c]				
	MS[d] (range 0-64)			
		CAPABLE[e]×month 3	−1.54 (−5.37 to 2.29)	.43
		CAPABLE×month 6	−0.82 (−4.78 to 3.14)	.69

[a]HRQoL: health-related quality of life.

[b]Results presented are adjusted βs coming from interaction between cohort and time. Matched controls at baseline are reference group.

[c]FACT-M: Functional Assessment of Cancer Therapy-Melanoma.

[d]MS: melanoma subscale.

[e]CAPABLE: Cancer Patients Better Life Experience.

[f]MSS: melanoma surgery subscale.

[g]VAS: visual analog scale.

Information Needs

Overall, information provision as reported by the EORTC QLQ-INFO25 was significantly lower in the control cohort on both baseline and month 6 (Table S4 in Multimedia Appendix 1). When adjusting for age, sex, and baseline scores, no separate domains showed significant improvements of the CAPABLE cohort. However, information satisfaction was significantly higher in the CAPABLE cohort (B=8.71, 95% CI 1.54 - 15.88; *P*=.02) (Table 5).

Table . Adjusted univariable mixed effects linear regression analyses on information domains between CAPABLE group and PRO-MEL controls. Analyses are adjusted for age, sex, stage, and baseline scores.

Information domains[a]	β (95% CI)	*P* value
Disease	3.38 (−5.49 to 12.25)	.46
Medical tests	9.35 (0.22 to 18.48)	.05
Treatment	1.59 (−6.89 to 10.06)	.71
Other services	2.46 (−7.28 to 12.19)	.62
Different places of care	−2.19 (−14.04 to 9.67)	.72
Things you can do to help yourself	−6.12 (−15.54 to 3.30)	.20
Satisfaction with information received	8.71 (1.54 to 15.88)	.02
Overall the information has been helpful	3.69 (−4.77 to 12.14)	.39

[a]Controls are reference group.

Feasibility

Because of project time constraints, only 31 of the planned 36 patients were included in this study. In total, 59 patients were eligible for study participation, resulting in a recruitment rate of 53% in the set period, whereas the planned recruitment rate for reaching the feasibility end point was 60%. However, patient compliance and patient retention remained high in the patients that were included. Patient compliance to the PROMs at baseline was 98% (30/31), at T1 was 90% (27/30), and at T2 was 79%

(22/28). Finally, 27 out of 31 (87%) patients adhered to using the CAPABLE app until at least T1, which dropped to 24 patients (77%) using the app at T2. Furthermore, 2 of those patients died because of rapidly progressive disease during the trial. Adherence to smartwatch use was lower with only 43% (13/30) usage at T2 due to smartwatch issues. In total, 27 individual problems with the CAPABLE app and smartwatch were reported during the trial, mostly in the first 3 months of usage. Almost half of patients (14/30, 47%) reported at least 1 problem with the CAPABLE app or one of its functionalities. The majority of reported problems were related to login issues (7/20, 35%), smartwatch problems (communication between app and discomfort of the smartwatch; 8/20, 41%), and problems with the symptom reporting workflow (3/20, 15%).

Engagement With the System

Concerning the symptom reporting functionality, 18 out of 30 patients have actively used the CAPABLE app and reported at least 1 distinct symptom or symptom episode (range 1 - 7) (Figure S2 in Multimedia Appendix 1). In total, 20 distinct immune-related AEs were reported through the CAPABLE app, with reports of 33 grade 1, 28 grade 2, 17 grade 3, and 3 grade 4 symptoms according to the mapped Common Terminology Criteria for AEs version 5 (Table S5 in Multimedia Appendix 1). Symptom episodes ranged from 1.5 days for headache to 149.6 days for muscle pain (Table S6 in Multimedia Appendix 1).

Engagement with the well-being interventions was on average lower than symptoms reporting (Table S7 in Multimedia Appendix 1). Interventions were not prescribed by HCPs and were free to use by the patients. The intervention related to taking a walk was the most often used, with 327 execution times, reported by 9 distinct patients. Some patients used the other interventions infrequently. Furthermore, 8 out of 30 patients used the interventions more than 5 times (range 8 - 213). Interventions that were used infrequently were mainly used during the first weeks of enrollment, suggesting that the interventions were tried out at the start of the pilot. The walking intervention was executed throughout the course of the pilot study, with more engagement in summer than in fall and winter (October-December).

Discussion

Principal Findings

The aim of this pilot study was to explore the effect of the CAPABLE mobile app on patient-reported outcomes, specifically fatigue, in patients with melanoma starting ICIs, compared with a historical control group receiving standard care. Our results showed no significant adjusted differences on fatigue and other HRQoL domains between the CAPABLE cohort and matched controls during the first 6 months of treatment. However, although not statistically significant, we did find that the CAPABLE cohort reported a smaller relevant increase in fatigue at month 3 follow-up compared with matched controls. Furthermore, information satisfaction was significantly higher in the CAPABLE users. The secondary goal of this study was to show patients' acceptance and feasibility of the CAPABLE app. With an observed recruitment rate of 53%, our feasibility end point of 60% was not met. A third of the patients refused to participate because study and questionnaires were expected to be too burdensome. Furthermore, HCPs did not feel comfortable including patients in the study because they expected it to be too burdensome for some patients (based on oral feedback). Furthermore, technology barriers might have played a role, as observed in other studies with eHealth apps [53].

We observed a significant baseline difference in almost all the HRQoL domains between the CAPABLE cohort and matched controls, suggesting a selection bias. Although matched on baseline characteristics, HRQoL domains in the CAPABLE group are clinically relevantly and significantly higher than in the matched controls. Therefore, results obtained in the CAPABLE group could have been influenced by the phenomenon "regression towards the mean," as improvement of HRQoL was almost impossible to achieve [54]. However, this phenomenon looks like it occurred in all HRQoL domains, except for fatigue, as we see an improvement only in fatigue for the CAPABLE cohort, although not statistically significant. This observation also underscores the importance of including patients with lower HRQoL in interventions designed to improve this outcome, for example, by minimizing the expected burden of participation [55].

Several studies have shown the benefits of eHealth on CRF. Supporting the small (nonsignificant) difference found in fatigue in our study, a meta-analysis done on 9 studies showed a statistically significant beneficial effect of eHealth interventions on CRF [23]. Furthermore, these eHealth tools were mostly designed to target CRF solely and did not have the multimodal aspects of our CAPABLE app. Furthermore, we were not able to disentangle which specific functionality was responsible for possible changes in fatigue, or if it was a combination of all functionalities. In addition, our sample size was not large enough to provide statistical significance; our pilot study was designed to provide descriptive statistics and focused largely on clinical relevance [51].

A similar study in Denmark, with electronic symptom monitoring carried out in patients with metastatic melanoma starting treatment with ICIs yielded improved HRQoL in the intervention group, as measured by the FACT-M and EQ-5D-5L [34,37], although the differences Tolstrup et al [37] obtained were also not clinically relevant. The Danish study was a randomized controlled trial (RCT) and had an active weekly symptom-monitoring component by their HCP; components of the trial that could have influenced the results compared with passive HCP monitoring in our real-world single-arm setting [56,57].

Information satisfaction was significantly higher in the CAPABLE cohort compared with the control group. Studies done on information provision through eHealth tools in the Dutch cancer care are still conflicting [58]. For example, in an RCT investigating a web-based eHealth app to support multiple cancer patient groups, improvement of knowledge was not reached [59]. However, another study showed that higher information satisfaction might contribute to patient knowledge and decision involvement [60]. Therefore, an eHealth tool, such

as CAPABLE, might still support patient knowledge and shared decision-making.

Results of our study might have been influenced by barriers when integrating and implementing eHealth into clinical practic. Although the CAPABLE system was developed using all relevant stakeholders, the CAPABLE app was not integrated in our electronic health record, causing our HCPs to work with 2 different systems, leading to resistance. In-depth results of user experience and usability research done in HCPs still need to be analyzed, but verbal feedback suggested this was a large barrier for monitoring patients with this app. To date, successful implementation and use of digital health interventions remains limited worldwide by integration into electronic health records, impairing the possible positive effect of such interventions [53]. Second, an existing challenge in digital health interventions research is the recruitment of target populations in need of such interventions [53,61,62]. Both not reaching our feasibility end point of 60% and high HRQoL baseline scores (probably because of selection bias) confirm this challenge. Consequently, results of this study need to be interpreted with caution and future research should make more effort into recruitment strategies including weaker populations, as well as considering health literacy. Furthermore, efforts are needed to reduce patient burden in this type of studies, both in terms of intervention as with research questionnaires, as it is essential to include all patients with serious health conditions [55].

Limitations

Several limitations of this study need to be considered when interpreting the results. Our sample size was too small to prove significant differences on HRQoL outcomes. Because of time constraints of our project, whose main focus was the design and development of the system, inclusion period was short and only 31 patients out of the anticipated 36 were included. Second, most of the control group was collected during the COVID-19 pandemic, which might have influenced HRQoL outcomes in these patients. However, a study done by van de Poll-Franse et al [63] showed that the crisis might have affected well-being of general population more than in that of cancer patients. In addition, another negative aspect of the COVID-19 pandemic was related to some delays in the software development for the CAPABLE eHealth app in an already-restricted project timeframe, which might have resulted in an increase in app issues reported by patients. While in-depth usability outcomes of this study have yet to be analyzed, we observed a relatively high proportion of technical problems during our study and we gathered multiple areas of improvement from verbal feedback from patients, which could have affected the results. Another limitation of the study was our decision to use a matched historical control cohort rather than an RCT. An RCT would have allowed better isolation of the effect of using the app. However, use of the historical cohort allowed us to recognize and characterize the participation bias in the intervention participants. This bias may have contributed to the lack of a clinically relevant effect in our main outcome.

However, a large strength of this study has been that CAPABLE was developed with co-design of patients and HCPs, following user-centered design principles, starting with explorative interviews and undergoing 3 testing rounds. Furthermore, our study was conducted in the real-world setting of the pilot trial; included patients were treated according to clinical practice. The CAPABLE app was added as a monitoring and coaching system tool and could intervene in management of patients after severe symptom reports. Due to the real-world setting of this trial, results on PROs, feasibility, and engagement with eHealth might be more generalizable to real-world patients compared with results found in clinical trials.

Future and larger studies could benefit from including patients more inclusively in terms of low health literacy and social economic status. Inclusion criteria should be broadened to reduce ceiling effects at baseline. Furthermore, the setting of this pilot study might have played a pivotal role, as we included patients in a dedicated cancer and melanoma center with a lot of ongoing clinical trials and other intervention studies and also standard care including easily accessible specialized nurse practitioners.

Conclusion

In our small, nonrandomized study we were unable to show that mobile-based coaching and follow-up affected HRQoL significantly, although results suggest a small clinical improvement of fatigue at 3 months follow-up in the app users. Ceiling effects due to large baseline differences might have caused the impact of CAPABLE to be negligible for patients with higher baseline HRQoL. CAPABLE resulted in significantly higher information satisfaction compared with controls. Although the feasibility end point of 60% was not met, adherence to the system was high. Further optimization of CAPABLE, taking into account patient-related and technology-related barriers is needed before future investigation in an RCT and might influence HRQoL end points. Furthermore, when aiming at personalized patient and survivorship care, further optimization and prospective investigation of eHealth tools is warranted.

Acknowledgments

This work was supported by the European Union (EU)'s Horizon 2020 research and innovation programme (grant agreement No 875052). The Cancer Patients Better Life Experience (CAPABLE) system was developed during the first 3 years of an EU project funded under the Horizon 2020 Research and Innovation Programme. CAPABLE is a 4-year project coordinated by the University of Pavia, Italy, and carried out by 12 partners in Europe and Israel. We like to thank all the partners and participants involved in this and previous CAPABLE-project studies.

Data Availability

The datasets generated during and analyzed during this study are not publicly available due to the sensitive information of patients but are available from the corresponding author on reasonable request.

Authors' Contributions

Conceptualization was contributed by all authors. Data curation and formal analysis was contributed by IF, LVvdPF, SW, and LS. Funding acquisition was managed by all authors. Investigation was handled by IF and SW. Methodology was contributed by IF, LVvdPF, SW, LDC, VT, RC, and SM. Project administration, resources, software supervision, and validation was handled by all authors. Visualization was contributed by IF, LVvdPF, SW, and LS. Writing – original draft was contributed by IF, SW, and LS. Writing – review and editing was contributed by all authors.

Conflicts of Interest

DG is an employee of and shareholder in Deontics Ltd. Deontics provided the Computer Decision Support platform component for the Cancer Patients Better Life Experience (CAPABLE) system used in the study. LDL reported the following: Conference honoraria/Advisory Board: EISAI, MSD, Merck Serono, Eli Lilly, Sanofi, Sunpharma, IPSEN, Bayer, Roche, Istituto Gentili Srl; New Bridge; Seagen; Novartis; Travel grant: Gilead.
All other authors report no conflict of interest.
