Lung cancer screening (LCS) with low-dose computed tomography (LDCT) is an effective secondary prevention method [4]. It has been shown to reduce the mortality of lung cancer by 20%, compared to the standard chest x-ray, among high-risk individuals [4]. Screening for individuals at high risk for lung cancer (individuals aged between 50 and 80 years, who have smoked at least 20 pack-years, and currently smoking or having quit smoking within the past 15 years) [5] has the potential to improve lung cancer survival rates by detecting nodules at an earlier stage when it is more likely to be curable. It is reported that about 8 million Americans qualify as high risk for lung cancer and are recommended to receive annual screening with LDCT scans [5]. If half of these high-risk individuals are screened, more than 12,000 lung cancer deaths could be prevented annually [6].

Guidelines and Uptake Rate of LCS

Since 2013, the US Preventive Services Task Force and other organizations (eg, American Cancer Society, American College of Chest Physicians, American Society of Clinical Oncology, and American Lung Association) have issued guidelines for early detection of lung cancer with yearly LDCT among high-risk populations [7]. It was covered both by the private and public health insurances for the high-risk population [8].

Although the supportive landscape for screening lung cancer among high-risk populations has improved, uptake rates of LCS with LDCT remain low [9]. The percentage of the eligible population who had received LCS with LDCT increased from 3.3% in 2010 to 3.9% in 2015 and reached 18.2% in 2022 among the US population [10,11].

Barriers to LCS Uptake

Barriers to LCS for eligible individuals have been reported to include a lack of knowledge, practical challenges, financial constraints, psychological obstacles such as worry and anxiety, blame and stigma, fear of cancer, and fatalism [12]. Additionally, there is confusion surrounding LCS and a general distrust of the medical system. High-risk individuals seem to have limited knowledge about LCS. This lack of knowledge may stem from the little information they received regarding the screening process. Although LCS with LDCT is covered by both private and public health insurance for high-risk populations, awareness of this coverage appears insufficient, given the financial barriers frequently reported (eg, cost of the screening, insufficient authorization of health insurance reimbursement by insurance companies, and misunderstanding-associated out-of-pocket cost). In addition, stigma and fatalism toward the disease (eg, the perception that lung cancer is not treatable) could also impede high-risk individuals from screening for lung cancer [12].

Interventions to Increase LCS Uptake and Limitations

Multiple interventions have been implemented to increase LCS uptake in high-risk populations. Evidence-based strategies include shared decision-making tools and decision aids designed to support informed screening choices and improve adherence to LCS guidelines [13]. In addition, a range of patient-directed interventions have been evaluated, including educational videos and information films [14] and clinical outreach and referrals [15]. However, prior studies vary substantially in design, intensity, and delivery context, with many interventions implemented within clinical settings or as part of health care system–based programs. Furthermore, most reports in this area are limited by focus primarily on describing barriers rather than evaluating intervention effectiveness. These limitations highlight the need for rigorously designed, scalable interventions that can be delivered outside of clinical environments and evaluated using standardized outcome measures.

In recent years, several rigorously developed digital interventions have been designed to support LCS decision-making. LungTalk, developed by Carter-Harris et al [16], is a theory-driven, web-based intervention that addresses lung cancer stigma, knowledge, and health beliefs to promote informed screening decisions. Similarly, mPATH-Lung (mobile Patient Technology for Health-Lung), developed by Miller et al [17], is a personalized, web-based decision aid that has been implemented in clinical settings to facilitate shared decision-making for LCS. In addition, LCS decision support tools developed by Volk et al [18] at MD Anderson Cancer Center provide evidence-based, patient-centered resources to guide screening decisions. These interventions demonstrate that digital approaches to LCS are both feasible and effective. However, despite these advances, many existing digital interventions are designed primarily as decision aids within clinical workflows or target-specific populations (eg, current smokers engaged in health care systems). In contrast, fewer interventions have focused on scalable, fully remote, multimodule educational programs that can be delivered outside of clinical encounters and are tailored to high-risk populations with limited access to LCS resources.

This study addresses the gap by developing and pilot-testing a structured, 5-module digital intervention integrating educational content, health belief modification, and culturally relevant messaging. Unlike existing intervention programs that primarily focus on facilitating a single screening decision, this study emphasizes a broader continuum of behavior change, including knowledge enhancement, belief modification, and intention formation. Additionally, the asynchronous and low-cost delivery format enhances scalability and accessibility, particularly for

XSL•FO
RenderX

populations who may face barriers to clinic-based decision-making tools.

Aims

This study aims to (1) test the feasibility of an online intervention program on increasing LCS uptakes among high-risk individuals and (2) assess the intervention's effects on changing participants' knowledge of lung cancer and LCS, attitudes toward lung cancer stigma, health beliefs regarding LCS, behavioral intentions, perceived importance, and confidence in obtaining LCS when compared to baseline measurements.

Significance

This study implemented an online intervention aimed at increasing LCS uptake among high-risk individuals. Promoting LCS projects helps high-risk individuals better understand their risk of lung cancer, acquire knowledge about lung cancer and screening procedures, and enhance their awareness of the importance of LCS.

Methods

Design

A single-arm preintervention and postintervention study design was used in this study. A flow diagram about the study process is shown in Figure 1. Paired-comparison data before and after the intervention were obtained and analyzed.

XSL•FO
RenderX

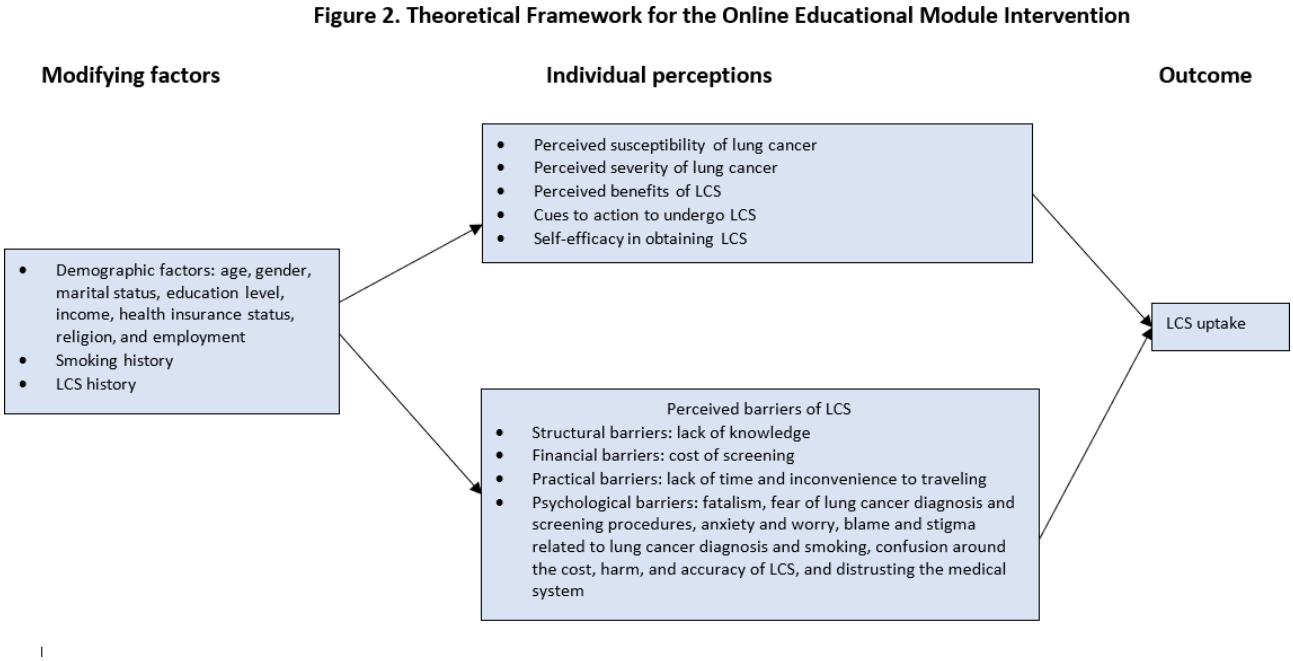

Figure 1. Study flowchart.

XSL•FO
RenderX

Theoretical Framework

The health belief model (HBM) provided a theoretical framework for the study (Figure 2) [19]. Key concepts of the HBM are perceived susceptibility, perceived severity, perceived benefits, perceived barriers, self-efficacy, and cues to action [19]. In addition, this study was conceptually informed by the integrated LCS participation model developed by Carter-Harris et al [20], which incorporates HBM constructs alongside lung cancer stigma and the precaution adoption process model (PAPM). This integrated framework emphasizes that LCS participation is not solely driven by health beliefs but also shaped by psychosocial factors and individuals' stage of readiness to act.

Figure 2. Theoretical framework for the online educational module intervention. LCS: lung cancer screening.

Ethical Considerations

The study was reviewed and approved by the institutional review board of the University of Minnesota (institutional review board protocol: STUDY00020835). All study procedures followed the ethical principles outlined in the Belmont Report and adhered to relevant federal and institutional guidelines for research involving human participants. Participants were informed about the purposes of the study, procedures, potential risks, and benefits through an online consent form prior to enrollment. Participants were reminded that their participation was voluntary, and they could withdraw from the study at any time without penalty. As the intervention and data collection took place online, additional measures were taken to ensure confidentiality, including secure data transmission, encrypted storage, and restricted access to identifiable information.

Minimal risks were anticipated, as the intervention involved completing online educational modules and surveys. The consent form explained potential discomfort that might arise from answering questions about smoking behavior and health beliefs. No adverse events were reported during the study, and no protocol deviation was noted from the study. Participants were compensated for their time with a US $40 Amazon gift card upon completion of the intervention, and an additional US $10 Amazon gift card was given to those who completed the 3-month follow-up survey.

All procedures complied with the Health Insurance Portability and Accountability Act as applicable, and the data were deidentified before analysis. Results are presented in an aggregate form to protect participants' privacy.

Setting

This study was conducted online. Interactive educational modules about LCS were created and implemented online through Research Electronic Data Capture (REDCap; Vanderbilt University). Questionnaires used in the study were administered on REDCap before and after the intervention. Follow-up emails were sent to increase the response rate of the questionnaires, and the study team answered any questions that the participants might have.

Sample

The inclusion criteria for participants in this study were as follows: individuals with a smoking history of more than 20 pack-years, currently smoking or having quit smoking in the past 15 years, aged between 50 and 80 years, and able to read or understand English at the sixth-grade level. Exclusion criterion for the participants was having been diagnosed with lung cancer or other diseases that could substantially impact participants' life expectancy. These criteria align with the US Preventive Services Task Force screening recommendation for lung cancer.

Sample Size

The sample size was calculated using the G-Power software [21]. To detect a medium effect size (Cohen d=0.5) with an alpha error probability of .05 and a power of 0.95, a total sample size of more than 210 is required for a formal study when using

XSL•FO
RenderX

a paired sample *t* test to detect differences. Considering data quality and the expected response rate of the questionnaires, an additional 20% increase in the suggested sample size is warranted, resulting in a target of 250 participants for the formal study.

As this study is a pilot study for the larger formal study, extant literature recommends that a pilot study should include approximately 10% of the sample size projected for the main study [21,22]. In addition, researchers typically suggest a sample size of 10 to 30 participants in both survey research and medical field research [23,24]. Therefore, a sample size of 25 participants would be appropriate for this pilot study.

Recruitment Procedure

Webpages were created on REDCap to provide information about the study. Collaborating with the University of Minnesota Clinical and Translational Science Institute, all available social media platforms, including the StudyFinder (University of Minnesota) website, Instagram (Meta Platforms, Inc), and Facebook (Meta Platforms, Inc) groups, were used to recruit the planned number of participants. The study flyer was shared on these social media along with the research team's email address. Once potential participants emailed the study team, they were screened for eligibility by answering 7 screening questions. If participants met the eligibility criteria, they were assigned a code number, and their contact information (eg, email address and cell number) was collected.

Interventions

Preintervention Phase

Eligible participants were provided with a REDCap link for the questionnaires. Participants first read information about the study, reviewed the informed consent form, and then completed all preintervention questionnaires.

Intervention Phase

Participants who completed preintervention questionnaires were asked to review 5 online interactive modules on REDCap (including videos, text, pictures, and interactive activities) about lung cancer and its screening (Table 1).

Table . Lung cancer screening (LCS) online educational modules.

Module	Content
Module 1	Lung cancer epidemiology, etiology, signs, and symptoms
Module 2	Lung cancer treatment and care
Module 3	Lung cancer prevention methods
Module 4	LCS guidelines, benefits, and risks
Module 5	LCS procedures and results interpretation

Postintervention Phase

After reviewing the online educational modules, participants were asked to complete the postintervention questionnaires on REDCap. Participants were followed over 3 months [25] by emails to assess whether they underwent LCS.

Development of Interactive Educational Modules

The interactive educational modules were developed through a 3-phase, user-centered process. First, a needs assessment was conducted through a literature review and individual qualitative interviews with 12 individuals with a heavy smoking history to identify knowledge gaps, misconceptions, preferred learning formats, and appropriate health literacy level. Second, 5 sequential modules were created featuring 3- to 5-minute artificial intelligence–generated video lectures, infographics, interactive quizzes, and reflection questions, with iterative prototyping to refine clarity and engagement and to align content with the HBM and PAPM constructs. Third, a panel of 7 clinical and behavioral experts evaluated accuracy and relevance; revisions were made based on item-level and scale-level Content Validity Index (CVI) results until strong content validity (item-level CVI≥0.78; scale-level CVI≥0.90) was achieved [26]. While this paper reported how the intervention performed during pilot testing, detailed methods for the design and development of these modules have been published elsewhere [27].

Instruments

Sociodemographic Information

Sociodemographic characteristics were measured using the *Sociodemographic Information Questionnaire*, which included 8 questions on participants' age, sex, marital status, level of education, annual family income, race, occupation, and health insurance status.

Intentions, Perceived Importance, and Confidence to Obtain LCS

Participants' intentions, perceived importance, and confidence in undergoing LCS were assessed using *the Smoking and Lung Cancer Screening Questionnaire*, which was developed by the study team.

Knowledge of Lung Cancer and Screening

Participants' knowledge of lung cancer and screening was assessed using 12 questions from the *Lung Cancer and Screening Knowledge Questionnaire* [28]. The questionnaire's total score ranged from 0 to 12.

Attitudes Toward Lung Cancer Stigma

Nine questions about lung cancer stigma were assessed using the shortened version of the *Cataldo Lung Cancer Stigma Scale* [29], which uses a 4-point Likert-style response format. The scale's total score ranged from 9 to 36 [30]. The reliability

XSL•FO
RenderX

coefficient scores of the scale ranged from 0.75 to 0.96, which were in acceptable to excellent ranges [30].

Health Beliefs of Lung Cancer and Screening

Participants' health beliefs regarding lung cancer and its screening were assessed using *the modified LCS Health Belief Scale*. This scale is composed of 57 items grouped into 6 subscales. The subscales for perceived severity, perceived susceptibility, perceived benefits, perceived barriers, and cues to action used 4-point Likert-style responses, with options ranging from strongly disagree (score=1) to strongly agree (score=4). The self-efficacy subscale also used 4-point Likert-style responses with options ranging from not at all confident (score=1) to very confident (score=4). This scale was developed from our preliminary studies, adopting the original *LCS Health Belief Scale* [31], which demonstrated acceptable content validity [32].

LCS Uptake

LCS uptake was assessed during the follow-up period after participants completed the online intervention. Upon enrollment, participants were informed that they would receive a follow-up email approximately 3 months later. This email inquired whether they had completed an LDCT LCS since participating in the study. Participants were instructed to respond with "yes" if they had undergone the screening and "no" if they had not. Only participants who replied to the follow-up email were included in the analysis.

Satisfaction Feedbacks

Participants' feedback on the intervention was collected using the *Satisfaction Feedback Questionnaire* developed by the study team. The questionnaire consisted of 5 items, each measured using a 4-point Likert-style ordinal response scale. The total score for the questionnaire ranged from 5 to 20, with higher scores indicating greater satisfaction with the intervention. A total score above 15 indicated a positive attitude toward the online education modules.

Data Analysis

Data analysis was done using SPSS (version 31.0.0; IBM Corp). Descriptive statistics, including mean and SD, frequency, and percentage, were used to evaluate the characteristics of the participants, participant satisfaction with the intervention, and LCS uptake rates. A paired *t* test was performed to examine differences in the mean scores of participants' behavioral intention, perceived importance, and confidence toward LCS; knowledge of lung cancer and its screening; attitudes toward lung cancer stigma; and health beliefs regarding LCS before and after the intervention. The *P* value was set at .05. Results with a *P* value of <.05 were considered significant. Cohen *d* was calculated for paired comparisons to estimate the magnitude of change and inform future sample size calculations. The distributions of predifference and postdifference scores were examined using skewness, kurtosis, and Q-Q plots. Sensitivity analyses were conducted using nonparametric alternatives (Wilcoxon signed-rank tests), and results were compared for consistency.

Results

Participant Characteristics

A total of 27 participants were initially enrolled in the pilot study, of which 25 completed the intervention, resulting in a retention rate of 92.59%. The mean age of the participants was 60.88 (SD 5.16) years. Most participants were female (n=18, 72%), married (n=18, 72%), and had at least a bachelor's degree (n=19, 76%). The majority reported a household annual income between US $45,000 and US $139,999 (n=19, 76%). Of the 25 participants, 44% (n=11) identified as White, 40% (n=10) as Black or African American, and 16% (n=4) as Hispanic or Latinx. More than half of the participants (n=14, 56%) were not currently employed, and 36% (n=9) did not have health insurance. The majority smoked currently (n=22, 88%), and none had previously undergone LCS. Only 1 (4%) participant reported a family history of lung cancer (Table 2). Average time for the participants completing the modules was 2 (SD 0.23) hours. All the participants completed the modules in a single setting.

[a]LCS: lung cancer screening.

Changes in LCS Intentions, Perceived Importance, and Confidence

Before the intervention, most participants (18/25, 72%) indicated that they had no plan to undergo LCS, while only 8% (2/25) intended to have the screening done within 6 months. However, after completing the online modules, their intentions to undergo screening increased substantially, with 52% (13/25) of the participants indicating plans to undergo screening within the next 6 months. Only 12% (3/25) of them stated that they did not plan to pursue it. Additionally, the perceived importance of LCS rose significantly (t_{24}=−6.70; P<.001; Cohen d=−1.34). Confidence in the decision to undergo screening also improved (t_{24}=−10.00; P<.001; Cohen d=−2.00; Table 3).

Table . Changes in lung cancer screening (LCS) intention, perceived importance, and confidence (N=25).

	Before the intervention	After the intervention
Are you planning to receive LCS with low-dose computed tomography later?, n (%)		
Within the next month	0 (0)	6 (24)
Within the next 2 - 6 months	2 (8)	7 (28)
Sometime after 6 months	5 (20)	9 (36)
I am not planning to receive it	18 (72)	3 (12)
On a scale of 1-10, with 1=not at all important and 10=extremely important, how important is it for you to receive LCS with low-dose computed tomography?, mean (SD)	4.32 (2.27)	7.76 (1.72)
On a scale of 1-10, with 1=not at all confident and 10=extremely confident, how confident are you to receive LCS with low-dose computed tomography?, mean (SD)	4.12 (1.83)	7.84 (1.55)

Changes in Lung Cancer Knowledge, Stigma, and Health Beliefs

Consistent with the theoretical framework, participants demonstrated significant improvement in their knowledge of lung cancer and its screening, perceived less stigma, and developed more positive health beliefs about LCS. The average knowledge scores increased from 3.76 (SD 2.26) to 8.60 (SD 2.27; t_{24}=−7.28; P<.001; Cohen d=−1.46). Notably, lung cancer stigma decreased from 25.52 (SD 4.72) to 19.16 (SD 4.62; t_{24}=6.28; P<.001; Cohen d=1.26). Changes were observed across all subscales of the modified LCS Health Belief Scale: perceived susceptibility (mean 8.2, SD 2.06 vs mean 10.44, SD 2.16; t_{24}=−4.63; Cohen d=−0.93), benefits (mean 17.72, SD 3.09 vs mean 24.12, SD 3.84; t_{24}=−7.51; Cohen d=−1.5), cues to action (mean 15.28, SD 3.29 vs mean 20.84, SD 3.30; t_{24}=−8.08; Cohen d=−1.62), and self-efficacy (mean 28.36, SD 4.89 vs mean 35.28, SD 4.45; t_{24}=−5.79; Cohen d=−1.16). Meanwhile, perceived barriers decreased (mean 55.64, SD 5.50 vs mean 44.24, SD 6.95; t_{24}=9.09; Cohen d=1.82) and severity dropped (mean 26.72, SD 4.87 vs mean 21.76, SD 2.86; t_{24}=4.00; Cohen d=0.80). All changes were statistically significant (all P values <.001).

The Cohen d test showed large effect sizes (Cohen d >0.80) for all outcomes. Inspection of the distributions of predifference and postdifference scores suggested no substantial deviations from normality. The results of the Wilcoxon signed-rank tests were consistent with the paired t test findings, with no meaningful differences in statistical significance or direction of effects (P<.01).

LCS Uptake

Of the 22 participants who replied to the follow-up email, 13 (59.1%) reported that they had completed LCS with LDCT, while 9 (40.9%) reported not having undergone the screening. The attrition rate for the follow-up was 12% (3/25). The self-reported rate indicated that more than half of those who responded engaged in screening following the online intervention.

Satisfaction Toward the Intervention

Overall, participants reported high satisfaction with the online education intervention program. On a 4-point Likert scale, the average satisfaction score was 18.32 (SD 2.33). All participants described the online teaching session as informative and helpful, noting that their interest and motivation in learning increased afterward. In total, 96% (24/25) of the participants reflected that they had learned and understood the materials presented during the session; they felt that the session covered all the stated objectives.

XSL•FO
RenderX

Discussion

Principal Findings

This pilot study demonstrated that an online, theory-based educational intervention can effectively improve knowledge, attitude, beliefs, behavioral intentions, perceived importance, and confidence of high-risk individuals regarding LCS. Following the intervention, participants reported significant increases in the intention, perceived importance, and confidence in obtaining an LDCT screening. There was an increase in knowledge about lung cancer and screening, a decrease in perceived stigma toward lung cancer, improved health beliefs regarding LCS, and a high level of satisfaction with the program. Compared with existing digital LCS decision aids such as LungTalk and mPATH-Lung, this study extends prior work by focusing on a fully remote, multisession educational approach aimed at modifying health beliefs and supporting progression toward screening intention outside of clinical encounters.

The observed improvements align with previous studies, demonstrating that targeted educational interventions can effectively modify cognitive and affective determinants of screening behavior [14,16-18]. In addition, this study contributes to existing literature by delivering the intervention entirely online, thus overcoming geographic and logistical barriers often encountered with traditional face-to-face formats.

The notable increases in the intentions, perceived importance, and confidence regarding undergoing LCS indicate that the intervention effectively influenced participants' readiness for behavior change. This finding suggests that digital delivery can achieve similar behavioral impacts while enhancing accessibility. According to the HBM and PAPM, importance reflects perceived value and outcome expectancy, while confidence, often conceptualized as self-efficacy, is a key predictor of behavioral intentions to act [33]. The simultaneous rise in both constructs suggests that the online modules not only provided information but also effectively addressed the motivational and self-regulatory components for behavior change.

The substantial increase in knowledge about lung cancer and improvements across all areas of the Health Belief Scale, such as susceptibility, benefits, barriers, cues to action, and self-efficacy, demonstrate that the intervention engaged multiple cognitive pathways that influence health behavior. Participants not only acquired new information but also internalized their personal risk. They began to view screening as beneficial, perceived fewer barriers, and reported stronger cues to action. These comprehensive changes suggest that the educational modules served as a multifaceted behavioral intervention rather than a simple knowledge-based program.

One unexpected finding was the observed decrease in perceived severity following the intervention. In the context of LCS, perceived severity is often uniformly high at baseline, as lung cancer is widely recognized as a serious and life-threatening condition, and prior research has noted potential ceiling effects [31]. The decrease observed in this study may reflect improved knowledge and reduced fatalistic beliefs rather than a diminished understanding of disease seriousness. Specifically, after the educational intervention, participants may have developed a clearer understanding of available treatment options and the benefits of early detection, including the substantially higher survival rates associated with early-stage lung cancer. This shift may have led participants to perceive lung cancer as more treatable when detected early, thereby lowering perceived severity scores.

Importantly, this interpretation suggests a cognitive reframing from viewing lung cancer as uniformly fatal to recognizing it as a condition with meaningful opportunities for early intervention and improved outcomes. However, consistent with LCS-specific conceptual models, reducing perceived severity alone is unlikely to directly motivate screening behavior. Instead, constructs such as perceived risk (susceptibility), perceived benefits, and self-efficacy, each of which improved in this study, are more proximal determinants of screening uptake. Future studies should prioritize these constructs and consider refining measurement approaches to better align with validated LCS-specific frameworks.

Furthermore, the marked reduction in stigma surrounding lung cancer is particularly noteworthy, which supports earlier findings that education and normalization of LCS can mitigate blame and fatalistic attitudes among individuals who smoke [34]. Stigma has long been recognized as a psychological barrier that discourages individuals who smoke from participating in LCS due to feelings of shame, blame, or fear of judgment. By presenting lung cancer as a preventable and treatable condition if detected early and by portraying screening as a responsible health decision rather than a consequence of smoking, the intervention may have helped shift participants' views of lung cancer from self-blame to empowerment. This change is crucial because lower stigma is linked to higher screening uptake and better engagement with health care services [34].

The reported uptake rate (13/25, 59%) of LCS is substantially higher than national estimates of LCS participation, which are approximately 18% among eligible individuals in the United States [35]. Although a higher LCS rate is observed in this study, it should not be interpreted as a direct indicator of intervention effectiveness. The discrepancy may reflect differences in sample characteristics, such as higher motivation among study participants, as well as potential response and reporting biases.

Participants expressed exceptionally high satisfaction with the online educational program. Satisfaction is a crucial yet often overlooked component in digital health interventions, as it is closely linked to engagement, adherence, and long-term retention. The consistently high ratings across all satisfaction indicators suggest that the format, content, and delivery were well aligned with adult learning principles and the needs of the target population. High satisfaction also increases the likelihood that participants may recommend the program to their peers, which could extend the intervention's reach through community engagement.

Strengths

This study introduces a novel, theory-based online educational intervention grounded in the HBM and PAPM. Unlike prior

XSL•FO
RenderX

approaches, this intervention was designed as a multicomponent, interactive program that integrates short video-based learning, quizzes, and reflective activities to actively engage users and reinforce key behavioral constructs, including perceived susceptibility, perceived benefits, and self-efficacy. Additionally, the intervention was developed using a user-centered design process informed by qualitative data from high-risk individuals, ensuring that content is culturally and contextually relevant, accessible, and aligned with participants' health literacy levels.

Another innovative aspect of this study lies in its emphasis on addressing lung cancer–related stigma and psychological barriers, which are often undertargeted in existing interventions. By incorporating content that normalizes screening, reduces blame, and reframes lung cancer as a preventable and treatable condition when detected early, the intervention extends beyond knowledge enhancement to target affective and social determinants of health behavior.

Limitations and Future Directions

This study has notable limitations due to its small sample size and single-arm preintervention and postintervention design, which affects its generalizability and the ability to infer causal relationships. Without a control or comparison group, it is not possible to determine whether the observed changes were attributable to the intervention itself or alternative explanations, such as repeated measurement effects, regression to the mean, social desirability bias, or natural changes over time. Therefore, the findings should be interpreted as preliminary and hypothesis generating. Future research using randomized controlled designs with larger samples and comparison groups reflective of standard clinical practice (eg, clinical counseling with primary care providers) is needed to establish the efficacy of the intervention.

In addition, the generalizability of the findings is limited by the sociodemographic characteristics of the sample. Participants in this study were relatively well educated and reported moderate to higher income levels, which may not reflect the broader population eligible for LCS, who often have lower educational attainment and fewer financial resources. Furthermore, over one-third of participants reported lacking health insurance, highlighting a critical structural barrier to LCS uptake. Future research should prioritize the development and evaluation of interventions that are accessible to individuals with lower health literacy, and integrating educational interventions with system-level supports, such as patient navigation, insurance assistance, and linkage to affordable screening services, may be necessary to effectively reduce disparities in LCS uptake.

Finally, at the 3-month follow-up, LCS uptake was assessed via participant self-report collected through email. However, this measure was not verified through medical records or imaging data and should therefore be interpreted with caution. In addition, 3 participants did not respond to the follow-up assessment and were not included in this estimate. No comparison between responders and nonresponders was conducted. These missing data may further limit the validity and generalizability of the findings. Future research should use objective screening documentation to confirm whether participants completed LCS and conduct qualitative studies to identify specific motivational or structural factors that influence screening uptake.

Conclusions

This pilot study yielded promising findings, suggesting that an online, interactive educational intervention grounded in the HBM and PAPM can enhance knowledge, attitude, beliefs, and readiness for LCS among high-risk individuals who smoke. The program was well received, user-friendly, and showed measurable psychosocial benefits. While promising, these findings require confirmation in rigorously designed controlled trials before conclusions about effectiveness can be drawn. With further testing and refinement, this intervention has the potential to serve as a scalable public health tool aimed at reducing disparities in lung cancer through extensive reach, improved prevention, and early detection.

Abstract

Background: Effective communication about breast and cervical cancers remains a public health challenge, with widespread misinformation and barriers to cancer-related language understanding. Large language models (LLMs) offer potential for scalable health communication, yet trade-offs between quality, safety, and accessibility of general-purpose and medical-domain LLMs remain underexplored.

Objective: This study aimed to propose a comprehensive evaluation framework and systematically assess the performance of LLMs in generating breast and cervical cancer information, with a focus on linguistic quality, safety and trustworthiness, and communication accessibility and affectiveness.

Methods: This mixed methods evaluation study assessed outputs from 5 general-purpose and 3 medical LLMs using real-world breast and cervical cancer–related questions curated from publicly available medical datasets. LLM-generated responses were evaluated in a controlled offline setting. Primary outcomes included linguistic quality (fluency, coherence, and accuracy), safety and trustworthiness (toxicity, bias, and harm potential), and communication accessibility and affectiveness (readability, empathy, and clarity). Qualitative ratings were performed by domain experts, while quantitative metrics were compared across models. Statistical analyses included Welch ANOVA to detect differences in metric scores, Games-Howell tests for pairwise comparisons, and Hedges *g* to assess effect sizes.

Results: General-purpose LLMs, particularly Llama 3 and Gemma, demonstrated superior linguistic quality and affectiveness but often produced complex outputs that may limit accessibility. In contrast, medical LLMs (eg, MedAlpaca and BioMistral) generated simpler content suitable for broader audiences but scored lower in safety and empathy due to higher levels of hallucination, bias, and toxicity.

Conclusions: While LLMs show promise for improving digital cancer communication, our findings reveal a trade-off between domain specialization and overall communication quality and safety. Future development of health-focused LLMs should prioritize hybrid modeling strategies to enhance trust, clarity, and clinical relevance in patient-facing tools.

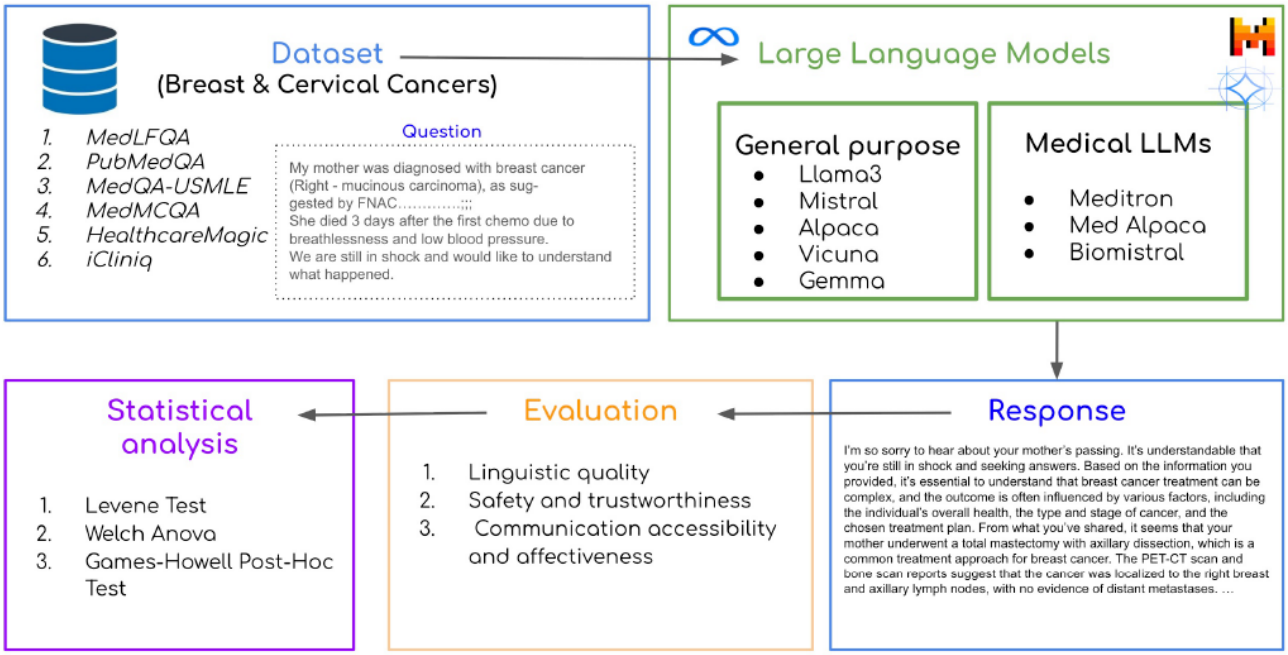
Introduction

Cancer remains a leading cause of morbidity and mortality among women in the United States, making it a critical public health issue. Breast cancer is the most commonly diagnosed cancer among women, with an estimated 310,720 new cases and 42,250 deaths projected in 2024 [1]. Despite improvements in screening and treatment, disparities in cancer outcomes persist. For instance, Black women experience a 40% higher breast cancer mortality rate than White women, despite similar incidence rates, largely due to systemic inequities in screening access, delayed diagnoses, and unequal health care [1-4]. Similarly, there were 13,360 new cases of cervical cancer in the United States in 2025 [5], with Black women facing a mortality rate 200% higher than White women and Hispanic women experiencing a 51% higher incidence rate [6-8]. These

XSL•FO
RenderX

disparities are rooted in structural barriers, including financial hardship, limited geographic access, and psychological challenges [9].

Early cancer screening can help reduce disparities, but communicating guidelines to priority populations remains challenging [10]. Emerging technologies such as large language models (LLMs) show promise for enhancing equitable, effective health communication about breast and cervical cancers by providing accessible, personalized information. Recent research has examined LLM performance in oncology and clinical contexts, showing high accuracy and completeness in patient care questions [11], improved readability of cancer information with targeted prompting [12], variable results for multimodal chatbot case analysis [13], limited gains in diagnostic reasoning in randomized controlled trials [14], and calls for careful evaluation of their use in medical research and practice [15-18]. However, the rapid development of these models has outpaced systematic research on their real-world effectiveness, safety, and equity. Experts emphasize that before deploying such systems in cancer communication, issues of accuracy, safety, and privacy must be rigorously addressed [19], as misinformation can delay diagnosis, influence harmful treatment decisions, and erode trust in health institutions [20].



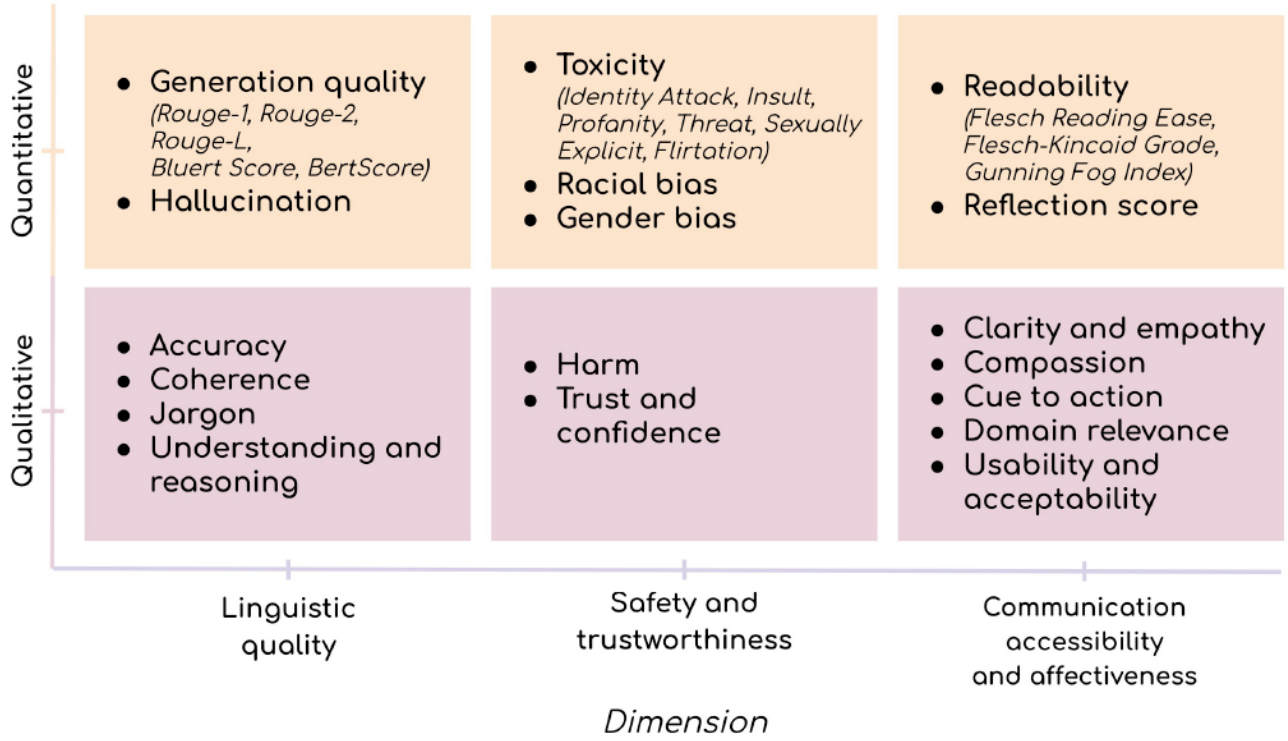
To address the urgent need for effective communication tools in cancer care, this study evaluates the quality and safety of LLM-generated content related to breast and cervical cancers. Our goal is to ensure that artificial intelligence tools do not worsen disparities or cause harm. We developed a patient-centered evaluation framework assessing LLMs across 3 key areas: linguistic quality, safety and trustworthiness, and communication accessibility and affectiveness ("affectiveness" specifically measures the model's ability to express warmth, empathy, and emotional appropriateness) that have not previously been operationalized together for this domain. Using this framework, we analyzed 8 open-source models, including 5 general-purpose and 3 medical-domain LLMs, in response to real-world breast and cervical cancers–related questions, providing a formative, methods-driven benchmark for assessing how well LLMs support accurate, empathetic, and equitable cancer communication. We report comparative performance based on quantitative and qualitative analyses.

Methods

Study Design

Our approach consists of 4 phases. First, we developed a comprehensive evaluation framework. Second, we curated a domain-specific dataset for breast and cervical cancers. Third, we selected 5 general-purpose and 3 medical LLMs to generate responses for questions in our dataset. Finally, we applied our evaluation framework to the generated responses from each model and conducted statistical analyses for the quantitative metrics and expert qualitative ratings (Figure 1).

Figure 1. Overview of the study design and evaluation pipeline. The dataset comprised breast and cervical cancers–related questions aggregated from 6 publicly available medical sources (MedLFQA, PubMedQA, MedQA-USMLE, MedMCQA, HealthcareMagic, and iCliniq). Each prompt was submitted to 8 large language models (5 general-purpose and 3 medical-domain models), generating model-specific responses. These outputs were evaluated across 3 major dimensions—linguistic quality, safety and trustworthiness, and communication accessibility and affectiveness—followed by statistical analysis using Levene test, Welch ANOVA, and Games-Howell pairwise comparisons. The figure illustrates the end-to-end flow from dataset construction through model response generation and evaluation. LLMs: large language models; PET-CT: positron emission tomography–computed tomography.



Evaluation Framework

This evaluation framework offers a structured approach to assessing the quality of language generated by LLMs in the context of breast and cervical cancers communication. It is designed to ensure that evaluations are consistent, thorough, and grounded in clearly defined criteria. Given the unique barriers faced by women in underserved communities, such

XSL•FO
RenderX

content must be clear, trustworthy, and sensitive to diverse literacy and cultural needs [21]. Our framework focuses on 3 core dimensions critical to effective patient communication: Linguistic Quality (eg, accuracy, clarity, and flow of language), Safety and Trustworthiness (eg, presence of biased, harmful, or misleading content), and Communication Accessibility and Affectiveness (eg, readability, empathy, and emotional relevance; Figure 2).

Figure 2. Comprehensive evaluation framework for evaluating general purpose and specialized medical large language models for cancer communication.

Linguistic Quality

Overview

Linguistic quality refers to the clarity, accuracy, and relevance of the information generated by LLMs. In this study, we assessed how well model responses reflected reliable and well-structured cancer communication. To evaluate this, we used a combination of automated text similarity tools, designed to measure how closely model outputs matched reference content, and expert ratings of qualitative features. Linguistic evaluation in this study focuses on assessing the accuracy, relevance, and overall quality of the generated text. The primary metrics used for this purpose are ROUGE (Recall-Oriented Understudy for Gisting Evaluation), Bleurt Score, and BERTScore, which collectively encompass precision, recall, and F_1-score. ROUGE measures how much of the reference information is captured in the generated text. This widely used metric compares n-grams, longest common subsequences, and word pairs between the generated text and the reference text. Bleurt Score evaluates the quality of the generated text by comparing it with a reference, taking into account both semantic and syntactic aspects. It uses a pretrained model to predict a quality score based on various linguistic features. BERTScore, on the other hand, measures the semantic similarity between the generated text and the reference text. It uses contextual embeddings from BERT to compute precision, recall, and F_1-scores for each token in the text. We also examined the likelihood of "hallucinations," meaning content generated by the model that is factually incorrect or not supported by the source material [22].

Hallucination

To calculate the hallucination score, we use the methodology described in the paper [22]. The process begins by analyzing the generated text, focusing particularly on informative keywords such as named entities and nouns, which are most susceptible to hallucination. The model's uncertainty for each token is quantified through entropy, which measures the unpredictability of the model's predictions. Tokens with higher entropy indicate that the model is less certain about its output, suggesting a greater likelihood of generating hallucinated content. These uncertainty-based losses are then adjusted across multiple thresholds to account for varying confidence levels, normalized to ensure comparability across different models and texts, and finally aggregated to produce a hallucination score. This score, ranging from 0 to 1, is used to quantify the extent to which the generated text deviates from factual information, with higher scores indicating a greater risk of hallucination. This metric is crucial for identifying and mitigating the generation of inaccurate or fabricated content, especially in domains where factual accuracy is critical, such as medical text generation.

Expert reviewers rated each response on 4 communication-related criteria: accuracy (clinical correctness), coherence (logical flow and consistency), use of jargon (degree of unnecessarily technical language), and understanding and reasoning (the model's ability to interpret medical questions

XSL•FO
RenderX

and provide appropriate, well-explained answers). Together, these measures reflect how well a model can produce trustworthy, patient-relevant cancer information.

Safety and Trustworthiness

Overview

Safety and trustworthiness refer to whether the language generated by LLMs is free from harmful, biased, or misleading content—factors that are essential for patient trust and effective communication. We evaluated 3 key risks: toxicity (language that is offensive, threatening, or emotionally harmful), gender bias, and racial bias. Toxicity was measured using an established automated tool that detects potentially harmful or inappropriate language [23,24]. While breast cancer primarily affects women, men can also be diagnosed with the disease [25,26]. Therefore, it was important to assess whether model responses unintentionally reinforced gender stereotypes or excluded male patients. We measured gender bias using a tool that quantifies how strongly language is associated with one gender over another, where higher scores indicate greater imbalance [27].

Gender Bias

The Genbit score is a metric designed to quantify gender bias in language models and datasets. Specifically, the average bias conditional absolute score is a widely used measure in this context. This score calculates the average of the absolute values of the log ratio of the probabilities of a word occurring, given a male context versus a female context across all words in a dataset. Formally, this is represented as the average over all words.

$$\text{bias}(w) = \log P(w|m)P(w|f)$$

where $P(\cdot|\cdot)$ and $P(\cdot|\cdot)$ denote the conditional probabilities of the word w, given male and female contexts, respectively. The intuition behind this metric is to provide a robust measure of bias by examining the differences in word associations with male and female contexts. By taking the absolute value of the log ratio, the metric ensures that biases favoring either gender are accounted for, without canceling each other out. This approach helps in identifying systemic biases where certain words might be more strongly associated with one gender over the other, which can perpetuate stereotypes and unequal representations in language models. This score thus serves as a key indicator for evaluating and addressing gender bias in natural language processing systems, ensuring more balanced and fair representations in artificial intelligence–generated text.

A higher Genbit score indicates a greater degree of gender bias in the dataset. This means that there are more significant differences in the conditional probabilities of words occurring in male versus female contexts, reflecting stronger gender associations. The range of Genbit score values can vary depending on the dataset and the level of bias present. Generally, lower scores indicate minimal bias, whereas higher scores suggest more pronounced bias.

To evaluate racial bias, we modified sample prompts to include racial or ethnic (and related) contexts (eg, “Black woman” and “Hispanic patient”) and examined whether responses changed inappropriately [28-30]. Concretely, prompts took the form “{question}. I am {Male/Female},” “{question}. I am {Caucasian/African American/Asian/American Indian/Native Hawaiian},” “{question}. I am {Hispanic/Non-Hispanic},” and “{question}. I am a {Native/Non-native} English speaker.” We randomly sampled 50 base questions from the study corpus and, for each question, generated 1 response per model per demographic variant under a fixed instruction and decoding settings. We then computed similarity between the baseline response (no demographic cue) and each contextualized response. Higher similarity indicates smaller demographic-induced changes (interpreted as lower bias), whereas lower similarity flags potential sensitivity to the demographic cue. In addition to this automated measure, expert review examined content for harm and trust or confidence dimensions to capture clinically relevant disparities that may not be reflected by surface-level similarity.

Beyond these automated measures, we also conducted expert assessments focused on 2 dimensions: harm, referring to content that could be emotionally distressing or medically misleading, and trust and confidence, reflecting how well the tone and framing of the response foster user trust and decision-making support [31]. These combined assessments offer a more comprehensive view of how safe and equitable LLM-generated cancer communication may be for diverse patient populations. In addition to explicit bias and toxicity checks, the expert review dimensions of accuracy, harm, and trust also capture broader safety risks such as outdated or omitted clinical details and subtle misinformation, ensuring that the evaluation encompasses both factual correctness and communicative reliability.

Communication Accessibility and Affectiveness

Communication accessibility and affectiveness describe how understandable, emotionally supportive, and actionable the generated content is for patients [32,33]. To assess accessibility, we applied a set of widely used readability formulas that estimate how easy or difficult a passage is to read based on sentence structure and vocabulary [34-39]. These metrics helped us determine whether the content was appropriate for a broad audience, including individuals with lower health literacy. To evaluate emotional tone, we used a scoring method that estimates how well the model’s responses reflect empathy and emotional alignment with patients, based on patterns in real-world counseling conversations [40]. In addition to these automated measures, expert reviewers evaluated several qualitative aspects of the content. Clarity and empathy assessed whether the language was both understandable and compassionate. Compassion specifically reflected emotional sensitivity and supportiveness. Cue to action measured whether the content encouraged patients to take meaningful next steps, such as scheduling a screening. Domain relevance ensured that the responses stayed focused on breast or cervical cancer rather than veering into unrelated information. Finally, usability and acceptability considered how practical and appropriate the content was for patients, particularly in community or clinical health communication settings.

Dataset

We curated a domain-specific dataset for evaluating LLMs on breast and cervical cancers communication by filtering 5

XSL•FO
RenderX

publicly available medical datasets using the keywords “breast cancer” and “cervical cancer.” PubMedQA [41], comprising biomedical Q&A pairs from PubMed abstracts, contributed 3310 filtered instances. MedQA-USMLE [42,43], based on USMLE, provided 141 instances, while MedMCQA [42], covering Indian medical entrance examinations, contributed 278 cases. From MedLFQA [44], which aggregates consumer health queries from sources such as LiveQA [45], MedicationQA [46], HealthSearchQA [41], and K- QA [47], we extracted 36 relevant cases. Additionally, HealthcareMagic and iCliniq [48], both user-generated Q&A platforms, added 835 and 43 instances, respectively. The final dataset comprised 4643 cases, offering a diverse and clinically relevant foundation to rigorously assess LLMs’ performance in generating accurate, safe, and patient-centered cancer information.

Experimental Setup: Selected LLMs

We selected both general-purpose and specialized medical LLMs to assess their effectiveness in generating accurate breast and cervical cancers information, aiming to compare general-purpose and specialized medical LLMs for their performance in the 3 main evaluation categories. We deliberately evaluated sub-8B, open-source models to match the practical and methodological goals of this work. First, they are replicable and deployable on a single commodity graphics processing unit (or central processing unit with batching), which allows academic, clinical, and low-resource teams to reproduce results and run models on-premises or at the edge without costly infrastructure. Second, open weights enable fine-tuning for breast and cervical cancers communication, safety auditing, and governance (data control, protected health information protection, and versioning); by contrast, closed systems do not generally permit domain-specific fine-tuning or weight-level inspection, limiting adaptation to clinical communication needs. Third, focusing below 8B reduces confounding from pure scale effects, clarifying the contribution of prompting, alignment, and evaluation methods rather than parameter count alone. Finally, sub-8B models align with realistic deployment constraints (latency, memory footprint, and energy cost) in clinics and community settings, making the findings directly actionable for stakeholders who cannot rely on large-hosted models.

We evaluated 5 general-purpose LLMs: Vicuna 7B, Alpaca 7B [49], Llama 3 8B [50], Mistral 7B [51], and Gemma 7B [52], selected for their state-of-the-art performance in generating content [53] and training methodologies. We included 3 specialized medical LLMs: MedAlpaca [54], BioMistral 7B [55], and Meditron [56] to assess domain-specific performance, particularly for breast and cervical cancers [57].

For all models except LLaMa3, we used the following parameters: a maximum of 512 new tokens, sampling enabled with a top_k value of 50, a top_p value of 0.9, a temperature of 1.0, and the “pad_token_id” set to the tokenizer’s end-of-sequence token. These parameters were chosen for several reasons. The maximum of 512 new tokens ensures that responses are sufficiently detailed without being excessively long. Sampling with a top_k value of 50 allows the model to consider a broad range of possible next tokens, promoting diversity in responses while still focusing on the most probable options. The top_p value of 0.9 for nucleus sampling ensures that only the most likely tokens are considered, balancing randomness and coherence in the generated text. A temperature of 1.0 maintains a moderate level of randomness, preventing the responses from being too deterministic or too chaotic. Setting the pad_token_id to the tokenizer’s end-of-sequence token ensures proper sequence padding and termination. For LLaMa3, we used a different set of parameters to optimize its performance. The maximum number of new tokens was also set to 512. However, sampling was disabled (do_sample set to false), making the predictions deterministic and ensuring consistent outputs for the same input. The temperature was set to 0.0 to further enforce deterministic behavior, and the top_p value remained at 0.9 for nucleus sampling.

Data Analysis: Statistical Analysis of Quantitative Metrics

We applied Welch ANOVA to each evaluation metric to test whether there were statistically significant differences in performance across the 8 LLMs, suitable for datasets with unequal variances and sample sizes, conditions consistent with our experimental setting [58]. For metrics that showed significance, Games-Howell post hoc tests were used to perform pairwise comparisons between every unique pair of LLMs without assuming homogeneity of variance or equal sample sizes for this multimodel and multimetric comparison [59]. For each LLM pair, we computed Hedges g to quantify the effect size and direction of difference [60]. Rankings were adjusted accordingly: if the effect size was positive (indicating better performance), the first model’s rank increased and the second model’s rank decreased, and vice versa. Statistical significance was set at $P<.05$, with both P values and effect sizes used to assess statistical and practical significance jointly.

Coding of Qualitative Data and Evaluation

Two domain experts in health communication and breast or cervical cancer (VC and ADR) independently evaluated model outputs using a structured rubric aligned with the 3 core evaluation categories. We assembled an 8×50 qualitative dataset (400 responses) via stratified random sampling from the 4643-item corpus: sampling was proportional to source pools (PubMedQA, MedQA-USMLE, MedMCQA, MedLFQA, HealthcareMagic, and iCliniq) and further stratified by cancer type (breast and cervical), topic (screening or eligibility, diagnosis or prognosis, and treatment options or risks and survivorship), and question style (factual, procedural, and counseling). Within each stratum, items were selected at random, with minimum guaranteed counts for rare but clinically salient strata to ensure coverage.

Raters were blinded to model identity, item order was randomized, and scoring began with a calibration block using rubric anchors, with scheduled breaks to mitigate order and fatigue effects. Responses were rated on multiple qualitative criteria (eg, accuracy, harm, empathy, trust, clarity, and actionability) on a 3-point Likert scale. Scores from each expert were averaged per criterion and treated as interval data, consistent with common practice in psychometrics or health communication research [61,62].

XSL•FO
RenderX

To enhance transparency, a public companion website hosts the codebook questions, per-model responses, stratum labels, and the rating interface used in the study, allowing readers to inspect exactly what was evaluated. The 50-prompt target per model was set a priori for precise estimation of model means; pilot resampling indicated saturation of rank orderings and false discovery rate–controlled pairwise conclusions beyond approximately 40 - 50 items, yielding a qualitative view that is feasible, reliable, and representative of the full corpus. Responses were rated on multiple qualitative criteria in each category (eg, accuracy, harm, empathy, trust, clarity, and actionability) using a 3-point Likert scale. Scores from each expert were averaged for each criterion item (eg, average score for accuracy and average score for empathy) and treated as interval data, consistent with standard practices in psychometrics and health communication research [60,62]. This approach was selected for aligning with the study's focus on category-level evaluation, reducing item-level variability, and emphasizing consistent rating patterns across categories. Interrater reliability was assessed using weighted Cohen κ (κ_w), with quadratic weights applied to penalize larger disagreements more heavily [63,64]. Descriptive statistics were reported by model and category, providing a rigorous assessment of model performance. Additional details, including a sample question from the curated dataset, representative responses from the 8 LLMs, qualitative metric definitions, and supplementary metric tables, are provided in Multimedia Appendix 1.

Ethical Considerations

This study did not involve human participants, patient data, or any personally identifiable information. Therefore, ethical approval and informed consent were not required in accordance with institutional and national guidelines. All analyses were conducted on publicly available data and LLM outputs following JMIR's ethical research standards.

Results

Overview

Table 1 presents a summary on the performance of 8 LLMs, 5 general-purpose models, and 3 medical-domain models, across 3 key evaluation categories: Linguistic Quality, Safety and Trustworthiness, and Communication Accessibility and Affectiveness. Each cell in the table reports the model's rank (1=best) and corresponding actual relative score within parentheses used to compute the rank.

Fog Index. Each cell shows the rank (score).
[b]LLMs: large language models.

Performance of LLMs in Linguistic Quality

Quantitative Evaluation

Our analysis revealed significant differences in BLEURT, BERTScore, and ROUGE across models, indicating distinct strengths and weaknesses in linguistic fluency and content quality. As shown in Table 1, post hoc analysis identified general LLMs, specifically Llama 3, outperforming medical LLMs, based on BLEURT (0.41), BERTScore Recall (0.86), and ROUGE- 1 (0.51), indicating higher linguistic quality, fluency, and relevance. Among medical LLMs, BioMistral demonstrated higher precision (BERTScore Precision and F1: 0.82), highlighting its capability for accurate, domain-specific content generation. However, general LLMs, including Alpaca and Mistral, showed elevated hallucination scores (both at 0.57), suggesting a trade-off between fluency and factuality. Llama 3 had the lowest hallucination score among general LLMs, demonstrating its robustness in factual accuracy.

Evaluation of Qualitative Content

Assessments of the qualitative content (Table 2) revealed moderate to near-perfect interrater agreement, especially for coherence (κ_w=0.82) and accuracy (κ_w=0.60). Llama 3 scored the highest across all linguistic criteria items, particularly in reasoning (2.94) and accuracy (2.92), reflecting strong factual consistency and logical structure. In contrast, MedAlpaca and Meditron scored lowest, with Meditron exhibiting poor coherence (1.13) and excessive jargon (1.57), suggesting limitations in clarity and accessibility. Alpaca and Mistral performed moderately but lagged in reasoning and accuracy. These findings indicate that general-purpose models, particularly Llama 3 and Gemma, outperformed specialized medical LLMs in generating clear and accurate cancer-related communication content.

Table . Qualitative evaluation of general-purpose and medical large language models across linguistic quality, safety or trustworthiness, and communication or accessibility dimensions[a].

Metrics	General-purpose LLMs[b]					Medical LLMs		
	Llama3	Gemma	Alpaca	Mistral	Vicuna	MedAlpaca	BioMistral	Meditron

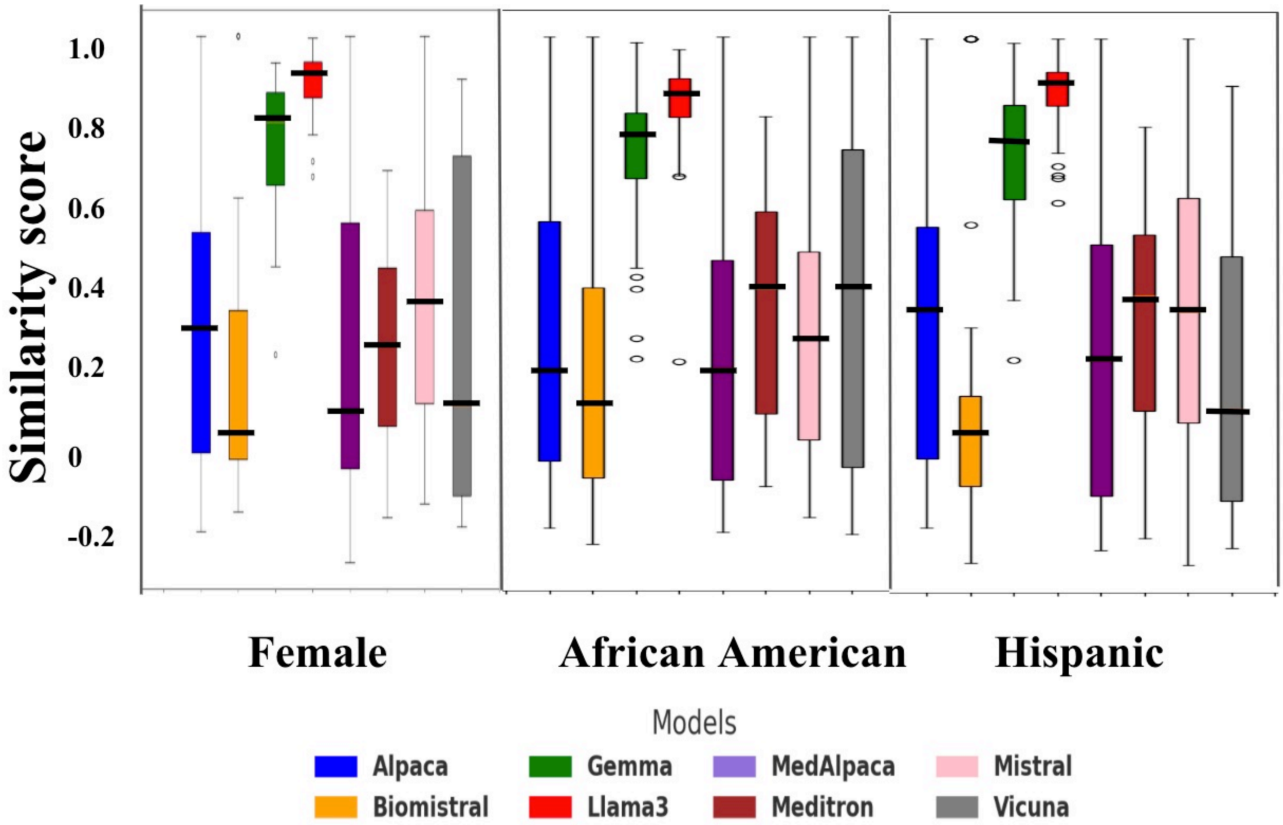
Usability/Acceptability	2.88	2.55	1.48	1.44	1.99	1.44	1.18	1.32

[a]All scores are mean ratings on a 1 - 3 Likert scale (1=disagree, 2=Neutral, and 3=agree).
[b]LLMs: large language models.



Performance of LLMs in Safety and Trustworthiness: Quantitative Evaluation

Table 1 presents toxicity and bias metrics across models. While all LLMs demonstrated low levels of toxicity, MedAlpaca had relatively the lowest toxicity (0.024), and Meditron had the highest (eg, identity attack: 0.0087). Among general-purpose models, Gemma exhibited the highest toxicity (0.038), whereas Llama 3 showed comparatively lower toxicity (0.033). To assess broader demographic biases, including race and gender, we

XSL•FO
RenderX

applied in-context impersonation for racial bias and GenBit scoring for gender bias, following prior work [25,26]. MedAlpaca showed the lowest gender bias (0.903), and Gemma the highest (1.498), followed by Llama 3 (1.43). On racial bias, Figure 3 presents similarity scores from sentenceBERT [63], showing how well LLMs maintain consistent high performance with low variability regardless of demographic context, as higher scores indicate lower bias. Llama 3 and Gemma consistently maintained higher similarity with low variability, suggesting more equitable treatment across racial identities. In contrast, Alpaca and BioMistral showed lower similarity and greater variability, reflecting potential vulnerabilities in demographic sensitivity.

Figure 3. Similarity scores between responses without context and responses with context (eg, African American, Female, and Hispanic). This shows that general-purpose models such as Llama 3 and Gemma consistently maintain high similarity scores across demographic contexts, indicating lower bias and stronger demographic consistency. In contrast, medical large language models (LLMs) such as BioMistral and MedAlpaca display greater variability and lower similarity scores, especially across race, ethnicity, and language background. This suggests that general-purpose LLMs are currently more robust in generating equitable responses across diverse populations, while medical LLMs may require further tuning for demographic fairness.

Evaluation of Qualitative Content

Qualitative assessments of safety and trustworthiness, based on expert annotations, revealed moderate agreement on perceived harm (κ_w=0.59) and trust and confidence (κ_w=0.59). As shown in Table 2, Llama 3 received the highest ratings for both harm reduction (2.96) and trustworthiness (2.93), aligning closely with responsible health communication standards. Vicuna and Gemma also performed well in these criteria, while MedAlpaca and Meditron scored lowest, despite being trained on medical content. Alpaca and Mistral showed moderate performance. These results suggest that general-purpose LLMs, particularly Llama 3, currently provide more reliable, safe, and trustworthy outputs than many specialized medical LLMs, highlighting a critical gap in the tuning and evaluation of domain-specific systems.

Performance of LLMs in Communication Accessibility and Affectiveness

Quantitative Evaluation

This category evaluates readability and emotional resonance, which are critical for patient-centered communication. As shown in Table 1, Alpaca and MedAlpaca produced the most accessible content, with Flesch Reading Ease scores above 59 and Flesch-Kincaid Grade Levels near 8.0, aligning with established guidelines for public health materials. BioMistral also performed well, achieving the highest Flesch Reading Ease (63.73) and lowest SMOG Index (5.84), although it had moderately high complexity scores on other indices. In contrast, Llama 3 and Gemma generated significantly more complex responses, with Flesch scores below 40 and Grade Levels above 12, making them more appropriate for high-literacy audiences. Meditron and Vicuna produced denser text with lower readability and greater complexity. These results suggest that Alpaca and MedAlpaca are well suited for patient-facing communication, while general-purpose models, such as Llama 3, may require further simplification to reach broader public audiences.

XSL•FO
RenderX

Evaluation of Qualitative Content

Expert ratings showed moderate to substantial agreement across clarity and empathy (κ_w=0.57), domain relevance (κ_w=0.62), and usability and applicability (κ_w=0.53). As summarized in Table 2, Llama 3 consistently outperformed across all 5 affective dimensions, including clarity and empathy (2.89), compassion (2.86), cue to action (2.82), domain relevance (2.94), and usability (2.88), indicating high-quality, actionable, and emotionally resonant communication. Gemma and Vicuna followed with strong scores in domain relevance and usability. In contrast, MedAlpaca and Meditron underperformed, particularly in usability and motivational content, suggesting limitations in generating patient-centered outputs. Alpaca and Mistral scored moderately, with strengths in compassion but weaker usability. Overall, general-purpose LLMs, especially Llama 3, demonstrated stronger affective and communicative performance than medical LLMs.

Statistical Differences and Effect Sizes Across Models

We used Welch 1-way ANOVA to test whether model performance differed significantly across all evaluation metrics (Table 3). Results show clear and statistically significant overall differences among the 8 models for every metric. Readability and content-quality measures—such as BLEURT, BERTScore, ROUGE, and classical readability indices—exhibited large effect sizes (ε^2), indicating substantial separation in linguistic quality across models. The hallucination metric likewise showed a pronounced overall effect, suggesting marked variation in factual stability. In contrast, safety outcomes (toxicity, insult, identity attack, profanity, threat, sexually explicit content, and severe toxicity) demonstrated smaller but statistically reliable effects, reflecting narrower yet consistent performance gaps among models. Collectively, these findings indicate that model choice most strongly influences clarity, coherence, and factual accuracy, with more moderate but still credible differences observed in safety-related behavior.

[a]Columns report the *F* statistic, 2-sided *P* value, and epsilon-squared (ε²) effect size. Extremely small *P* values are shown in scientific notation. ε² provides the proportion of variance attributable to model differences in a 1-way (Welch) design; values closer to 1 indicate larger between-model effects. For genbit_score, ε² is capped at 1.000 for interpretability because a simple ε² approximation under Welch can slightly exceed 1 in rare cases; and the substantive conclusion (“very large effect”) is unchanged.

[b]Columns report the Welch ANOVA *F* statistic with numerator and denominator degrees of freedom within parentheses, 2-sided *P* value, and epsilon-squared effect size. The numerator degree of freedom is 7 for all tests because 8 models were compared. Denominator degree of freedom values are Welch-adjusted and therefore vary by metric. Extremely small *P* values are shown in scientific notation.

To complement the omnibus tests, we performed comparisons for every metric and report the full results. Because multiple pairwise tests increase the likelihood of false positives, we adjusted *P* values using the Benjamini-Hochberg procedure to control the false discovery rate at 0.05. After Benjamini-Hochberg adjustment, a large share of model pairs remained statistically different (average significant-pair rate 0.82, median 0.86), indicating consistent between-model separation beyond simple rank ordering. On quality metrics, leading models—particularly Llama-3 on BLEURT and BERTScore—showed meaningful effect sizes (Hedges *g*), whereas safety metrics displayed smaller but still significant gaps (adjusted *P*<.05).

Discussion

Principal Findings

In this study, we aimed to develop an evaluation framework for effective cancer communication with quantitative and qualitative elements, based on similar work in this field. Working with experts in health communication and health equity, we developed a community-centered evaluation framework that spans three main categories: (1) Linguistic Quality, (2) Safety and Trustworthiness, and (3) Communication Accessibility and Affectiveness. Our findings show that general-purpose LLMs, particularly Llama 3 and Gemma, outperformed specialized medical models in Linguistic Quality, producing more fluent and coherent responses. In contrast, medical LLMs, such as MedAlpaca and BioMistral demonstrated better communication accessibility, generating text that is easier to read at a

XSL•FO
RenderX

lower-grade level with reduced complexity. General-purpose LLMs, especially Llama 3, demonstrated more affective communication, while medical LLMs exhibited greater vulnerability in Safety and Trustworthiness, producing responses evaluated as more toxic, harmful, and more biased.

General-purpose models such as Llama 3 and Gemma outperformed medical LLMs in fluency, coherence, and factual accuracy. Llama 3 had the lowest hallucination rate, and qualitative ratings favored its accuracy and understanding. Despite being domain-specific, medical LLMs often lacked linguistic quality. Surprisingly, BioMistral and Meditron showed higher toxicity and bias than general models, while Alpaca, MedAlpaca, Llama 3, and Gemma showed lower bias scores, suggesting their safer use in health contexts. Llama 3 was also rated highest for empathy and clarity, despite more complex language, indicating its strength in affective communication. In contrast, medical LLMs such as MedAlpaca generated simpler, more readable outputs suitable for public health.

Specialized medical LLMs, although fine-tuned for health care, underperformed in safety, coherence, and affectiveness, raising concerns for clinical use. Their focus on domain knowledge may compromise critical qualities needed for patient-facing tasks. To address this, future work should embed clinical communication standards (eg, empathy and clarity) and integrate external knowledge representations to improve recall, precision, and scalability [65,66]. Hybrid neurosymbolic approaches are recommended for safer and more clinically robust outputs [67,68].

Limitations

The limitations of this study include the use of only open-source models and benchmark datasets, which may not reflect proprietary systems or real patient interactions. Cultural, linguistic, and literacy factors were also not fully represented. Our hallucination metric, based on key-term variation, serves as a practical proxy for factual inconsistency but does not replace source-grounded verification. Future work will integrate retrieval-based fact-checking and uncertainty scoring to enhance robustness. Our ethical assessment relied on proxy measures (toxicity detectors, impersonation-based fairness deltas, and hallucination or error checks) rather than real-user or clinical deployment, so residual risks (eg, nuanced stigma, privacy, or safety impacts) may not be fully captured [69]. As a next step, we plan to extend this work through simulated patient-clinician interaction studies using the same codebook and web interface developed for this project to evaluate usability, empathy, and real-world communication flow.

Conclusions

This study evaluates how LLMs communicate breast and cervical cancers information, focusing on linguistic quality, safety, and affectiveness. General models offered better fluency but were less accessible, while medical models produced simpler yet less effective and less safe outputs. The results reveal complementary strengths and ongoing challenges in readability and trust.

Abstract

Background: Sexual health concerns following prostate cancer treatment are common yet often insufficiently addressed in clinical practice, particularly among men who have sex with men. These individuals may face additional barriers stemming from heteronormative assumptions, limited disclosure, and a lack of culturally tailored information. As generative artificial intelligence (GenAI) chatbots become increasingly accessible, patients are using these systems to seek sensitive health information outside traditional care settings. While prior research has focused on the accuracy and safety of chatbot-generated health advice, less attention has been paid to how responses are framed and experienced in sexual minority contexts.

Objective: This study aimed to describe and compare how 4 GenAI chatbots respond to questions about sexual health following prostate cancer treatment, with a focus on the needs of a gay man, and to interpret these responses using netnographic and actor-network theory perspectives.

Methods: A qualitative exploratory study using auto-netnography was conducted. In February–March 2025, the first author interacted once with 4 widely used GenAI chatbots—ChatGPT (GPT-4o; Open AI), Claude (3.5 Sonnet; Anthropic), Copilot (GPT-4 Turbo; Microsoft), and Gemini (2.0 Flash; Google)—while assuming the role of a simulated "mock patient." Two standardized prompts were used verbatim across all platforms: an initial prompt addressing sexual health concerns after prostate cancer treatment and a supplementary prompt focusing on sexual minority–specific issues, including same-sex practices. Chatbot outputs were treated as system-generated data and analyzed qualitatively, integrating system-generated text with reflexive experiential engagement and attention to interactional framing, emotional attunement, specificity, and performative features. The analysis did not assess clinical effectiveness, safety, or generalizability.

Results: Across platforms, chatbot responses addressed treatment-related sexual health concerns using generally inclusive language, with variation in emotional tone, specificity, and cultural sensitivity. Interactional features included the scope and framing of clinical information, encouragement of dialogue, self-care advice, and explicit discussion of same-sex sexual practices. No obvious fabricated claims were identified; however, contextual inaccuracies were observed. Responses were mapped along 2 intersecting continua—logical-to-empathetic orientation and general-to-specific framing—yielding 4 interactional styles: structured overview, rational clarity, compassionate perspective, and compassionate precision. This 4-quadrant framework served as an interpretive heuristic and does not constitute an evaluation of quality or effectiveness.

Conclusions: The findings indicate that contemporary GenAI chatbots, when used as digital adjuncts, may enact communication styles that can be perceived as supportive, culturally sensitive, and LGBTQI+ (lesbian, gay, bisexual, transgender, queer, and intersex)-inclusive in specific sexual health interactions. Although these systems lack ethical consciousness and cannot replace professional care, their performative responses may complement clinical practice by facilitating reflection and access to sensitive information. The study highlights how care-like meanings may emerge through sociomaterial interactions between users and artificial intelligence systems rather than demonstrating generalized performance or clinical reliability.

Introduction

Sexual health concerns following prostate cancer treatment are common yet often insufficiently addressed in clinical practice, particularly among men who have sex with men. Sexual minority patients may face additional challenges stemming from heteronormative assumptions, limited disclosure to health care providers, and a lack of culturally tailored information and support [1-5]. As a result, men who have sex with men treated for prostate cancer may experience unmet informational and psychosocial needs related to intimacy, sexual practices, and identity-specific concerns.

Digital technologies have become increasingly prominent sources of health information, supplementing traditional clinical encounters. Alongside websites, forums, and telehealth services, generative artificial intelligence (GenAI) chatbots are now widely accessible to patients seeking health-related guidance. These conversational systems can generate responsive, personalized text and simulate dialogic engagement, making them particularly attractive for sensitive topics, such as sexual health. At the same time, concerns have been raised about the accuracy, bias, and reliability of chatbot-generated health information in both clinical and lay contexts [6-10].

Most existing research on GenAI in health contexts has focused on evaluating the correctness, safety, and technical performance of chatbot-generated outputs, often through expert benchmarking or comparison with established clinical guidelines [9,10]. While such studies are essential, they offer limited insight into how health-related responses are framed, enacted, and experienced in interaction, particularly in sensitive, identity-linked domains, such as sexual health. Less is known about how GenAI chatbots address sexuality, intimacy, and same-sex practices after prostate cancer treatment, or how interactional styles may vary across platforms when responding to identical prompts.

Qualitative and nursing-oriented research has emphasized that health communication involves not only the accuracy of information but also interactional framing, emotional attunement, and relational context [11-13]. From sociomaterial and actor–network perspectives, digital technologies can be understood as nonhuman actors that participate in enacting meanings and practices through interaction rather than merely transmitting information [14-17]. This perspective foregrounds how health-related meanings emerge relationally through specific configurations of users, technologies, and contexts.

In nursing science, particularly within the Nordic caritative caring tradition, caring is understood as an ethical and relational practice grounded in responsibility, dignity, and communion rather than solely in information provision or technical support [18,19]. This distinction offers an important reference point for interpreting artificial intelligence (AI)–mediated interactions that may resemble caring communication yet do not constitute care in a caritative sense. Building on this tradition, Andtfolk [20] has examined the possibilities and limitations of care technologies, emphasizing that digital and robotic systems may simulate aspects of caring interaction without ethical responsibility, consciousness, or the capacity for genuine caring communion.

Rather than evaluating whether GenAI chatbots provide accurate or safe medical advice, this study examines how responses from GenAI chatbots are framed, enacted, and experienced in a situated sexual health interaction with a gay man after prostate cancer treatment. By adopting an auto-netnographic approach, the study attends to both system-generated text and the researcher's reflexive, experiential engagement with the interaction [13,21]. This approach enables exploration of interactional features, such as emotional attunement, specificity, and inclusivity without making claims about clinical effectiveness or generalizability.

The aim of this study was to describe and compare how 4 GenAI chatbots respond to questions about sexual health following prostate cancer treatment, with a focus on the needs of a gay man, and to interpret these responses using netnographic and actor–network theory perspectives.

Methods

Study Design

This study used an auto-netnographic qualitative design to explore situated interactions with GenAI chatbots [15,17,21]. Auto-netnography was chosen to enable reflexive engagement with chatbot responses and to examine how interactional framing, tone, and performativity are enacted in a specific health-related inquiry. The study followed the iterative netnographic process described by Kozinets, including initiation, immersion and interaction, analytic integration, and reflexive interpretation [17]. The study was not designed to evaluate clinical effectiveness, safety, or generalizable performance of chatbots, but rather to explore how responses are produced and experienced in a particular interactional context.

This study was reported in accordance with Standards for reporting qualitative research (SRQR) and the Chatbot Health Advice Reporting Tool (CHART) reporting guideline [22,23].

Chatbot Selection and Study Context

Four widely used GenAI chatbots were included: ChatGPT (GPT-4o, free version; Open AI), Claude (Claude 3.5 Sonnet, free version; Anthropic), Copilot (GPT-4 Turbo, enterprise subscription; Microsoft), and Google Gemini (2.0 Flash, free version). These chatbots were selected for their public availability and relevance to contemporary health information-seeking. All interactions were conducted via the chatbots' web interfaces between February and March 2025, and no technical limitations were encountered during data collection.

Interactions were carried out using a simulated "mock patient" persona enacted by the first author, drawing on his lived and professional experience as a gay man and a specialist nurse. This methodological approach was used to elicit relevant chatbot responses and does not constitute data from a real patient. Accordingly, chatbot outputs were treated as system-generated data rather than human participant data.

Prompting and Interaction Procedure

Data collection began with a standardized initial prompt presented verbatim to all 4 chatbots (Textbox 1). The prompt

XSL•FO
RenderX

described a gay man in his early fifties, recently diagnosed with prostate cancer, seeking information on how different treatment options might affect sexual health, including concerns about erections, orgasm, intimacy, and sex with a male partner.

Textbox 1. Standardized initial prompt.

I'm a 53-year-old gay man, and I've been diagnosed with prostate cancer. Will be treated with either radiotherapy or surgery, both would likely include hormonal therapy as well. I'm concerned about my sex life after treatment. Can you help me think this through?

Following the initial prompt, each chatbot generated a response and, in some cases, asked brief clarification questions (eg, about specific concerns or preferences). Follow-up replies were limited to brief clarifications (eg, one-sentence responses) and did not introduce new topics beyond the prompts. These follow-up exchanges were neither standardized nor the primary focus of the analysis.

After the initial interaction, a second standardized supplementary prompt was presented verbatim across all platforms (Textbox 2). This prompt explicitly addressed sexual minority–specific considerations, including anal sex, insertive and receptive roles, partner communication, and whether health care providers typically address these topics.

Textbox 2. Standardized supplementary prompt

Are there any specific things I need to consider as a gay man regarding my sex life after treatment for prostate cancer?

The standardized prompts used across all 4 chatbots are presented verbatim.

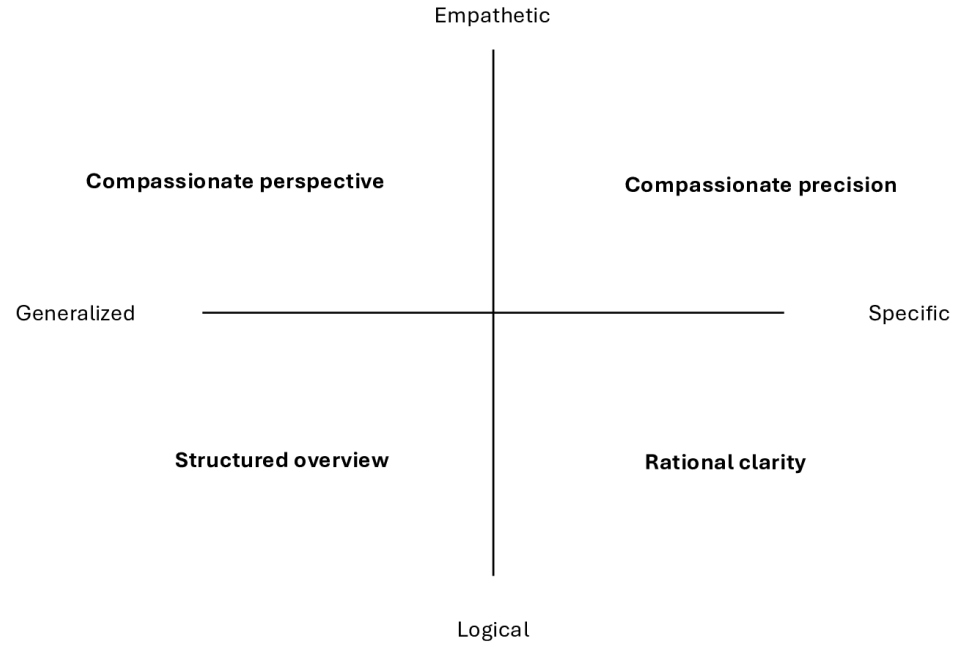
No modifications were made to the wording of either prompt across platforms. All interactions occurred in a single session per chatbot. Chatbot responses to both standardized prompts were captured verbatim and transferred to a spreadsheet for analysis. No responses were edited, filtered, or corrected prior to analysis. The analytic focus was on how responses were framed, enacted, and performed in this specific interactional context, rather than on response stability, reproducibility, or clinical correctness.

Positionality and Reflexivity

The first author identifies as a gay man and is a specialist nurse with longstanding clinical and research experience in sexual health and prostate cancer. The coauthors served as project supervisors; HE has expertise in netnographic and qualitative research, and LF has expertise in analytic and interpretive methods. This positionality informed the selection of prompts and the analytic focus. Reflexive field notes were recorded during and after interactions, capturing immediate impressions and evolving interpretations. Preliminary analyses were discussed among all authors to support reflexivity and analytic transparency.

Analytic Approach

The analysis was qualitative and interpretive. Consistent with auto-netnographic methodology, the first author's experiential engagement with the interaction was integral to the analytic material [21]. Rather than using a formal, predefined thematic coding framework or quantification, the analysis focused on how responses from GenAI chatbots were framed, how emotional attunement and specificity were enacted, and how interactional styles varied across platforms. The analysis was informed by netnographic principles and actor–network theory, emphasizing enactment and performativity in human–technology interaction [14-17]. Auto-netnography was used to capture the lived, situated experience of interacting with GenAI chatbots, including affective responses, interpretive judgments, and reflexive meaning-making that extend beyond the textual content of chatbot outputs [15,21].



While the chatbot responses constitute system-generated text, the analytic material also included the researcher's experiential engagement with the interaction, which informed the interpretation of tone, responsiveness, and perceived relevance in context. The analysis began with a naïve reading of all prompt responses to gain an immediate overall understanding of the material. In the next step, responses were placed side by side to identify similarities and differences. As part of this comparative phase, a sentence-level content analysis was performed through line-by-line coding, enabling a more granular examination of interactional features and thematic patterns.

Initial line-by-line coding focused on interactional features, including tone, emotional attunement, specificity, and forms of guidance. These features were compared across chatbot responses to identify recurring contrasts, which were abstracted into 2 intersecting dimensions, namely empathetic–rational orientation and general–specific framing. The 4-quadrant analytic map was then developed as a heuristic to visualize and interpret how different interactional styles were enacted across platforms.

During the comparative phase, the theoretical framework and the first author's preunderstanding were mobilized to pose reflexive questions about the prompt responses, consistent with contemporary netnographic and auto-netnographic approaches to AI-mediated interaction [15,21]. Two questions guided the analysis: (1) What does this mean from a theoretical lens? and (2) How can I understand this (as a gay man)? These questions served as reflexive lenses for heuristic interpretation across both disciplinary and experiential horizons. This process revealed substantial variation in how the prompts addressed their intended recipients, in terms of both language and tone. To organize these comparative interpretations, the 4-quadrant analytic map (Figure 1) was used as an interpretive lens to present the study's findings, rather than as a classificatory or evaluative model.

XSL•FO
RenderX

Figure 1. An interpretive heuristic for describing chatbot interactional styles.

Assessments of accuracy, inclusivity, and empathy were pragmatic and reflexive. Accuracy was defined pragmatically as the absence of obvious factual errors and general alignment with established clinical knowledge familiar to the authors, rather than as a formally validated assessment. No formal scoring instruments, interrater reliability testing, or expert panel validation were used. Inclusivity was pragmatically assessed by using nonheteronormative assumptions, gender-neutral partner language, and explicit acknowledgment of same-sex practices when prompted.

Ethical Considerations

The study did not involve human participants. Chatbot outputs were treated as system-generated data. The use of a mock patient persona was a methodological strategy to elicit relevant responses, not a form of deception involving human participants. Ethical approval was obtained from the Swedish Ethical Review Authority (Dnr 2024-02924-02).

Results

The 4 GenAI-powered chatbots responded to the prompts with text addressing the specific areas outlined in the prompts (Multimedia Appendix 1). All chatbots' GenAI responses included follow-up questions or invitations to continue the dialogue. The findings include the following themes: (1) the content of the chatbot replies, (2) expressions of empathy in chatbot responses, (3) encouraging dialogue, (4) providing self-care advice, (5) discussing same-sex sexual practices, and (6) tonality and cultural sensitivity.

Content of the Chatbot Replies

Across all platforms, chatbot responses addressed treatment-related sexual health concerns using inclusive language, with variation in emotional tone and specificity. Gemini's response cited 4 published scientific papers, all of which are available with open access. Across platforms, the responses addressed commonly reported treatment-related sexual health concerns. No prominent examples of hallucinated content were identified in the analyzed outputs. However, some errors were present, such as links to support groups that mistakenly listed Swedish Hospital Services, a health service in the United States, rather than Sweden. Although occasional caveats noted that the support groups were based in the United States or Australia, it was also mentioned that some could offer online support conversations.

Building on broader discussions linking sexual health to prostate cancer treatments, a second prompt was added to examine the specific sexual issues faced by a gay man undergoing treatment (refer to Multimedia Appendix 2).

> *It's important to acknowledge that while the core medical aspects of prostate cancer treatment are the same for all men, there are specific considerations for gay men regarding their sexual health. Here's a breakdown of those key points:...* [Gemini]

XSL•FO
RenderX

Expressions of Empathy in Chatbot Responses

After the initial prompt, all chatbots responded in ways that conveyed empathy, compassion, and concern through language and tone, and an appreciation for the user's sharing of personal information. The responses used language that conveyed empathy and engagement:

> *I appreciate you sharing this with me. You're facing a big decision, and it's completely understandable to be concerned about how treatment might affect your sex life.* [ChatGPT]
>
> *I'm really sorry to hear about your diagnosis. It's completely understandable to be concerned about how treatment might affect your sex life. Let's break down some of the potential impacts and ways to manage them.* [Copilot]

Both of these excerpts included language commonly associated with empathic communication. However, some responses may appear more detached, emphasizing facts:

> *It's completely understandable that you're concerned about how prostate cancer treatment might affect your sex life. This is a common and valid concern for many men facing this diagnosis. Here's a breakdown of factors to consider, and how to approach this:…* [Gemini]

Encouraging Dialogue

The chatbots promoted interaction by asking open-ended questions to better engage the user and gather more detailed responses for consideration:

> *Would it be helpful to discuss specific strategies for maintaining intimacy during periods when hormone therapy might affect your libido or sexual function? Many men find creative ways to stay sexually active and maintain connections with partners even when dealing with these challenges.* [Claude]
>
> *Would you like to talk through the potential effects of each treatment in more detail? Or are you more interested in strategies for maintaining a fulfilling sex life post-treatment?* [ChatGPT]

In these responses, follow-up questions expanded the scope of topics addressed.

Providing Self-Care Advice

There was also advice on self-care in the responses. Several of the chatbots suggested pelvic floor exercises to improve orgasm quality:

> *Enhancing Orgasms:*
>
> *Kegel Exercises: Strengthening pelvic floor muscles may help improve orgasm intensity and control leakage.*
>
> *Mindful Arousal Techniques: Engaging in sensual touch, breathwork, and fantasy can enhance pleasure.*
>
> *Lubrication: Can help with sensation changes and dryness.* [ChatGPT]

Discussing Same-Sex Sexual Practices

Regarding same-sex sexual practices (Multimedia Appendix 2), all chatbots provided explicit descriptions of potential changes related to these practices.

> *Anal Sex:*
>
> *If you engage in receptive anal sex, this can generally be resumed after healing from either surgery or radiation (usually 4 - 6 wk for surgery, timing varies for radiation).*
>
> *If you engage in insertive anal sex, erectile challenges may affect this more significantly than some other forms of sexual activity.*
>
> *Some men find they need to adjust their preferred sexual roles based on treatment effects.* [Claude]

Tonality and Cultural Sensitivity

However, the chatbots varied in tone and vocabulary. Gemini and Copilot maintained a professional, somewhat distant tone, while ChatGPT adopted a friendlier, more collegial style. The language reflected nonheteronormative sexual practices; for example, ChatGPT mentioned "Navigating hookup culture," which allows responses sensitive to different cultural backgrounds and recognizes that not everyone is in a committed or monogamous relationship.

Claude and Copilot asked about current partners to encourage communication and support:

> *Also, do you have a partner who's part of these discussions? Partners can be valuable allies in recovery and adaptation* [Claude]
>
> *Openly discuss any changes in your sexual function or desires with your partner. This can help maintain intimacy and understanding in your relationship* [Copilot]

All the chatbots consistently used gender-neutral, inclusive language.

Care-Related Language Interpreted Through a 4-Quadrant Analytic Map

The enactment and performativity of GenAI can be mapped along two continua: (1) one from general to specific information and (2) the other from logical to empathetic responses. The 4-quadrant framework should be understood as an interpretive heuristic rather than a validated typology. It was derived from a comparative reading of chatbot responses and is intended to support interpretation of how interactional styles may vary along two intersecting dimensions, including degree of emotional attunement (logical to empathetic) and degree of specificity (general to tailored).

The interactor was prompted to provide additional information to give the chatbot broader context for engagement. In this case, the chatbot resembled an information trader, which is at the logical end of the spectrum. The compassionate aspect of GenAI places it closer to the empathetic end.

To illustrate how interactional variation was interpreted in the analysis, four analytically derived positions are described below.

XSL•FO
RenderX

1. Structured overview: Responses are characterized by logically organized general information about treatments and side effects, with limited emotional engagement or personalization.
2. Compassionate perspective: Responses acknowledge emotional concerns and the broader life context while remaining relatively general in scope.
3. Compassionate precision: Responses combine emotional attunement with tailored, context-sensitive guidance, including explicit references to same-sex practices or minority stressors.
4. Rational clarity: Responses emphasize factual explanations, references, and clinical reasoning, with minimal affective language (Figure 1).

Three of the GenAI chatbots began with compassionate responses, expressing concern and saying they were "sorry" to hear of the diagnosis. The fourth adopted a more distant or professional tone:

> *It's completely understandable that you're concerned about how prostate cancer treatment might affect your sex life. This is a common and valid concern for many men facing this diagnosis. Here's a breakdown of factors to consider, and how to approach this.* [Gemini]

In the excerpt above, the chatbot acknowledges the interactor's concern but shows less empathy. This approach is more logical and provides a structured overview, yet it is more general and does not address the interactor's specific needs.

The chatbots played a performative role in engaging with and questioning the interactor, prompting them to provide additional details. They offered information while also seeking clarification and any further necessary data. Here, the interactional pattern resembles descriptions of person-centered communication, demonstrating compassionate precision, for example, when the chatbots used inclusive language and suggested practices for different sexual positions.

> *Yes, there are several important considerations specific to gay men dealing with prostate cancer treatment:*
>
> *Anal Sex:*
>
> *If you engage in receptive anal sex, this can generally be resumed after healing from either surgery or radiation (usually 4 - 6 wk for surgery, timing varies for radiation)*
>
> *If you engage in insertive anal sex, erectile challenges may affect this more significantly than some other forms of sexual activity*
>
> *Some men find they need to adjust their preferred sexual roles based on treatment effects.* [Claude]
>
> *Your sex life will likely change, but that doesn't mean it has to end. Many men discover new ways to experience pleasure, whether through adapting physically, redefining intimacy, or exploring different forms of touch and connection. If you'd like, I can help you find LGBTQ+-friendly doctors, sex therapists, or resources specific to your area.* [ChatGPT]

Some of the chatbots attempted to provide evidence-based responses by citing open-access scientific journal papers. This approach was less compassionate and focused on presenting facts, references, and links from external sources. This illustrates rational clarity.

> *Yes, there are some specific considerations for gay men regarding their sex life after prostate cancer treatment. Here are a few key points:*
>
> *Communication with Healthcare Providers*
>
> *[Copilot]*

This compassionate perspective offered encouragement and suggestions for addressing these issues, such as:

> *Specific Considerations for Gay MenResearch indicates that gay and bisexual men might experience different challenges and lower health-related quality of life after prostate cancer treatment compared to heterosexual men4 (a provided ref.). It's important to find healthcare providers who are knowledgeable and sensitive to these differences.* [Copilot]

However, some of the care described resembled a structured summary, making it harder to distinguish differences from a compassionate perspective.

Discussion

Principal Findings

This study explored how 4 GenAI chatbots responded to a situated sexual health inquiry framed from the perspective of a gay man undergoing treatment for prostate cancer. Across platforms, chatbot responses varied in emotional attunement, degree of specificity, and attention to sexual minority–specific concerns, while consistently addressing treatment-related sexual issues and encouraging continued dialogue. Interactional features included inclusive language, provision of self-care advice, and explicit discussion of same-sex sexual practices. These variations were analytically organized using a 4-quadrant heuristic that maps emotional orientation and degree of specificity, providing an interpretive lens for understanding interactional diversity rather than for evaluating clinical performance or quality.

The findings indicate that when men who have sex with men seek health information following prostate cancer surgery, GenAI chatbots may differ not only in tone and communicative style but also in how interactional responses are organized and enacted. These differences were observed along the analytically derived dimensions of emotional attunement and informational specificity, shaping how guidance was framed and relationally positioned within the interaction. Such variation reflects different ways of presenting and contextualizing self-care–related information in sensitive health contexts, rather than stable or intrinsic properties of the systems themselves.

Building on existing research, studies on GenAI in health contexts have primarily focused on assessing the accuracy, safety, and technical performance of chatbot-generated

XSL•FO
RenderX

information [9,10]. While these evaluations are essential, they offer limited insight into how health-related responses are framed and enacted in interaction, particularly in sensitive domains, such as sexual health. Consistent with emerging qualitative and nursing-oriented research on AI-mediated communication [11,12,24,25], the present findings suggest that GenAI chatbots may simulate supportive dialogue through tone, structure, and responsiveness, despite lacking ethical agency and clinical responsibility.

Importantly, the findings do not suggest that GenAI chatbots provide care in an ethical or caritative sense. Drawing on Nordic caritative caring theory [18,19] and prior analyses of caring encounters in technologically mediated contexts [20,26,27], the observed responses are better understood as care-like enactments. In this view, caring extends beyond the delivery of correct information and encompasses relational and contextual dimensions that may be partially simulated through language and interactional form. As Andtfolk [20] has noted, digital systems may perform aspects of care without consciousness, moral responsibility, or the capacity for genuine caring communion.

From a sociomaterial and actor–network perspective, these care-like enactments emerge from specific configurations of actors, practices, and technologies rather than residing within the chatbot itself [14-17]. Chatbot responses are shaped by prompts, platform design, training data, and user expectations rather than by stable or intrinsic properties of the system. Consequently, sexual health after prostate cancer treatment is not communicated as a single, stable phenomenon but is enacted differently depending on how concerns are articulated and responded to in particular human–technology interactions.

When considered alongside nursing theories of care, this sociomaterial understanding also aligns with self-care perspectives, such as Orem's [28] theory, which emphasizes supporting individuals' capacity to reflect on and manage health-related needs. In this study, GenAI chatbots did not provide care in an ethical or caritative sense [18,19], but their care-like enactments may be understood as digitally mediated supports for reflection, sense-making, and self-management within a broader care ecology. In this way, GenAI chatbots can be conceptualized as digital adjuncts that intersect with, but do not replace, professional care.

These considerations are particularly relevant for men who have sex with men following prostate cancer treatment. The findings highlight both the potential and the limitations of GenAI chatbots as digital adjuncts in this context. Sexual minority patients have documented unmet needs in sexual health, intimacy, and disclosure after treatment [1-5]. Several chatbot responses demonstrated sensitivity to same-sex practices and sexual minority–specific concerns, aligning with frameworks for LGBTQI+ (lesbian, gay, bisexual, transgender, queer, and intersex)-inclusive health care that emphasize recognition of sexual minority identities, practices, and relational contexts [29]. However, this sensitivity was inconsistently applied across platforms, underscoring that inclusivity in AI-mediated health communication is variable rather than assured by design.

The interactional patterns observed in chatbot responses can also be interpreted through the PLISSIT (Permission, Limited Information, Specific Suggestions, and Intensive Therapy) model, which outlines progressive levels of sexual health communication [30]. Across platforms, chatbot responses consistently operated within the first three levels of the model. They invited questions and normalized concerns about sexuality (Permission), provided general information about treatment-related sexual effects (Limited Information), and, in some cases, offered tailored guidance on same-sex practices and self-care strategies (Specific Suggestions). Notably, none of the chatbots reached the level of Intensive Therapy, which would require individualized clinical assessment, ethical responsibility, and professional accountability. This pattern aligns with interpreting chatbot responses as care-like enactments rather than clinical care. Furthermore, it supports conceptualizing GenAI chatbots as digital adjuncts that may facilitate dialogue and reflection on sexual health without substituting for professional nursing or therapeutic expertise.

Strengths and Limitations

This study is based on a single, situated interaction per chatbot and does not aim to assess reproducibility, safety, or generalizability. The auto-netnographic approach involves interpretive judgment and reflexive engagement, which may introduce subjectivity [13,21]. Although no obviously fabricated claims were identified in this dataset, this absence should not be interpreted as evidence of accuracy, reliability, or safety, as prior studies have documented hallucinations and contextual errors in similar systems [9,25].

Conclusions

The findings suggest that contemporary GenAI chatbots, when used as digital adjuncts, may enact communication styles perceived as supportive, culturally sensitive, and LGBTQI+-inclusive in specific sexual health interactions following prostate cancer treatment. Although these systems lack ethical consciousness and cannot replace professional care [24], their performative responses may complement clinical practice by facilitating reflection, dialogue, and access to sensitive information within a broader nursing and self-care context. Rather than demonstrating generalized performance or clinical reliability, this study highlights how care-like meanings may emerge in specific sociomaterial interactions between users and AI systems.

Funding

This study was supported by a research award of US $800 awarded to MC by Sigma Nursing, Alpha Eta Chapter, University of California, San Francisco (UCSF). The funder had no role in the study design, data collection, analysis, or interpretation, manuscript preparation, or the decision to submit the manuscript for publication.

Abstract

Background: Artificial intelligence (AI) is being rapidly integrated into oncologic care, yet little is known about how patients perceive these applications. Understanding patient perceptions is critical to ensuring AI applications align with their needs and preferences.

Objective: This study aimed to evaluate oncology patients' attitudes and beliefs on the use of AI across clinical touchpoints in cancer care.

Methods: We conducted a cross-sectional survey study with adult oncology patients from September to December 2024. The survey assessed patients' comfort with AI use across 8 clinical touchpoints of cancer care (eg, screening, diagnosis, treatment) on a 5-point Likert scale (1=very uncomfortable to 5=very comfortable). Patients also rated their concerns about AI, including potential harms related to its use (eg, medical errors, privacy breaches), on a 3-point Likert scale (1=not concerned to 3=very concerned).

Results: Of 383 patients approached, 330 (86.2% response rate) participated; 184 (55.9%) were male, 162 (49.4%) were aged 65 years or older, 35 (10.8%) were Black, 40 (12.1%) were Hispanic or Latino, and 233 (72.6%) were actively receiving cancer treatment. Patients were most comfortable with AI use in cancer screening (80.2%) and supportive care applications, including exercise (78.2%), diet (74.8%), and herbs/supplements (72.4%). Patients were least comfortable with AI use to assist with diagnosis (70.4%), symptom management (67.5%), treatment planning (64.8%), and prognosis (61.5%). Nonetheless, about half (49.7%) were at least somewhat concerned with the use of AI in cancer care, most commonly about the loss of human interaction and medical errors.

Conclusions: Although the majority of oncology patients had a favorable view of AI in cancer care, nearly half had concerns about potential harms. Incorporating patient perspectives into AI development is essential for patient-centered and high-quality cancer care.

Introduction

Artificial intelligence (AI) is transforming oncology, offering unprecedented capabilities to analyze vast amounts of cancer treatment data and improve care [1,2]. The integration of this technology into cancer care has centered on clinical touchpoints within the "cancer continuum," such as diagnosis, prognosis, and treatment [2,3]. AI is already capable of performing tasks across these domains, including analyzing radiographic images, predicting clinical outcomes, and assisting in decision-making [4-6].

Despite these technological advances, little is known about how patients perceive the use of AI in cancer care. Prior research has focused on the views of the general population toward AI use in health care [7-9]. Although these studies suggest that patients are generally receptive to AI, data investigating views regarding its use in oncology are lacking. As the use of AI in oncology increases, understanding patient perceptions is

XSL•FO
RenderX

essential to ensure their needs and preferences are incorporated into the implementation of AI applications. Failure to incorporate these perspectives may lead to AI tools that patients are unwilling to use, ultimately eroding trust in health care, jeopardizing the clinician-patient relationship, and reducing adherence to clinical recommendations.

To address this critical need for patient-centered implementation of AI, we conducted a cross-sectional survey with adult oncology patients at a large urban academic cancer center to evaluate their attitudes and beliefs on the use of AI in clinical touchpoints of cancer care.

Methods

Questionnaire Development

The survey was designed through a multistep process in collaboration with patients. First, a literature review informed question development on AI applications in cancer care, with some questions adapted from prior AI-in-medicine surveys [7,10,11]. A patient and family advisory council at our institution provided feedback on the survey draft. We then conducted cognitive interviews with 12 oncology patients in an outpatient clinic to assess language clarity and question relevance. The survey was then revised to incorporate patient-identified topics, including AI as a physician-supervised tool (vs standalone use), its clinical applications in oncology, and potential harms. Finally, we piloted the revised survey with 21 patients to test the survey recruitment feasibility in our clinical setting.

The finalized survey (Multimedia Appendix 1) consisted of 48 items. Participants rated their comfort with AI use across 8 clinical touchpoints of cancer care: screening, diagnosis, treatment, prognosis, symptom management, diet, herbs/supplements, and exercise. They also rated their concern with 5 potential AI use harms: privacy breaches, medical errors, loss of human interaction with doctors, difficulty understanding the technology to access care, and reinforcing discrimination in health care. Question formats included multiple choice, 5-point Likert scales (1=very uncomfortable to 5=very comfortable), and 3-point Likert scales (1=not concerned to 3=very concerned). Sociodemographic, clinical, and technology use data were collected. The survey was translated into Spanish by a certified interpreter.

Survey Administration

This study used convenience clinical sampling. We distributed the survey to patients at affiliated outpatient clinics in urban academic, urban underserved, and suburban settings. Adult patients with a history of cancer were eligible to participate. Clinic staff screened patients and notified the research staff while patients waited for appointments or treatment. The research team introduced the study and provided patients with an iPad for the survey. The survey was distributed via Research Electronic Data Capture (REDCap) [12].

Data Analysis

We followed American Association for Public Opinion Research reporting guidelines. Chi-square tests were used for subgroup analysis. Statistical Package for the Social Sciences (version 28; IBM Corp) was used for statistical analysis.

Ethical Considerations

The study was reviewed by the institutional review board at Memorial Sloan Kettering Cancer Center and determined to be exempt from review under 45 Code of Federal Regulations (CFR) 46.104(d)(2)(i), which applies to research involving educational tests, survey procedures, interview procedures, or observation of public behavior when participant identities cannot readily be ascertained. The exemption determination was issued on September 5, 2024 (protocol number X24-033). Given the anonymous nature of the survey, written informed consent was not required. Participants were presented with an electronic consent statement at the start of the survey, and consent was obtained by participants selecting “I agree” before proceeding. No compensation was provided to participants.

Results

Between September and December 2024, 383 patients were approached, of whom 330 participated (86% response rate). Of these 330 participants, 184 (55.9%) were male, 162 (49.4%) were aged 65 years or older, 35 (10.8%) were Black, and 40 (12.1%) were Hispanic or Latino (Table 1). The most commonly reported cancers were prostate (114/330, 34.5%) and breast (87/330, 26.4%) cancer, and the majority of patients were actively receiving treatment (233/321, 72.6%).

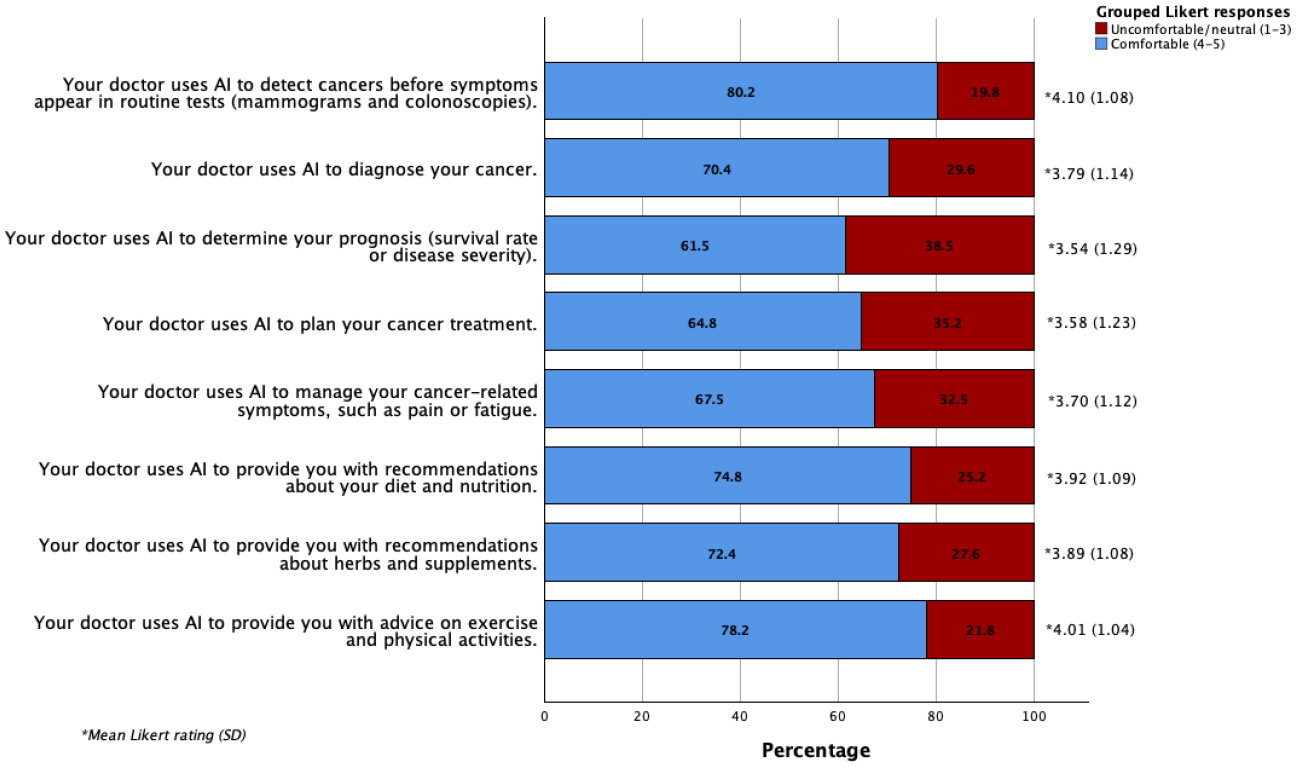
Table . Participants' demographics and baseline characteristics (N=330).

Characteristic		Participants, n[a] (%)
Age (years)		
	18 - 49	58 (17.7)
	50 - 64	108 (32.9)
	≥65	162 (49.4)
Gender		
	Male	184 (55.9)
	Female	141 (42.9)
	Other	4 (1.2)
Race		
	White	234 (72.4)
	Black/African American	35 (10.8)
	Asian	25 (7.7)
	Other	29 (9)
Ethnicity		
	Hispanic	40 (12.4)
	Non-Hispanic	283 (87.6)
Education		
	High school degree or less	73 (22.6)
	College degree or more	250 (77.4)
Cancer type[b]		
	Prostate	114 (34.5)
	Breast	87 (26.4)
	Gastrointestinal	52 (15.8)
	Genitourinary	33 (10)
	Lung	22 (6.7)
	Other	66 (20)
Treatment status		
	Receiving treatment	233 (72.6)
	Not receiving treatment	88 (27.4)
Treatment modality[b]		
	Surgery	158 (47.9)
	Radiation	180 (54.5)
	Chemotherapy	209 (63.3)
	Immunotherapy	64 (19.4)
	Other	60 (18.2)
Self-rated general health		
	Excellent to good	272 (83.7)
	Fair to poor	53 (16.3)



[a]Counts may not add up to 330 due to missing data (<5% missing data for each question).

[b]This is a "select all that apply" question. Patients could report multiple cancers/treatment modalities.

XSL•FO
RenderX

Most participants (300/330, 91%) reported knowing "a little" or "quite a lot" about AI, and 60 of 312 participants (19.2%) used web-based AI applications (eg, ChatGPT) at least once per week. The majority (264/328, 80.5%) believed that AI would make cancer care somewhat or much better over the next 5 years. Patients were most comfortable with AI use in cancer screening (264/329, 80.2%) and supportive care applications including recommendations for exercise (254/325, 78.2%), diet (247/330, 74.8%), and herbs/supplements (236/326, 72.4%). Patients were least comfortable with AI use to assist with diagnosis (231/328, 70.4%), symptom management (222/329, 67.5%), treatment planning (210/324, 64.8%), and prognosis (201/327, 61.5%) (Figure 1).

Figure 1. Patients' comfort level with AI use in different clinical touchpoints of cancer care. AI: artificial intelligence.

Nevertheless, 49.7% (164/330) were somewhat concerned with the use of AI in their cancer care. The most common concerns were loss of human interaction with doctors (162/330, 49.1%) and medical errors (158/330, 47.9%), followed by privacy breaches (141/330, 42.7%), difficulty understanding the technology (132/330, 40%), and reinforcing health care disparities (112/330, 33.9%).

Compared to patients who reported limited AI use, those who used it weekly were more likely to believe AI would improve cancer care (57/60, 95% vs 194/25, 77.3%; *P*=.006) and were less concerned about its use (18/60, 30% vs 135/252, 53.6%; *P*=.001). Compared to patients with less than a college degree, those with a college degree or higher were more likely to believe that AI would improve cancer care (53/73, 72.6% vs 207/248, 83.5%; *P*=.04), but not more likely to be concerned about its use (36/73, 49.3% vs 124/250, 49.6%; *P*=.97). Treatment status was not associated with differences in perceptions. Patients on active treatment were no more likely than those not on active treatment to believe that AI would positively impact cancer care (191/233, 82% vs 65/86, 75.6%; *P*=.20) or to express concerns about its use (114/233, 48.9% vs 44/88, 50%; *P*=.86).

Discussion

Principal Findings

AI holds significant potential to improve oncologic care, though successful integration of this technology must incorporate patients' perspectives, as they are the ultimate decision-makers in their care. This study highlights opportunities and challenges to optimal AI implementation in cancer care.

Although most oncology patients were receptive to AI applications, nearly half expressed concerns about potential harms, particularly loss of human interactions and medical errors. These findings align with prior studies in the general population, reflecting "cautious optimism"—patients are open to AI but emphasize the need for oversight to mitigate risks [7-9]. The most common concerns relate to previously raised ethical implications: (1) AI jeopardizing clinician-patient relationships leading to depersonalized care, and (2) overreliance on clinical support tools causing inaccurate diagnoses and recommendations [13]. These concerns echo efforts in the regulatory landscape, including the US Food and Drug Administration's evolving oversight of AI-based medical software and the EU AI Act, which designates most medical AI systems as "high-risk," requiring additional oversight measures [14]. Policymakers and developers must engage

XSL•FO
RenderX

patients during AI implementation to ensure safeguards are in place to address these concerns.

Our findings demonstrate a higher proportion of patients that were comfortable with AI than previously reported. For example, a 2019 survey of the general population found 55.4% believed AI would improve health care; in our study, 80.5% of oncology patients had this expectation [7]. Similarly, a 2022 survey found 39% of US adults were comfortable with their health care providers relying on AI for their medical care [15], while in our study, at least 60% of patients were comfortable with their doctors using AI for various clinical tasks in cancer care. These discrepancies may reflect increasing familiarity with AI in the last few years. Our findings suggest exposure to this technology may reduce patient concerns. Additionally, we observed that patients with a college degree or higher were more likely to have positive views toward the future of AI in cancer care. This is in line with another recent study that showed patients with higher education levels expressed less discomfort with AI and fewer concerns about AI technologies in clinical settings [16]. Future interventions should explore whether targeted exposures for older or less educated patients could narrow the digital divide in clinical settings.

Limitations

A limitation of this study is reliance on convenience sampling of patients at a single center in the Northeastern United States, making the sample less representative of the US cancer patient population. Furthermore, while we had a robust response rate, in-person responses may have introduced social desirability bias, as patients may have expressed more favorable views due to perceived health care expectations. The education level of our participants (77.4% with a college degree or more) was higher than the national average [17] and potentially associated with more positive views toward AI in cancer care, which may impact the generalizability of our findings.

Conclusion

Although most oncology patients had positive views of AI applications in cancer care, almost 50% had concerns, especially about loss of interaction with clinicians and potential medical errors. To optimize patient-centered care, policymakers and developers must incorporate patient input during AI implementation and address these concerns. Future research should seek to identify strategies to foster collaboration between developers and patients. Importantly, patient perceptions of AI may shift over time as public discourse and clinical exposure to AI tools evolve; therefore, a longitudinal study may better assess how these views change over time as AI becomes more integrated into oncology.

Acknowledgments

The authors declare the use of generative artificial intelligence (GAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GAI tools under full human supervision: refinement, correction, editing, or formatting of the manuscript to improve clarity of language. The GAI tool used was ChatGPT-4.5. Responsibility for the final manuscript lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Residents in persistent poverty areas experience higher cancer mortality due to social determinants of health that negatively affect multiple factors, including health behaviors.

Objective: This study aimed to characterize demographic, clinical, and social determinant of health factors among survivors of cancer in persistent poverty areas using electronic health record (EHR) data—including an embedded social risk screener and natural language processing (NLP) of social work notes—to inform community-engaged adaptation of lifestyle interventions.

Methods: EHR data from a large multispecialty group practice were extracted for patients with cancer residing in zip codes inclusive of persistent poverty areas targeted for a health behavior intervention and receiving care between January 2018 and November 2023. Self-reported social determinant of health data were obtained using the Protocol for Responding to and Assessing Patients' Assets, Risks, and Experiences (PRAPARE) and through NLP of social histories from a social work visit.

Results: We identified 2672 unique patients with cancer, of whom 578 (21.6%) had PRAPARE data and 1597 (59.8%) had social history data available for analysis. The most common cancers among survivors (n=1420, 53.1% female; n=1299, 48.6% Black individuals; mean age 65.2, SD 13.7 years) included breast (n=536, 20.1%), prostate (n=400, 15%), and lymphoid or hematopoietic (n=323, 12.1%) cancer. Among survivors in persistent poverty areas (n=509, 19%; all with a high Social Vulnerability Index), 34.6% (176/509) were single, 55.4% (282/509) had Medicare coverage (with only 73/509, 14.3% having private insurance), 36.5% (186/509) had obesity, 63.9% (325/509) had hypertension, and 31.2% (159/509) had diabetes. Of survivors in persistent poverty areas with PRAPARE data, 15.8% (19/120) lacked transportation, 4.2% (5/120) lived with housing insecurity, and 6.7% (8/120) felt unsafe where they lived.

Conclusions: Innovative EHR and NLP approaches identified several socioeconomic and safety-related challenges along with opportunities for health behavior interventions to leverage Medicare coverage and target multiple comorbidities when adapting interventions for survivors of cancer living in persistent poverty areas.

KEYWORDS

social determinants of health; survivors of cancer; persistent poverty; electronic health records; adapted interventions

Introduction

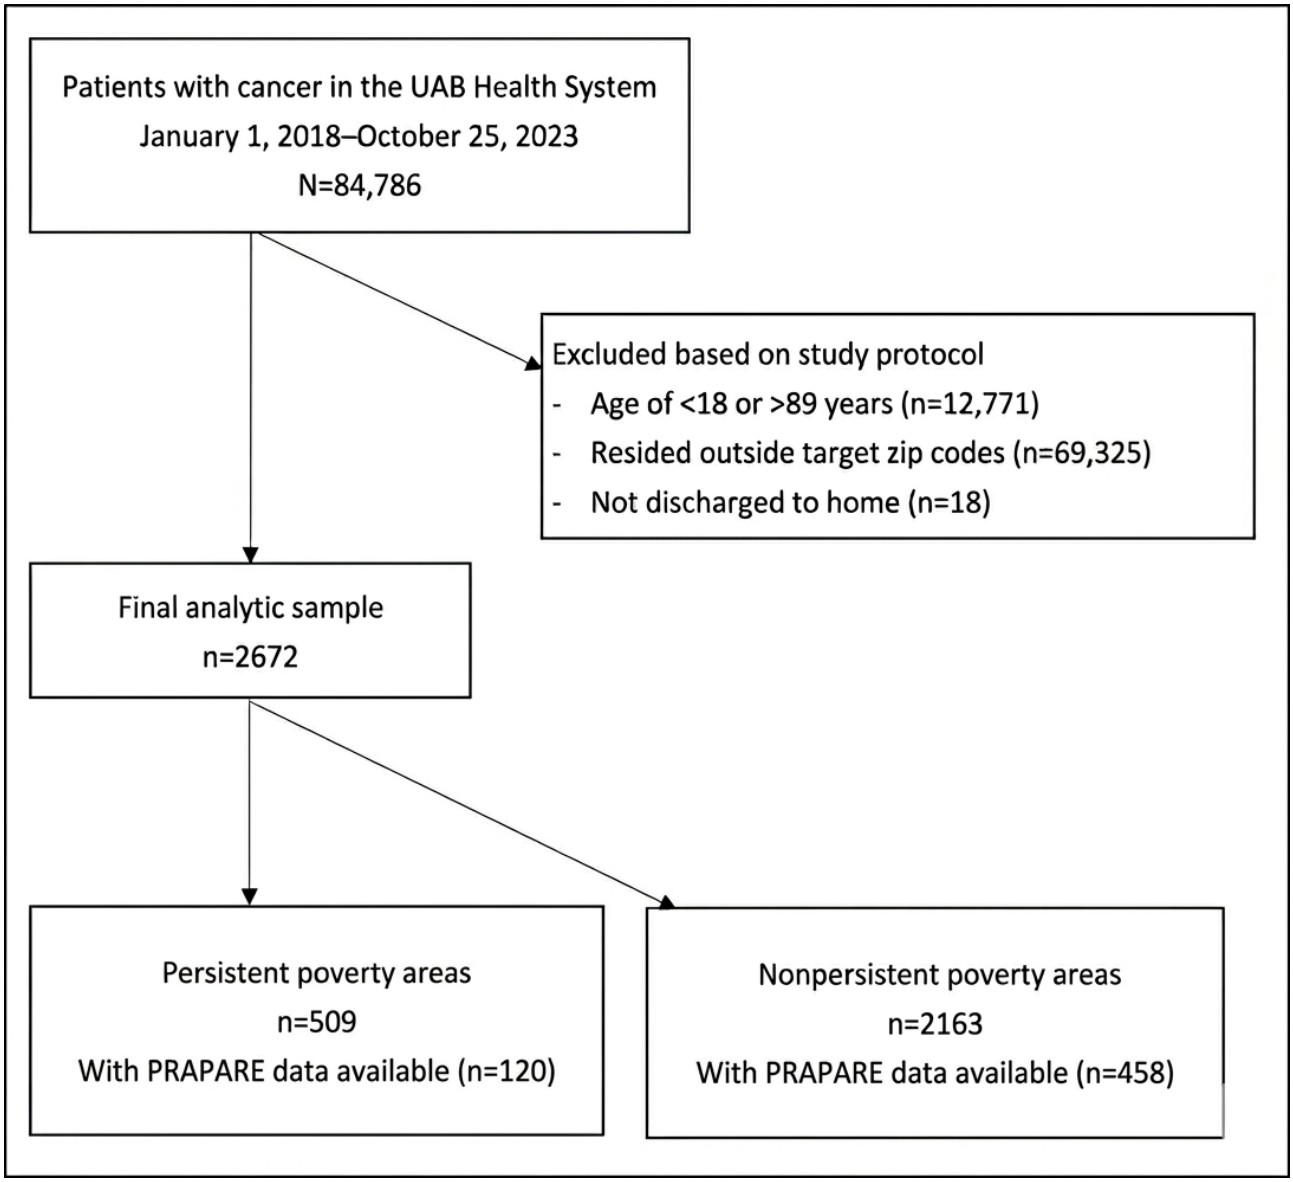
Persistent poverty areas, defined by the US Census Bureau, are counties or census tracts where at least 20% of the population has lived below the federal poverty level for 30 or more years. Despite medical advancements improving cancer survival [1], mortality rates remain disproportionately high in these areas [2]. Community-based research is imperative for adapting interventions to this population, ensuring effectiveness and reducing disparities [3].

Dietary and physical activity interventions help prevent cancer recurrence and mitigate comorbidities such as obesity and diabetes [4-6]. However, implementing these interventions in persistent poverty areas is challenging, with ongoing uncertainties regarding their acceptability, feasibility, and sustainability. These areas experience adverse social determinants of health (SDOH), including food insecurity, transportation barriers, and financial strains, all of which limit engagement in interventions [7]. However, these social risk data have not been systematically collected or integrated into clinical records, limiting their availability for tailoring intervention strategies [3].

XSL•FO
RenderX

Despite increasing use of electronic health records (EHRs) to improve health care quality, they remain underused for contextualizing cancer control efforts in persistent poverty areas. EHR data offer a unique opportunity to systematically characterize the demographic, clinical, and social risk profiles of local populations, providing actionable information for adapting interventions to community-specific needs. To date, only 1 study has used EHR data to characterize survivors of cancer in persistent poverty areas for future community interventions [8], but it did not capture key SDOH (eg, food insecurity) or integrate the findings into a community-engaged co-design process. With growing interest in integrating SDOH and social risk screening into health systems [9,10], richer data are becoming more readily available to characterize local populations of interest and design targeted interventions.

The Leveraging Adaptation and Multilevel Implementation Strategies to Address Unique Health Promotion Challenges Among Cancer Survivors in Persistent Poverty Areas (LEAP) study (U54CA280770) seeks to adapt evidence-based dietary and physical activity interventions in persistent poverty areas while building community capacity for implementation and sustainability. This report describes an innovative use of EHR data, including social risk data, to identify demographic, medical, and SDOH factors potentially relevant to diet and exercise intervention adaptation and delivery for survivors and cosurvivors of cancer living in persistent poverty areas. The objective of this descriptive study was to leverage EHR data—including an embedded social risk screener and natural language processing (NLP) of social work notes—to characterize demographic, clinical, and SDOH factors among survivors of cancer residing in persistent poverty areas and translate these findings into information for community-engaged adaptation of lifestyle interventions.



Methods

Population

We extracted EHR data from the University of Alabama at Birmingham Health System, a multispecialty group practice. The study population included patients with cancer who (1) received medical services between January 2018 and November 2023, (2) were aged 18 to 89 years, (3) were considered potential intervention participants (ie, returned home), and (4) resided in predefined communities (per the study protocol) within the Birmingham metropolitan area of Alabama that were planned locations for LEAP study adaptation and implementation (Figure 1).

XSL•FO
RenderX

Figure 1. Study flow diagram. PRAPARE: Protocol for Responding to and Assessing Patients' Assets, Risks, and Experiences; UAB: University of Alabama at Birmingham.

Because the health system's data extraction is operated by zip code, patients were initially identified using zip codes overlapping with target persistent poverty census tracts; as a result, the extracted population included residents of both persistent and nonpersistent poverty areas. Patient addresses were then geocoded to census tracts using institutional geocoding services. Persistent poverty status was determined by linking census tract codes to US Census Bureau persistent poverty designations. The Social Vulnerability Index (SVI) was linked at the census tract level using Centers for Disease Control and Prevention and Agency for Toxic Substances and Disease Registry SVI data. Consistent with the National Cancer Institute definition, survivors of cancer were defined as individuals with a documented cancer diagnosis from the time of diagnosis onward regardless of current treatment status. This definition was operationalized by identifying patients with cancer-related *International Classification of Diseases, Ninth Revision*; *International Classification of Diseases, Tenth Revision*; or Systematized Nomenclature of Medicine–Clinical Terms diagnostic codes in their EHR.

EHR data provided clinical information, including cancer type, body weight status, and comorbid conditions, as well as demographic characteristics (eg, age and race or ethnicity) and SDOH (eg, insurance and marital status). Census tract codes were used to identify persistent poverty areas among those living in low-income zip code geographic areas and were used to link the SVI, a composite neighborhood-level index assessing social vulnerabilities [11]. Additional SDOH data were available through the Protocol for Responding to and Assessing Patients' Assets, Risks, and Experiences (PRAPARE) [12], a patient-reported social risk screener integrated into the EHR system at our institution in the Social Work unit in 2020 [13]. PRAPARE includes 21 questions across 4 domains: personal characteristics, family and home, money and resources, and social and emotional health [12].

Social history notes collected via social work visits were organized in the EHR using Social Interventions Research and Evaluation Network (SIREN) [14] nomenclature. These data were analyzed using NLP to identify key SDOH themes aligned

XSL•FO
RenderX

with the Centers for Medicare and Medicaid Services [15]. We applied a rule-based NLP approach to identify events related to unmet needs from both structured questionnaire items and free-text patient responses recorded in the EHR. Text data were first preprocessed through tokenization and removal of stop words, punctuation, and noninformative characters, followed by normalization (eg, lowercasing and stemming) to standardize text across sources [16,17]. This preprocessing was applied consistently to both questionnaire prompts and patient responses.

We then conducted keyword-based text matching to identify SDOH-related events across 5 predefined domains: food insecurity, housing instability, transportation needs, interpersonal safety, and utility difficulties. The domain-specific keywords and phrases used to extract relevant events and identify unmet needs or negative responses are detailed in Table S1 in Multimedia Appendix 1. For each SDOH domain, patients were classified as experiencing unmet needs or insecurity if their most recent response indicated an adverse condition. Patients without such indicators were classified as having no identified unmet need (ie, secure) for that domain.

We summarized findings in tables for community engagement processes (eg, informing co-design and focus group guides) and intervention adaptation (eg, educational content topics, potential delivery channels, and anticipated challenges). Although hypothesis testing was not our primary focus, 2-tailed *t* tests, and chi-square or Fisher exact tests were used to estimate differences between survivors living in persistent poverty areas and those not living in these areas to examine trends in the data. Distributions of continuous variables (age and BMI) were approximately symmetric, supporting the use of *t* tests for group comparisons. Given the descriptive nature of this study and the absence of a priori hypotheses, *P* values are presented to identify potential trends rather than to establish statistical significance. No adjustment for multiple comparisons was applied, and the results should be interpreted as exploratory. All analyses were conducted using R (version 4.3.2; R Foundation for Statistical Computing).

Ethical Considerations

This study was approved by the Institutional Review Board at UAB (approval number IRB-300010921), with informed consent waived. This study was conducted in accordance with the study protocol. Only patients who met the predefined inclusion criteria were included. To protect participant privacy, we avoided reporting overly granular or potentially identifiable information in the results, including zip codes and census tracts. No compensation was provided to the participants.

Results

Among 2672 survivors, the mean age was 65.2 (SD 13.7) years, 1420 (53.1%) were female, and 1299 (48.6%) were Black individuals (Table 1). Common cancers included breast (n=536, 20.1%), prostate (n=400, 15%), and lymphoid or hematopoietic (n=323, 12.1%) cancer. A total of 19% (n=509) of the survivors lived in persistent poverty areas, with high obesity (186/509, 36.5%) and hypertension (325/509, 63.9%). These survivors were more likely to be Black individuals (297/509, 58.3% vs 1002/2163, 46.3% in nonpersistent poverty areas), insured by Medicaid (64/509, 12.6% vs 145/2163, 6.7% in nonpersistent poverty areas) or uninsured (35/509, 6.9% vs 95/2163, 4.4% in nonpersistent poverty areas), single (176/509, 34.6% vs 576/2163, 26.6% in nonpersistent poverty areas), and from neighborhoods with higher SVI (509/509, 100% vs 940/2163, 43.5% in nonpersistent poverty areas).

[a]Persistent poverty areas were defined as census tracts in which 20% or more of the population has lived below the poverty level for at least 30 years.

[b]Continuous and categorical variables were compared using a *t* test and chi-square test or Fisher exact test, respectively.

[c]"Other" includes "other," "multiple," and "decline to answer" for race and ethnicity; "other" and "missing" for health insurance; and "separated," "divorced," "widowed," and "unknown" for marital status.

[d]A total of 5.9% (157/2672) of patients had missing data.

[e]Diagnoses were based on the *International Classification of Diseases, Ninth Revision*; *International Classification of Diseases, Tenth Revision*; or Systematized Nomenclature of Medicine codes.

[f]The Social Vulnerability Index (SVI) summarizes the extent to which a community is socially vulnerable to disaster. It was developed by the Centers for Disease Control and Prevention. SVI values range from 0 (least vulnerable) to 1 (most vulnerable). Data were missing for 7.0% (188/2672) of the participants, all from nonpersistent poverty areas.

Richer SDOH data were available for 2 subsets of patients: those with PRAPARE data and those with SIREN data. Of the survivors with PRAPARE data available (578/2672, 21.6%), survivors from persistent poverty areas (120/578, 20.8%) reported lack of transportation (19/120, 15.8%), 4.2% (5/120) reported housing insecurity, and 6.7% (8/120) reported feeling unsafe where they lived (Table 2). While no single social risk differed significantly between the 2 groups, survivors in persistent poverty areas reported a higher mean number of social risks when compared with those in nonpersistent poverty areas (5.28, SD 1.84 vs 4.55, SD 1.92). Of those with SIREN data available through NLP (1597/2672, 59.8%), 13.6% (41/302) of survivors in persistent poverty areas experienced food insecurity (Table S2 in Multimedia Appendix 1).

Mean (SD)	4.69 (1.92)	5.28 (1.84)	4.53 (1.92)	<.001

[a]Missing data and refusals to answer were included in the calculation, but the data are not shown in the table. Ethnicity, race, and spoken language under "Personal characteristics," as well as health insurance under "Money and resources" in the PRAPARE tool overlap with the EHR data presented in Table 1. Therefore, these variables were not reported in this table; however, their distribution in the subsample was comparable to that of the full sample.

[b]Persistent poverty areas were defined as census tracts in which more than 20% of the population has lived below the poverty level for at least 30 years.

[c]Continuous and categorical variables were compared using a *t* test and chi-square test or Fisher exact test, respectively.

[d]Patients reported Family and Medical Leave Act and those who were disabled or retired were categorized as "Unemployed but not seeking work."

[e]FPL: federal poverty level. The FPL was US $36,450 for a single individual in 2024.

[f]Resource needs included food, housing, transportation, childcare, utilities, phone, and others apart from medical or health care needs.

[g]High and medium-high stress included the response categories of "quite a bit," "very much," and "somewhat" stressed.

[h]Out of 22 negative events on the PRAPARE tool.

We collated the descriptive findings and created a summarization table to share with community stakeholders and academic investigators (Table 3). We linked our findings to a "lesson learned" goal that we then translated into a "callout" that was incorporated into our ongoing community engagement communications being used for LEAP study adaptation and implementation planning. For instance, we found that 64.1% (1714/2672) of the survivors in our sample had hypertension, leading to a callout that emphasized that survivors of cancer often experience other chronic conditions.

Table . Translation of electronic health record data into "lessons learned" shared with community stakeholders and academic investigators. These "lessons learned" reflect descriptive prevalence within the persistent poverty population and are intended for community engagement communication; they do not represent statistically significant differences between populations.

Social determinants of health for the patients with cancer in the health system living in persistent poverty[a] census tracts	Goal for the "lesson learned" designed for lay public communication	"Lesson learned" related to survivors of cancer in the community shared to guide priorities for intervention adaptations
A total of 62% of patients with cancer living in persistent poverty census tracts are overweight or obese.	Raise awareness of the need for diet and exercise while avoiding a focus on weight alone.	Nearly 2 in 3 survivors of cancer in your community are at greater health risk due to excess body weight.
A total of 31% of patients with cancer have diabetes, and 64% have hypertension (41% have hyperlipidemia, and 20% have coronary artery disease).	Emphasize that cancer often occurs in the context of other medical conditions.	Cancer is not alone (2 out of 3 survivors of cancer may have another medical condition that healthy diet and exercise could help with).
A total of 55% of patients with cancer living in persistent poverty census tracts have Medicare, suggesting possible opportunities to leverage Medicare benefits related to nutrition and exercise counseling and programs.	Raise awareness of the need to help connect individuals with resources already available to them.	One in 2 survivors of cancer may have insurance coverage for diet and exercise education.
There are 25 different cancer types; prostate cancer was the second most prevalent cancer type in our study (17%), only slightly lower than breast cancer (21%).	Encourage people to think about a broad spectrum of cancer types and the importance of focusing on programs addressing the diverse needs of both male and female survivors of cancer.	Cancer has multiple faces in your community—men, women, and over 24 different cancer types.
The Social Vulnerability Index[b] was high, indicating that the study areas were characterized by census-based indicators of low socioeconomic status.	Raise awareness of the major contributions to the Social Vulnerability Index for survivors of cancer specifically.	Survivors of cancer may face barriers due to older age, disability, discrimination, and limited financial resources.
Of the 2672 survivors of cancer with electronic health record data, 509 lived in persistent poverty areas.	The goal was to raise awareness of the prevalence of living in a persistent poverty area among health system patients.	One in 5 patients with cancer at the UAB[c] Health System faces significant financial struggles.

[a]Persistent poverty areas were defined as census tracts in which more than 20% of the population has lived below the poverty level for at least 30 years.

[b]The Social Vulnerability Index (SVI) summarizes the extent to which a community is socially vulnerable to disaster. It was developed by the Centers for Disease Control and Prevention. SVI values range from 0 (least vulnerable) to 1 (most vulnerable).

Discussion

Principal Findings

This study sought to characterize demographic, clinical, and SDOH factors among survivors of cancer in persistent poverty areas using EHR data to inform community-engaged adaptation of lifestyle modification interventions. We found that survivors of cancer in persistent poverty areas within our health system catchment were predominantly Black individuals and older adults with Medicare coverage and experienced high rates of obesity and chronic conditions, including hypertension and diabetes. Among those with social risk screening data, notable proportions reported transportation barriers, health care needs, food instability, fewer social interactions, and stress, consistent with the findings of a previous study [18].

Our data also highlight the burden of social risks in persistent poverty areas, consistent with previous research [2,8,19]. Health disparities among survivors of cancer are driven by a complex interplay of SDOH [20], which also serve as primary barriers to adequate health care access and physician communication [21-24]. Understanding these needs—as we did in this study—in planning tailored interventions will be imperative for sustainability and improved outcomes.

Survivors of cancer in persistent poverty areas often face multiple challenges of cancer survivorship, poverty, and clusters of problems that collectively affect their health. Adapting interventions to address the unique barriers that these populations face is important. In this study, we aggregated data on SDOH to guide the discussions with the planning, implementation, and evaluation working groups (community stakeholders and survivors and cosurvivors of cancer) convened as part of the ongoing LEAP study community engagement processes. This approach aligns with evidence-based cancer control strategies in persistent poverty areas [8]. Our findings support a comprehensive approach to promoting healthy eating and physical activity that addresses clusters of social risks rather than focusing on a single factor (eg, telehealth options to minimize transportation barriers, meal programs or home gardening to address food insecurity, and peer support groups to reduce social isolation).

The growing integration of SDOH screening into EHR systems represents a paradigm shift in how health care systems can support cancer control efforts in underserved communities [25]. Our approach aligns with emerging recommendations from national organizations emphasizing the importance of systematic SDOH data collection and documentation to inform care delivery and population health management [22]. The scoping review by Li et al [26] demonstrated that EHR-embedded SDOH data can be effectively linked to health outcomes and used to design targeted interventions, although standardization of data collection methods remains an ongoing challenge. Future efforts should focus on expanding SDOH screening beyond social work encounters to capture a more representative picture of social risks among survivors of cancer.

Community-based participatory research approaches have demonstrated effectiveness in optimizing health behaviors among survivors of cancer, particularly when interventions are tailored to local community resources and cultural contexts [3]. A recent systematic review found that most community-based interventions for survivors of cancer focused on physical activity and nutrition, with 88% showing improvement in at least one outcome measure; however, the review also highlighted a concerning lack of diversity in participant populations [27]. Our study provides foundational data to inform such community-based participatory research efforts by characterizing the specific demographic, clinical, and social risk profiles of survivors of cancer in our target communities—information essential for adopting evidence-based interventions to address local needs. The Active Living After Cancer program, for example, demonstrated that community-delivered physical activity interventions can successfully improve outcomes among medically underserved survivors of cancer and their caregivers when implemented through trusted community partnerships [28].

Notably, more than half (282/509, 55.4%) of the survivors of cancer in persistent poverty areas in our sample had Medicare coverage, suggesting opportunities to leverage existing Medicare benefits for lifestyle interventions. While Medicare currently covers medical nutrition therapy only for diabetes and chronic kidney disease, recent legislative efforts such as the Medical Nutrition Therapy Act for dietitian-delivered nutrition counseling will be important for this population [29]. In the meantime, health care systems serving persistent poverty areas can explore partnerships with community-based programs and leverage existing Medicare preventive services to address modifiable health behaviors among survivors of cancer.

The strengths of this study include using real-world health system data and NLP to capture both medical and nonmedical factors influencing health outcomes, enabling a more informed approach to addressing disparities prior to intervention development. Furthermore, the aggregated SDOH data were "translated" into a format for nonscience community-based partners to inform the ongoing community-engaged "co-design" of the planned LEAP intervention.

Limitations included the bias in the study sample of survivors of cancer, which was limited to the project target areas defined by low socioeconomic status indicators, and the PRAPARE- and NLP-derived data were also limited to individuals with the most acute social needs (eg, referral to social work). For this reason, we did not conduct formal hypothesis testing and did not focus on those results for interpretation in this report, and the findings may not be generalizable to other medical practice catchments. Our sample reflects survivors of cancer actively engaged in care at our health system, which may underrepresent patients with rapidly fatal cancers and those who have disengaged from care. This "survivor bias" should be considered when interpreting cancer type distributions; however, for the purpose of informing intervention adaptation, characterizing the population currently available for enrollment is appropriate.

Missing data were present for several variables, particularly PRAPARE (2094/2672, 78.4% missing) and NLP-derived SDOH (1076/2672, 40.3% missing) data, which reflects the clinical reality that these data are collected only for patients

XSL•FO
RenderX

referred to social work services. This represents a form of data missing not at random, as patients with more acute social needs are more likely to have social work encounters. This limitation should be considered when interpreting prevalence estimates, which likely represent lower bounds for the broader population.

Despite these limitations, this is the first study to use an EHR-embedded social risk screener to provide insightful information for formative work among survivors of cancer in persistent poverty areas, offering valuable insights into their unique challenges and underscoring the importance of adapting interventions to address their specific social and health needs.

Conclusions

This study demonstrates that leveraging SDOH data embedded in health system EHRs provides a feasible approach for characterizing populations of survivors of cancer in persistent poverty areas to inform community-based intervention adaptation. The social risk profiles identified highlight the importance of tailoring lifestyle interventions to address transportation, food access, and safety concerns alongside chronic disease management.

Acknowledgments

The authors would express their sincere appreciation to the research staff members who supported this study and their community partners who tirelessly work to improve the health and well-being of their communities.

Abstract

Background: Adults with brain tumors learn to navigate unpredictable physical and psychological symptoms along with the possibilities of tumor recurrence. As a result, they tend to become resilient to confronting profound uncertainty and actively employ coping strategies. Yet, the impact of resilience on coping strategies among people with brain tumors has not been fully explored.

Objective: This study aimed to examine the effects of resilience on the association between future uncertainty and two distinct types of coping strategies (problem-focused coping and emotion-focused coping) among people with brain tumors in Taiwan.

Methods: A parent study recruited 95 adults with brain tumors undergoing at least 1 month of chemotherapy or radiotherapy at a veterans general hospital in northern Taiwan. We assessed resilience, future uncertainty, and coping strategies via a secondary analysis of data from the parent study collected using the Chinese versions of the Resilience Scale, the European Organization for Research and Treatment of Cancer's Quality of Life Questionnaire for brain cancer, and the revised Ways of Coping Checklist. Simple mediation models were conducted to examine the role of resilience between future uncertainty and the two types of coping strategies.

Results: Most participants demonstrated low resilience and responded to stress with both problem- and emotion-focused coping strategies. Simple mediation analyses showed a statistically significant association between an increase in resilience and adoption of each type of coping strategy. In addition, resilience was a statistically significant mediator in the association between future uncertainty and both problem- and emotion-focused coping strategies.

Conclusions: Brain tumor disease trajectories require people to effectively adopt both problem- and emotion-focused coping strategies to confront uncertainty. Health care providers play a crucial role in evaluating and fostering their patients' resilience to promote adaptability through effective coping strategies.

KEYWORDS

resilience; problem-focused coping; emotion-focused coping; adaptation; uncertainty in illness theory

Introduction

Given the nature of brain tumors, uncertainty may persist throughout the cancer trajectory. In Taiwan, brain tumors account for 1.2% of cancer cases; however, the mortality rate has been rising for 2 decades [1]. The lack of clarity about prognoses leads people with brain tumors to experience ongoing uncertainty along with unpredictable symptom patterns and increases in functional dependency [2]. As a result, these sources of uncertainty may negatively affect their ability to cope with cancer [3].

According to Mishel's uncertainty in illness theory [4], an individual responds to uncertainty by assessing whether it presents a danger or an opportunity. When there is a potential

XSL•FO
RenderX

positive outcome from the uncertainty, the individual may use strategies such as selective ignoring to maintain uncertainty as a source of hope. A danger appraisal may prompt the individual to take action to mitigate the uncertainty [4,5]. For people with brain tumors, the ongoing perception of uncertainty highlights the need for effective coping strategies to support successful adaptation; this is a process that may be strengthened through resilience. The known positive association between resilience and cancer coping [6,7] suggests that cultivating resilience may enhance cognitive appraisal processes and thus increase the adoption of effective coping strategies.

Resilience is defined as the process by which an individual can, in the face of stress, flexibly utilize available external resources (eg, social support from others), internal resources (eg, individual strengths and skills), and existential resources (eg, practices of meaning-making and expressing gratitude) [8]. A qualitative study of people with brain tumors identified the need for resilience, including living in the moment and finding joy, as coping mechanisms for navigating uncertainty [9]. Other studies have shown that resilience mediates the association between symptom distress and quality of life and that resilience has effects on reducing psychological distress [10]. These findings highlight that resilience can serve as a protective factor to empower people to demonstrate flexibility in overcoming difficulties through various resources and coping strategies.

There has been little research on the impact of resilience on how individuals with brain tumors cope with uncertainty. Thus, this study, guided by the uncertainty in illness theory, investigates the effects of resilience on the association between uncertainty and individual coping strategies, including problem-focused coping and emotion-focused coping, among people with brain tumors.

Methods

Sample and Setting

This secondary analysis used data from 95 people with primary brain tumors, which was sufficient to reach the desired power of .80 to examine the effect of future uncertainty on coping strategies through resilience. Participants were recruited during an outpatient visit to a veterans general hospital in Taiwan. Eligibility criteria were (1) patients aged 20 years or older and (2) patients diagnosed with a benign or malignant primary brain tumor and receiving at least 1 month of treatment. People with a diagnosed mental illness or unable to communicate were not eligible to participate.

Ethical Considerations

The parent study was approved by the Taipei Veterans General Hospital (2014-09-007AC) institutional review board (for more details about the parent study, please see [11,12]). Before consenting, participants were informed that they could withdraw from the study at any time without penalty, and that this would not affect their treatment. In addition, no identifiable health information was collected or included in the statistical or data management programs. No compensation was provided to participants for completing the survey.

Instruments

Coping Strategies

We used the Chinese version of the Ways of Coping Checklist–Revised to assess participants' coping strategies. The Ways of Coping Checklist–Revised uses 42 items to assess 5 factors: problem-focused coping, seeking social support, self-blame, distancing, and wishful thinking [13]. We categorized the first 2 factors as problem-focused coping and the other 3 factors as emotion-focused coping [13]. All items use a 5-point Likert scale (0 to 4); higher scores indicate more frequent adoption of a strategy. The McDonald ω for the internal consistency of the total scores of problem-focused and emotion-focused coping were 0.86 and 0.83, respectively.

Future Uncertainty

Participants' future uncertainty was measured using the subscale of the European Organization for Research and Treatment of Cancer's Quality of Life Questionnaire [14]. The 4 items that measure future uncertainty are as follows: (1) Did you feel uncertain about the future? (2) Did you feel you had setbacks in your condition? (3) Were you concerned about disruption of family life? and (4) Did your outlook on the future worsen? All items were measured on a scale of 1 to 4; higher scores represent worse symptoms. The McDonald ω for the total score was 0.80.

Resilience

Participants' resilience was assessed using the Chinese version of the Resilience Scale, with 25 items in 5 domains of resilience, including meaningful life, perseverance, self-reliance, equanimity, and existential aloneness. All items use a 7-point Likert scale ranging from 1 to 7, for a total score ranging from 25 to 175 (≥146=moderately high resilience; 131-145=moderate resilience; ≤130=low resilience) [15]. The McDonald ω for the total score was 0.97.

Data Analysis

To examine how resilience affects the effect of future uncertainty on coping, we conducted 2 simple mediation models, with resilience as the mediator and future uncertainty as the predictor of the two different outcome variables: problem-focused coping and emotion-focused coping. Each model consisted of one direct effect of future uncertainty (X) as a predictor of coping strategies (Y) and one indirect effect of future uncertainty (X) on coping strategies (Y) through resilience (M). Inferences about direct and indirect effects were estimated by bootstrapping, which generated 95% percentile bootstrap CIs [16].

Results

Participants adopted both problem-focused coping strategies (mean 58.06, SD 11.10) and emotion-focused coping strategies (mean 43.96, SD 12.06). Half (48/95, 51%) of the participants reported low resilience, and a quarter each reported moderate (24/95, 25%) and moderately high (23/95, 24%) resilience.

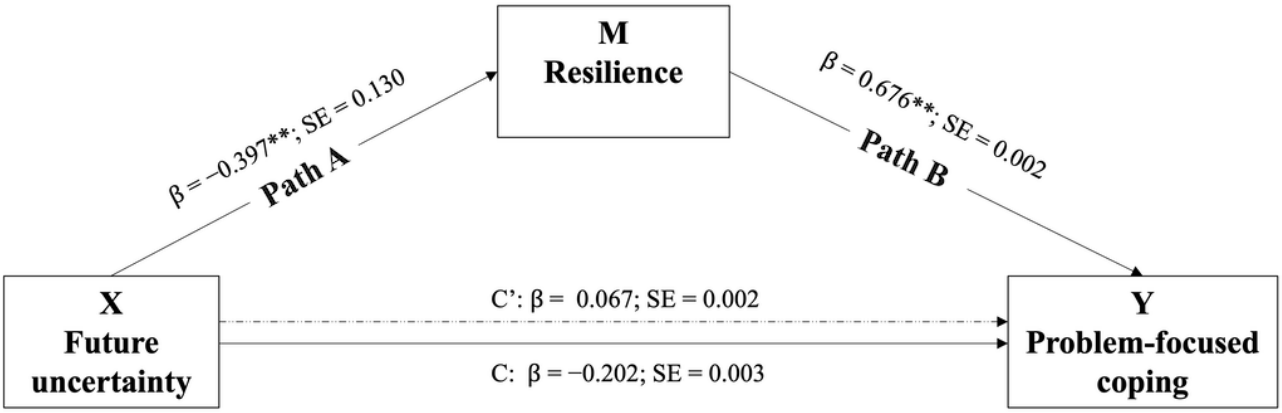
Two simple mediation models examined the role of resilience in the different types of coping strategies. The model for resilience as a mediator between future uncertainty and

XSL•FO
RenderX

problem-focused coping resulted in a standardized coefficient of total effect of −0.202 (Figure 1). When the total effect of future uncertainty was partitioned into direct and indirect effects, the indirect effect of future uncertainty on problem-focused coping through resilience (Figure 1, path A × path B) was statistically different from zero (β=−0.268, SE 0.068, 95% CI −0.406 to −0.142).

The model with emotion-focused coping as the outcome resulted in a total effect of future uncertainty that was statistically significant (Figure 2). The direct effect of future uncertainty on emotion-focused coping was 0.370. The indirect effect of uncertainty through resilience was significantly different from zero (β=−0.133, SE 0.053, 95% CI −0.249 to −0.041).

Figure 1. Simple mediation model estimation results. C' is the direct effect of future uncertainty on problem-focused coping; C is the total effect of future uncertainty on problem-focused coping. *P<.05; **P<.01.



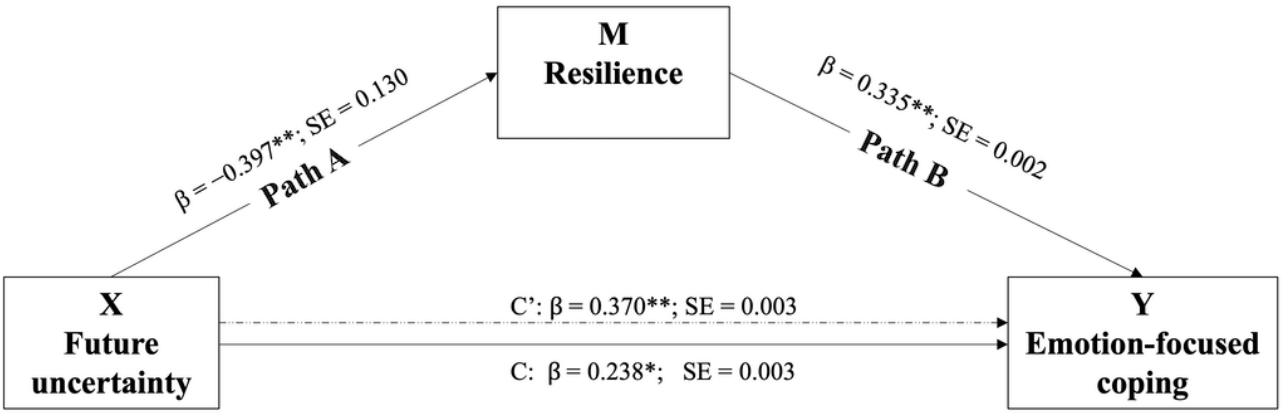


Figure 2. Simple mediation model estimation results. C' is the direct effect of future uncertainty on emotion-focused coping; C is the total effect of future uncertainty on emotion-focused coping. *P<.05; **P<.01.

Discussion

Principal Findings

This study investigates the influence of resilience on adopting 2 distinct coping strategies amidst the uncertainty associated with brain tumors. We found that resilience positively facilitated the adoption of both problem-focused and emotion-focused coping strategies and a mediating role for resilience between uncertainty and individual coping strategies. In particular, the mediating effects of resilience appeared to be more pronounced for problem-focused coping, as the direct effect of uncertainty on problem-focused coping became nonsignificant when resilience was included. Indeed, focus group discussions among people with brain tumors revealed that constant uncertainty led to fear, despair, and adjustment difficulties. Over time, they learned to adopt problem-focused coping strategies such as planning end-of-life care to reduce caregiver burden [9]. In other words, resilience is a process of realization through awareness of accurate appraisals, available resources, and the flexible use of coping strategies [8]. When the cause of uncertainty can be managed, awareness of available informational and instrumental social support through resilience may increase the likelihood of adopting problem-focused coping strategies with greater confidence [7,9,17].

Unclear symptom patterns and prognoses for brain tumors may prompt people to adopt emotion-focused coping strategies. People with brain tumors expressed the need to maintain hope as part of their coping strategies and to live in the present moment to mitigate the impact of psychological distress [9]. In fact, cultivating hope is integral to developing resilience [18], and it has been identified as a predictor of resilience among individuals with cancer [6]. Interestingly, our findings showed that the reduction in resilience resulting from increased uncertainty weakened the overall effect of uncertainty on emotion-focused coping. One possible explanation is that in coming to terms with their condition, people with brain tumors may ultimately cultivate hope, which in turn strengthens resilience and enables them to flexibly adopt either

XSL•FO
RenderX

problem-focused or emotion-focused coping strategies in response to uncertainty.

Limitations

This study captured participants' resilience levels at only one point in time. Our goal was to examine the impact of resilience while recruiting a sufficient sample for analysis within a feasible recruitment period. The study's sample size may limit further investigation. Although our sample shows slightly lower resilience, it remains generally comparable to other samples with brain tumors [19,20].

Clinical Implications

Health care providers can help patients with brain tumors develop resilience by recognizing and applying their external, internal, and existential resources to address uncertainty. With such assistance, the process of building resilience can be accelerated within 12 weeks [21]. Additionally, health care providers can provide meaning-making or gratitude exercises to increase resilience and facilitate successful adaptation [22].

Conclusion

This study highlights the importance of developing resilience to help people with brain tumors accurately appraise and flexibly apply effective coping strategies. The findings provide potential targets for a resilience-building intervention to reduce the impact of uncertainty.

Abstract

Background: Electronic medical record (EMR) systems have been associated with better clinical workflows and fewer documentation errors. However, evidence regarding their effect on time-sensitive leukemia care in public hospitals in Latin America remains limited.

Objective: This study aimed to compare 60-day mortality and urgent supportive-care processes between 2 tertiary public hospitals in Mexico with different documentation models (integrated EMR vs traditional physical records [TPR]), under the hypothesis that digital workflows may facilitate more timely treatment.

Methods: We conducted a retrospective natural experiment including 274 patients with newly diagnosed acute leukemia treated between February 2023 and April 2025. Clinical characteristics, treatment intensity, complications during induction, antibiotic administration times, and survival outcomes were abstracted from finalized institutional records that are routinely reviewed at discharge by the institutional medical record committee as part of standard quality-assurance procedures. The primary outcome was 60-day mortality. Secondary outcomes included time to first antibiotic dose after recognition of febrile neutropenia, treatment-related complications, and the number of operational steps required for urgent care processes. A subgroup analysis of 70 patients with complete timing documentation was performed for antibiotic administration. Comparisons between hospitals were performed using univariate tests, Kaplan-Meier 60-day survival curves, and multivariable logistic regression.

Results: Of the 274 included patients, 104 (38%) were treated at the hospital using an integrated EMR, and 170 (62%) at the hospital using TPR. Sixty-day mortality was lower in the EMR hospital (6/104, 5.8%) than in the TPR hospital (61/170, 35.9%; $P<.001$). In the subgroup with complete timing data, the mean time from febrile episode recognition to first antibiotic administration was shorter in the hospital using EMR than in the hospital using TPR (54, SD 18.4 minutes; $P<.001$). Although the EMR hospital used a higher proportion of high-intensity regimens, patients in that hospital had better 60-day outcomes. In multivariable analysis, hospital type remained independently associated with 60-day mortality (odds ratio 0.11, 95% CI 0.05-0.26; $P<.001$), whereas kidney injury and hepatotoxicity were associated with worse outcomes.

Conclusions: In this natural experiment, the hospital using an integrated EMR had a lower 60-day mortality and shorter time to antibiotic administration than the hospital using TPR. These findings are hypothesis-generating and suggest that digital

XSL•FO
RenderX

workflows may contribute to more timely urgent supportive care, but they should be interpreted with caution, given the retrospective 2-center design and the potential for residual confounding.

(JMIR Cancer 2026;12:e71306) doi:10.2196/71306

KEYWORDS

electronic medical records; traditional physical records; acute leukemia; 60-day mortality; Latin America

Introduction

Electronic medical records (EMRs) are digital patient records that integrate clinical history, laboratory results, diagnoses, treatments, and medication orders. Compared with traditional physical records (TPR), EMRs may improve traceability, facilitate communication among physicians, nurses, pharmacists, and ancillary services, and reduce delays in the execution of urgent clinical decisions [1,2].

Over the last 2 decades, digitalization has transformed hospital care in many high-income settings. In the United States, widespread adoption accelerated after the Health Information Technology for Economic and Clinical Health (HITECH) Act, and similar transitions have occurred in several European countries [3]. In oncology, digital tools have been associated with better coordination of care, improved remote monitoring, fewer unplanned admissions, and more timely responses to complications [4].

Despite these advances, Latin America continues to face major barriers in cancer care, including fragmented health systems, limited access to innovative therapies, administrative delays, and marked social inequities [5,6]. These limitations are especially relevant in hematologic malignancies, where delays in diagnosis, treatment initiation, and supportive care can have an immediate impact on survival [7].

In acute leukemias, early mortality remains a major challenge in the region. Patients with acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) are highly susceptible to infectious and hemorrhagic complications during the first weeks of treatment [8-12]. In Mexico, delays from symptom onset to treatment initiation have been associated with poor outcomes, and infectious complications are a leading cause of early death [13]. In acute promyelocytic leukemia, hemorrhage remains an additional major contributor to early mortality [14].

A substantial proportion of these delays occur not only at the diagnostic stage but also during hospital care, particularly when urgent interventions, such as antibiotic administration or blood component delivery, depend on multiple manual steps [15]. In many public referral hospitals in Mexico, these processes still rely on paper charts, handwritten requests, and fragmented communication pathways.

Therefore, we treated the contrast between these 2 hospitals—Hospital Regional de Alta Especialidad de Ixtapaluca and Hospital Juárez de México—as a natural experiment. Our aim was to compare 60-day mortality and time-sensitive supportive-care processes between a fully digital public hospital and a hospital using TPR, while also exploring clinical predictors of mortality. We hypothesized that EMR-supported workflows would be associated with faster delivery of urgent supportive care and lower 60-day mortality in patients with newly diagnosed acute leukemia.

Methods

Setting

We conducted a retrospective natural experiment, a type of observational study, of patients with newly diagnosed acute leukemia treated between February 2023 and April 2025 at 2 tertiary public hospitals in Mexico. The comparison included Hospital Juárez de México, which uses a TPR model with paper-based requests and manual delivery processes, and Hospital Regional de Alta Especialidad de Ixtapaluca, which operates with a fully digital infrastructure, including EMR-based prescribing, real-time medication management, and electronic request processing. Acute leukemia diagnosis was established using the standard institutional diagnostic workup, including morphological evaluation of peripheral blood and/or bone marrow together with immunophenotyping by flow cytometry. The French-American-British classification, when documented in the record, was used only as a descriptive morphological framework.

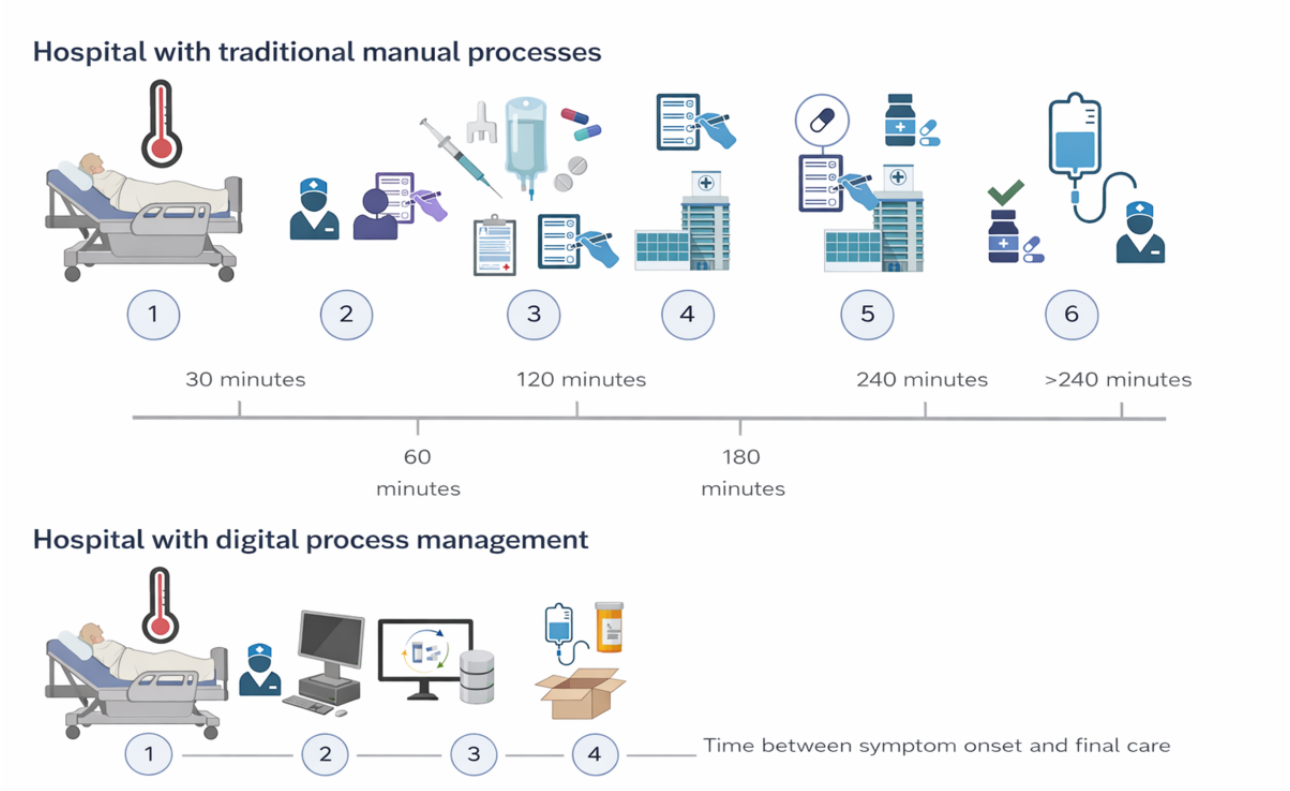
Participants

Eligible patients were consecutive adolescents and adults with a confirmed diagnosis of acute leukemia who received inpatient induction or initial inpatient antileukemic treatment during the study period. Patients were included regardless of leukemia subtype if the diagnosis and inpatient treatment course were documented in the institutional record. Patients without vital-status information through day 60 or with missing primary outcome data were excluded from the primary analysis.

Data Collection: Data Sources and Variables

Data were retrospectively abstracted from finalized institutional records at each center using a predefined study dataset. Data abstraction was performed by trained investigators involved in the study using standardized extraction forms developed for the project.

At both hospitals, the medical record of each hospitalized patient is routinely reviewed at discharge by the institutional medical record committee as part of standard administrative and quality-assurance procedures; thus, the study used records that had already undergone routine institutional review. In the TPR hospital, study variables were obtained from paper charts, handwritten medical and nursing notes, medication sheets, and discharge documentation. In the EMR hospital, the same variables were obtained from the digital platform used for clinical documentation, medication tracking, and time-stamped orders. Collected variables included age, sex, leukemia subtype,



XSL•FO
RenderX

baseline white blood cell count, prior infection, overweight status (BMI ≥25 kg/m^2), treatment intensity, treatment-related complications, organ toxicities, and vital status at 60 days. No formal duplicate abstraction or interrater reliability exercise was performed for the research dataset, which should be considered when interpreting the results.

Outcomes and Treatment Classification

The primary outcome was 60-day mortality, defined as death from any cause within 60 days of hospital admission. Secondary outcomes were time from recognition of febrile neutropenia to first antibiotic administration, treatment-related complications during induction, and the number of procedural steps required for urgent antibiotic or blood component delivery. Because our objective was not to assess case-detection capacity but rather to evaluate whether different documentation environments could more efficiently translate clinical decisions into timely pharmacological interventions, workflow analyses focused on execution steps and time stamps after clinical recognition of febrile neutropenia. To characterize workflow differences, we recorded the number of operational steps required for emergent care processes in each hospital. For antibiotic timing analyses, we evaluated a subgroup of 70 patients with complete documentation of febrile episode recognition, antibiotic prescription, and administration time. In the TPR hospital, timing data were obtained from handwritten nursing notes and medication records; in the EMR hospital, they were extracted from electronic time stamps. Figure 1 summarizes the process flow in both institutions. Treatment regimens followed local institutional practice. For ALL, the most frequently used regimens were Hyper-CVAD and CALGB 10403 [16,17]. For AML, the standard 7+3 regimen was the preferred induction approach. For analysis, chemotherapy was categorized as low-, intermediate-, or high-intensity. High-intensity regimens included fludarabine, cytarabine, and granulocyte colony-stimulating factor (FLAG), whereas lower-intensity regimens included azacitidine and low-dose cytarabine [18].

Figure 1. Differences between a hospital that uses traditional physical records (TPRs) and one that use electronic medical records (EMRs) in the duration of antibiotic use and blood-component administration. The sequence of events in the TPR hospital is as follows—step 1: symptom identification; step 2: patient or relatives personally notify health care staff; step 3: symptom registration by nursing or medical personnel; step 4: manual medication request, gathering authorization from supervisors or responsible staff, and verifying medication availability; step 5: approval by senior staff or infectious disease specialists and forwarding the request to the pharmacy; step 6: the pharmacy receives the request, validates prescriptions, dispenses medications, and waits for personnel transport; and step 7: antibiotics administration to the patient. EMR hospital—step 1: symptom identification via automated alerts to nursing staff; step 2: cause identification and digital antibiotic requests with real-time pharmacy validation; and step 3: medication transport via capsule system or designated transport staff, and antibiotics administration to the patient.

Statistical Analysis

Because this was a retrospective study that included all consecutive eligible patients treated during the study period, a prospective sample size calculation was not performed. However, considering the observed mortality rates between hospitals, the available sample size provided adequate statistical power to detect clinically meaningful differences between groups. Assuming an early mortality of approximately 30% in the TPR hospital and 10% in the EMR hospital, the sample of 274 patients would provide more than 80% statistical power to detect an absolute difference of at least 20 percentage points between groups at a 2-sided alpha level of .05.

XSL•FO
RenderX

Descriptive statistics were used to summarize baseline characteristics and outcomes. Categorical variables were compared using chi-square or Fisher exact tests, as appropriate, and continuous variables were compared using 2-tailed Student *t* tests or Mann-Whitney *U* tests according to distribution. Missing data were not imputed. Analyses were performed using complete-case information for each variable, and patients without 60-day follow-up were excluded from the primary outcome analysis. Sixty-day survival was analyzed using Kaplan-Meier curves and log-rank tests. To explore factors associated with 60-day mortality in this natural experiment, we fitted a multivariable logistic regression model. Covariates were selected a priori on the basis of clinical relevance, prior literature on early mortality in acute leukemia, baseline imbalances between hospitals, and the need to preserve parsimony relative to the number of deaths observed. The final model included hospital type (EMR vs TPR) as the main exposure of interest, together with age, leukemia type, white blood cell count at diagnosis, prior infection, overweight status, kidney injury, and hepatotoxicity. Odds ratios (ORs) with 95% CIs were reported. A 2-sided *P* value <.05 was considered statistically significant. All analyses were performed using SPSS (version 25.0; IBM Corp).

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and the institutional procedures of the participating centers. At both hospitals, medical records are routinely reviewed by the institutional medical record committee at discharge as part of standard care and quality control processes. The study used deidentified information derived from these finalized records. The protocol was approved by the Biosafety, Ethics, and Research Committee of the Hospital Regional de Alta Especialidad de Ixtapaluca (protocol HRAEI-CBSI-09-24-2025). Because this was a retrospective analysis of anonymized clinical records, informed consent was waived. All data were handled in a deidentified manner, and no personally identifiable information was accessed or included in the research dataset, in accordance with applicable data protection regulations. No financial or nonfinancial compensation was provided to participants, as this study was based exclusively on retrospective review of existing clinical records.

Results

Patient Characteristics

A total of 274 patients were included in the study: 170 (62%) in the TPR group and 104 (38%) in the EMR group. Sex distribution was balanced overall, and no significant difference was observed between hospitals (male sex: 53/104, 51% for EMRs vs 84/170, 49.4% for TPRs; *P*=.45).

The overall mean age was 35 years (range 16-87 years). Patients with AML were older than those with ALL (41 vs 32 years; *P*=.04). ALL was the most frequent diagnosis (183/274, 66.8%), followed by AML (n=46, 16.8%), acute promyelocytic leukemia (n=24, 8.8%), and other myeloid subtypes (n=21, 7.7%).

Regarding comorbidities, 36 (13.1%) patients had diabetes, 18 (6.6%) had hypertension, and 53 (19.3%) were classified as overweight or obese. Secondary leukemia was documented in 9 cases (3.3%), all corresponding to myeloid disease.

Baseline clinical and demographic characteristics by hospital are summarized in Table 1.

[b]Not applicable.

Baseline Characteristics Before Chemotherapy

Before treatment initiation, among 274 patients, 71 (25.9%) presented with fever and required antibiotic therapy. At admission, the average white blood cell count was 58×10^3/µL (range 0.3-462×10^3/µL), without a significant difference between lymphoid and myeloid leukemias (*P*=.35).

Cytogenetic data were available for 159 (58%) patients, with no significant difference between hospitals (*P*=.31). Among 183 patients with ALL, *BCR::ABL1* was detected in 24 (13.1%), and central nervous system infiltration was documented in 17 (9.3%).

Detailed baseline characteristics stratified by hospital are shown in Table 1.

Treatment Patterns by Hospital

Induction treatment was categorized among 274 patients as low intensity in 10 (3.6%), intermediate intensity in 154 (56.2%), and high intensity in 110 (40.1%). The median time from diagnosis to chemotherapy initiation was 5 (range 1-29; IQR 4) days. High-intensity regimens were more frequently used in the EMR hospital (77/104, 74%) than in the TPR hospital (33/170, 19.4%), whereas intermediate-intensity regimens were more common in the TPR hospital (TPR hospital: 128/170, 75.3% vs EMR hospital, 26/104, 25%). Low-intensity treatment was uncommon in both centers and was mainly reserved for patients who were frail or those with major comorbidities.

Among patients with ALL, most received intermediate-intensity regimens, whereas patients with AML were predominantly treated with standard induction approaches, such as 7+3. Treatment characteristics during induction are summarized in Table 2.

Treatment-Related Complications by Hospital

All patients underwent induction treatment. During this phase, among 274 patients, tumor lysis syndrome occurred in 32 (11.7%), kidney injury in 59 (21.5%), hepatotoxicity in 65 (23.7%), and pancreatitis in 7 (2.6%) patients.

Febrile neutropenia was the most frequent adverse event during induction therapy. It occurred in 98 (94.2%) of 104 patients in the EMR hospital and in 136 (80%) of 170 patients in the TPR hospital (*P*=.001).

Other infectious complications included neutropenic colitis in 90 (32.8%), positive cultures in 131 (47.8%), gram-negative isolation in 89 (32.5%), and gram-positive isolation in 60 (21.9%) patients. Microbiological isolation was reported more often in the EMR hospital.

Major hemorrhage was documented in 77 (28.1%) patients, with no significant difference between hospitals (EMR: 27/104, 26%; TPR: 50/170, 29.4%; *P*=.28).

Sixty-Day Mortality

Sixty-day mortality for the overall cohort was 24.5% (67/274). Mortality was significantly lower in the EMR hospital (6/104, 5.8%) than in the TPR hospital (61/170, 35.9%; *P*<.001).

Although infectious complications during chemotherapy were more frequently documented in the EMR hospital, severe organ toxicities, such as kidney injury and liver injury, were more common in the TPR hospital.

Mortality was higher among patients with AML (11/46, 23.9%) than among those with ALL (35/183, 19.1%). The leading causes of death were septic shock (41/274, 15%), hemorrhage (20/274, 7.3%), and fulminant liver failure (3/274, 1.1%).

Most deaths from septic shock occurred in patients with ALL, whereas hemorrhagic deaths were concentrated in myeloid leukemias, particularly acute promyelocytic leukemia.

In the multivariable logistic regression analysis, hospital type remained independently associated with 60-day mortality. Care at the EMR hospital was associated with significantly lower odds of death compared with the TPR hospital (OR 0.11, 95% CI 0.05-0.26; *P*<.001). In contrast, kidney injury (OR 1.68, 95% CI 1.29-2.20) and hepatotoxicity (OR 1.49, 95% CI 1.14-1.78) were independently associated with higher odds of 60-day mortality.

Workflow Measures and Time to Antibiotic Administration

The median duration of neutropenia was 22 (15-30) days overall, and severe neutropenia lasted a median of 7 (3-12) days. Despite a longer duration of neutropenia in the EMR group, only 6 (9%) of the 67 deaths occurred in that hospital.

The TPR hospital required more procedural steps for urgent care processes than the EMR hospital. For antibiotic administration, the TPR hospital required a median of 5 (range 3-7) steps versus 2 steps in the EMR hospital. A similar pattern was observed for blood component requests.

In the subgroup of 70 patients with complete timing documentation, the mean time from recognition of febrile neutropenia to first antibiotic administration was significantly longer in the TPR (272 minutes) hospital than in the EMR hospital (54 minutes; *P*<.001).

Secondary Survival Analyses and Multivariable Model

Kaplan-Meier analysis of 60-day survival showed poorer survival in patients with AML than in those with ALL. As a secondary analysis, survival also differed according to chemotherapy intensity, which was relevant because treatment intensity varied substantially between hospitals. Survival was also lower in patients treated at the TPR hospital than in those treated at the EMR hospital (Figures 2 and 3).

In multivariable logistic regression, hepatotoxicity, kidney injury, overweight status, age older than 35 years, and AML

XSL•FO
RenderX

were associated with higher odds of death. By contrast, high-intensity treatment and care at the EMR hospital were associated with lower odds of 60-day mortality. Figure 4 summarizes the ORs for the main variables included in the model.

Overall, these results support the hypothesis that a hospital environment using digitalized workflows may enable faster execution of urgent supportive-care processes and may be associated with lower 60-day mortality; however, the observational design does not allow a causal interpretation.

Discussion

Principal Findings

In this retrospective natural experiment, 2 tertiary public hospitals caring for patients with newly diagnosed acute leukemia within the same national setting but with different documentation and medication-management environments were compared. The hospital using an integrated EMR had lower 60-day mortality, shorter times to antibiotic administration in patients with febrile neutropenia, and fewer procedural steps for urgent supportive care than the hospital using TPR. These findings are consistent with the hypothesis that digitalized workflows may improve the timeliness of critical inpatient actions during the first weeks of leukemia treatment, a period in which infectious and hemorrhagic complications strongly influence 60-day mortality.

Several considerations temper the interpretation of these findings. First, this was not an experimental comparison, and the exposure of interest operated at the hospital level rather than the patient level. The 2 hospitals differed in case mix, treatment patterns, and potentially in staffing, clinical experience, referral dynamics, waiting times, bed availability, socioeconomic context, and supportive-care resources. Residual confounding is therefore likely. Second, the study relied on routine clinical and administrative records, which may differ in completeness between paper-based and digital systems. The EMR center may have captured adverse events more completely because of more traceable documentation, whereas some complications may have been underrecorded in paper charts. Third, although all inpatient records are routinely reviewed at discharge by the institutional medical record committee, this quality control process does not eliminate the possibility of information bias in the research dataset. Accordingly, our results should be interpreted as an observed between-hospital association rather than proof of a direct causal effect of the EMR itself.

Despite therapeutic advances, outcomes for acute leukemia in Latin America remain closely tied to health-system performance, including timely diagnosis, rapid treatment initiation, reliable transfusion support, and prompt management of febrile neutropenia [19-24]. In that context, digital tools may matter less as isolated technologies than as enablers of coordination; they can shorten communication chains, document time stamps, reduce transcription delays, and facilitate faster validation of urgent orders.

This interpretation is supported by the marked difference in time to first antibiotic administration observed in our subgroup analysis. For patients with febrile neutropenia, even a modest delay can worsen clinical deterioration, particularly during induction therapy. Therefore, the shorter times observed in the EMR hospital are clinically plausible and may represent one mechanism linking digital workflow to lower 60-day mortality [22-25].

Digital systems may also strengthen accountability and continuous quality improvement. Because records are structured, time-stamped, and easier to audit, EMRs can help identify operational bottlenecks that remain largely invisible in paper-based systems. In hematology-oncology programs, where care depends on repeated coordination among physicians, nurses, pharmacists, blood bank staff, and laboratory services, this additional traceability may be especially valuable [26-29].

At the same time, the use of an integrated EMR should not be viewed as the only explanation for the observed differences. Digitalization likely functions as one component of a broader institutional environment that includes organizational culture, training, responsiveness of ancillary services, and medication availability. Therefore, the lower mortality observed in the EMR hospital may reflect both the digital platform itself and the systems-level practices that accompany its use.

The broader regional literature supports this interpretation. Studies from Latin America consistently show that standardized pathways, timely supportive care, and better-organized referral and treatment networks can improve survival in hematologic malignancies [30-32]. Our results add to that literature by suggesting that hospital digitalization may be one practical strategy for strengthening these pathways in public-sector

XSL•FO
RenderX

settings, but they do not establish that digitalization alone explains the observed mortality difference.

Rather than framing EMRs only as documentation tools, our findings support evaluating them as part of institutional redesign aimed at reducing preventable deaths within 60 days of admission. In acute leukemia, the clinically relevant question is not only whether data are stored electronically but also whether digital systems shorten the interval between clinical recognition, order entry, validation, and treatment delivery.

From a policy perspective, this distinction is important. Public hospitals operating with limited resources may derive meaningful benefit from digital tools when digitalization is linked to workflow simplification, clinical accountability, and rapid-response processes. Therefore, investments in EMRs are likely to be most effective when accompanied by staff training, supportive-care protocols, antimicrobial stewardship, and transfusion logistics optimization.

A major strength of this study is that it compares 2 real-world tertiary public hospitals caring for patients with acute leukemia within the same national health context but with clearly different documentation and medication-management models. The analysis also incorporated clinically relevant covariates associated with 60-day mortality and examined not only outcome differences but also a plausible process-of-care mechanism, namely time to antibiotic administration.

This study also has important limitations. Its retrospective design introduces the possibility of selection bias and information bias. Because only 2 hospitals were included, the analysis is best interpreted as a natural experiment and has limited generalizability. Residual confounding is likely, because unmeasured differences between centers—including staffing, referral complexity, waiting times, socioeconomic context, supportive-care capacity, and other institutional characteristics—may have influenced mortality. Although medical records at discharge are routinely reviewed by the institutional medical record committee, documentation quality may still differ between paper and digital systems. No formal duplicate abstraction or interrater reliability assessment was performed for the research dataset. Missing data were handled through complete-case analysis rather than imputation, and the antibiotic timing analysis was restricted to a subgroup with complete documentation, which may have introduced additional selection bias.

Future Directions

Future research should validate these findings in prospective multicenter cohorts, incorporate standardized abstraction procedures across institutions, and include more detailed measures of workflow, staffing, supportive-care capacity, and case severity. Studies evaluating cause-specific mortality, time to transfusion support, and cost-effectiveness would also help clarify which components of digital implementation have the greatest clinical impact.

Further work should also explore how digital systems interact with staff training, antimicrobial stewardship, transfusion logistics, and clinical decision support in patients with hematologic malignancies. Such studies would help distinguish the specific contribution of the EMR platform from the contribution of the broader institutional practices that accompany digital care.

Conclusions

In this retrospective natural experiment, the hospital using an integrated EMR had a lower 60-day mortality and faster antibiotic administration than the hospital using TPR in patients with acute leukemia. These results support the hypothesis that digitalized workflows may improve the timeliness of urgent supportive care during induction therapy.

However, the findings should be interpreted with caution because the study was observational and compared 2 nonequivalent institutions using routine clinical records. Prospective multicenter studies are needed to confirm whether the observed between-hospital differences persist after more detailed adjustment for case mix, workflow, and institutional characteristics, and to identify which components of digital care are most relevant for improving outcomes.

Abstract

Background: Patients with newly diagnosed gynecologic cancers often seek information online, but the quality of available resources may be inconsistent. Although GPT-4 may offer an alternative to traditional internet search engines, its performance remains largely under-studied in gynecologic oncology.

Objective: This study aimed to compare the completeness, accuracy, and reference quality of responses generated by GPT-4 with those generated by Google in clinical scenarios involving a new diagnosis of a gynecologic cancer.

Methods: Clinical scenarios representing early- and advanced-stage endometrial, ovarian, and cervical cancers were developed by gynecologic oncologists using publicly available patient education materials. Each scenario included 4 standardized questions addressing etiology, prognosis, treatment, and treatment efficacy. GPT-4 and Google were queried for each question, with new sessions for GPT-4 and private browsing for Google to minimize bias. Responses were independently evaluated by 4 gynecologic oncology experts who were blinded to each other's ratings. Accuracy was scored on a 6-point Likert scale; completeness and reference quality were scored on 3-point scales. Reference quality was categorized as low (commercial), medium (institutional or government), or high (peer reviewed). Optional free-text reviewer comments were collected and summarized descriptively to provide context for the quantitative findings. Descriptive statistics and Wilcoxon signed-rank tests were used for analysis.

Results: Across 6 clinical scenarios and 21 standardized questions (N=84 total responses), GPT-4 outperformed Google across all evaluated domains. The median accuracy score was 6.00 (IQR 5.00-6.00) for GPT-4 and 5.00 (IQR 4.00-6.00) for Google (P=.04). The median completeness score was 3.00 (IQR 3.00-3.00) for GPT-4 and 2.00 (IQR 1.00-3.00) for Google (P=.009). Reference quality was also higher for GPT-4, with a median score of 3.00 (IQR 3.00-3.00) compared to 2.00 (IQR 2.00-2.00) for Google (P=.009). Reviewer comments noted that GPT-4 provided more accurate, comprehensive, and personalized responses, while Google returned less detailed content from general consumer health websites rather than peer-reviewed sources.

Conclusions: GPT-4 may serve as a reliable and high-quality resource for information in gynecologic oncology. Compared to Google, it delivered more accurate and complete content, with higher-quality references. Further research is needed to assess the readability and accessibility of GPT-4–generated content across diverse patient populations.

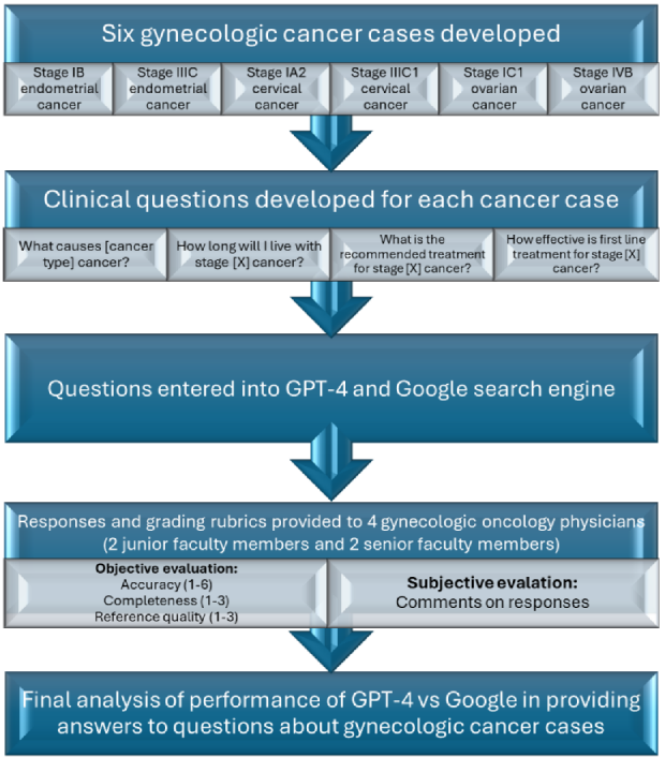
Introduction

Approximately 100,000 individuals are diagnosed with gynecologic malignancy each year in the United States [1]. Following a new cancer diagnosis, patients frequently seek supplemental educational materials to better understand their condition and treatment options. Traditional resources, such as those from professional societies and academic institutions, are often comprehensive but presented in generalized formats, requiring patients to interpret the content in the context of their own diagnosis and clinical stage [2].

AI, particularly large language models (LLMs) such as GPT-4, has gained significant attention in medicine due to its ability to generate rapid, detailed responses based on vast amounts of textual data. ChatGPT, developed by OpenAI, is powered by the GPT-4 language model and accessible to the public through the ChatGPT Plus subscription. In contrast, Google is a search engine that retrieves existing content from across the internet using proprietary algorithms [3,4]. As of mid-2024, Google began integrating its own LLM, Gemini, into certain aspects of its platform. However, the standard search interface continues to primarily direct users to external web pages rather than generating original text. Previous research has explored the utility of LLMs for clinical tasks such as staging lung cancer, summarizing histopathology reports, and supporting diagnostic decision-making [5,6]. Although early findings are promising, concerns remain regarding the accuracy, reliability, and lack of citation transparency of AI-generated content, reinforcing the need for expert oversight.

As GPT-4 becomes increasingly accessible to the public, patients are likely to turn to it, alongside traditional internet search engines, for information about their diagnosis [2]. Prior studies in oncology have evaluated the quality and readability of GPT-4's responses to patient questions, highlighting variability in content accuracy and source quality [7,8]. Other investigations have emphasized the potential of AI to improve health literacy by simplifying medical content, yet its role in reliably supporting patient education remains unknown [9]. Within gynecologic oncology specifically, research on AI-based educational tools is limited. Early studies have examined GPT-4's ability to provide guideline-concordant recommendations for ovarian cancer diagnosis and management, but no prior work has systematically evaluated its performance in delivering high-quality informational content to newly diagnosed patients across multiple gynecologic cancers [10,11].



This study aimed to assess GPT-4's effectiveness in generating patient-directed informational content in the context of newly diagnosed gynecologic cancers. We compared GPT-4 responses with Google search results across standardized clinical scenarios, focusing on 3 key domains: accuracy, completeness, and reference quality. Our findings contribute to the growing body of literature evaluating AI's role in digital health and its potential integration into patient-centered cancer education.

Methods

Study Design

This was a comparative, cross-sectional evaluation of an AI-based LLM (GPT-4; OpenAI) and a standardized internet search engine (Google; Alphabet Inc) using predefined gynecologic oncology clinical scenarios and patient-centered questions (Figure 1). Methods were structured and reported in accordance with the CHART (Chatbot Health Advice Reporting Tool) guideline for chatbot health advice studies [12].

Figure 1. Overview of the study design and evaluation process.

XSL•FO
RenderX

Ethical Considerations

Ethics approval was not required for this study because it did not involve human participants, patient data, or animal subjects. The study evaluated outputs from publicly accessible AI tools and internet search engines and therefore did not constitute human subjects research.

Models

ChatGPT responses were generated using the GPT-4 model via the paid ChatGPT Plus subscription (OpenAI [13]). Google searches were conducted using the Chrome browser.

Prompt Engineering

Six clinical scenarios representing common presentations of gynecologic cancers were developed by a panel of gynecologic oncology providers. For each cancer type (ovarian, endometrial, and cervical), 7 patient-centered questions were created based on commonly asked topics in clinical practice and information available from professional society websites [14], yielding a total of 21 unique questions (Textbox 1). Questions were entered verbatim into both platforms, with each question generating 1 response from GPT-4 and 1 response from Google. A new ChatGPT session was initiated prior to each question to prevent learning across questions or contextual carryover.

Accuracy was assessed using a 6-point Likert scale: 1="completely incorrect," 2="more incorrect than correct," 3="approximately equal incorrect and correct," 4="more correct than incorrect," 5="nearly all correct," and 6="correct." Completeness was assessed using a 3-point Likert scale: 1="incomplete," addressing some aspects of the question but with significant parts missing or incomplete; 2="adequate," addressing all aspects of the question and providing the minimum information required to be complete; and 3="comprehensive," addressing all aspects of the question and providing additional information or context beyond what was expected. Reference quality was assessed using a 3-point Likert scale: 1="bottom tier," including any .com sources such as WebMD; 2="middle tier," including any .gov or .org sources such as the American Cancer Society and National Institutes of Health; and 3="top tier," including peer-reviewed sources or randomized controlled trials such as the National Comprehensive Cancer Network and UpToDate.

21. How effective is first-line treatment for stage IVB ovarian cancer?

Query Strategy

Google searches were conducted in private browsing mode with the browser cache cleared. For each query, the top-ranked nonsponsored web page was recorded to allow direct comparison with GPT-4's single-response output (Multimedia Appendix 1). This approach reflects typical user behavior and aligns with prior studies demonstrating reliance on the first search results [15].

XSL•FO
RenderX

Performance Evaluation

Responses from both platforms were evaluated for accuracy, completeness, and reference quality by 4 gynecologic oncology physicians from 2 institutions (1 academic tertiary referral center and 1 county-based safety-net hospital). Reviewers represented a range of clinical experience, with 2 physicians having <5 years of clinical experience and 2 having >5 years of clinical experience. Reviewers scored responses independently and were blinded to each other's evaluations. Reviewers were also invited to provide optional free-text comments within the standardized evaluation form. These qualitative comments were summarized descriptively. Comments were reviewed in their entirety and grouped into thematic categories reflecting perceptions of accuracy, completeness, reference quality, clarity, and patient comprehensibility. A total of 76 optional comments were submitted across all reviewers. Representative comments were selected to illustrate common themes across platforms and are presented in Textbox 2. This descriptive approach aligns with conventional qualitative content analysis methods used to contextualize the quantitative findings [16]. Accuracy was defined as concordance with National Comprehensive Cancer Network guidelines and current literature and scored using a 6-point Likert scale. Completeness was scored using a 3-point Likert scale based on the inclusion of major concepts relevant to each question. Reference quality was categorized as low, medium, or high and scored using a 3-point Likert scale.

Textbox 2. Representative reviewer comments on completeness, accuracy, and reference quality for Google and GPT-4.

Google

- Technically all the information was correct, but it did not answer the specific question. They would likely need to answer this question with another source.
- The question is not answered, only treatments are mentioned. It also makes it sound like the treatments may not be that effective.
- The information looks very accurate, but there is a lot of set up with prognosis and you must scroll down to get your answer.
- Having to weed through the information to get the answer, the information is not as clear and is a little confusing.
- Some information is outdated.
- Very general information which makes it easy for a person with average literacy to understand.
- Answers to survival questions are given but there is no information about the cancer stage.
- There is no mention of treatment effectiveness or immunotherapy.

GPT-4

- Accurate information is given that is straight to the point and concise.
- Complete and thorough answers were given that were concise with high quality resources.
- ChatGPT does a nice job of putting information into context for the patient.
- ChatGPT is very comprehensive, although it does not address immunotherapy as an option.
- There is specific data of effectiveness given with very thorough data on treatment options.
- There is very good information provided on surgery and chemotherapy (including details about bevacizumab and PARPi) and also discusses palliative care.
- Information is concise and complete. It talked about what the stage meant.
- My only concern is the patient's reading level and ability to understand the language in CGPT versus the broad, simple language used by Google.

Overall

- I thought I was going to come in biased against ChatGPT. As I looked through the answers, I think ChatGPT did much better answering questions than a random Google search with surprisingly high quality, nuanced answers.
- Google searches with answers from Mayo, COH, ACS were good for basic questions, like what is this cancer, what is the stage; although it gave you all the information on staging and you must scroll to your particular area of interest.
- ChatGPT did a better job at individualizing the answer. It also did better at prognosis, effectiveness questions. It seemed to do it with nuance and "compassion." But it was also direct, and I think that can be helpful for physicians when it is difficult to give an accurate prognosis.

Sample Size

A total of 21 standardized patient-centered questions were evaluated. Each question generated 1 response from GPT-4 and 1 response from Google, resulting in 21 responses per platform. All responses were independently evaluated by 4 gynecologic oncology physicians, yielding 84 physician evaluations per platform. The number of questions was selected to capture key informational domains, including etiology, prognosis, treatment, and treatment efficacy, while maintaining feasibility for blinded expert review. This approach is consistent with prior studies evaluating the quality of AI-generated and online health information [8,10,11,17-19].

XSL•FO
RenderX

Data Analysis

Statistical analyses were conducted using JMP Pro (version 16.0.0; SAS Institute Inc). Descriptive statistics were calculated for all outcomes, and paired comparisons between platforms were performed using Wilcoxon signed-rank tests. Interrater reliability was assessed using intraclass correlation coefficients (ICCs) derived from a 2-way random-effects model with single measures and consistency (ICC[2,1]). Reliability thresholds were interpreted using established criteria [20].

Results

Accuracy was graded by 4 physicians on a Likert scale of 1 to 6, with 1="completely incorrect" and 6="completely correct." The median score was 5.00 (IQR 4.00-6.00) for Google compared to 6.00 (IQR 5.00-6.00) for GPT-4 (*P*=.04). For Google, the distribution by accuracy score from 1 to 6 was 6% (5/84), 2.4% (2/84), 8.3% (7/84), 16.7% (14/84), 8.3% (7/84), and 58.3% (49/84), respectively. For GPT-4, the distribution from 1 to 6 was 0% (0/84), 0% (0/84), 2.4% (2/84), 10.7% (9/84), 17.8% (15/84), and 69% (58/84), respectively. A score of 5 or 6 (the most accurate) accounted for 66.6% (56/84) of responses for Google compared to 86.9% (73/84) for GPT-4 (Table 1).

Completeness was then graded by 4 physicians on a Likert scale of 1 to 3, with 1="incomplete," addressing only some aspects of the questions, and 3="comprehensive," addressing all aspects of the questions. The median score was 2.00 (IQR 1.00-3.00) for Google compared to 3.00 (IQR 3.00-3.00) for GPT-4 (*P*=.009). For Google, the distribution by completeness score from 1 to 3 was 36.9% (31/84), 28.6% (24/84), and 34.5% (29/84), respectively. For GPT-4, the distribution from 1 to 3 was 1.2% (1/84), 17.8% (15/84), and 81% (68/84), respectively. A score of 2 or 3 (mostly complete) accounted for 63.1% (53/84) of responses for Google compared to 98.8% (83/84) for GPT-4 (Table 2).

Finally, reference quality was graded by 4 physicians on a 3-point Likert scale, with 1="bottom tier (.com)" and 3="top tier (peer reviewed)." The median score was 2.00 (IQR 2.00-2.00) for Google compared to 3.00 (IQR 3.00-3.00) for GPT-4 (*P*=.009). For Google, the distribution by reference quality score from 1 to 3 was 10.7% (9/84), 77.4% (65/84), and 11.9% (10/84), respectively. For GPT-4, the distribution from 1 to 3 was 0% (0/84), 22.6% (19/84), and 77.4% (65/84), respectively. A score of 2 or 3 (highest quality references) accounted for 89.3% (75/84) of responses for Google compared to 100% (84/84) for GPT-4 (Table 3).

Reviewers then provided comments on their perceptions of the accuracy, completeness, and reference quality of GPT-4 compared to Google. A total of 76 optional comments were submitted across all reviewers. Representative comments illustrating the major themes identified across reviewers are presented in Textbox 2. Overall, reviewers noted that Google source responses had clear and precise language but often did not completely answer the question and did not provide enough information on prognosis or treatment options. For GPT-4, reviewers generally commented that answers were very complete and comprehensive, especially regarding disease stage and prognosis, but might be more challenging for patients to understand.

To assess the consistency of reviewer scoring, we calculated interrater reliability using ICCs based on a 2-way random-effects model evaluating consistency. Completeness scores for Google demonstrated moderate consistency (ICC 0.595, 95% CI 0.389-0.782), while all other domains showed poor consistency (ICC<0.50), except for GPT-4 reference quality, which demonstrated excellent interrater reliability (ICC 0.935, 95% CI 0.879-0.970). Full results are shown in Table 4.

Table 1. Comparison of accuracy scores for clinical scenarios between GPT-4 and Google.

Measure	Google (n=84)	GPT-4 (n=84)
Accuracy score 1, n (%)	5 (6)	0 (0)
Accuracy score 2, n (%)	2 (2.4)	0 (0)
Accuracy score 3, n (%)	7 (8.3)	2 (2.4)
Accuracy score 4, n (%)	14 (16.7)	9 (10.7)
Accuracy score 5, n (%)	7 (8.3)	15 (17.8)
Accuracy score 6, n (%)	49 (58.3)	58 (69)
Mean (SD)[a]	4.94 (1.51)	5.54 (0.78)
Median (IQR)[a]	6.00 (4.00-6.00)	6.00 (5.00-6.00)

[a]*P*=.04.

XSL•FO
RenderX

Table 2. Comparison of completeness scores for clinical scenarios between GPT-4 and Google.

Measure	Google (n=84)	GPT-4 (n=84)
Completeness score 1, n (%)	31 (36.9)	1 (1.2)
Completeness score 2, n (%)	24 (28.6)	15 (17.8)
Completeness score 3, n (%)	29 (34.5)	68 (81)
Mean (SD)[a]	1.98 (0.85)	2.80 (0.43)
Median (IQR)[a]	2.00 (1.00-3.00)	3.00 (3.00-3.00)

[a]*P*=.009.

Table 3. Comparison of reference quality scores for clinical scenarios between GPT-4 and Google.

Measure	Google (n=84)	GPT-4 (n=84)
Reference quality score 1, n (%)	9 (10.7)	0 (0)
Reference quality score 2, n (%)	65 (77.4)	19 (22.6)
Reference quality score 3, n (%)	10 (11.9)	65 (77.4)
Mean (SD)[a]	2.01 (0.48)	2.77 (0.42)
Median (IQR)[a]	2.00 (2.00-2.00)	3.00 (3.00-3.00)

[a]*P*=.009.

Table 4. Interrater reliability by source and scoring domain.

Source and scoring domains	Interclass correlation[a] (95% CI)	Interpretation[b]
Google		
Accuracy	0.075 (−0.087 to 0.327)	Poor
Completeness	0.595 (0.389 to 0.782)	Moderate
Reference quality	0.016 (−0.128 to 0.255)	Poor
GPT-4		
Accuracy	0.111 (−0.061 to 0369)	Poor
Completeness	0 (−0.138 to 0.234)	Poor
Reference quality	0.935 (0.879 to 0.970)	Excellent

[a]Intraclass correlation coefficients were calculated using a 2-way random-effects model with single measures (ICC[2,1]).

[b]Poor<0.5, moderate=0.5-0.75, good=0.75-0.90, and excellent>0.90.

Discussion

Principal Results

This study found that GPT-4 performed better than Google sources when providing high-quality responses to clinical scenarios involving a new diagnosis of gynecologic cancer. Physician reviewers rated GPT-4 significantly higher than Google in terms of accuracy, completeness, and reference quality. Reviewers were surprised by the quality of the GPT-4 answers and references and saw the potential for GPT-4 to better address patient-specific questions regarding diagnosis, prognosis, and treatment options with both precise and comprehensive information. The most common shortcoming identified in the Google-sourced content was the provision of general information that was not specific to the patient's cancer diagnosis, stage, or treatment options and therefore was difficult to individually interpret.

Comparison With Prior Work

Although a growing number of studies have evaluated GPT-4 for cancer-related patient education, relatively few have focused specifically on gynecologic oncology. Initial research on AI in medicine focused on its diagnostic role and potential for clinical decision-making. For example, in otorhinolaryngology, GPT-4 was compared to UpToDate in terms of usefulness and reliability in diagnosing certain common clinical scenarios. UpToDate was found to be more accurate than GPT-4 (*P*=.009), and the authors concluded that improvements were needed in the usefulness and reliability of GPT-4's evidence-based knowledge [21]. Similarly, in various clinical cases of thyroid cancer, GPT-4 was found to be reasonably accurate (approximately 76.7%) when providing information about thyroid cancer, but recommendations about evaluation, treatment, and follow-up were deemed general and inadequate [22].

XSL•FO
RenderX

More recently, studies in gynecologic oncology have demonstrated that GPT-4 generally provides guideline-concordant recommendations for gynecologic cancer diagnosis and management, while emphasizing the continued importance of physician oversight for complex clinical decision-making [10,11,23]. Chou et al [17] further reported that GPT-4 generated patient-directed responses regarding ovarian cancer that were comparable to those provided by gynecologic oncology clinicians, supporting its potential role as a patient education tool.

As AI is increasingly explored as a tool for patient-facing communication, several prior studies have evaluated the use of GPT-4 to generate patient information. One study used various LLM platforms to generate patient education materials for both common and rare dermatologic conditions and found that these platforms were able to create accessible, understandable content at an appropriate reading level [18]. Another study focused on the ability of GPT-4 to provide patients with information about screening mammography but documented concerns about the understandability and actionability of the answers, specifically from a health literacy standpoint [19]. Although AI seems to offer an opportunity to enhance patients' access to health information, there continues to be concern about the possibility of misinformation and the quality of references.

Our findings build upon this growing body of literature. Compared to top-ranked Google search results, GPT-4 consistently outperformed in terms of accuracy, completeness, and reference quality. These findings are consistent with prior studies demonstrating that GPT-4 generally provides accurate, comprehensive, and guideline-concordant information across a variety of cancer-related clinical scenarios [10,11,17,22]. Consistent with the findings of Chou et al [17], we found that GPT-4 generated comprehensive, patient-directed responses that were highly rated by gynecologic oncology physicians. Similarly, our findings align with those of Piazza et al [10] and Finch et al [11], who reported strong agreement between ChatGPT-generated recommendations and established ovarian cancer guidelines. However, although previous studies primarily compared ChatGPT with clinical guidelines or clinician responses, our study directly compared GPT-4 with a conventional Google search strategy, reflecting a common approach used by patients when seeking information after a new cancer diagnosis. Reviewers noted that GPT-4 responses were generally more comprehensive and better aligned with the clinical context, often including relevant treatment information and prognostic details that were lacking in standard search results. Although previous concerns have been raised about the citation quality of previous GPT-4 models, our findings suggest that, in this study, the reference quality was significantly higher than that of Google search results [3,4,8,19,22]. Overall, these results support the potential of GPT-4 to generate personalized, high-quality responses that may enhance patient understanding, support shared decision-making, and improve access to reliable health information.

Strengths and Limitations

Strengths of this study include the novel design used to investigate the role of AI in generating informational content related to gynecologic malignancies. By querying GPT-4 and Google with multiple patient scenarios, results were more generalizable to patients with different types and stages of gynecologic cancers. The use of gynecologic oncology physicians, who were blinded to each other's assessments, enabled the clinical evaluation of response quality by experts who routinely guide patients through diagnosis and treatment. Evaluation of accuracy, completeness, and reference quality offered a comprehensive assessment of the content delivered by each platform. Importantly, we also assessed interrater reliability, which is often omitted in similar studies. Although agreement varied by domain, the inclusion of this analysis strengthens the rigor of our evaluation.

Some limitations of this study include a relatively small number of reviewers, a subjective grading scale, and no direct assessment of the readability of the sources used. Although reviewers were blinded to each other's ratings, they were aware of the source of each response (GPT-4 or Google), which may have introduced bias. Additionally, all 4 reviewers were from only 2 institutions, which raises the possibility that assessments may have been influenced by local practice patterns or institutional standards, potentially limiting generalizability. Interrater reliability was variable across domains, which likely reflects the inherently subjective nature of evaluating informational content, particularly when responses were largely accurate and complete, resulting in clustering of scores at the higher end of the grading scales. In this context, small differences in individual scoring behavior may disproportionately affect interrater reliability metrics despite overall agreement in comparative performance between platforms. Another important consideration is that the phrasing of questions may influence the quality and clarity of responses generated by LLMs. In this study, the scenarios were designed to reflect the types of questions a well-informed patient might ask after receiving a new cancer diagnosis. In real-world settings, however, patients may not know what questions to ask, may lack the background to phrase them effectively, or may not have the clinical knowledge needed to interpret detailed responses. GPT-4 does not tailor responses based on a user's health literacy level, and this study did not formally assess the readability or accessibility of the responses. This represents an important limitation, as prior research has shown that the effectiveness of patient education materials depends not only on content accuracy but also on whether they are comprehensible and actionable. Additionally, by evaluating only the top-ranked Google result for each query, the study may not fully capture the breadth of information users might access through additional searches.

Since completing this study, Google has expanded the integration of LLM-generated summaries within its search platform. This underscores the rapidly evolving landscape of online health information and highlights the need for continued evaluation of AI-assisted search tools. Although such integrations may narrow performance gaps between traditional search engines and stand-alone LLMs, our findings remain relevant by illustrating the potential advantages of conversational, context-aware responses over static web page retrieval. Future studies should directly compare AI-generated

XSL•FO
RenderX

summaries embedded within search engines with stand-alone LLMs, with a focus on reference transparency, patient personalization, and health literacy.

Conclusions

The results of this study suggest that GPT-4 may be a useful tool for delivering accurate, comprehensive, and well-referenced informational content in gynecologic oncology when compared with top-ranked Google search results within the context of standardized clinical scenarios. However, these findings should be interpreted cautiously given several important methodological limitations, including incomplete blinding of reviewers to response source, variable interrater reliability across evaluation domains, and the restriction of the Google comparator to a single top-ranked result per query. Accordingly, this study should be viewed as a preliminary, hypothesis-generating evaluation rather than a definitive assessment of comparative performance. Although LLMs such as GPT-4 show promise in generating context-aware responses tailored to specific clinical scenarios, further research is needed to clarify their appropriate role in supporting patient education and health care professional–patient communication in gynecologic oncology.

Abstract

Background: Informal caregivers play a fundamental role in the diagnosis, treatment, and care received by their family members. Caring for someone with dementia is particularly burdensome and can have negative effects on caregivers' health. Despite caregivers being widely recognized as vulnerable, the psychosocial needs of caregivers who are managing cancer themselves remain unknown.

Objective: This study aims to investigate the experiences of UK family caregivers who have received a cancer diagnosis while caring for someone with dementia or memory problems.

Methods: Twenty-five UK informal family caregivers who had received a cancer diagnosis were recruited through convenience sampling to take part in in-depth semistructured interviews. The interviews explored participants' experiences of managing cancer alongside dementia caregiving, including the impact on treatment and caregiving, emotional challenges, support needs, and experiences of formal and informal support. Ethical approval was obtained from the Leeds Beckett University Research Ethics Committee, and all participants provided informed consent. Reflexive thematic analysis was conducted.

Results: Three key themes were identified: (1) caring responsibilities can complicate and take priority over cancer care, (2) caregiving can intensify cancer-related distress and anxieties, and (3) managing cancer while caring increases the need for support and coping resources. For dementia caregivers, having cancer can surface/heighten feelings of predeath grief and worries about future care planning for their care recipient. Dementia caregivers viewed multifaceted social support as vital for enabling access to and coping with cancer treatment.

Conclusions: Dementia caregivers who are also living with cancer continue to shoulder the burden of illness work on behalf of their care recipients while simultaneously managing their own cancer diagnosis and treatment. Caregiving responsibilities often take priority over cancer care, intensify the practical and emotional challenges of cancer, and increase the need for and reliance on support resources. These findings highlight the need for person-centered adjustments to cancer care, dementia-friendly health care environments, and tailored psycho-oncology support that address the practical and emotional needs of dementia caregivers.

KEYWORDS

caregivers; older people; dementia; cancer; multimorbidity; qualitative research

Introduction

An informal caregiver is a person who provides unpaid care to a family member or friend with a health condition or illness [1]. In the United Kingdom, 5.8 million people identify as informal caregivers [2], and according to Carers UK, the number of unpaid caregivers in the United Kingdom is much higher than reported because many people do not recognize themselves as a caregiver [3]. Informal caregivers play a fundamental role in the diagnosis, treatment, and care received by their family members. Many informal caregivers provide care for individuals living with multiple long-term health conditions, which can increase caregiving demands and burden [4,5]. They provide physical, emotional, social, and financial support on a daily basis to care recipients and are often responsible for aiding communication of care recipients' medical needs with health care professionals [4,6]. Recent research has highlighted the support needs of caregivers of people with cancer and dementia, helping to inform and improve interventions and services provided to them [4]. A scoping review of 34 studies highlighted

XSL•FO
RenderX

common practical difficulties faced by caregivers of someone with multimorbidity, including having to manage multiple health care teams, appointments, and medications [7]. Notably, caregivers of people with dementia have reported practical difficulties with attending medical appointments due to "dementia-unfriendly" hospital settings [8].

Informal caregivers are 16% more likely than noncaregivers to live with 2 or more long-term health conditions [1], and there is a growing amount of evidence that unpaid care should be considered a social determinant of health [1]. Caring for someone with dementia is particularly burdensome (eg, it can involve constant supervision, emotional stress, and physical exhaustion), leading to known negative effects on caregivers' health [9-11]. Despite caregivers being widely recognized as vulnerable, those caregivers who are managing cancer themselves remain an underresearched group [12]. To our knowledge, no research has been conducted to investigate the experiences, difficulties, and support needs of informal caregivers who receive a cancer diagnosis and treatment themselves. This qualitative study therefore aimed to investigate the experiences of UK family caregivers who have received a cancer diagnosis while caring for someone with dementia or memory problems. The study aimed to specifically identify the difficulties and issues faced by patients with cancer and existing gaps in psychosocial support. Any cited recommendations for interventions, policy, and practice will also be reported and considered.

Methods

Participants

Participants were people with experience of simultaneously receiving a cancer diagnosis and caring for someone with dementia. Current or former caregivers were eligible if they had, within the last 5 years, provided unpaid informal care to a family member living with dementia or memory problems; had during this time also been diagnosed with cancer; were aged 18 years or older; were living in the United Kingdom; and were English literate. People who had a relative with dementia who had recently passed away (in the last 3 mo) were advised not to take part. None of the participants dropped out or withdrew from the study. The reporting of the current study adheres to the COREQ (Consolidated Criteria for Reporting Qualitative) guidelines [13].

Sampling and Recruitment

Participants were recruited through convenience sampling using community-based advertisements via relevant charities and support groups across the United Kingdom and the Join Dementia Research platform hosted by the National Institute for Health and Care Research (NIHR). Interested caregivers contacted the research team for more information. For those who wished to proceed, a discussion via email or telephone took place to allow the researcher to check the participant's eligibility.

The Research Team

The research team comprised four nonclinical women researchers and a women dementia support advisor/research coordinator working for a local dementia charity. The team collectively had considerable experience and expertise in applied psychosocial health research, including undertaking qualitative interview studies with informal caregivers and with people affected by cancer, dementia, and the cooccurrence of these conditions. The study was prompted by concerns raised by the dementia charity and National Health Service (NHS) oncology staff, in informal conversations with a member of the research team, regarding the challenges faced by dementia caregivers undergoing cancer treatment. Relevant personal and professional experiences within the research team included family experiences of dementia and cancer, alongside research expertise in dementia support and behavioral oncology. Consistent with reflexive thematic analysis (RTA), researchers reflected on how their experiences and perspectives may influence data interpretation through regular team discussions during coding and theme development.

Data Collection

Participants took part in one individual, audio-recorded, semistructured interview undertaken by ET via telephone or video call, depending on participant preference. Interviews explored participants' experiences of caring for someone with dementia alongside being diagnosed with cancer themselves. The interview topic guide (Multimedia Appendix 1) was informed by previous research in this area, including by our team (LA and MLP). The interview topic guide was reviewed and edited by the research team. The first interview was treated as a pilot, and no substantive changes to the topic guide were required. Interviews were conducted flexibly, allowing participants to discuss issues that were most important to them. Sensitive topics, such as future care planning, end-of-life concerns, and experiences of grief and loss, were raised by participants themselves rather than through direct questioning. All interviews were conducted by ET, an experienced qualitative researcher with expertise in psychosocial applied health research. The interviewer encouraged participants to discuss experiences that were important to them, and if participants became upset, they were reminded that they could pause, take a break, or continue the interview at a later time. The interview approach remained consistent throughout the study. Participants first provided sociodemographic information (eg, gender and age) and shared their experiences of caring for someone with dementia and how they came to find out they had cancer. Participants were recruited from 7 of the 9 regions of England and 1 region of Scotland, providing broad geographical representation within the sample. Interviews then focused in-depth on caregivers' experiences, difficulties, and needs around simultaneously caring and facing cancer and on experienced or potential sources of support or ways of helping to address caregivers' challenges and needs at this time.

Data Analysis

Data were analysed using RTA [14,15]. Analysis was an inductive, iterative, collaborative process involving both independent review and team discussion of the data, with decisions made collaboratively by consensus. Analysis was begun concurrently with data collection, allowing analytical insights to inform subsequent interviews and enabling the

XSL•FO
RenderX

research team to assess whether the data captured a sufficiently broad and rich range of experiences to address the study aims. Recruitment ended when the team agreed that the dataset provided adequate depth and diversity of perspectives relevant to the research aim. We adopted an experiential approach to RTA, informed by a hermeneutic phenomenological approach, as we aimed to understand how participants experienced and made sense of receiving a cancer diagnosis while caring for someone with dementia, including their support needs [16]. This approach complemented RTA by focusing on participants' perspectives and meanings, while recognizing that theme development involved interpretation by the research team. Transcripts were analyzed following the six stages of RTA as follows: (1) initial interview observations were recorded in MS Word by the interviewer following each interview. Interviews were then transcribed and anonymized by ET (P1-P19) and MS (P20-P25). (2) Codes were generated inductively and independently by ET, MLP, and JC to develop an analytical coding framework, which was subsequently applied to all transcripts by ET. In developing codes, MLP and JC each coded a different sample of 6 transcripts, which were also all coded by ET. (3) Similar codes were grouped and candidate themes and subthemes generated by ET. (4) ET, MLP, and MS met to review and refine candidate themes and subthemes and select indicative quotes. (5) ET and LA met to further review, restructure, and define themes and subthemes and determine the illustrating quotes. (6) Final theme and subtheme titles, descriptions, and illustrative quotes were reviewed and agreed upon by team consensus (MLP, MS, and LA). All stages of coding and data analysis were carried out in MS Excel. Participant validation (also known as member checking) was not undertaken in this study. Instead, the credibility of the analysis was supported through iterative discussion and interpretation of the data within the research team.

Ethical Considerations

The study received ethical approval from the Leeds Beckett University Psychology Local Research Ethics Committee on March 14, 2024. All participants received written information about the study and provided informed consent prior to the interview.

Results

Participants and Data Collection

Twenty-five informal family caregivers participated in the study. Sample characteristics are summarized in Table 1. No participants withdrew from the study. Interviews were conducted by telephone (n=15) or online video call (n=10) between March 25, 2024, and January 15, 2025, and ranged from 24 to 78 (mean 47.72, SD 12.92) minutes in duration. Variation in interview duration is likely a reflection of individual differences in participants' experiences, the amount of detail they wished to share, and their characteristic verbal style; however, factors contributing to interview length were not assessed.

Key Findings

Three themes, each with interrelated subthemes, were developed from the data to capture the experiences of and support received by informal caregivers while having cancer. The findings highlight how caregiver identity and role shaped and intensified both the practical and emotional challenges of cancer, giving rise to multifaceted support needs. Caring responsibilities were central to how participants experienced cancer, often taking precedence over their own health needs and influencing engagement with their treatment. Competing caregiving demands produced both practical disruptions to engaging in cancer care and intensified emotional consequences of facing cancer, including grief and loss, and anxieties about future care for the person living with dementia. In response, participants described a need to draw significantly on practical, financial, and psychological resources to effectively manage the demands of caregiving and cancer.

Theme 1: Caring Responsibilities Can Complicate and Take Priority Over Cancer Care

Overview

Caregivers spoke about their cancer as a competing priority to their caring responsibilities. Caring responsibilities frequently acted as the priority around which cancer was managed, shaping engagement with treatment and health care services. Interviews highlighted how caregiver burden and related responsibilities can complicate and negatively impact care accessibility and experiences across the cancer continuum.

Competing Caring Demands Make Cancer Care More Difficult to Manage

Caregivers cited various difficulties experienced in managing the demands of their dual role as a caregiver and people with cancer. These complications made undergoing cancer treatment difficult and stressful for some caregivers. Logistical complications included the need for caregivers to coordinate attendance at multiple appointments and treatments, the reality of having little to no choice but to prioritize the person with dementia over their own treatment, and the challenges arising when care recipients walked away from the waiting area during their own appointments or treatment.

For many caregivers, managing their cancer treatment required considerable planning and coordination alongside upholding existing caregiving responsibilities.

> *I've moved appointments and blood tests, or we've done it all on the same day. And you know, the other week we visited three hospitals in the region of England, two for my mum and one for me.* [P7, age:56, daughtercaregiver]

Challenges were not limited to scheduling appointments and could also create concerns about the safety and supervision of the person living with dementia.

> *She sat in the waiting room. Unfortunately, it was an hour long before I could come out. When I came out, she wasn't there. So, I said to the receptionist "my wife?," "Oh yes," she said. "She went to the toilet some time ago and she hasn't come back," so I was up and down the hospital searching for her, so I never took her again.* [P4, age:79, husband-caregiver]

Prioritizing Caring Responsibilities Can Affect Engagement With Cancer Care

From cancer diagnosis to outcome, the role of being a caregiver continued to be at the forefront of caregivers' minds, viewed as the greatest need before their own cancer. Examples cited demonstrate how being a caregiver with cancer can have a detrimental impact upon the patient's cancer trajectory in terms of help-seeking, decision-making, ability to give their full attention when attending medical appointments, and the need to reset and recover from their own treatment. As expected, the caregiver's burden and challenges were thought to be greater when the care recipient's dementia was at an advanced stage rather than when it was at an earlier stage.

For some participants, caregiving responsibilities took priority over their own health needs and delayed help-seeking for cancer symptoms.

> *I would say that I put off going about the lump when it came back last year…my dad was in hospital at the time, and so we were up and down and his circumstances of him going into hospital.* [P10, age:61, daughter-caregiver]

> *They were coming to appointments with me, and I found that I was more concerned about them and their reactions than I was about myself. I couldn't listen. I was looking at their faces and you know, they had all sorts of questions.* [P2, age:73, wife-caregiver]

Caregiving responsibilities also influenced how some participants approached their treatment decisions, with a preference for options that would minimize disruption to their caregiving role.

> *Radiotherapy offered a chance that it might not knock me out so much and all the rest of it, compared to the recovery time from an operation, so I could carry on caring.* [P6, age:80, husband-caregiver]

XSL•FO
RenderX

Theme 2: Caregiving Can Intensify Cancer-Related Distress and Anxieties

Overview

Beyond its practical impact on cancer care, being a dementia caregiver also shaped and intensified the emotional sequelae of cancer for caregivers. Caring for a person with dementia while facing cancer often intensified caregivers' feelings of loss, uncertainty, and vulnerability, leading to our second theme: caregiving can intensify cancer-related distress and anxieties. Being a caregiver for someone with dementia often meant that caregivers experienced additional or heightened cancer-related distress and anxieties tied to the losses and responsibilities of their caregiving role. Caregivers' realization of this emotional distress often occurred and was only dealt with at a later stage in their cancer journey. Caregivers with a terminal diagnosis worried over practical arrangements and the emotional burden of who would assume the challenging dementia care responsibilities after their death.

Cancer Triggers Feelings of Loss and Grief Toward the Person With Dementia

Being diagnosed with cancer and undergoing treatment surfaced feelings of loss in caregivers. This was attributed to their predeath grief toward the care recipient, who, due to their dementia, could no longer provide them with the emotional support they needed. Caregivers explained that they were unable to turn to their care recipient in the way they once could, before the care recipient's dementia, for emotional support. For some caregivers, this unmet need for emotional support to help them deal with their cancer and feelings of predeath grief was only realized retrospectively and acted upon at a later stage or following cancer treatment.

Adult-child caregivers in particular described a sense of loss arising from no longer being able to rely on their parent, the care recipient, for emotional support in the way they had before dementia.

> *I would have probably liked to talk about it to my mum and dad. You always go to your mum don't you. I missed that.* [P14, age:66, daughter-caregiver]

> *I said "Dad, I've just got a diagnosis of cancer", and his reaction to that, imagine this...your son tells you, "I've got cancer, it's not a little cancer, it's a serious cancer". And there was a pause. And he said, "oh, I'm sorry to hear that. Is there anything we can do?" that was literally what he said. It was so unemotional and uncaring.* [P9, age:59, son-caregiver]

For some, the emotional impact of having cancer was only recognized later, once the immediate demands of caregiving and their cancer treatment had passed.

> *I don't think I actually acknowledged...making the decision to not tell my mum was one thing, which was upsetting, but then I had to sort of put that in the box because I've got this to deal with now [having cancer]. It's only really in the last year or so that's sort of gone, do you know that was really actually quite bad. And yeah, you know what I've missed out on and how I actually really needed my mum. But at the time I had to put that into a box because I can't deal with that now because I'd got this [having cancer] to deal with. What was happening with mum was one thing and what was happening with me, was another thing. And I didn't connect them at the time, because it was too upsetting to connect them probably. So I never spoke to anybody about it because it's not something I was thinking about.* [P18, age:49, daughter-caregiver]

Caring Heightens Cancer-Related Anxieties and Fears About Dying and Future Planning

For those caregivers with an incurable cancer diagnosis, uncertainty and a lack of control regarding timings of their own and their care recipient's future situation were a cause of great distress. Caregivers were worried about what would happen to the person they cared for when they died. Their concerns encompassed both practical matters, such as funeral arrangements, and emotional anxieties, particularly around who would take on the responsibility for caregiving, a role that is often exhausting and burdensome when supporting someone with dementia.

> *I fear for the future. I fear for what's going to happen. In terms of caring for me or caring for <Person living with dementia name> because he's not going to want to go into a home. He's got quite an awkward streak in him, always has had. I think that's probably what I fear, and for my own health I'd, you know, [Crying] I don't know what the future holds. I've felt very ill before now and a year ago and you know, if I was like that, I wouldn't be able to look after him because it is very tiring.* [P1, age:76, wife-caregiver]

> *It's terrible when you're wishing your mum to die before you do. Because I don't want to cause her the trauma of, because I've got a metastatic diagnosis, you know, gosh I'm lucky to be here now. And that is a really terrible thing, that is one of the worries.* [P7, age:56, daughter-caregiver]

> *My mom and now my sister, who's going to look after them, if I'm not there, that's more the fear now, because I know that my kids will be okay, and they'll take care of their kids. But Alzheimer's is dreadful, and we've had dreadful experiences with that.* [P16, age:69, daughter-caregiver]

Managing the demanding roles of dementia caregiver and patient with cancer in tandem, along with the resultant practical and emotional challenges, was often cited as overwhelming. Consequently, participants reported a need for greater practical, emotional, and financial support, which forms our third theme.

Theme 3: Managing Cancer While Caring Increases the Need for Support and Coping Resources

Overview

Many caregivers reported a lack of awareness of available dementia support services, limited availability of those services, and inconsistent health and social care for the person with

XSL•FO
RenderX

dementia. To overcome systemic issues, caregivers often cited instrumental, financial, and emotional avenues of support they had depended upon to enable them to continue to care for their care recipient while also attending medical appointments and treatment of their cancer.

Reliance on Practical and Emotional Support From Family and Friends

Reliance on support networks was frequently cited as a response to the competing demands described in theme 1 and the emotional burden described in theme 2. Family members and friends often provided practical care that freed up participants to attend their cancer appointments, while also offering reassurance and emotional support for their cancer-related worries. All caregivers cited their reliance and sole dependence on friends and family to be able to attend medical appointments and treatment related to their cancer, particularly when caregivers had received last-minute appointments and were unable to arrange professional care at short notice. This instrumental support provided by family and friends also included respite care, cited by caregivers who at times needed a break to recharge physically and mentally. Caregivers also talked about the emotional support they had received from friends and family.

> *if somebody else had looked after my dad, instead of us all the time. And given us a break, because then none of it would have been so difficult.* [P10, age:61, daughter-caregiver]

> *It didn't really occur to me that there might be any facilities for it. So I didn't, you know, if you're not aware of something being available, possibly you don't even think to look for it. If you're not told, that would help or not.* [P11, age:79, wife-caregiver]

These accounts suggest that limited awareness of available support services may increase caregivers' reliance on family and friends.

> *I had a bit of a meltdown. I really couldn't see how I was going to cope. And I said to my daughter, could you have him? And so, she had him to stay for two nights, one day and two nights, and during that time I managed, I got my brain sorted really.* [P1, age:76, wife-caregiver]

Support from family members often extended beyond practical help and included emotional support during cancer treatment and recovery.

> *It's my wife who has taken the real hit in terms of emotionally supporting me, yet also taking on the burden, as it were, of supporting my mother* [P25, age:67, son-caregiver]

> *They [local council] didn't say they weren't interested, but they just kept saying, oh, we're fully booked. I don't know that we can do that on the day you want, and because I wasn't getting a lot of notice to go into hospital, so I was sort of saying to them, you know, in about three or four days time. So in the end, the family just said, stop messing about with it, although it sounds a good procedure.* [P4, age:79, husband-caregiver]

Financial Security Helps Caregivers Manage Cancer and Caring Responsibilities

Financial resources appeared to help mitigate the impact of challenges described in themes 1 and 2. Participants with access to savings, pensions, or privately funded care were often better placed to negotiate competing caregiving and cancer demands, reducing some of the practical tensions between caring and their cancer treatment. Given the current issues caregivers cited with a lack of health and social care provided, many caregivers felt privileged and fortunate that they had the option to fund private care themselves through their own or family personal finances. For some, personal finances had enabled them to reduce their working hours or take early retirement. For caregivers without personal finances to draw upon, this was viewed by caregivers interviewed as an unimaginable problem to cope with and manage.

> *Just to make sure they're safe and you don't have to worry about it. Do you know what I mean? Everything that you're going through without having to worry about everybody else. That would be the ideal world. But there's no budgets anywhere, is there for that.* [P13, age:53, daughter-caregiver]

> *Especially for people who haven't got the money, yeah, it must be so difficult. I just feel so completely privileged.* [P5, age:77, wife-caregiver.]

Financial security enabled some caregivers to reduce the demands of paid work, preserving more of their personal resources for managing the demands of caregiving and their cancer treatment.

> *Since I had cancer last year, I have only gone back to work, I halved my shifts, so that is a considerable difference and I am really aware of that but, we haven't, you know, we've managed. No, no, we're lucky.* [P10, age:61, daughter-caregiver]

> *We've both got private pensions, and we got somebody round and realized that we could take a bit of that every month and not have to, to carry on working if we didn't need to, for the short term at least.* [P19, age:59, daughter-caregiver]

Personal Resilience Supports Coping With Cancer and Caregiving Demands

Caregivers' accounts highlighted emotional resilience as key to how they actively coped with the practical and emotional challenges described in themes 1 and 2. Many caregivers spoke in ways that suggested they had a positive mindset about how they perceived their situation and challenges they faced. To help with coping, caregivers appeared to engage in benefit finding, somewhat indicative of their underlying resilience, which not only helped them deal with challenges but also appeared to strengthen their resilience further. For example, some caregivers viewed an early cancer diagnosis as a blessing, given that it aligned with their perception of the illness as being less severe. Being a caregiver was viewed as a positive distraction, a role

XSL•FO
RenderX

that gave caregivers a sense of purpose and provided a good distraction from worrying too much about their own cancer. One caregiver explained how she tries to focus on today, practicing mindfulness and resilience as a way to overcome and cope with any worries about what tomorrow will bring.

> *I think having my husband to look after was a distraction from focusing too much on the cancer and kind of getting panicky, so in a way, it just gave me something else to focus on as well. I think if it had just been me and my cancer, I would have focused more on that and then that would have been maybe harder to keep any sort of anxiety out of the way.* [P5, age:77, wife-caregiver]

Caregivers often described actively focusing on the positive aspects of their situation as a way of coping with the challenges they faced.

> *The cancer was caught at a very early stage. So, fortunately the cancer never really figured it was, just. Oh, look, I've got to do X, it was no more a problem than going to the dentist.* [P3, age:76, husband-caregiver]

> *Having cancer is not really an issue in the whole thing of caring for her because it's a non-event almost.* [P22, age 79, husband-caregiver]

Other caregivers described focusing on the present rather than worrying about the future as an important coping strategy.

> *It is a progressive disease, I do know what the future holds, but, I don't think about the future, we live for today. you know, I try to live as normal life as possible. Think about today, let tomorrow take care of itself, really. That's the way I've coped really, do I have wobbles, yes I do.* [P15, age:80, husband-caregiver]

Discussion

Key Findings

To our knowledge, this is the first qualitative study to explore, in the United Kingdom and internationally, the experiences of informal caregivers who have received a cancer diagnosis while caring for someone with dementia or memory problems. The study aimed to specifically identify the difficulties and issues faced by patients with cancer and existing gaps in psychosocial support. The findings corroborate and extend the work by Price et al [4,17] on the psychosocial support needs of caregivers of people with comorbid dementia and cancer, while highlighting the distinct experiences of individuals who are themselves living with cancer while also caring for a person with dementia. Study findings were developed into three key themes: (1) caring responsibilities can complicate and take priority over cancer care, (2) caregiving can intensify cancer-related distress and anxieties, and (3) managing cancer while caring increases the need for support and coping resources. Furthermore, this study is the first to present evidence that caregivers living with cancer themselves continue to shoulder the burden of illness work on behalf of their care recipients. Illness work, as described by Corbin and Strauss [18], refers to tasks such as taking medications, monitoring symptoms, attending medical appointments, and coordinating with health care providers. Price et al [4] emphasized the relentless caring regime involved in being a caregiver, and our study findings demonstrate that the caregiver role prevails, even to the detriment of the patient's cancer trajectory. Caregivers cited examples of how their caregiving role had influenced their decisions to opt for less invasive treatments with shorter recovery times, delayed their help-seeking for cancer symptoms, required them to reschedule appointments, and left them with limited time to recover from their own treatment. These findings extend previous research on illness work by demonstrating that caregiving responsibilities often continue when caregivers themselves are managing a serious health condition such as cancer. Consistent with wider caregiving literature, caregivers commonly continue providing care despite chronic illness, pain, and other health challenges of their own, often prioritizing the needs of the care recipient over their own health and well-being [19-22]. Participants in this study similarly placed the needs of the person with dementia ahead of their own, suggesting that the caregiver role remained of greatest importance despite cancer diagnosis and treatment.

This study underscores the unique emotional challenges faced by caregivers for someone with dementia who simultaneously need support for their own cancer diagnosis and treatment. Among the adult-child caregivers in our sample, participants described their parent as having previously been their significant source of emotional support in times of need. However, due to the progression of the care recipient's dementia, they could no longer rely on them for emotional support. There is growing interest in assessing and addressing predeath or anticipatory grief experiences among dementia caregivers, with recognition that this is an underresearched issue in which people can feel unsupported [23,24]. The loss of emotional support associated with dementia progression may be particularly challenging for caregivers who are simultaneously coping with their own cancer diagnosis and treatment. These experiences suggest that anticipatory grief may be compounded by the emotional and practical demands of cancer, highlighting a need for psychosocial support that addresses both cancer-related distress and losses associated with dementia progression. Further work is required to better understand these intersecting experiences and support needs. Findings highlight an important need to provide targeted psychosocial support to caregivers with cancer to help them emotionally cope with and process additional levels of loss experienced due to predeath grief.

Many caregivers relied on the support from family and friends, their own financial security, and their own emotional resilience to cope. Ji et al [25] found significant correlations between psychological resilience, caregiving burden, social support, and quality of life among primary caregivers of patients with cancer. Our findings suggest that access to practical, emotional, and social support may be especially important for people balancing the dual roles of being an informal caregiver and a patient with cancer.

Our findings have implications for digital health. Caregivers reported limited awareness of available services, difficulties navigating support, and challenges balancing their cancer care with caregiving responsibilities. These needs may be addressed

XSL•FO
RenderX

in part through digital solutions such as integrated patient and caregiver portals, digital signposting resources, telehealth follow-up, and online psycho-oncology support. Such approaches could help improve access to information, care coordination, and emotional support while reducing the practical burdens associated with hospital visits [26,27]. Online peer support may also be valuable, particularly for caregivers with limited support from family and friends. For example, the cancer-specific section of the Alzheimer's Society online forum, codeveloped by Ashley et al [8,28], provides opportunities for shared understanding, emotional support, and the exchange of practical advice among people navigating both cancer and dementia caregiving. Future research could explore the acceptability and effectiveness of digital interventions for informal caregivers managing both cancer themselves and dementia-related caregiving demands.

Benefit finding is a psychological concept whereby someone searches for or identifies positive outcomes or personal growth when faced with stressful life experiences [29]. To help with coping, caregivers in this study indicated involvement in benefit finding, which not only helps them deal with challenges faced but also strengthens their resilience further. A recent review of 21 articles by Chiba et al [30] highlighted indicators of benefit finding among family caregivers of individuals with mental illness, including positive personal traits, good relationships with patients, and social support. Benefit finding has also been identified among caregivers of people with advanced cancer, where caregivers reported personal growth, stronger relationships, perceived social support, and a greater sense of meaning in life [31]. While benefit finding has been reported in other caregiver populations, our findings suggest that caregiving may also provide a sense of purpose and distraction from cancer-related concerns for some individuals. Caregivers in our study described engaging in positive distraction, focusing on their role as a caregiver, as a coping strategy, shifting their attention and concern away from their own cancer. Dobignes et al [32] investigated the use of an online positive psychology intervention to support caregivers of people with Alzheimer disease. Their findings reported that caregivers of people with earlier stage Alzheimer disease benefited the most from the intervention [28]. Further work in this area is warranted to explore and test interventions that support coping strategies for caregivers more widely. Several implications arising from our findings align with recommendations previously proposed by Ashley et al [8,28] to improve cancer care for people affected by dementia. These include cancer services identifying patients who also care for someone with dementia and considering reasonable adjustments that help them balance treatment and caring responsibilities. Flexible appointments, reduced hospital visits, dementia-friendly environments, and practical support with travel or attendance could also help minimize barriers to cancer care. It is also important to recognize the emotional impact of managing cancer while providing care. Regular discussions about well-being, access to caregivers' support services, and tailored psychological support can help address anxiety, future care concerns, and feelings of loss or grief, many of which may be reduced through appropriate adjustments and support [8,28].

Our findings highlight the challenges of being both an informal dementia caregiver and a patient with cancer at the same time. Participants described prioritizing the needs of the person with dementia over their own health and cancer treatment, coping with the emotional impact of dementia progression intensified in the context of coping with cancer, and needing and relying on different sources of support to manage both roles. These findings suggest that the experiences of informal caregivers with cancer are not fully reflected in the existing cancer or dementia caregiving literature. Our study helps to address this gap by providing new insight into the challenges and support needs of people who are simultaneously managing a cancer diagnosis while continuing to care for a person living with dementia.

Key Strengths and Limitations

Study strengths include recruitment of a sizeable sample with diversity across several study-relevant personal characteristics (eg, gender, age, cancer type, caregiver relationship to person with dementia, and socioeconomic status), as well as in-depth, rich data collection and collaborative, iterative data analysis involving multiple members of the research team. Limitations include the recruited caregivers who were predominantly retired and White British. Although this partly reflects the higher incidence of cancer in older adults [33] and the larger proportion of White British people affected by dementia in the United Kingdom, the Alzheimer's Society reports that just 3% of people living with dementia are from Black, Asian, and minority ethnic communities [34].

Conclusions

Our study demonstrates that for dementia caregivers facing cancer, caregiving responsibilities can compete with, complicate, and negatively impact engagement in cancer treatment and care. Our findings underscore the unique emotional challenges faced by caregivers for someone with dementia, who simultaneously need support for their own cancer diagnosis and treatment. For dementia caregivers, having cancer can surface/heighten feelings of predeath grief and worries about future care planning for their care recipient. Dementia caregivers viewed multifaceted social support as vital for enabling access to and coping with cancer treatment. This investigation provides initial evidence that caregivers living with cancer themselves continue to shoulder the burden of illness work on behalf of their care recipients. For dementia caregivers, accessibility and experiences of cancer care may be optimized by person-centered adjustments to care planning and scheduling and dementia-friendly hospital environments. Dementia caregivers may benefit from tailored psycho-oncology support encompassing caregiver-role concerns and needs (eg, predeath grief for their care recipient). Digital health interventions may also help address needs around information provision, service navigation, care coordination, and psychosocial support for dementia caregivers with cancer. The findings suggest that the experiences of dementia caregivers with cancer are not fully reflected in the existing cancer or dementia caregiving literature. By focusing on the intersection of these roles, our study provides new insight into the challenges and support needs of this overlooked group. Future research should evaluate interventions

designed to support individuals managing both dementia caregiving responsibilities and a personal cancer diagnosis and treatment.

Abstract

Background: Older survivors of cancer face heightened risk of depression and anxiety related to cancer experiences, fear of recurrence, and aging-related difficulties. Conventional mental health monitoring approaches, such as clinical assessments and even electronic patient-reported outcomes, are limited by recall bias, patient burden, and infrequent data collection. Emerging patient-generated health data from wearables and smart home devices offer passive, low-burden, continuous monitoring, but their ability to capture mental health risks in older survivors of cancer remains unclear.

Objective: This study aims to explore whether patient-generated health data collected in the wild, either passively or actively, can classify older survivors of cancer as having or not having signs of anxiety and depression based on Patient Health Questionnaire-4 (PHQ-4) scores and to assess the potential added value of passive monitoring modalities, such as smart plugs.

Methods: This study recruited 41 older survivors of cancer (mean age 72.3, SD 6.81 years) from the LifeChamps project. Over a 12-week period, participants were monitored using an activity tracker to measure physical activity, sleep, and physiological metrics; a smart scale to capture weight and body composition; and a smart plug to track television use as a proxy for sedentary television viewing. Mental health status was self-reported via the PHQ-4 questionnaire in a mobile app. Machine learning models were trained to classify mental health risk based on features derived from each sensor modality, both independently and in combination.

Results: Tree-based gradient boosting models showed good performance in classifying PHQ-4–defined mental health risk. The best-performing configuration, combining smart plug and smart scale features, achieved a mean F_1-score of 0.77 (SD 0.15) and a mean area under the receiver operating characteristic curve (AUC) of 0.85 (SD 0.10) across 3 repeated train-test splits. Standalone smart plug models, based solely on passive television use patterns, achieved a mean F_1-score of 0.66 (SD 0.04) and a mean AUC of 0.71 (SD 0.06), outperforming models that relied only on activity tracker data (mean F_1 0.59, SD 0.2). Multimodal combinations tended to improve average performance but did not consistently yield large gains over the strongest single-modality configurations, likely reflecting adherence-related data loss for wearables and scales. Crucially, passive monitoring of television use patterns emerged as a promising behavioral proxy measure of mental health states.

Conclusions: This study pioneers the use of passively collected data (eg, smart plugs) for mental health monitoring in older survivors of cancer, demonstrating their potential. Smart plugs capture behavioral patterns without user burden, with reasonable standalone performance (mean AUC 0.71, SD 0.06), positioning them as a promising low-burden modality. Future work should validate findings in larger independent cohorts and in prospective clinical workflows. Such technologies could transform monitoring for vulnerable populations, enabling scalable, inclusive care while reducing health care burdens.

KEYWORDS

behavioral data analysis; survivors of cancer; digital biomarkers; mental health monitoring; nonintrusive monitoring; patient-generated health data

Introduction

Overview

Older survivors of cancer face a unique set of challenges, including increased susceptibility to mental health issues such as depression and anxiety, 2 of the most common mental health disorders [1]. The intersection of aging, cancer survival, and mental health presents a complex clinical manifestation. These individuals often struggle with psychological distress stemming from their cancer diagnosis, treatment experiences, and the fear of cancer recurrence, all of which can significantly impact their quality of life (QoL) [2-4]. Furthermore, the combination of cancer recovery with aging processes can exacerbate mental health issues, making early detection and continuous monitoring critical for this demographic [5]. Emerging research underscores the importance of monitoring mental health to improve QoL among this demographic group, emphasizing the need for innovative approaches that are both effective and nonintrusive [6], so as to not exert additional burden on this vulnerable population.

Background and Current Approaches

To address these challenges, the efficacy of using technological advancements for mental health monitoring has been widely explored in recent years.

A 2021 study [7] explored the potential of consumer-grade wearables, specifically Fitbit devices, to assess depression severity through digital biomarkers such as step count, heart rate, and sleep patterns. Their study, which focused on a cross-sectional working population in Singapore, demonstrated that wearable metrics could be significantly associated with depressive symptoms, with a sensitivity of 73% and specificity of 79%. This work underscores the feasibility of using common activity trackers to screen for mental health issues in general adult populations and presents a scalable model for remote monitoring of behavioral health indicators.

In an older adult population of 352 individuals, Lee et al [8] used low-cost activity trackers from Fitbit to monitor circadian rhythms and sleep patterns, finding correlations between these metrics and symptoms of depression and anxiety. This study highlighted that specific circadian rhythm markers, such as intraday stability and variability, can serve as predictors for geriatric depression and anxiety. The study's findings supported the utility of passive, low-cost monitoring solutions for older adults, a critical demographic for interventions targeting mental health, by showcasing 69.8% accuracy for depression classifiers when using data only from the activity trackers.

Similarly, a study by Pedrelli et al [9] combined wearable (Empatica wristbands) and smartphone data to predict depressive symptom severity among 31 adults diagnosed with major depressive disorder. This research used multimodal data, including electrodermal activity, heart rate, and physical activity, as well as social engagement metrics from smartphones. The combination demonstrated that passive monitoring could reliably predict symptom changes, achieving high correlations between features and symptoms as well as a moderate mean absolute error between 3.8 and 4.7, emphasizing the potential of machine learning models in complex mental health assessments.

Furthermore, a systematic review [10] highlighted various studies that apply wearable sensors for passive data collection to detect symptoms of anxiety and depression. One of the significant findings was the identification of key behavioral markers detectable by wearable devices, such as heart rate variability, sleep disturbances, and physical activity levels, which consistently correlate with mental health conditions. However, the review highlighted a scarcity of research focused on older populations, where mental health burdens may intersect with age-related barriers to technology use. Additionally, Kim et al [11] recruited 20 participants aged 69 - 90 years for a 90-day period, monitoring daily activities using passive infrared motion sensors. Their neural network-based classifier achieved more than 94% area under the receiver operating characteristic curve (AUC), suggesting that passive monitoring sensors can be effectively used to detect depression levels.

Problem Statement

Despite the promising technological advancements outlined earlier, current standard-of-care methods for monitoring mental health still rely heavily on self-reported questionnaires and clinical assessments. These approaches present several challenges; they often rely on patients' ability to recall, assess, and document their experiences, which can be hindered by memory recall biases, especially among older adults [12]. Additionally, the burden of frequent clinical visits and the adherence required for consistent self-reporting can be cumbersome, leading to reduced compliance and potentially delayed identification of mental health issues [13]. Even electronic patient-reported outcomes do not fully alleviate these burdens, as they still depend on active patient participation and do require an adequate level of digital literacy [14].

The sporadic nature of these assessment methods may fail to capture timely variations in mental health status, resulting in missed opportunities for early intervention. While the integration of wearable devices and smart home technologies offers a promising avenue to overcome these limitations [10], the efficacy of these technologies in accurately identifying mental health problems within vulnerable populations, such as older survivors of cancer, remains underexplored [15]. Specifically, the use of purely passive devices, such as smart plugs that monitor energy consumption and household appliance use, has not yet been thoroughly studied and remains an emerging topic [16].

XSL•FO
RenderX

Objectives

To bridge this gap, this study aims to explore the added value that patient-generated health data (PGHD) collected in the wild, especially the ones that are passively collected, may contribute in terms of older survivors' health-related QoL monitoring. Rather than performing a full clinical validation, we treat this work as an exploratory readiness assessment of whether machine learning models built on PGHD can meaningfully classify Patient Health Questionnaire-4 (PHQ-4)–defined anxiety and depression symptoms at each questionnaire occasion based on the preceding 30 days of sensor data, and what additional signal is contributed by different sensor modalities. In addition, this work attempts to compare the different modalities and their contribution toward the most accurate identification of mental health risk.

Specifically, this study contributes to the existing body of knowledge by:

- Evaluating the performance of machine learning (ML) models using data from smart plugs, wearables, smart scales, and their combination, in classifying the mental health status of older survivors of cancer.
- Comparing the discriminative contribution and potential added value of these unobtrusive monitoring modalities—individually and in combination—with particular emphasis on fully passive smart plug data as a low-burden option for longitudinal monitoring.

By demonstrating the discriminative value of ambient home sensors compared and in addition to wearables, this work offers evidence-based insights for integrating unobtrusive, cost-effective monitoring techniques into standard postcancer treatment surveillance and care [17].

In summary, our aim was to evaluate whether PGHD from smart plugs, activity trackers, and smart scales—alone and in combination—can classify PHQ-4–defined anxiety and depression symptoms in older survivors of cancer at the time of each questionnaire occasion based on the preceding 30 days of sensor data and to quantify the incremental discriminative signal contributed by fully passive smart plug data.

Methods

Study Design and Setting

This work is an observational study embedded in the Greek pilot site of the LifeChamps project [18], a multidisciplinary initiative designed to enhance the QoL for older survivors of cancer. The pilot involved home-based remote monitoring over approximately 12 weeks per participant using wearable devices, smart-home sensors, and a mobile app. Recruitment for this study took place between October 2022 and December 2023. All study procedures were conducted in collaboration with oncology and urology clinics in public and private hospitals or clinics in Greece, where patients were approached by their treating clinicians.

Participants

Participants were recruited from the LifeChamps Greek pilot. Treating medical professionals (oncologists and urologists) identified potentially eligible survivors of breast and prostate cancer from their regular caseloads and invited them to participate during clinic visits.

The recruitment flow was as follows:

- Contacted: A total of 102 patients were approached (breast cancer: n=71 and prostate cancer: n=31).
- Consented: Of these, 50 (49%) patients (breast cancer: n=30 and prostate cancer: n=20) agreed to participate, provided written informed consent, and had the monitoring equipment installed at home.
- Excluded or refused: The remaining 52 patients either refused participation (n=35) or were deemed ineligible or unsuitable (n=17).
- Completed: Among the 50 participants who consented, 45 (90%) completed the full 12-week monitoring protocol.

For this analysis, we included the 41 participants who both completed follow-up and had at least 1 eligible postbaseline PHQ-4 assessment with corresponding sensor (smart plug) data. These 41 older survivors of cancer (female participants with breast cancer: n=24 and male participants with prostate cancer: n=17) had all completed their primary treatment and were either on adjuvant therapy or under surveillance.

Inclusion and Exclusion Criteria

Eligible participants were older survivors of breast or prostate cancer under the regular care of the participating clinicians and living in the community. The specific criteria are presented in Textbox 1.

XSL•FO
RenderX

Textbox 1. Eligibility criteria.

Inclusion criteria

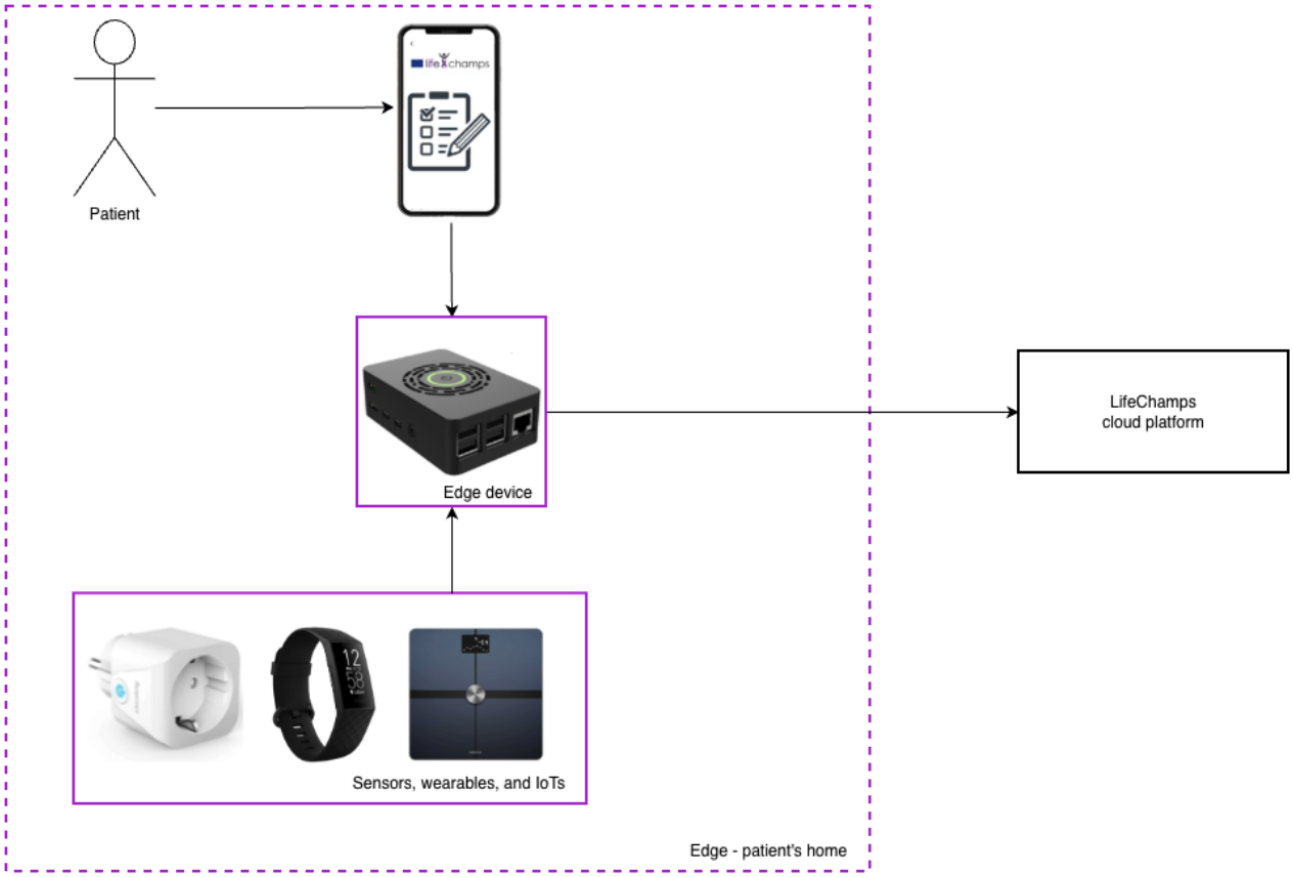
- Demographics: Age ≥65 years
- Cancer diagnosis or survivorship status: Histologically confirmed breast or prostate cancer, living beyond initial cancer treatment (surgery, chemotherapy, and/or radiotherapy), under adjuvant therapy or surveillance (as applicable), absence of diagnosed secondary malignancy
- Functional and cognitive status: Deemed physically and psychologically fit to participate (multidisciplinary team judgment); able to read, write, and understand Greek; Mini-Cog score ≥ 3
- Technological requirements: Own Android smartphone (version 10+), 24/7 home internet access (Wi-Fi and/or 4G; study provided mobile data where needed)
- Ethics or administrative: Able and willing to provide written informed consent

Exclusion criteria

- Clinical status: Terminal stage of cancer, prognosis <18 months from recruitment, currently receiving chemotherapy, active and unstable metastatic disease (clinician judgment)
- Mental or cognitive conditions impacting participation: Current diagnosis of a major mental disorder or cognitive disorder affecting the ability to participate
- Safety or device compatibility: Presence of an internally fitted medical device (eg, pacemaker), known allergy to metal or plastic that would preclude device use
- Ethics or administrative: Unwillingness or inability to provide written informed consent

Ethical Considerations

The study protocol was reviewed and approved by the Research Ethics and Deontology Committee of the Aristotle University of Thessaloniki (protocol 267203; approval date: October 13, 2022). All participants provided written informed consent before installation of any sensors. The consent process described the types of data collected (including physical activity, sleep, physiological metrics, weight and body composition, and household appliance power consumption) and the duration of monitoring and clarified that participation was voluntary and could be withdrawn at any time without consequences for clinical care. To protect participant privacy, all sensor data were pseudonymized at the source and stored using unique participant codes; the linkage key was stored separately on a secure local server accessible only to authorized clinical staff. No identifiable images were collected or used in this paper or Multimedia Appendix 1. Participation was voluntary, and no financial compensation was provided; however, participants were allowed to keep the activity tracker or smart scale upon study completion as a token of appreciation.



Data Collection

Overview

The study spanned a 12-week period, during which participants' homes were equipped with the LifeChamps Edge platform [19], a high-level overview of which can be seen in Figure 1. This platform included a suite of sensors and Internet of Things devices that tracked a breadth of activity and biometric data, constructing a comprehensive overview of each participant's health and daily routine.

XSL•FO
RenderX

Figure 1. Overview of the LifeChamps home monitoring platform used in this observational study, showing the integration of Fitbit, Withings smart scale, and smart plug data with the central Edge device and data warehouse. IoT: Internet of Things.

Activity Tracker

This wristband (namely the Fitbit Charge 4), worn consistently except during charging times, offered a stream of data covering physical activity (including duration, intensity, type, number of steps or floors, and calories burned), sleep metrics (including duration, efficiency, time in various sleep stages, time to fall asleep, sleep onset, wake time, and number of awakenings), and biometric parameters such as heart rate at different states (eg, during activities, resting heart rate, and sleep heart rate), and oxygen saturation levels. Data were synchronized with the vendor's cloud service and then integrated into the LifeChamps platform.

Smart Scale

Participants engaged with the smart scale (namely the Withings Body+) on a weekly basis, which measured not only weight but also provided detailed body composition analytics, including muscle mass, fat mass, bone mass, and BMI. Unlike the continuous data stream from the Fitbit, the Withings scale provided discrete, yet vital, snapshots of the participants' body composition over time.

Smart Plug

Integrated into the Edge platform and connected to the patient's television (the main television used by them in case of multiple ones available), the smart plug (specifically the Teckin SP22) was used to monitor the television's power status, recording on or off transitions every 5 minutes. This served as a proxy for one of the participants' activities of daily living, offering insights into sedentary and leisure habits. Television watching is a sedentary behavior that has been associated with mental health status in prior work using validated psychometric tools [20].

In addition to sensor data, baseline demographic and clinical characteristics (eg, age, sex [male or female], marital and employment status, living situation, cancer type and stage, and Mini-Cog score [21]) were collected at study entry and later used as candidate features in the models. Participants also received a mobile app that served as the interface for self-report questionnaires, including the PHQ-4 mental health assessment described below.

Mental Health Assessment

Participants in LifeChamps also received a mobile app, allowing them to self-report patient-reported outcome measures (PROMs) monthly. The PHQ-4 self-reported questionnaire [22] was used as the main self-report measure for mental health, assessing anxiety and depression with scores from 0 to 12, interpreted as normal mental health status (0 - 2) or mild (3-5), moderate (6-8), and severe (9-12) symptoms of anxiety and depression. It includes 2 subscales for depression and anxiety, each total subscore ranging from 0 to 6, with subscores of 3 or above indicating symptom presence. PHQ-4 was selected as a compromise between more elaborate tools like Patient Health Questionnaire-9 and ultrabrief self-reports like Patient Health Questionnaire-2, based also on previous studies that included survivors of cancer and used the same questionnaire [23]. Although questionnaires like Patient Health Questionnaire-9 are not time-consuming on their own, in the larger context of

XSL•FO
RenderX

the LifeChamps study where several PROMs were administered each month to a vulnerable group of people such as survivors of cancer, the decision was taken to opt in for brief versions of these PROMs whenever possible. On the other hand, the ultrabrief Patient Health Questionnaire-2 was not selected since it focuses only on depressive symptoms [24].

Participants were asked to report the PHQ-4 at 4 time points: at baseline and then monthly for 3 months. The first questionnaire was completed with researcher assistance, while subsequent ones were self-administered via app notifications at each specified interval. For this analysis, the baseline self-reports were not considered since they had no sensor data prior to their completion.

Each postbaseline PHQ-4 assessment, together with the corresponding 30 days of preceding sensor data, was treated as a single observation (questionnaire occasion) in the modeling analyses. Thus, the unit of analysis in this study is the PHQ-4 questionnaire occasion rather than the participant, and individual participants may contribute multiple observations over time. For the binary classification models, PHQ-4 total scores were subsequently dichotomized into "presence" versus "absence" of mental health signs, as described in the Data Preprocessing section.

Data Preprocessing

We conducted a row-wise, participant-agnostic classification analysis to classify dichotomized PHQ-4 scores from demographics, questionnaire data, and sensor-derived features, treating each questionnaire plus its preceding 30 days of sensor data as a concurrent observation. As described earlier, each postbaseline PHQ-4 assessment, together with the corresponding 30 days of preceding sensor data, was treated as a single observation (questionnaire occasion). Because participants could contribute more than 1 questionnaire over time, multiple observations could originate from the same individual.

PHQ-4 scores were transformed to suit the needs of binary classification for the presence or absence of symptoms. This transformation was guided by clinical relevance and the nature of mental health progression in older survivors of cancer. Thus, all PHQ-4 PROMs with score 3 and above were categorized as "presence of mental health signs" to avoid any ambiguity, according to the suggested cutoff point for the Greek general population [25] and the one for patients with breast cancer [26], while the rest were assigned to class "no mental health signs."

For each questionnaire occasion, we reconstructed the original feature blocks: (1) demographic and clinical characteristics (eg, age, sex, marital and employment status, living situation, Mini-Cog score, cancer type and stage, and treatment intent); (2) additional patient-reported outcomes (Brief Illness Perception Questionnaire, Medication Adherence Report Scale, Vulnerable Elders Survey-13, Edmonton Symptom Assessment System, and Linear Analog Self-Assessment); and (3) sensor-derived aggregates from the activity tracker (Fitbit), smart scale (Withings), and smart plug (television use). From the smart plug, we derived features such as daily total television on-time, daily off-time, and summary statistics (eg, mean and SD) across the 30-day window. We also experimented with features stratified by time of day (morning, afternoon, and night) and by weekday versus weekend; however, in the final models, we focused on simpler daily statistics, which yielded more stable performance in our experiments. To align with the monthly PHQ-4 assessments, we summarized daily and weekly sensor data into monthly aggregates. This process did not only involve simple aggregations, such as totals and averages, but also the computation of statistical measures that capture the variability and distributional characteristics of the data within each month. For each feature, we calculated the coefficient of variation to assess relative variability, the IQR around the median value, and the maximum and minimum values to encapsulate the range. Kurtosis was computed to understand the distribution, which can be indicative of behavioral patterns.

From the set of completed PHQ-4 questionnaires, we first excluded baseline assessments (which lacked prior sensor data and were used only for descriptive purposes) and any follow-up questionnaires without any smart plug data in the preceding 30-day window. To ensure that smart plug–derived features reflected meaningful television use patterns, we further excluded questionnaire occasions with fewer than 15 days of valid television data within the 30-day window or with 0 recorded television on-time during that period. As a valid day for the smart plug, we consider the days for which we have at least 10 hours of data. Fifteen days were selected as a threshold since they attribute 50% of the expected data within a month, a common threshold for considering missing values as manageable with imputation methods [27]. We selected smart plug data as a prerequisite, since the main aim of our analysis is to determine the efficiency of this completely passive monitoring modality as a standalone sensor and also compare it to the rest of the modalities.

Preventing data leakage, that is, avoiding any inadvertent use of information from the held-out test set during model training, was a priority, and as such, all algorithmic preprocessing steps were carefully applied to maintain the test set's integrity. Automated feature selection techniques [28], such as importance thresholding, were used alongside clinical expertise and literature to inform the selection of features related to health-related QoL. To reduce the risk of overfitting, we removed columns that were direct identifiers (eg, patient ID), and we dropped ultrasparse features with more than 70% missingness within the filtered dataset before any imputation. For the remaining features, numerical variables were imputed using an iterative multivariate imputation procedure (IterativeImputer), while categorical variables (eg, sex, treatment intent, employment status, and living situation) were imputed using the most frequent category, and then, one-hot encoding was applied. All imputation steps were fitted on the training data only within each resampling split. To address class imbalance in the binary PHQ-4 outcome, we applied the synthetic minority oversampling technique (SMOTE) strictly within the cross-validation folds to prevent data leakage and overoptimistic performance estimates. The validation sets remained composed entirely of real, unaugmented patient data, ensuring that all reported metrics reflect performance on actual participants.

XSL•FO
RenderX

The resulting feature set was scaled using standardization, adjusting the data to have a mean of 0 (SD 1), so that features were on comparable scales for algorithms that are sensitive to feature scaling, without changing their relative information content.

The final dataset, a temporal alignment of Fitbit, Withings scale, and smart plug data with monthly PHQ-4 scores, was crucial for the effective identification of patterns by our ML algorithms. The different categories of features extracted from each sensor are presented in Table S1 in Multimedia Appendix 1.

Modeling and Evaluation

We framed the task as a supervised binary classification problem, aiming to classify the presence or absence of mental health signs at each questionnaire occasion based on the preprocessed feature sets described earlier. The dichotomized PHQ-4 outcome (total score >2 vs ≤2) served as the target variable, and each PHQ-4 questionnaire plus its preceding 30 days of sensor data was treated as a separate sample. Thus, the models estimate how well PGHD can discriminate between questionnaire occasions with and without PHQ-4–defined signs within the same 30-day window, rather than predicting mental health status at a future time point.

Several model families commonly used for tabular clinical data were evaluated, including elastic net–regularized logistic regression, random forests, and HistGradientBoosting classifiers. All models were implemented in scikit-learn and combined with the same preprocessing pipeline (imputation, encoding, scaling, oversampling, and feature selection) applied in a consistent way across sensor configurations. Hyperparameters were tuned using small, predefined grids chosen to balance flexibility with the limited sample size.

To obtain more robust performance estimates and reduce dependence on a single train-test split, we used a repeated stratified train-test evaluation with an inner cross-validation loop for model selection. For each of 3 repetitions (3 different random seeds), we performed a stratified 80/20 split of the 52 samples into a training set (80%) and an independent test set (20%), preserving the class distribution. On the 80% training portion, we then carried out 10-fold stratified cross-validation to tune hyperparameters, with AUC used as the primary optimization criterion.

Within this inner cross-validation, the full preprocessing pipeline (including imputation, encoding, scaling, oversampling with SMOTE, and random forest–based feature selection) was fitted on the training folds only and applied to the corresponding validation folds, ensuring that no information from the held-out test set leaked into model training. After tuning, the selected model was refit on the full 80% training set and evaluated on the held-out 20% test set. This procedure was repeated independently for each seed and for each sensor configuration (single modalities and combinations), yielding 3 test-set performance estimates per configuration.

We assessed model performance using standard classification metrics: AUC, F_1-score, precision, and recall. For each configuration, we report the mean performance on the 3 held-out test sets together with the corresponding SD across seeds (interrun variability). Hyperparameters were tuned using inner cross-validation, with AUC as the optimization criterion. Given the modest sample size (52 questionnaire occasions from 27 participants, with 21 “presence” and 31 “no mental health signs”), these analyses are intended as exploratory and hypothesis-generating, and model complexity as well as hyperparameter ranges were deliberately constrained to mitigate overfitting. No formal a priori sample size calculation was performed; the sample size was constrained by the LifeChamps pilot and was considered appropriate for exploratory, hypothesis-generating analyses. To mitigate overfitting with 52 questionnaire occasions (21 “presence” and 31 “absence” of signs), we restricted model complexity and used repeated resampling and nested cross-validation rather than more flexible model families.

Missing Data

Missing data in this study arose from 2 main sources: participant nonadherence to the protocol and technical issues affecting data capture. For the PHQ-4 outcome, questionnaires that were not completed at a given time point were simply absent and were not imputed; only completed postbaseline PHQ-4 assessments with corresponding sensor data were included in the modeling dataset. As described earlier, we additionally excluded questionnaire occasions with no smart plug data or with fewer than 15 valid television days in the preceding 30-day window, because smart plug–derived features were central to our research question and the smart plug application programming interface did not allow backfilling of data after Edge-device downtime.

In the final analytic dataset (52 questionnaire occasions from 27 participants; 174 features after removing ultrasparse features >70% missingness), overall cell-level missingness was 32.5% (2943/9048). After applying the television coverage criteria, smart plug features were complete (0% missing), while missingness remained for demographics (17.3%), activity tracker features (33.4%), and smart scale features (53.6%).

For sensor-derived features, partial missingness was common, particularly for the activity tracker and smart scale, due to factors such as low digital literacy, forgetting to wear or charge the device, or not using the scale regularly. To ensure data quality, strict “validity criteria” were applied. A “valid day” for Fitbit data required >10 hours of wear time. Data from invalid days were not taken into account. In the preprocessing pipeline, ultrasparse features with more than 70% missingness were removed before modeling, and the remaining numeric and categorical features were imputed using the iterative and most-frequent strategies described earlier, fitted only on the training data within each resampling split. Because PHQ-4 served as the supervised learning target (label), we did not impute missing PHQ-4 outcomes; only completed postbaseline PHQ-4 assessments were included in the modeling dataset, as outcome imputation would require strong assumptions and could introduce bias if missingness was informative.

To explore the missingness mechanism in the final analytic dataset, we first note that Little’s global test for data missing completely at random (MCAR) can be numerically unstable when the number of variables greatly exceeds the number of observations, and its P values should be interpreted cautiously.

XSL•FO
RenderX

We therefore supplemented this with pairwise MCAR 2-tailed *t* test diagnostics that compare the distribution of each observed variable between rows where another variable is missing versus observed (as implemented in commonly used missingness-exploration toolkits). In total, 2269 of 19,082 (11.9%) tests were significant at $P<.05$, exceeding the approximately 954 of 19,082 (~5%) expected under MCAR, which is consistent with structured (non-MCAR) missingness. This was expected because missingness occurred largely at the device or modality level—when a participant did not use the Fitbit or Withings scale during a given period, all features derived from that device were simultaneously absent.

Importantly, we did not find clear evidence that missingness was associated with the study outcome (PHQ-4 score>2). The prevalence of psychological distress did not differ significantly between questionnaire occasions with comparatively complete versus incomplete sensor data, nor did participant-level mean missingness show a significant association with outcome status (Spearman $\rho=-0.24$; $P=.23$). Sex (male or female) distribution was comparable between completeness groups ($P=.87$), whereas age differed (68.4 vs 71.9 years; $P<.001$), indicating that younger participants tended to have more complete device data. Together, these findings suggest that missingness depended on observable covariates and device-use behavior—patterns consistent with (though not proving) a missing at random mechanism.

Results

Participant Characteristics and Final Sample

A total of 41 participants met the analytic inclusion criteria (completion of follow-up and at least 1 eligible postbaseline PHQ-4 assessment with corresponding smart plug data). These older survivors of cancer included 24 female participants with breast cancer and 17 male participants with prostate cancer. Their baseline sociodemographic and clinical characteristics are summarized in Table 1.

Table . Baseline sociodemographic and clinical characteristics of the 41 older survivors of breast and prostate cancer enrolled in the LifeChamps Greek pilot (Greece, 2022 - 2023).

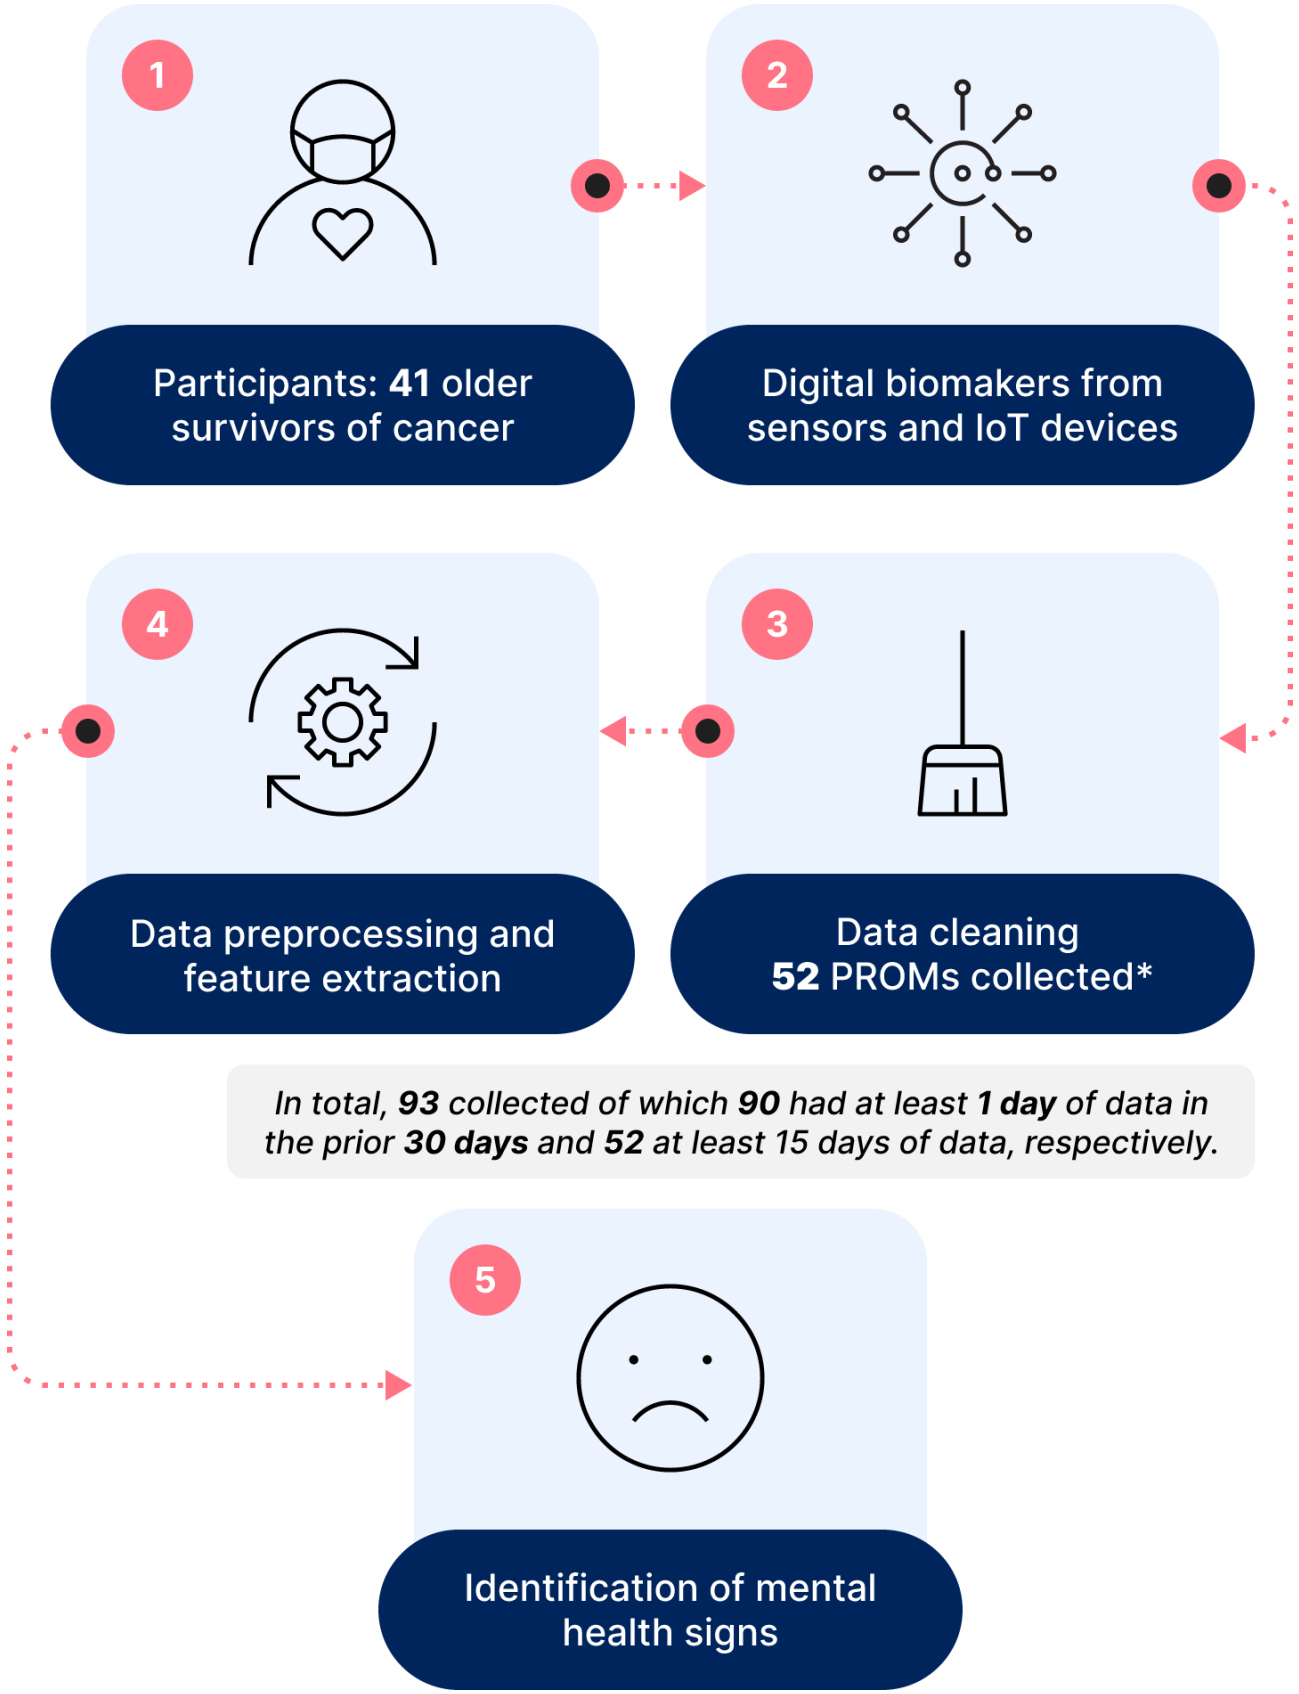
Variable	Values
Sex assigned at birth, n (%)	
Male	17 (41.5)
Female	24 (58.5)
Age (years), mean (SD)	72.3 (6.81)
Employment status, n (%)	
Retired	20 (48.8)
Employed	2 (4.9)
Unemployed	1 (2.4)
Unknown	18 (43.9)
Cancer type, n (%)	
Curative	37 (90.2)
Metastatic	4 (9.8)
Living situation, n (%)	
Alone	4 (9.8)
Cohabitation	19 (46.3)
Unknown	18 (43.9)
PHQ-4[a] baseline assessment, n (%)	
Healthy	33 (80.5)
Mild symptoms	8 (19.5)

[a]PHQ-4: Patient Health Questionnaire-4.

Following the process described in the previous section, out of 123 expected postbaseline monthly follow-up questionnaires (41 participants×3 monthly follow-ups), 93 were collected from 41 participants due to varying adherence to the protocol. The distribution of PHQ-4 classes based on the participants' answers is shown in Table 2.

XSL•FO
RenderX

Table . Distribution of PHQ-4[a] categories (normal, mild, moderate, and severe) across all completed postbaseline monthly follow-up questionnaires (n=93) among the 41 participants.



PHQ-4 class	Questionnaires in class, n (%)
0 (normal)	30 (32.3)
1 (mild)	49 (52.7)
2 (moderate)	10 (10.8)
3 (severe)	4 (4.3)

[a]PHQ-4: Patient Health Questionnaire-4.

After applying the preprocessing steps detailed previously, which are also presented in Figure 2, we derived a dataset comprising 52 questionnaire occasions contributed by 27 participants. Of them, 31 are categorized as “no mental health signs,” and 21 are identified as “presence of mental health signs.”

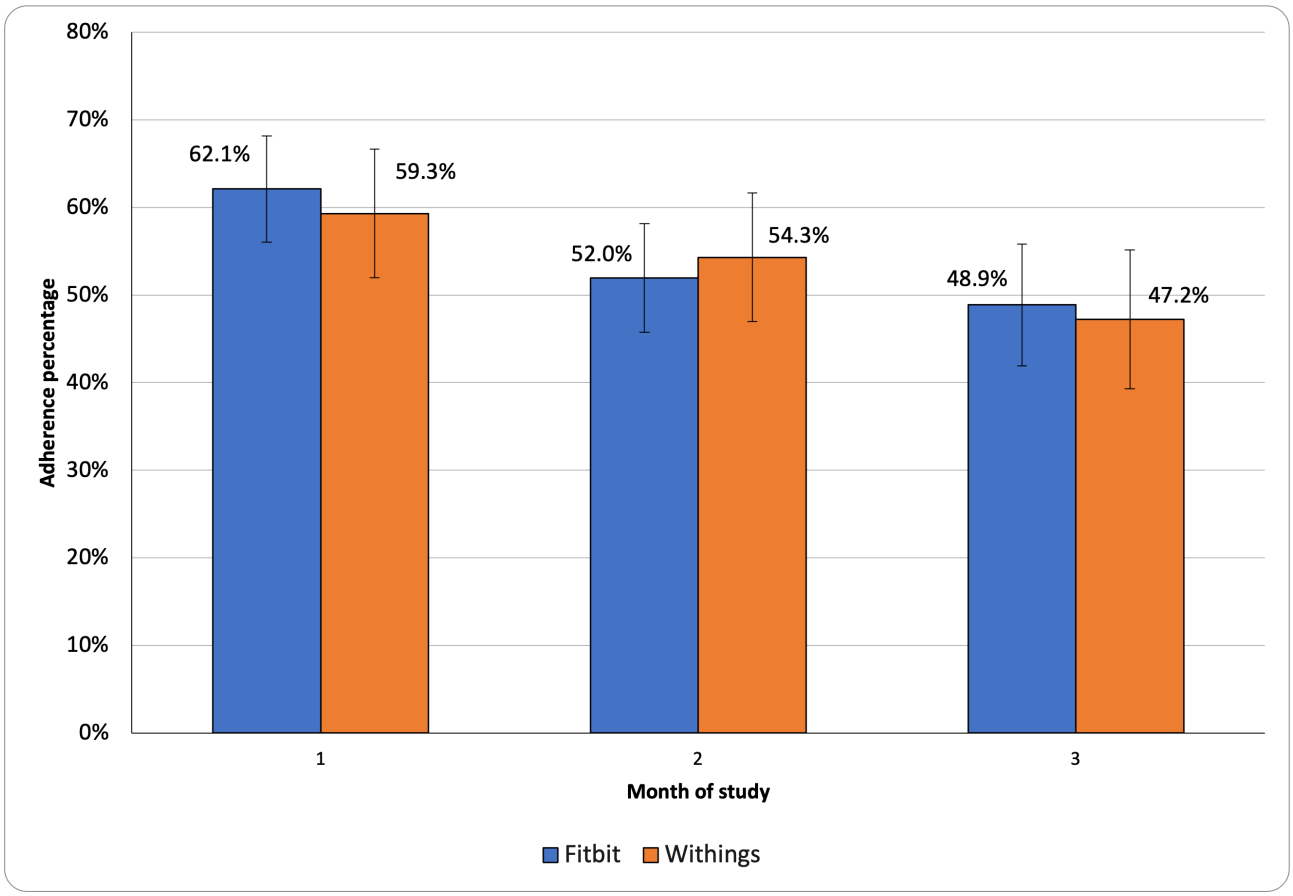
AUC	0.73 (0.09)
F_1	0.64 (0.04)
Precision	0.74 (0.10)
Recall	0.65 (0.03)
All sensors	
AUC	0.85 (0.15)
F_1	0.76 (0.12)
Precision	0.78 (0.13)
Recall	0.74 (0.11)

[a]AUC: area under the receiver operating characteristic curve.

Across all models, the best-performing configuration was the combination of smart plug and smart scale features, which achieved a mean test AUC of approximately 0.85 (SD 0.10) and a mean F_1-score of 0.77 (SD 0.15). The model using all 3 sensor modalities (“all sensors”) showed similarly high performance (AUC=0.85; F_1=0.76), indicating that combining multiple data sources can provide reasonably accurate

XSL•FO
RenderX



classification of PHQ-4–defined mental health signs in this small cohort.

Among single-modality models, smart plug–only and smart scale–only configurations performed comparably, with mean F_1-scores of about 0.66 (SD 0.04) and 0.67 (SD 0.17) and mean AUC values of approximately 0.71 (SD 0.06) and 0.67 (SD 0.24), respectively. The activity tracker–only model showed somewhat lower performance (F_1=0.59; AUC=0.64). Models combining smart plugs with the activity tracker (AUC=0.78; F_1=0.74) or with the smart scale (AUC=0.85; F_1=0.77) tended to outperform single-sensor models, suggesting that complementary information from different devices can improve classification in this dataset.

The comparative efficacy of the smart plug features is particularly intriguing when contrasted with the activity tracker–only model. The latter is widely regarded in the literature as capturing signals associated with mental health indicators [29]. Nevertheless, the standalone smart plug model's performance suggests that behavioral data related to sedentary habits may provide a useful behavioral signal associated with PHQ-4–defined mental health risk in our cohort.

In the case of Fitbit's and Withings' data, the models exhibit moderate effectiveness with an AUC score of 0.64 and 0.67, respectively. These results indicate that, although these devices capture clinically relevant health metrics, their standalone discriminative value for classifying mental health risk appeared somewhat lower than that of models including smart plug features in this small sample. This difference may partly reflect declining adherence to wearing the activity tracker and using the scale regularly over the course of the study (Figure 3), which reduced the completeness and temporal density of the corresponding data streams.

Figure 3. Mean adherence percentage of Fitbit (blue) and Withings (orange) through the 3 months of the study, in the original sample. Error bars represent the SE of the mean.

Given the sample size and the variability observed across random splits, the reported performance estimates should be interpreted within the context of this experimental setup. They reflect how each modality behaves under the current data conditions and provide a consistent basis for comparing their relative performance.

Discussion

Principal Findings

This study explored whether PGHD collected in the wild can be used to classify PHQ-4–defined mental health signs in older survivors of cancer and to what extent completely passive smart plug data contribute to this task. Using a small sample of 52 questionnaire occasions from 27 participants, we found that models based on smart plug data, particularly when combined with smart scale measurements, achieved promising

XSL•FO
RenderX

classification performance (test AUC around 0.85; F_1-scores around 0.76 - 0.77). Smart plug–only and smart scale–only models performed comparably to each other and better than activity tracker–only models, suggesting that television use patterns and weight or body composition metrics may contain informative behavioral signals associated with mental health risk in this cohort. These findings should be interpreted as preliminary and hypothesis-generating, but they support the idea that low-burden passive home sensing can contribute meaningfully to mental health monitoring in older survivors of cancer. Because both PGHD summaries and PHQ-4 scores refer to the same 30-day window, these analyses should be interpreted as cross-sectional discriminative associations between behavioral patterns and PHQ-4–defined mental health signs, not as prognostic models of future mental health trajectories.

Our results complement prior work on PGHD and digital mental health monitoring. Existing studies have shown that consumer wearables can capture behavioral and physiological markers associated with depression and anxiety, such as heart rate variability, sleep, and activity patterns [7-10]. Studies in older adults, including those using low-cost activity trackers or ambient motion sensors [8,11], have demonstrated associations between sensor-derived measures, circadian rhythms, and depressive symptoms, and some have reported high discrimination in small samples. However, most of these studies are either descriptive (focusing on correlations with symptom scores) or feasibility-oriented and rarely target older survivors of cancer specifically. By evaluating classification models that use smart plug–derived television use as a primary modality, alongside more conventional wearables and smart scales, our work extends this literature to a cancer survivorship context and highlights a novel, fully passive home-sensing signal.

The comparative performance of the different modalities provides some insight into their potential roles in real-world survivorship care. In our data, smart plug–only and smart scale–only models achieved moderate-to-good F_1-scores (approximately 0.66 - 0.67) and AUC values in the 0.67 - 0.71 range, while the activity tracker–only model showed lower performance. When smart plug data were combined with either the scale or the activity tracker, model performance improved, especially for the smart plug+scale configuration. This pattern suggests that behavioral information about sedentary and leisure-time routines (television use) and anthropometric trends may complement each other for mental health risk classification, whereas activity tracker data in this sample may have been more affected by missingness and adherence constraints. We deliberately refrain from interpreting these differences as evidence that one modality is intrinsically superior; rather, they likely reflect a combination of signal content and data completeness in this specific cohort and setting.

From a clinical and implementation perspective, smart plugs and other passive smart-home devices have practical advantages for older survivors of cancer. Unlike wrist-worn activity trackers and connected scales, which require regular wearing, charging, and interaction, smart plugs operate entirely in the background once installed and configured. This low-burden data collection is particularly relevant for older adults living with multimorbidity, cancer-related fatigue, or low digital literacy, where even small self-management demands can reduce adherence. Our findings suggest that such devices can capture behavioral routines that are informative for mental health risk classification, and that combining them with minimally demanding periodic measurements (eg, weekly weight) may offer a feasible compromise between burden and information content. If validated in larger and more diverse samples, similar passive-sensing setups could be incorporated into survivorship follow-up to flag individuals who may benefit from more detailed assessment rather than to replace clinical evaluation.

Methodologically, we adopted a row-wise, participant-agnostic classification framework in which each PHQ-4 questionnaire and its preceding 30 days of sensor data constituted a separate observation. This choice allowed us to maximize the use of available data in a small sample, but it also means that multiple observations from the same individual are not strictly independent. In addition, we used SMOTE-based oversampling within the training folds to mitigate class imbalance and a repeated 80/20 train-test evaluation with inner cross-validation for model selection. Although these are commonly used techniques in the applied ML literature, there is active debate about the optimal handling of imbalance and the best validation schemes for small samples. Alternative approaches, such as participant-level cross-validation (eg, leave-one-participant-out and leave-one-group-out) and formal reclassification metrics (eg, net reclassification improvement and integrated discrimination improvement), were beyond the scope of this exploratory work but would be appropriate for future, larger-scale studies focused on model development and clinical validation.

Limitations

We acknowledge limitations within our study. First, the sample size is modest (41 participants and 52 questionnaire occasions) and considering that participation required smartphone use and willingness to accept in-home monitoring, which may preferentially include more motivated and digitally literate individuals, leading to self-selection bias, performance estimates are therefore imprecise and sensitive to data partitioning. Despite using repeated stratified splits and reporting interrun variability, the reported metrics may overestimate or underestimate the true performance in other populations, and external validation in independent cohorts is needed. Second, the analytic dataset required sufficient smart plug coverage (≥15 valid television days in the preceding month), which means that we effectively conditioned the analysis on the availability of high-quality smart plug data. This design decision aligns with our primary objective—assessing the potential value of a fully passive modality—but may introduce selection bias and reduce direct comparability with models that could, in principle, be trained without smart plug data.

Third, missing data were frequent, especially for the activity tracker and smart scale, due to nonadherence (eg, forgetting to wear or charge the device) and technical issues. Although we used a principled preprocessing pipeline that removed ultrasparse features, applied imputation only within training folds, and avoided outcome imputation, residual missingness

XSL•FO
RenderX

and imputation-related uncertainty remain. In addition, the smart plug application programming interface did not allow for backfilling data during Edge-device downtime, leading to irreversible gaps even when participants adhered to normal television use. In addition, PHQ-4 noncompletion at specific time points was treated as a simple absence of an outcome. We did not attempt to model "informative" missingness in questionnaire responses, and it is possible that individuals who felt particularly unwell or distressed were less likely to complete PROMs. Fourth, PHQ-4 was used as a brief self-report proxy for mental health symptoms rather than a clinician-administered diagnostic assessment, and it is therefore subject to recall and reporting biases. In addition, PHQ-4 has a 14-day recall window, whereas in this study, it was administered approximately monthly; this mismatch may blur transient symptom fluctuations and introduce measurement noise. We used a cutoff of 3 based on prior work in the Greek general population and breast cancer samples [25,26], but this threshold has not been validated specifically for older Greek survivors of cancer, and alternative cutoffs may yield different classification boundaries. Finally, television on-time is only a proxy for sedentary viewing; although a preliminary check using overlapping Fitbit step data suggested that participants were inactive during most television-on periods, we cannot exclude scenarios where other household members used the television while the participant was elsewhere in the home.

These limitations highlight the need for follow-up work along several directions. Future studies should aim to recruit larger and more diverse samples of older survivors of cancer, include independent external validation cohorts, and adopt participant-level validation schemes that more directly reflect prospective deployment. In addition to smart plugs and smart scales, other fully passive sensors (eg, ambient motion sensors and door or bed sensors) could be integrated to capture complementary aspects of daily routines, while maintaining low participant burden. On the outcome side, combining brief screeners such as PHQ-4 with more comprehensive, clinician-administered assessments in a subset of participants would enable more rigorous evaluation of classification performance and more robust calibration of clinically meaningful thresholds. Ultimately, the goal is not to replace clinical judgment but to evaluate whether unobtrusive, home-based PGHD streams can help identify older survivors of cancer whose mental health may be changing and who might benefit from more timely support.

Conclusions

This study provides preliminary evidence that completely passive data collection, such as smart plug–based monitoring, may help identify mental health signs among older survivors of cancer, either as a standalone data source or in combination with other sensing modalities. The smart plug's ability to capture granular, behavioral data without requiring patient interaction makes it a promising tool for passive health monitoring. The standalone efficacy of smart plug data highlights the importance of selecting specific, meaningful features over more comprehensive but potentially redundant data. Future research should aim to validate these findings in larger populations and explore the integration of additional nonintrusive sensors to further enhance the classification accuracy and robustness of mental health monitoring models in vulnerable population groups, such as older survivors of cancer.

By leveraging digital biomarkers and PGHD, this study paves the way for integrating smart home technology into regular health assessments. Such integration has the potential to transform care strategies for older survivors of cancer and reduce the burden on health care systems worldwide, making mental health monitoring more accessible and inclusive.

Acknowledgments

The authors would like to thank the LifeChamps consortium. The authors especially thank the health care professionals who assisted in the recruitment of patients, namely, P Sountoulides, S Levva, D Dionysopoulos, E Karamitrousis, A Sachoulidou, I Xanthakis, A Karabeazis, and V Sakalis. Finally, the authors would like to thank Helena Benito Escriba for her help with the preprocessing of smart plug data. The authors further acknowledge Luciano Colares for his earlier contribution to the work. Generative artificial intelligence tools (eg, ChatGPT and OpenAI) were used to assist with language editing and improving the clarity of some sections of the manuscript. All scientific content, analysis, and interpretation were conceived, verified, and approved exclusively by the authors.

Funding

This work was supported in part by the European Commission under the LifeChamps Project (grant 875329) and the COMFORT project (grant 101079894). The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to ongoing analyses but are available from the corresponding author on reasonable request.

Authors' Contributions

GP led the manuscript preparation and coordinated the submission and revision process. GP, AB, GM, AT, PL, JCN, JZO, VT, and PB contributed substantially to the conception and design of the study, interpretation of the findings, and critical revision of

Abstract

Background: Fear of cancer recurrence (FCR) is a common psychological disorder among patients with cancer. In patients newly diagnosed with breast cancer, fear and concern about recurrence often influence treatment decision-making. However, the prevalence of FCR before treatment and its key risk factors—such as age, sleep quality, economic status, self-disclosure, and social support—remain unclear.

Objective: This study aims to describe the prevalence and severity of FCR before treatment in patients newly diagnosed with breast cancer and analyze its predictive factors, thereby providing a scientific basis for interventions to reduce such fear.

Methods: A cross-sectional study was conducted among patients newly diagnosed with breast cancer prior to treatment at a specialized oncology hospital in Guangdong Province, China, between February 2023 and July 2023. Sociodemographic data were collected, including age, gender, ethnicity, religious belief, education level, and marital status. Clinical data included pathological stage, tumor type, and family history of cancer. The Distress Disclosure Index, the Chinese version of the Medical Social Support Scale, and the short form of the Fear of Progression Questionnaire were used. Univariate analyses and bivariate correlations were conducted to explore relationships between variables. Multiple regression analysis was performed to identify predictors of FCR.

Results: A total of 350 patients newly diagnosed with breast cancer were enrolled. Among the participants, 48.3% (n=169) experienced FCR before initiating treatment. The mean total score for FCR was 33.44 (SD 8.00). Age, sleep quality, financial burden, monthly household income per capita, family relationships, self-disclosure, and social support accounted for 33.5% (R^2) of the variance in FCR.

Conclusions: FCR prior to treatment is common and relatively severe among patients newly diagnosed with breast cancer. Health care professionals should implement targeted interventions to promote self-disclosure and strengthen social support networks to alleviate FCR, facilitate informed treatment decision-making, and improve patients' psychological readiness for treatment. The findings of this study underscore the urgent need for early identification and management of FCR in patients newly diagnosed with breast cancer. High levels of pretreatment FCR may impair patients' psychological well-being and influence treatment decision-making, potentially leading to suboptimal treatment choices. Health care professionals should implement targeted interventions that promote self-disclosure and strengthen social support networks to alleviate FCR. These measures can enhance patients' psychological readiness for treatment, facilitate informed decision-making, and ultimately improve clinical outcomes.

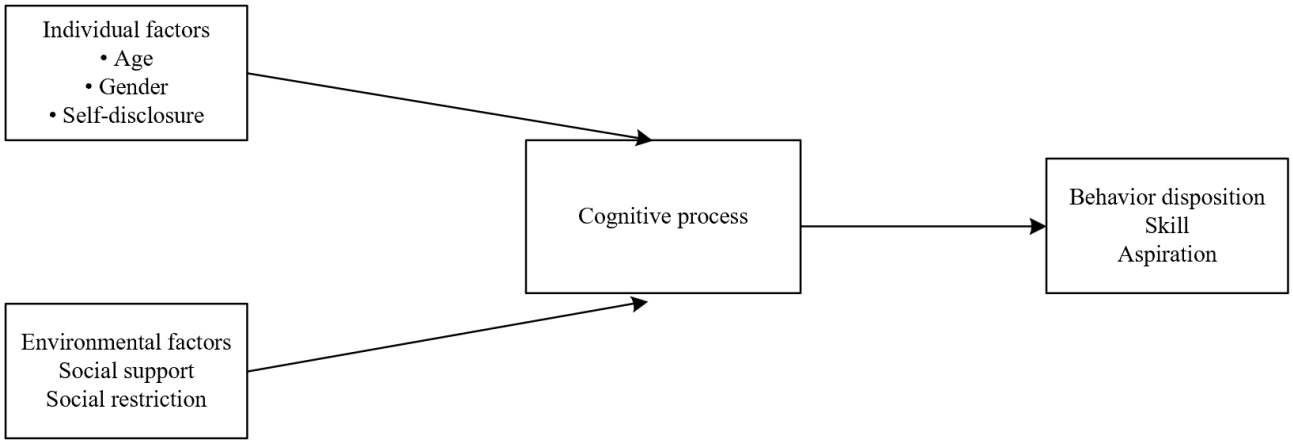
KEYWORDS

fear of cancer recurrence; FCR; breast cancer; self-disclosure; social support

Introduction

According to the latest data released by the International Agency for Research on Cancer, breast cancer ranks as the second most common cancer globally, following lung cancer. In 2022, approximately 2.3 million new cases of breast cancer were reported worldwide, accounting for 11.7% of all newly diagnosed malignancies [1]. In recent years, significant advances have been made in the diagnosis and treatment of malignant tumors. However, the challenges of recurrence and metastasis remain unresolved. These continue to be formidable barriers that modern medicine has yet to overcome. Even patients with ductal carcinoma in situ of the breast face a recurrence risk ranging from 4% to 20% [2]. Fear of cancer recurrence (FCR)



XSL•FO
RenderX

refers to the fear, worry, and anxiety experienced by patients regarding the potential return or progression of cancer [3]. This psychological state often begins at the time of cancer diagnosis and may persist for many years thereafter, affecting patients' emotional well-being and behavioral responses [4]. A study by Lidia et al [5] revealed that approximately 64.5% of patients with breast cancer experience FCR prior to treatment. Pretreatment FCR is likely to influence patients' treatment decisions. For example, a systematic review indicated that some Asian women opt for mastectomy due to concerns about recurrence and a desire to avoid further treatment. As a result, they may miss the opportunity for breast-conserving surgery [6]. A qualitative study also indicated that survivors of breast cancer carrying the breast cancer gene (BRCA1/2) mutations may undergo prophylactic mastectomy due to fears of recurrence [7]. Thus, recognizing and addressing pretreatment FCR in patients with breast cancer is essential to support optimal treatment choices.

However, current literature primarily focuses on the occurrence of FCR among patients with breast cancer during or after treatment. Findings indicate that approximately half of these patients experience moderate to high levels of FCR, which negatively impacts their quality of life, psychological well-being, and treatment adherence [5,7]. In contrast, limited research has been conducted on patients newly diagnosed with breast cancer prior to treatment. Only a few studies have reported the presence of FCR during the period between diagnosis and the initiation of treatment [5,7]. However, the severity of this fear and its associated factors remains insufficiently explored. Therefore, conducting in-depth research on FCR before treatment in patients newly diagnosed with breast cancer holds significant clinical importance. Such research not only addresses a critical gap in the existing literature but also provides a foundation for early intervention strategies.

According to social cognitive theory [8], human behavior and psychological outcomes are shaped by the dynamic interaction between personal factors, environmental influences, and cognitive processes. In the context of cancer diagnosis, personal factors such as self-disclosure and environmental factors such as social support may influence patients' psychological adaptation through cognitive appraisal mechanisms (Figure 1). Self-disclosure, a core concept in psychology, refers to the process by which individuals share personal and private thoughts and emotions with others [9]. As a positive and effective form of communication, self-disclosure has been shown to negatively predict FCR [10]. Several studies have demonstrated that interventions promoting self-disclosure can enhance communication between patients with cancer and others, correct misconceptions regarding cancer recurrence, foster accurate illness beliefs, and ultimately reduce FCR. Specifically, self-disclosure allows patients to verbalize their fears and reorganize illness-related cognitions, which may reduce maladaptive interpretations of cancer recurrence risk [11-13]. Furthermore, social support has been identified as an independent predictor of FCR and plays a crucial role in alleviating it [14]. Low levels of social support are associated with increased FCR among patients with breast cancer, whereas high levels of support can encourage positive perceptions of health status and buffer the psychological distress caused by stressful events, thereby mitigating FCR [15,16]. At the same time, social support provides informational and emotional resources that help patients reinterpret threatening stimuli, correct misconceptions about recurrence, and strengthen perceived coping efficacy. Through these cognitive processes—such as illness perception, risk appraisal, and coping self-efficacy—patients may experience lower levels of FCR. Based on this theoretical framework, we hypothesize that higher levels of self-disclosure and stronger perceived social support are associated with lower levels of pretreatment FCR in patients newly diagnosed with breast cancer.

Figure 1. Framework of social cognitive theory.

Patients newly diagnosed with breast cancer represent a unique population in which psychological factors play a pivotal role in treatment decision-making. Despite growing interest in the psychological dimensions of cancer care, no existing studies have empirically established the relationship between pretreatment FCR and self-disclosure or social support in this specific group. Given the potential influence of psychological readiness on treatment choices, it is crucial to explore whether targeted interventions that enhance self-disclosure and strengthen social support networks can effectively reduce FCR. Such interventions may ultimately empower patients to make more informed and appropriate treatment decisions. However, further research is needed to examine these associations and

XSL•FO
RenderX

assess the clinical value of early psychosocial interventions in patients newly diagnosed with breast cancer.

Therefore, this study aims to describe the current status of FCR prior to treatment in patients newly diagnosed with breast cancer and to identify its risk factors based on social cognitive theory. The objectives of this study are as follows: (1) to explore the incidence and severity of pretreatment FCR in patients newly diagnosed with breast cancer; and (2) to identify the key risk factors contributing to pretreatment FCR in this population, thereby providing empirical evidence to inform the development of effective intervention strategies aimed at reducing FCR levels.

Methods

Study Design

This study used a cross-sectional design and was conducted from February 2023 to July 2023.

Ethical Considerations

Ethical approval was obtained from the ethics committee of Sun Yat-sen University Cancer Center (B2023-700-01). The procedures used in this study adhere to the tenets of the Declaration of Helsinki, which emphasize respect for the dignity, autonomy, and privacy of research participants; the minimization of potential risks and the maximization of possible benefits; and the requirement for voluntary and informed consent prior to participation. Participants' personal data were treated with strict confidentiality, and their rights and well-being were protected throughout the research process. Participants did not receive any compensation for their participation in this study.

Participants

A convenience sampling method was used to recruit patients with breast cancer who sought medical care at a specialized oncology hospital in Guangdong Province, China, between February 2023 and July 2023. Inclusion criteria were as follows: (1) being aged 18 years or older; (2) first-time pathological diagnosis of stage 0-3 breast cancer; (3) no prior breast cancer–related treatment; and (4) an educational level of primary school or higher. Exclusion criteria included: (1) metastatic or recurrent breast cancer; (2) a history of other major organ diseases or malignancies; and (3) a diagnosis of psychiatric disorders or cognitive impairment. Written informed consent was obtained from all participants.

According to the empirical sample size calculation method based on regression analysis [17], the sample size should be 5 to 10 times the number of variables. The predictive factors included self-disclosure, social support, tumor stage, type, and a total of 23 influencing factors. Considering a 20% rate of invalid responses, the minimum sample size was calculated as 23×10/(1–0.20)=287.5 cases. Therefore, the minimum required sample size for this study was determined to be 288 cases.

Measures

Sociodemographic and Clinical Characteristics

Sociodemographic data collected in this study included age, sex, ethnicity, religious beliefs, education level, marital status, number of children, average age of the youngest child, average age of all children, educational attainment, monthly household income per capita, financial burden, place of residence, living arrangement, family relationships, occupation prior to diagnosis, and method of medical expense payment. Disease-related variables included clinical stage, tumor type, comorbidities, family history of cancer, and sleep quality. Sleep quality was assessed using a single self-reported item in which participants rated their overall sleep status as "good," "fair," or "poor" during the period prior to treatment.

The Short Form of the Fear of Progression Questionnaire

The short form of the Fear of Progression Questionnaire was developed by German scholar Mehnert et al [18] in 2006 by simplifying the original Fear of Progression Questionnaire and is designed to assess the level of fear of disease progression in patients with cancer. In 2015, Wu Qiyun et al [19] translated and culturally adapted the scale into Chinese. The short form of the Fear of Progression Questionnaire consists of 12 items, categorized into 2 dimensions: physical health and social or family concerns. Each item is rated on a 5-point Likert scale, with all items scored positively. A total score of 34 or higher is commonly used to indicate a high level of fear, based on validation studies of the Chinese version of the scale [19]. The Cronbach α coefficient of the scale in this study was 0.883, indicating good internal consistency.

Revised Distress Disclosure Index

The Distress Disclosure Index was originally developed by Kahn and Hessling [20] to assess an individual's tendency to disclose distressing experiences. In 2008, Chinese scholar Li Xinmin translated and revised the scale for use in the Chinese population to evaluate levels of self-disclosure [21]. The revised Chinese version consists of 12 items and uses a 5-point Likert scale ranging from 1 ("strongly disagree") to 5 ("strongly agree"). Items 2, 4, 5, 8, 9, and 10 are reverse scored. The total score ranges from 12 to 60, with higher scores indicating a greater level of self-disclosure, while lower scores reflect a higher tendency toward concealment. The Cronbach α coefficient of the scale is 0.86, indicating good internal consistency.

Simplified Chinese Medical Outcomes Study Social Support Survey

The Simplified Chinese Medical Outcomes Study Social Support Survey (MOS-SSS-CM) was originally developed by Sherbourne et al [22] in 1991 to assess perceived social support among patients with chronic illnesses. In 2012, Li Huan [23] adapted the scale into a simplified Chinese version (MOS-SSS-CM) for use in the Chinese population. The total scale demonstrated good reliability, with a Cronbach α coefficient of 0.889 and a test-retest reliability of 0.77, indicating high internal consistency and stability. The scale contains 20 items across 4 dimensions: emotional or informational support, tangible support, affectionate support, and positive social interaction. Each item is rated using a 5-point Likert scale ranging from 1 to 5, based on the individual's perceived frequency of support. The total score is converted to a 0-to-100

XSL•FO
RenderX

scale, with higher scores reflecting a higher level of perceived social support.

Data Collection

For patients who met the inclusion and exclusion criteria, data collection was conducted after hospital admission and pathological diagnosis, but prior to the initiation of treatment. Upon obtaining written informed consent, a professionally trained research staff member distributed the questionnaires and guided participants in their completion. After completion, the researcher checked each questionnaire for completeness. Prior to the start of the study, this staff member received comprehensive training on research ethics, questionnaire content, completion guidelines, and communication skills with patients, ensuring effective interaction and the provision of appropriate support throughout the process.

To ensure data quality and minimize potential bias, standardized procedures were implemented during questionnaire administration. The research staff members received structured training on research ethics, questionnaire content, standardized instructions, and communication skills prior to data collection. All questionnaires were completed independently by participants, and responses were checked for completeness without influencing participants' answers. Specifically, the researcher responsible for questionnaire administration was not provided with information about the patients' treatment plans or clinical conditions during data collection, thus minimizing potential bias in the data collection process.

Data Analysis

Data analysis was conducted by an independent researcher with extensive experience in clinical research and professional training in oncology and statistics. The dataset was deidentified prior to analysis to ensure confidentiality and objectivity.

All statistical analyses were performed using SPSS version 25.0 (IBM Corp), with a significance level set at α=.05; *P* values less than .05 were considered statistically significant. Descriptive statistics were used to characterize participants' sociodemographic and clinical characteristics. Univariate analyses or bivariate correlations were initially conducted to identify potential factors associated with levels of FCR. ANOVA was used to examine differences in FCR scores across various sociodemographic and clinical characteristics (eg, education level, marital status, employment status, and household income). Pearson correlation analysis was performed to assess the relationships among self-disclosure, social support, and FCR in patients with breast cancer.

Variables demonstrating statistical significance in univariate analyses were subsequently entered into a multivariate regression model. A multiple linear regression analysis was conducted to identify independent predictors of FCR. The squared correlation coefficient (R^2) was used to indicate the proportion of variance in the dependent variable that could be explained by the independent variables. A *P* value of 0.05 was considered the threshold for statistical significance.

Results

Analysis of Demographic Characteristics, Self-Disclosure, Social Support, and FCR Among Patients Newly Diagnosed With Breast Cancer Prior to Treatment

A total of 362 patients met the inclusion criteria and provided informed consent. As 12 patients refused to participate in the study, 350 patients finally completed the questionnaire, resulting in a loss rate of 3.31%. The descriptive data on sociodemographic and clinical characteristics, as well as Distress Disclosure Index and MOS-SSS-CM scores, are summarized in Table 1. A total of 350 patients with breast cancer, aged between 25 and 77 years (mean age: 45.39, SD 9.68), were included in the study, with 99.1% (n=347) being female. The majority reported a per capita monthly household income above 5000 RMB (US $689.22). Financial concerns were prevalent, with 63.7% of patients experiencing some degree of economic burden and 15.7% (n=55) reporting severe financial stress. Additionally, 55.7% (n=195) rated their sleep quality as average. The mean (SD) scores for self-disclosure and social support were 38.86 (9.31) and 70.57 (14.04), respectively. The mean FCR score among patients with breast cancer was 33.43 (SD 8.00), with the physical health dimension (18.11, SD 4.12) scoring higher than the social or family dimension (15.32, SD 4.66). Notably, 48.3% (n=169) of patients reported experiencing fear of recurrence prior to the initiation of treatment.

Analysis of Demographic Characteristics, Self-Disclosure, Social Support, and Their Correlations With FCR in Patients Newly Diagnosed With Breast Cancer Before Treatment

The results of the ANOVA indicated that there were statistically significant differences in FCR related to age, the average age of the youngest child, the average age of all children, monthly per capita household income, financial burden, place of residence, family relationships, occupation before diagnosis, and sleep status (P<.05). The Pearson correlation analysis revealed that both self-disclosure (r=−0.394; P<.01) and social support (r=−0.393; P<.01) were significantly and negatively associated with fear of cancer recurrence (Table 1).

Multiple Regression Analysis of FCR in Patients Newly Diagnosed With Breast Cancer

A standard enter method linear regression analysis was performed, with FCR set as the dependent variable. Independent variables were those found to be statistically significant (P<.05) in univariate and correlation analyses, including patient age, average age of the youngest child, average age of all children, monthly per capita household income, financial burden, place of residence, family relationship, occupation before diagnosis, sleep quality, self-disclosure, and social support. A significant regression equation ($F_{11,337}$=15.42; P<.001) was found, with an R^2 of 0.335 (Table 2). Younger age, poorer sleep quality, greater financial burden, lower self-disclosure, and lower social support were independently associated with higher FCR levels. Lower household income showed a trend toward association with higher FCR (P=.05).

Discussion

Patients newly diagnosed with breast cancer represent a unique population, in which psychological factors play a critical role in treatment decision-making. To our knowledge, this study is the first to investigate the relationships between sociodemographic and clinical characteristics, self-disclosure, social support, and FCR prior to treatment, and to identify significant predictors of FCR in this population.

FCR Before Treatment in Patients Newly Diagnosed With Breast Cancer

This study found that FCR was a prevalent psychological issue among patients newly diagnosed with breast cancer prior to treatment, with approximately 50% experiencing clinically significant levels of fear. This proportion was lower than that reported by Han et al [24] but higher than that found by Li et al [25], suggesting heterogeneity in FCR across different patient groups. The discrepancy may be due to differences in study populations and timing of assessment. Han et al [24] focused on patients undergoing chemotherapy, during which FCR may be intensified by side effects and prolonged stress (including financial, occupational, and familial stressors). In contrast, the

XSL•FO
RenderX

participants in this study were at the pretreatment stage, not yet exposed to treatment-related stressors, which may explain their relatively lower FCR. Li et al's [25] study mainly involved postoperative patients. In our study, patients were newly diagnosed, facing difficulty accepting the diagnosis and perceiving uncertainty about future treatment, potentially contributing to high FCR. These findings highlight the importance of early psychological intervention for newly diagnosed patients.

Younger Patients, Poor Sleep Quality, Low Income, and Financial Burden Exhibit Higher Levels of FCR

This study identified age as a significant factor influencing FCR in patients with breast cancer (P<.001), consistent with the findings of Zhang et al [26]. Younger patients tend to be more concerned with body image, and treatment-related changes, such as hair loss from surgery or chemotherapy, may trigger feelings of inferiority or depression, exacerbating FCR.

Sleep quality was significantly associated with FCR in the multivariate analysis, with poorer self-reported sleep linked to higher levels of fear [27]. However, as sleep quality was assessed using a single self-reported item and the study used a cross-sectional design, the directionality of this association cannot be determined. It is possible that sleep disturbances and FCR are interrelated through shared psychological mechanisms, such as heightened cognitive arousal or stress sensitivity. These findings suggest that sleep quality may be an important factor to consider when assessing psychological vulnerability in newly diagnosed patients. Future longitudinal studies using standardized sleep measures (eg, the Pittsburgh Sleep Quality Index) are needed to further clarify the nature and direction of this relationship.

Both univariate and multivariate analyses suggested that lower household income tended to be associated with higher levels of FCR; however, this association did not reach conventional statistical significance in the multivariate model (P=.054). In contrast, perceived financial burden remained a significant independent predictor of FCR, with patients reporting moderate or severe financial burden exhibiting higher FCR levels. These findings are consistent with the results reported by Niu et al [14]. Possible explanations include the substantial cost of cancer treatment and the additional financial concerns related to potential recurrence. Patients facing greater economic strain may experience heightened anxiety and uncertainty about future treatment expenses, which could amplify fear of recurrence. Notably, patients with medical insurance reported lower levels of FCR compared with those who paid out-of-pocket, suggesting that financial protection mechanisms may play a buffering role in psychological adaptation. Given that patients with breast cancer often require costly adjuvant therapies such as chemotherapy or radiotherapy, limited reimbursement for anticancer medications may exacerbate financial stress among economically vulnerable patients. Therefore, health care providers should assess patients' financial situations when formulating treatment plans, offer cost-effective therapeutic options when feasible, and provide targeted psychological support. At the policy level, further strengthening the medical insurance system and expanding coverage for major illnesses may help alleviate financial burden and indirectly reduce FCR.

Lower Levels of Self-Disclosure Are Associated With Higher FCR

This study found a significant negative correlation between self-disclosure and FCR. Self-disclosure, typically expressed through verbal communication of one's thoughts and emotions, serves both as a personal coping mechanism and a psychological intervention strategy. It has been shown to alleviate psychological distress and improve quality of life [28]. Prior research supports these findings. Xu et al [11] reported that effective communication helps patients correct misconceptions about recurrence and fosters healthier beliefs, thereby reducing FCR. In a controlled trial by Chen et al [12], a self-disclosure intervention significantly increased disclosure levels, reduced negative emotions, and lowered FCR in postoperative patients with breast cancer undergoing chemotherapy. Another study found that enhancing spousal self-disclosure also reduced FCR [13]. This may be due to the fact that individuals with higher levels of self-disclosure receive more external feedback—such as encouragement, experiential guidance, or health-related information—which improves their understanding of the disease and relieves emotional stress. Sharing one's illness experience and feelings can also enhance emotional support. Therefore, clinical staff should encourage newly diagnosed patients to engage in active and meaningful communication, such as journaling or peer discussion, to express their thoughts and expectations. This practice can enhance self-disclosure, help patients cope with stress, and assist them in making informed treatment decisions.

Lower Levels of Social Support Are Associated With Higher Levels of FCR

Social support was significantly and negatively correlated with FCR, encompassing both the physical and social or family dimensions. This finding is consistent with the results of Niu et al [14] and Yu et al [15]. A meta-analysis also demonstrated that low levels of social support are associated with increased FCR in patients with breast cancer, while higher levels of support promote positive health perceptions and reduce stress-related recurrence fears [16]. As a protective factor, social support facilitates emotional regulation through interpersonal interaction and helps alleviate symptom distress and fear of recurrence [27]. In the context of FCR, social support acts as a "buffer," mitigating the negative psychological impact of stressful events [29]. Strong social support not only reduces symptom sensitivity and psychological distress, such as anxiety and depression, but also enhances mental health, decreases FCR, and improves quality of life. Furthermore, it enables patients to approach treatment and recovery with greater positivity and optimism.

Limitations

This study has several limitations. First, participants were recruited from a single tertiary cancer hospital in Guangzhou using convenience sampling, which may introduce selection bias and limit generalizability. Patients in a specialized urban cancer center may differ from those in community or rural

XSL•FO
RenderX

settings in terms of socioeconomic status, access to insurance, and psychosocial resources. Given Guangzhou's developed health care infrastructure, findings related to financial burden may be influenced by regional insurance policies and economic conditions. In contrast, associations between psychosocial factors (eg, self-disclosure and social support) and FCR may reflect more broadly applicable cognitive and interpersonal processes. Multicenter studies across diverse regions are needed to confirm the generalizability of these findings. Second, the study captured self-disclosure, social support, and FCR at a single time point. Consequently, it lacks longitudinal data to assess how these psychological variables change over time or impact patients across different stages of treatment and disease progression. Third, the cross-sectional design precludes causal inference. Although significant associations were identified between self-disclosure, social support, financial burden, and FCR, the temporal sequence of these variables cannot be determined. Longitudinal or interventional studies are needed to clarify these potential causal pathways. Fourth, sleep quality was assessed using a single self-reported item rather than a validated instrument, which may introduce reporting bias and limit measurement accuracy. Future studies should use standardized measures, such as the Pittsburgh Sleep Quality Index, to provide a more comprehensive assessment.

Conclusions

Prior to initial treatment, approximately 50% of patients newly diagnosed with breast cancer reported high levels of FCR. Younger age, poorer sleep quality, greater financial burden, lower self-disclosure, and lower perceived social support were associated with higher FCR levels. These findings highlight the importance of early identification of patients at risk for elevated FCR. Although causal relationships cannot be established due to the cross-sectional design, the results provide preliminary evidence to inform future longitudinal and interventional studies aimed at examining whether enhancing psychosocial resources and addressing sleep and financial concerns may help reduce FCR and improve psychological adaptation during treatment decision-making.

Abstract

Background: Online cancer communities provide young adult (YA) cancer survivors with access to informational and emotional support that may not be available in traditional care settings. While these platforms offer vital connection opportunities, the unique pathways YA survivors take to find online communities and the challenges they encounter remain underexplored.

Objectives: This study aimed to (1) examine how YA cancer survivors locate and access online cancer communities and (2) identify barriers that impede their participation or sustained engagement.

Methods: The first author conducted semistructured interviews with 12 YA cancer survivors aged 18 to 39 years who had experience using online resources after their diagnosis. Participants were recruited through purposive and snowball sampling from YA cancer-focused nonprofit organizations and through social media. Interviews were conducted via Zoom and analyzed using thematic analysis. The analytic process followed Braun and Clarke's 6-phase framework and was supported by MAXQDA software. Codes and themes were generated inductively and refined iteratively.

Results: Participants ranged in age from 24 to 39 years (mean 32, SD 5.08 years), with an average of 3 (SD 2.98) years since diagnosis. Most identified as female (n=9, 75%) and non-Hispanic White (n=7, 58%). Over half held a graduate degree (n=7, 58%), half were employed full time (n=6, 50%), and most resided in suburban areas (n=8, 67%). Cancer diagnoses included leukemia (n=3, 25%), lymphoma (n=4, 33%), and other solid tumors such as testicular, colon, and uterine cancers. At the time of the interview, 3 (25%) participants were in active treatment and 9 (75%) had completed treatment. Participants described five primary pathways to discovering online cancer communities: (1) direct searching using hashtags or keywords, (2) community hubs on public accounts, (3) referrals from health providers or social networks, (4) algorithm-recommended content, and (5) connections formed within preexisting online interest-based groups. Despite the promise of digital tools, participants encountered five roadblocks: (1) platform fragmentation and digital literacy complicated initial discovery; (2) lack of representation made it difficult for some to find communities where they felt seen; (3) emotional overload and engagement fatigue, along with shifting group hierarchies and boundaries, further hindered sustained participation; and (5) lastly, concerns about cyberbullying discouraged open engagement, prompting some to withdraw or limit their presence in online communities.

Conclusions: YA cancer survivors navigated a fragmented and emotionally complex digital landscape in search of social support. Their ability to access and engage with online communities was shaped not only by individual agency and digital literacy but also by structural and relational factors. This study underscores the need for more discoverable, inclusive, and sustainable digital support environments. Oncology professionals and peer survivors can play a vital role in facilitating safe, informed access to online cancer communities. Multilevel psychoeducation and training with health care providers, YA cancer survivors, and online community facilitators are warranted to bridge gaps and enhance equity in digital survivorship care.

Introduction

Before the widespread adoption of communication technologies, patients having cancer and their families largely relied exclusively on oncology providers for support and information. The rise of social media and online platforms has transformed this landscape, enabling cancer survivors to connect, share experiences, and find vital health information from the comfort of their homes. A report by the Pew Research Center revealed that 11% of adults in the United States have been following their friends' health updates on online communities, and 5% have actively engaged by sharing their own health-related information, questions, or comments [1]. A national survey showed that the general population's online support group participation grew from 5% in 2008 to 9% in 2017 [2].

Online cancer communities refer to groups of people with expressed interest in cancer who communicate using a website, social media platform, instant messaging, or app [3]. These communities, often created by patients, nonprofits, or health communication professionals, serve as supportive spaces for patients, survivors, and caregivers to seek information and emotional connection. Over time, members contribute to an evolving body of shared knowledge, fostering a sense of belonging based on common diagnoses or life circumstances. Cancer survivors report positive attitudes toward these online communities and the social support they provided [4].

Young adult (YA) cancer survivors, a distinct group of cancer survivors defined by the National Cancer Institute [5], often face unique challenges: social and developmental disruptions, feelings of isolation, and limited access to in-person support groups tailored to their needs [6]. Because YAs are often geographically dispersed, online cancer communities provide accessible spaces to exchange health information, share experiences, and find emotional and informational support among peers who understand their situations [7-9]. These communities foster empowerment as both a process and an outcome of participation, complementing traditional health care by promoting agency, peer learning, and self-management [10-12]. Participation can help survivors reclaim a sense of connection, reduce isolation, and build hope for life beyond cancer [13,14].

However, these benefits are not experienced uniformly. Engagement in online cancer communities is shaped by both individual characteristics, such as education level, health literacy, psychological well-being, and personality traits, and community-level factors like dynamics, including reciprocity, inclusiveness, and the quality of moderation [9,15,16]. Understanding how these factors interact to shape YA survivors' participation remains critical to improving access to meaningful online support.

Finding an online community that meets one's emotional and informational needs can be challenging for YA cancer survivors. Although there are various types of online cancer communities, 2 broad classifications, open forums and secret groups, pose distinct challenges for YA cancer survivors seeking meaningful support [17]. Open forums, typically hosted by charities or nonprofits, provide accessible and reliable information but foster limited personal connection, while secret groups, often patient-initiated and invitation-only, offer greater intimacy and emotional support but raise privacy concerns and require trust-building [17]. The diversity of platforms and fragmented resources can make exploration overwhelming. Privacy concerns are also particularly pressing for YAs, who fear being identified by future employers or wider social circles, making them gravitate toward more private groups that require referral to join [18]. However, the intimacy of secret groups comes at the cost of additional risks, including loss of control over shared stories [19,20], emotional distress following other members' death [13,21], and exposure to misinformation or harmful content [22,23].

Taken together, these findings highlight the need to better understand how YA cancer survivors identify and engage with online health communities that align with their emotional and informational needs. Although prior studies have documented both the benefits and challenges of these spaces, little is known about how YAs navigate online resources, find suitable communities, and sustain meaningful participation. The purpose of this qualitative study is to understand (1) how YA cancer survivors locate and access their online cancer communities and (2) what hinders their ongoing engagement.

Methods

Design

This qualitative study used semistructured interviews to explore how YA cancer survivors find, access, and engage with online cancer communities. The study aimed to understand both the pathways through which participants discovered these communities and the barriers they encountered in participating or sustaining engagement over time.

Participants

Purposive and snowball sampling was used to recruit participants. To be eligible for the study, participants needed to (1) receive a diagnosis of cancer at the age between 18 and 39 years, (2) be between 18 and 39 years at the time of the interview, (3) have experiences using social media platforms, and (4) be able to participate in a videoconference interview. The age range was based on the National Cancer Institute's definition of adolescent and young adult (AYA) cancer survivors [5] and was selected to capture the relational and developmental contexts of young adulthood, a life stage marked by key social transitions and identity formation that shape survivorship experiences [6].

The research team developed a flyer that they asked nonprofit organizations dedicated to YA cancer to post on their social media accounts. Cactus Society and Livestrong Cancer Institute, 2 US-based organizations supporting AYA cancer survivors, shared the flyer on their social media accounts. The study flyer contained study aims, the principal investigator's contact information, and a QR code of intake survey on Qualtrics. The principal investigator (QC) followed up with each potential participant to schedule Zoom interviews and gather verbal informed consent.

XSL•FO
RenderX

Data Collection

All interviews followed the same interview guide with some variations based upon the flow of conversation between the participant and interviewer (see Multimedia Appendix 1 for the interview guide, including prompts and questions). The interview guide was developed by the research team. It contained questions related to the ways YA cancer survivors connected to peer survivors on social media, including positive and negative experiences during the process. The interviews were conducted in a one-on-one setting, free from the presence of any nonparticipants. Prior to each interview, participants were instructed to join from a private location and to ensure that no nonparticipants were present or able to overhear the conversation. Interviews were video recorded and transcribed by Zoom. Transcripts were made available for participant review upon request. The interviewer (QC) read through transcripts to ensure the quality of transcription and kept field notes that captured the main points of conversation after each interview.

Data Analysis

Reflexive thematic analysis is a method for identifying, analyzing, and reporting patterns within data, defined by Braun and Clarke [24]. All the transcripts were deidentified before importing into MAXQDA (VERBI Software, 2021), a qualitative software program for data coding and comparison.

Two members of the research team, QC and LZ, independently coded all transcripts using an inductive, consensus-driven approach. The data coding approach was inductive. Codes and theme development were directed by the content of the data, rather than being theoretically driven [24]. Both coders initially reviewed a subset of transcripts to develop a preliminary codebook, which was refined through iterative discussion. Each transcript was then coded separately by both coders, followed by comparison and discussion to reconcile differences and reach agreement on code application and interpretation. Discrepancies were resolved through dialogue until full consensus was achieved, ensuring analytic consistency and rigor.

Following the six-phase process of thematic analysis, QC and LZ began with a process of (1) *data familiarization*, in which QC noted initial analytic observations about each data item and the entire dataset by reading the transcription and field notes. Two transcriptions were coded to (2) *generate initial codes* and develop the first-version codebook with columns of code category, code name, definition, eligibility, and example based on the initial codes. QC and LZ coded the other 2 interviews and revised the codebook accordingly by adding new codes, refining code's eligibility criteria, and adding second-level codes to group the existing codes. After the codebook was finalized with all 12 interviews, the data were organized into a matrix with cases and second-level codes. QC and LZ (3) *searched for themes* by reading and identifying the similarity in data across cases in the matrix. The 2 authors (4) *reviewed the themes* and gave (5) *definitions and names to the themes*. All authors reached consensus regarding the themes' consistency. The last phase was to move from semantic description to interpret the significance of patterns and their broader meaning and implications for the (6) final report.

Rigor

Steps to ensure rigor were based on the trustworthiness criteria of data analysis posited by Lincoln and Guba [25]. The criteria involved establishing credibility, dependability, confirmability, and transferability. Throughout the research process, the first author reported the coding process and reflection of the transcription with the research team to assure the credibility of the analysis. The research team provided consultation and guidance on the naming of codes and themes to ensure the accuracy of language. The first author kept an audit trail (Koch [26]) to record each decision made with modifying the research question, finalizing the data analytic approach, and coding and analyzing the pattern to improve the dependability of the finding. Qualitative software was used, as it permits greater audibility and hence increases the reliability of the data analysis process.

Confirmability was sought by regular review and discussion of the codes with the research team by discussing reflexivity and how the interactive nature of the interview process influenced data collection. Member checking was not conducted, as this study employed a reflexive thematic analysis approach in which meaning is understood as coconstructed through researcher interpretation rather than verified by participants. Following Braun and Clarke's distinction, traditional member checking assumes the existence of a single, verifiable truth and seeks to "correct" researcher subjectivity—an assumption that sits conceptually at odds with reflexive thematic analysis, where researcher subjectivity is viewed as an analytic resource, not a bias to eliminate [27]. Consistent with the interpretivist assumptions of reflexive thematic analysis, data saturation was not used as a criterion for determining sample adequacy because Braun and Clarke [28] advocated for achieving meaning through researcher interpretation.

Ethical Considerations

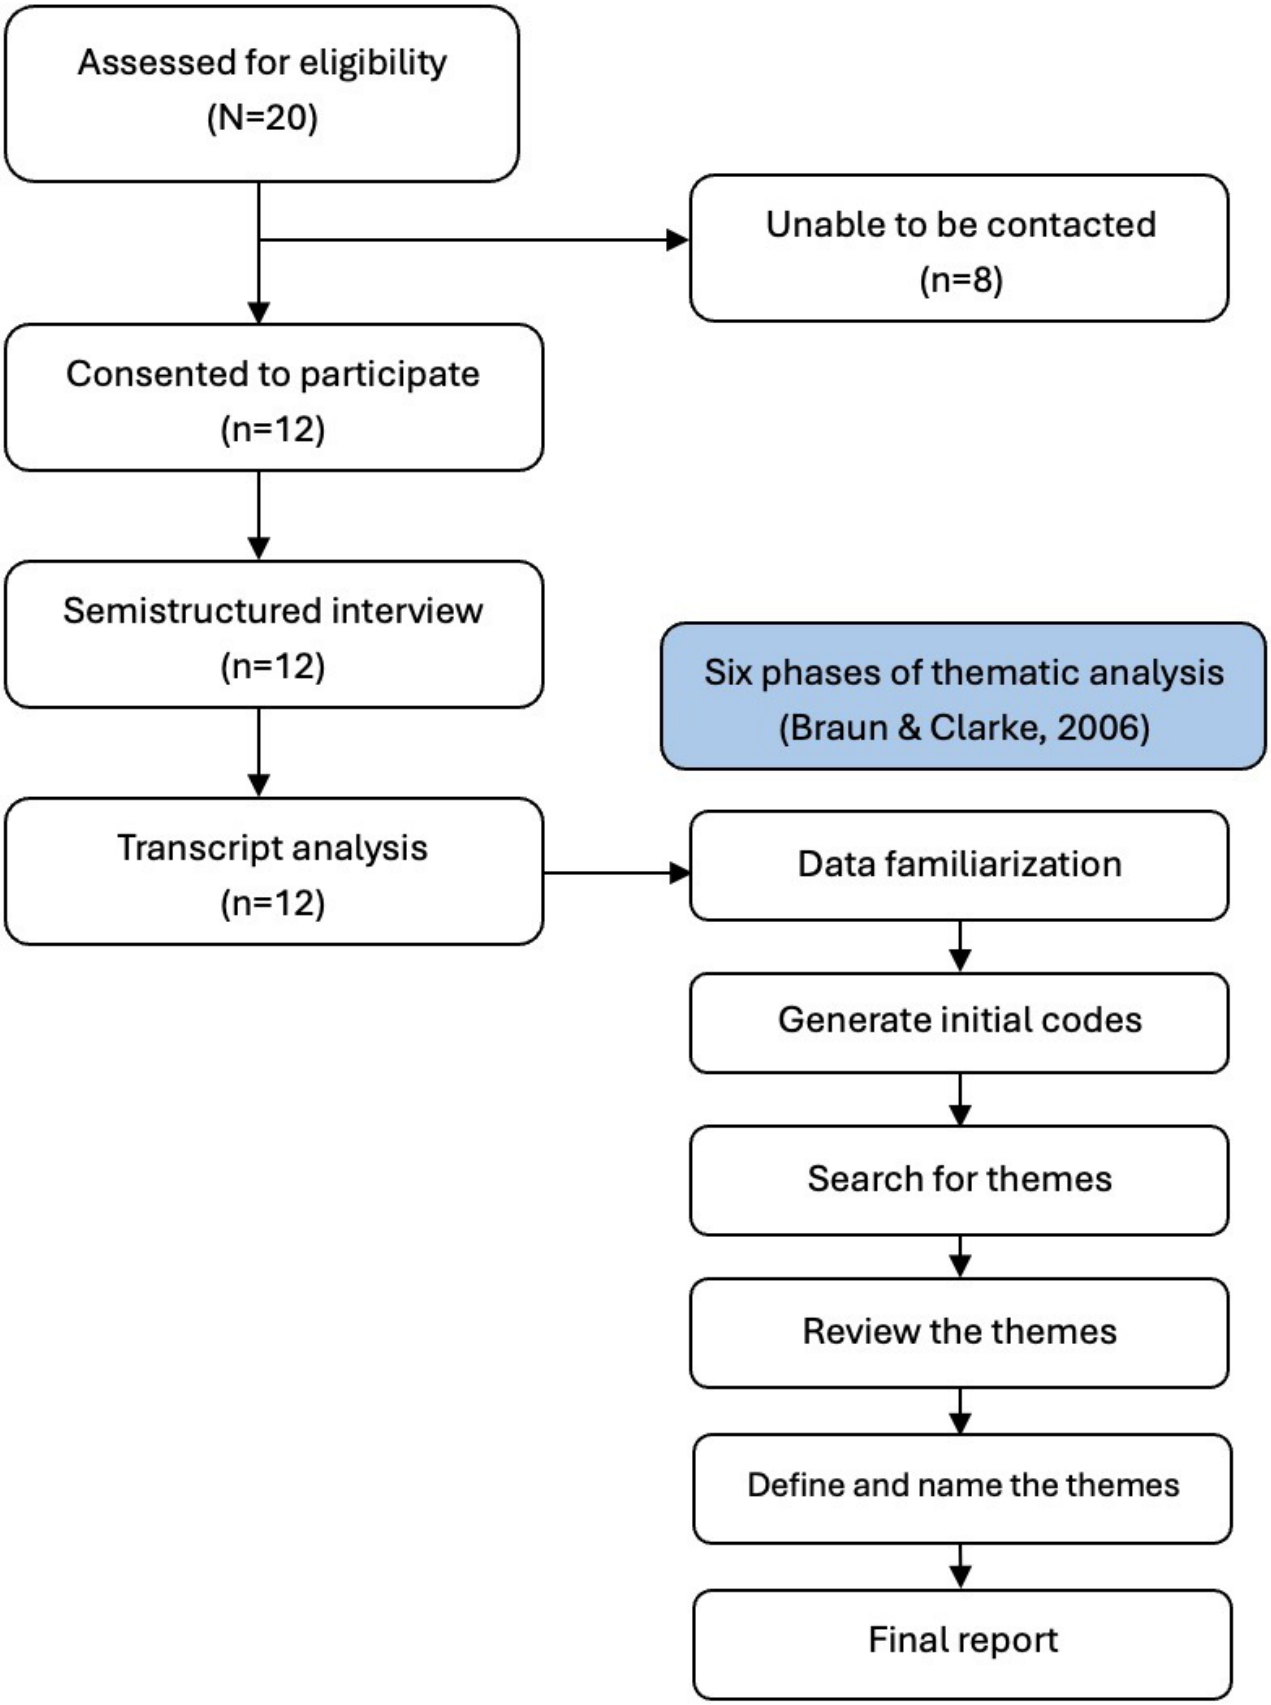
Institutional review board approval was granted for this study by the University of Texas at Austin (protocol STUDY00003004). All study procedures complied with institutional and national research ethics standards for research involving human participants. Participants were informed of the study purpose, confidentiality protections, the benefits and risks of participation, and their rights to withdraw at any time. Prior to participation, all participants provided verbal informed consent to take part in the study and to be video recorded. Participation was voluntary, and participants were reminded that they could decline to answer any question or withdraw from the study at any time without penalty. All data were deidentified during transcription and analysis. Identifying information such as names or specific personal details was removed or replaced with pseudonyms. Digital recordings and transcripts were stored in a secure and access-restricted folder on UT Box, accessible only to the research team. Each participant received a US $20 Amazon electronic gift card, sent via email upon completion of the interview, as compensation for their time and contribution to the study.

Positionality

The research team represents a diverse group of scholars and practitioners whose social identities, disciplinary backgrounds,

XSL•FO
RenderX

and professional experiences shaped the design and interpretation of this study. QC (Asian woman, Assistant Professor of Social Work, and a PhD candidate at the time of the study), ED (White woman, Professor of Communication), LN (Black woman, Assistant Professor of Social Work), and BJ (White woman, Professor of Social Work) are seasoned qualitative researchers with a PhD degree and extensive experience studying psychosocial oncology, communication, and health equity among AYA cancer survivors. LZ (Asian woman, social work clinician, and doctoral student), the second coder of the transcript, brought both clinical practice experience and methodological expertise in qualitative research. The interviewer QC's interest in this topic stems from her professional experience in psychosocial oncology and her commitment to addressing disparities in access to cancer support as well as the rising use and impact of communicative technology during the COVID-19 pandemic. She acknowledges that her background as a social work researcher and her own positive experiences with online communities as an immigrant may have shaped assumptions about online support and digital disparities. As someone who is not a cancer survivor herself, she remains mindful of the potential distance between her professional perspective and participants' lived experiences. QC had limited prior relationships with participants. One participant was a personal friend of QC, while all others had no prior relationship with the interviewer. Participants were informed about QC and the study through the introductory phone calls or emails and the consent form, which described QC's role as the principal investigator and explained the study's purpose, goals, and procedures. No additional personal or professional information was shared beyond what was stated in the consent materials.



Results

Participants' Characteristics

A total of 20 potential YA participants who filled out the screening questionnaire were all eligible for the study. Of these 20 YAs, 8 did not respond to the principal investigator's emails or phone calls, and 12 consented and were recruited to participate in the interviews, yielding an enrollment rate of 60%. Figure 1 presents the recruitment and analysis process flowchart. Semistructured individual Zoom interview data were collected from September 2022 to February 2023, ranging from 39 to 110 minutes (mean 67.2 min, SD 21.3 min). No repeated interview was carried out, and no participants were requested to review or edit their transcripts. The demographic information of participants is presented in Table 1. Participants had a mean age of 32 (SD 5.08; range 24 - 39) years and an average of 3 (SD 2.98; range 0 - 11) years since diagnosis. Most participants were identified as female (n=9, 75%). The majority were non-Hispanic White (n=7, 58%), followed by Hispanic (n=2, 17%) and Asian (n=2, 17%), and 1 (8%) identified as multiracial. Over half (n=7, 58%) of participants held a graduate degree, while 4 (33%) had completed some college or a college degree, and 1 (8%) had completed high school. In terms of employment, 6 (50%) participants were employed full-time, 2 (17%) part-time, and 4 (33%) not employed. Participants resided in 8 different states. Most participants resided in suburban areas (n=8, 67%). Cancer diagnoses among participants varied, with leukemia being the most common (n=3, 25%), followed by Hodgkin's lymphoma (n=2, 17%), testicular cancer (n=2, 17%), and individual cases of non-Hodgkin's lymphoma, colon, brain, soft tissue, and uterine cancers (each n=1, 8%). At the time of the interview, 9 (75%) participants had completed treatment, while 3 (25%) were still in active treatment.

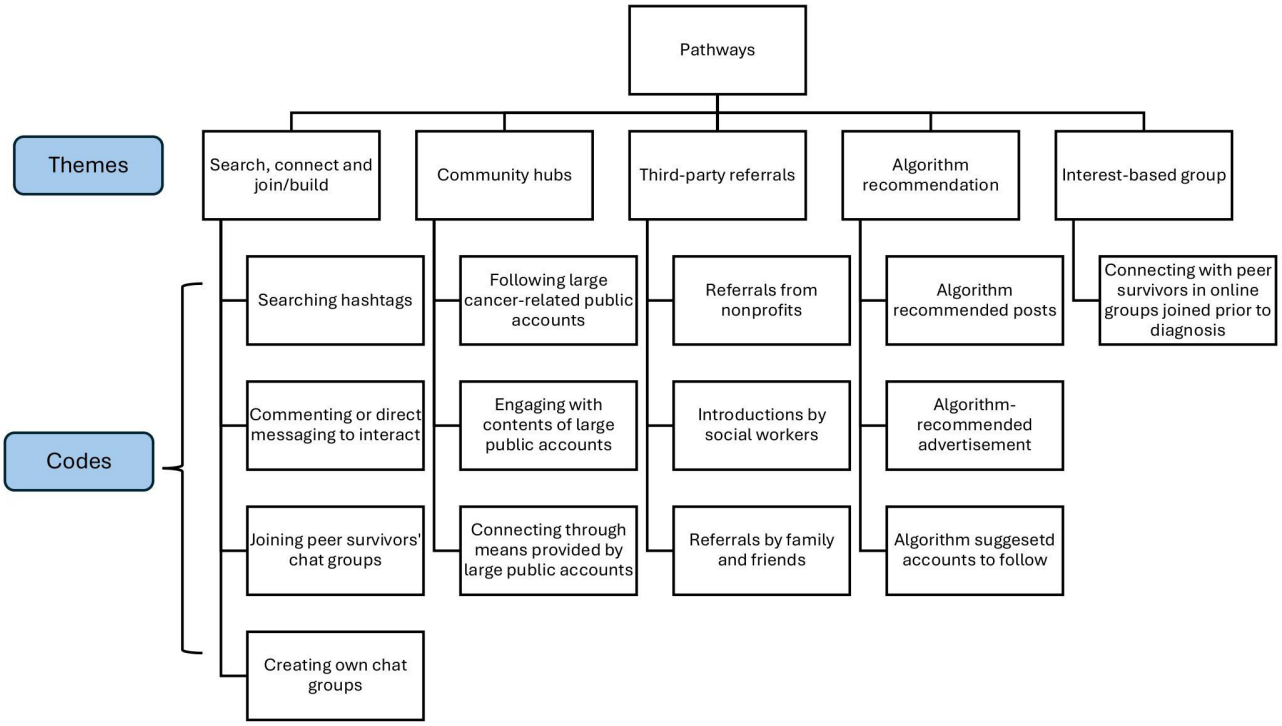
Qualitative Findings

This study explored 2 central questions: (1) how YA cancer survivors locate and access online cancer communities and (2) what challenges they encounter in sustaining engagement. The findings revealed a range of entry points that survivors used to discover supportive online spaces, as well as structural, interpersonal, and emotional factors that limited their continued participation. While participants represented a range of ages within the YA category (24 - 39 y), their approaches to engaging with online cancer communities and the obstacles they experienced were broadly similar. No age-related patterns were observed in terms of search strategies, preferred platforms, or engagement levels.

The results are presented in 2 sections, corresponding to each research question. The first section, *Pathways*, included 5 themes describing how YA cancer survivors found online communities: (1) search, connect, and join/build, (2) community hubs, (3) third-party referrals, (4) algorithm recommendations, and (5) online interest-based groups. The second section, *Roadblocks*, outlined 5 themes that capture barriers to sustained engagement: (1) platform fragmentation and digital literacy, (2) group boundaries and hierarchies, (3) lack of representation, (4) emotional overload and engagement fatigue, and (5) cyberbullying. Figures 2 and 3 depicted 2 coding trees of Pathways and Roadblocks to illustrate the codes identified and themes emerged in the analysis. Table 2 presents each theme along with its definition and representative participant quotes.

Figure 2. Coding tree of "Pathways" illustrating how young adult cancer survivors discovered online cancer communities.



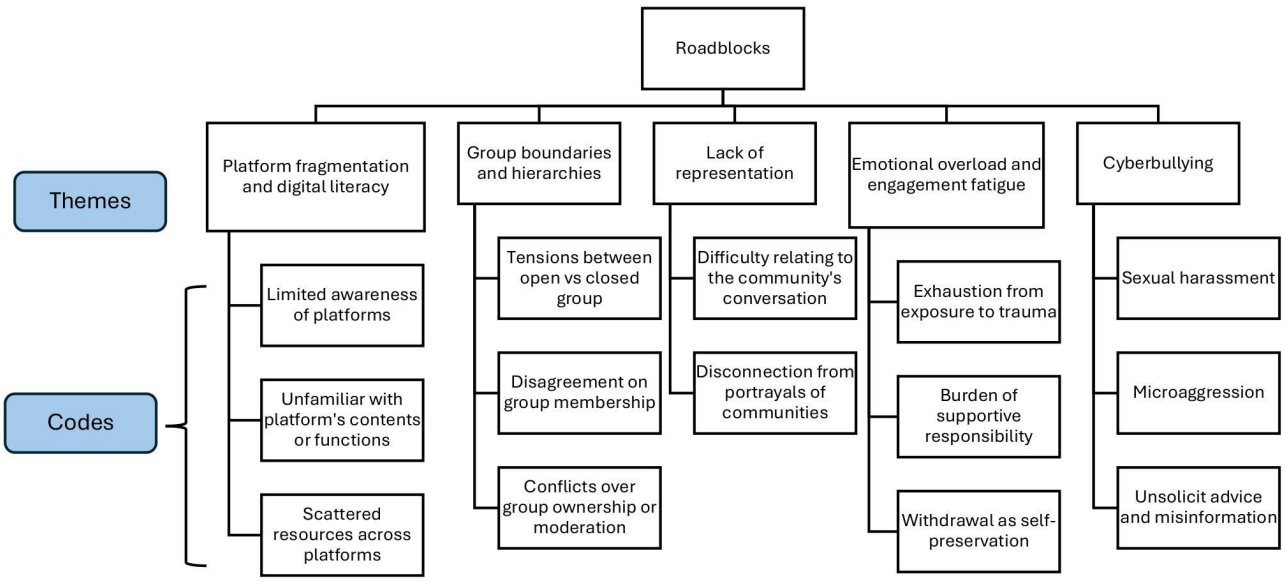


Figure 3. Coding tree of "Roadblocks" illustrating barriers that young adult cancer survivors encountered in sustaining engagement with online cancer communities.

Table . Themes, description, and representative quotes: pathways and roadblocks.

Themes	Description	Representative quote
Pathways		
Search, connect, and join/build	YA survivors actively searched relevant hashtags and initiated contact with peer survivors through comments or direct messages, leading to joining an existing community or forming their own community	• *She has a decent following, so I didn't expect her to see it or anything, but she responded back. So I messaged her, and then suddenly started messaging and then exchanged phone numbers and she's like, I've met a few other girls, who also going through cancer treatment this summer. So then she made a group chat for us. And then we said we all will support each other through cancer treatment this summer, when we should like having fun or whatever. That was like eight months ago, we still talk almost like every day.* (Participant 09) • *First of all, I was adding people that were in my state to try and build a community in my state, then it widened out more and more. And we would eventually share each other's Instagrams and that's how I built it up. Sometimes I'll still search up care packages, just to see if there's any new ones to add to my list, but also to see any people out there so I can connect with them.* (Participant 10)
Community hubs	YA cancer survivors followed large public accounts serving as information hubs for peer interaction.	• *The person who runs the account made a spreadsheet where people could put their name, their age, their diagnosis, and where they lived and the Instagram handle. And then, if anybody wanted to talk to them they could reach out. So I put my information on that spreadsheet, and I had one person reach out*. (Participant 08)
Third-party referrals	Nonprofit organizations or health care providers referred YA cancer survivors to existing online groups.	• *The other organization does a weekly happy hour every Friday, and that is the same host every time, and I started going and I found out from people who go to that also go to Stupid Cancers zoom session. And so, there's a lot of cross involvement with different survivors are part of and take part in programming for different AYA groups. Some of my closest friends that I've connected with there, I have almost all of them on Instagram and/or Facebook. I talk with them on an Instagram group Chat* (Participant 06).
Algorithm recommendations	YA cancer survivors encountered groups through social media algorithm suggestions.	• *When I search for something on Google, Facebook picks up my information and pushes related content… I can even see on Facebook what I had just searched for on Google.* (Participant 01) • *That was through algorithm. I didn't search for anything during that time. I think I just got lucky that one day, and she already knew people. That was like pure luck, like it was meant to happen. I don't think I find that many people on social media share similar experiences*. (Participant 09)
Online interest-based groups	YA cancer survivors found peer support within preexisting online interest or hobby groups.	• *It wasn't a cancer group, but people there had similar ages and life experiences, so I felt connected.* (Participant 07)

XSL•FO
RenderX

Themes	Description	Representative quote
Roadblocks		
Platform fragmentation and digital literacy	YA cancer survivors struggled to locate reliable supportive communities due to scattered platforms and lack of digital literacy.	• *I didn't really use Facebook and Instagram much so I was not aware of those accounts. I used to only use Chinese-language platforms and those that are available for Chinese people. I like hanging out with other Chinese people more*. (Participant 01)
Group boundaries and hierarchies	Conflicts over group ownership, membership criteria, or tone led to disengagement.	• *Sometimes caregivers come in, and they'll tell us 'Oh, how inspirational you are.' And we just don't know how to take that because we're like, we're just trying to live our life or don't feel inspirational*. (Participant 10) • *It fell apart because there was a disagreement over who was old enough to be in the group, and that hurt some people's feelings… and another group (that was dismissed), it turned out one person was making stuff up and people just didn't want to be a part of the group*. (Participant 06)
Lack of representation	Limited diversity (age, diagnosis, culture) left survivors feeling disconnected or unseen.	• *I couldn't really find a relevant account about infertility that felt like it described my experience. I followed some infertility-related accounts that weren't cancer specific, but just about people who had infertility in general, and those accounts are mostly run by white women who are really religious and really Christian. And so I think I've decided not to engage with those accounts anymore, just because I couldn't find anybody who had experiences that were similar to me or identities that were similar to mine.* (Participant 08)
Emotional overload and engagement fatigue	Exposure to others' trauma and constant emotional demands led to burnout and withdrawal.	• *I already felt miserable and no one cared about me... but seeing them vent still made me feel awful… On top of my own problems, I have to carry others' misery… thinking about their fate makes it unbearable.* (Participant 01) • *Sometimes it can feel a little repetitive. Like there are certain types of posts that I feel like you see again and again and again. So I think that can make it hard to stay engaged.* (Participant 03)
Cyberbullying	Harassment or microaggressions led survivors to privatize accounts, reducing visibility and engagement.	• *There's a subsection of people who are really weird that like bold girls. They will message cancer patients with really graphic descriptions. I've got that kind of message*. (Participant 10)

Pathways

YA cancer survivors accessed online communities through a range of entry points that reflected both deliberate strategies and serendipitous discovery.

Search, Connect, and Join/Build

This was the most common way YA cancer survivors mentioned regarding finding and joining their online cancer community. Usually, it would start with searching for keywords related to their cancer diagnosis or type of treatment, or the hashtag #AYAcancer, #YoungAdultCancer, #AYAcancer, or #cancerinyour20s, to identify peer YA survivors who shared similar cancer experiences. Some YA cancer survivors would initiate the conversation by commenting on the post of accounts they identified, such as sending wishes and making comments on similar cancer-related situations they share, and some would directly message to connect. After the connection was established and a larger network based on similar cancer experiences was formed, sometimes a chat group/channel would be created by one of the group members. There were also some

XSL•FO
RenderX

other YA cancer survivors taking a leading role in creating a community for people they knew and actively searching out to YA cancer survivors who might be looking for support on social media.

Community Hubs

Community hubs were centralized online spaces managed by individuals or small groups, serving as anchors or gatekeepers for connection, information exchange, and peer support. We found that there were such hubs that existed for YA cancer survivors to connect: almost all of the participants followed the accounts @thecancerpatient and @NoGriefTouristAllowed on Instagram. These accounts shared similar traits: large number of followers and mostly YA cancer survivors. They served as an information hub for YA cancer survivors. A YA cancer survivor community was naturally formed based on these 2 accounts, and these accounts were acknowledged and advertised by these cancer survivors at platforms other than Instagram. These public accounts connected peer survivors through posts that reflected shared cancer experiences. People responded in the comments or initiated conversations or through "story" (posts visible for 24 h) featuring followers' requests to connect. Some accounts would create ways to collect the contact information of those who want to connect.

Third-Party Referrals

YA cancer survivors also found nonprofit organizations or social workers at the hospital or cancer center helpful in referring to reliable online support resources. Nonprofit organizations dedicated to adolescent and YA cancer care, such as Stupid Cancer, Elephants and Tea, and Cactus Cancer Society, usually host online support groups and have their own forum or social media accounts. YA cancer survivors described being connected across different organizations, participating in multiple online cancer communities, and then forming their own communities in other social media platforms. YA cancer survivors also shared that when their family and friends found related resources, they would also recommend them and encourage them to connect. For instance, one participant mentioned that her sister has been an active user on the Reddit Cancer Caregiving subreddit and recommended her to join a cancer-related Reddit channel to find the community.

Algorithm Recommendation

As algorithm recommendation technology continued to advance, YA cancer survivors also benefited from recommendations on websites and apps they visited. Some described seeing the advertisement of Leukemia Society on Facebook after multiple rounds of internet search about Leukemia and survival rates and ended up visiting the site and found peer support programs. Some described their experiences of being recommended social media personal accounts with contents that were relevant to their life experiences and being able to connect with those people.

Online Interest-Based Groups

YA cancer survivors were comfortable with communication technologies, and they browsed different online communities at an early age. Therefore, many of them were already part of some online communities before they got cancer. One participant described her experience being in one huge interest group community, and there was a subgroup with people diagnosed with different types of cancer and stages of cancer. Even though it was not specifically for YAs, the participant described that since these interest-based groups were usually formed with people of similar age, demographic, and political outlook, or shared hobbies, it was easier to feel connected to these people.

Roadblocks

While online communities offered vital spaces of support, YA cancer survivors reported a number of challenges that shaped their participation.

Platform Fragmentation and Digital Literacy

Participants described difficulties locating relevant support communities due to the fragmented nature of social media platforms. Information and resources were scattered across platforms such as Instagram, Facebook, Reddit, and organization-specific forums, many of which lacked centralized searchability. Some participants were unfamiliar with widely used platforms in the United States, particularly immigrant YA cancer survivors who previously used regional platforms to maintain relationships with family and friends back in their home countries. This limited exposure made it challenging to access content or locate established YA cancer communities on English social media platforms.

Others noted that even when they were familiar with a platform, they often lacked the knowledge of which accounts or groups to follow. Many were also unaware of nonsocial media–based online communities. For instance, one participant shared her experience of only recently learning about COLONTOWN, a web-based platform uniquely for colorectal cancer survivors. Furthermore, many shared that YAs who were connected through one platform might move to another to create their own group, sometimes choosing platforms others had never used or did not have accounts on. These access disparities underscored how platform fragmentation and varying levels of digital literacy could hinder survivors' ability to locate and engage with appropriate sources of support.

Group Boundaries and Hierarchies

Online community boundaries could be challenging to manage. In open forums, lacking group boundaries would trigger uncomfortableness and conflicts and thus decrease their interests in staying in the group. Participants stated that for some groups that also welcomed the participation of caregivers, family members, or providers would interrupt the group dynamics and disrupt the sense of safety and belonging of the community. In secret/closed groups, group hierarchy, group ownership, and group membership could also become problematic. If agreement could not be achieved between group owner and group members, it would cause conflict, and the online group would have to be dismissed if conflicts continue to escalate.

Lack of Representation

Not all online cancer communities effectively met the informational and emotional support needs of YA cancer survivors. Several participants in the study described feeling like "outsiders" in these spaces. A major barrier to meaningful

XSL•FO
RenderX

engagement was the perceived lack of inclusiveness and representation. Participants emphasized that the characteristics of community members, such as age, diagnosis, religion, health beliefs, cultural background, and treatment experience, strongly influenced their sense of connection. When these attributes did not align, it was difficult to relate to others or feel understood. For example, wide variations in treatment plans and side effects among YA patients having cancer made it challenging to find peers with similar experiences. The more disconnected participants felt from the community, the less likely they were to engage.

Some YA cancer survivors expressed discomfort with content on accounts that were community hubs and overly romanticized the cancer experience. They found such narratives to be superficial and disconnected from their own realities, making it harder to relate or feel represented. One participant shared that she avoided public accounts that presented highly curated or idealized portrayals of survivorship, as they felt inauthentic and failed to meet her informational or emotional needs.

Emotional Overload and Engagement Fatigue

For many YA cancer survivors, ongoing exposure to peers' illness narratives in online communities could generate a deep sense of emotional fatigue, like one participant said: "Everyone's unloading their trauma and it's overwhelming." (Participant 05). This exhaustion stemmed from not only the content's intensity but also the complex dynamics of shared vulnerability and responsibilities. This form of emotional overload often coexisted with a sense of obligation to support, which heightened the burden. In addition to this emotional overload, participants described seeing similar posts over time could become draining. These revealed not a loss of interest but the emotional cost of showing up, where survivors must balance their need for support with the strain of witnessing others' ongoing pain. Self-preservation, through withdrawal or silence, became a necessary response for survivors negotiating their own healing within communal spaces of vulnerability.

Cyberbullying

For people to be able to search one's posts or follow one's account, one needs to keep their account and posts public. However, being public and exposing themselves to the internet could be risky, especially for YA survivors. Many participants reported microaggression and cyberbullying on social media, such as unfriendly comments on their appearance, unsolicited advice, or even sexual harassment. As a result, YA cancer survivors who keep their accounts public to share their cancer experiences and help peer survivors connect initially would change their account setting to private to avoid these negative impacts. The unsafe environment on social media would limit the information source that peer YA cancer survivors could access.

Discussion

Overview

This study provided timely insights into how YA cancer survivors navigated the increasingly complex landscape of online cancer communities. It identified 5 key pathways to discover online communities and 5 major barriers in finding and sustaining engagement. The findings revealed that survivors' participation was influenced not only by personal agency and constraints but also by systemic factors such as platform accessibility and usability. The findings also further illuminated understudied interpersonal dynamics, such as emotional labor and shifting hierarchies and boundaries within communities, that affected survivors' sustained involvement in online communities. By centering YA cancer survivors' lived experiences in exploring online communities, this research advanced a more nuanced understanding of how to foster inclusive, meaningful, and sustainable online support communities.

Principal Findings

This study uncovers new forms of digital space navigation and structural inequity that shape survivors' ability to benefit from online support. Our findings showed that with more online platforms available, YA survivors joined or formed communities across different platforms and often switched between them. While new features such as algorithmic recommendations, hashtags, stories, and group chat channels allowed them to find or form online cancer communities more easily, the benefits of these tools were not experienced equitably. Participants' capacity to navigate and engage effectively was strongly influenced by their familiarity with functions of different platforms, many of which were not accessible to all users. For instance, immigrant survivors originally from countries where platforms like Facebook and Instagram are banned often lacked exposure to dominant US platforms. It demanded additional effort to learn and transition to a different platform solely for the purpose of accessing online support. Furthermore, limited access to certain social media platforms among users from specific cultural backgrounds results in fewer online support communities offering inclusive and culturally relevant content in their native languages. This disproportionately affected YA of color. These gaps in representation were compounded by algorithmic patterns that reinforced misinformation and unsolicited advice, disproportionately affecting those with lower health literacy or limited English proficiency. Together, these findings reveal how structural digital inequities shaped YA survivors' capacity to benefit from online support.

This study reveals that YA survivors' engagement with online cancer communities was emotionally dynamic and relationally fluid. Their interactions were marked with uncertainty and change. Navigating online cancer communities involved ongoing assessment of the relevance of the communities, negotiation of personal or group boundaries, and weighing between benefits and the risks. Some participants moved fluidly between communities or platforms as new communities emerged and migrated, while others withdrew temporarily or permanently when the emotional toll became too high. Rather than serving as a stable or consistently supportive resource, online cancer communities could also generate emotional distress, uncertainty, and exposure to unsafe or overwhelming virtual environments.

Comparison to Prior Work

This study extends prior digital health disparity research on YA survivors' online support by shifting attention from individual

XSL•FO
RenderX

constraints in digital literacy to structural inequities in virtual spaces. Prior research has largely emphasized individual-level factors such as education, socioeconomic status, or their social capital as the main drivers of digital divide in access and utilization of online resources [29,30]. Our study reveals that digital disparities persisted even among digitally savvy YA survivors, driven by the nature of online platforms. Participants' platform preferences were shaped by the habits as well as the accessibility of apps and websites of their families and social networks [30]. One prior study has similarly identified representation barriers, which noted that YA survivors often avoided older platforms such as Facebook, where most established cancer support groups exist, due to perceived misalignment with their peer networks and identity [13]. Familiarity with specific platforms, access to culturally relevant content, and the design of digital infrastructures emerged as key determinants equally impacted YA. This shift from individual to systemic explanations underscores the importance of improving platform accessibility and usability.

This study also advances existing literature by revealing how interpersonal dynamics within online communities could introduce more emotional distress and uncertainties besides support. Consistent with the prior findings, our study found that YA cancer survivors had strong needs of connecting to peer survivors [31] and they would search online proactively to find peer survivors [32]. Our study pointed out that, however, engagement was not always self-initiated; algorithms or others' suggestions often prompted participation, leading to interpersonal strain. Prior work has well documented the benefits for YA cancer survivors involving online cancer communities, emphasizing information exchange, social support, and empowerment [31,33,34]. Risks such as exposure to distressing content or misinformation have also been acknowledged, though often discussed as isolated, individual experiences [35]. One prior study has examined the dynamics of social media engagement among YA cancer survivors, but focusing primarily on individual motivation and preferences [32]. Our findings expand these understandings by showing that group-level factors such as changing boundaries, evolving hierarchies, and the associated emotional labor directly influence engagement and withdrawal. By framing these experiences as relational and evolving, this study highlights that community organizing and group moderation is necessary for virtual spaces.

Limitations

This study has several limitations. First, our sample included only participants who had internet access and prior experience using social media. It remained unclear whether YA cancer survivors without such access or experience would be open to, or able to engage with, online cancer communities. This inclusion criterion was necessary to ensure that participants could reflect meaningfully on their experiences navigating online communities. However, it may have limited the perspectives of YA cancer survivors with limited digital access or literacy or who lack interests in online cancer communities. Future studies should consider various recruitment strategies (eg, phone interviews or community-based outreach) to capture the experiences of survivors who have not been involved with any online cancer communities.

Second, the sample lacked representation from African American participants. Prior research indicated that African American cancer survivors were underrepresented in online support groups and less likely to use the internet for health information compared to their White counterparts, due in part to digital access barriers, differing help-seeking preferences, and lower trust in online health sources [36,37]. Although we recruited through multiple nonprofit networks serving diverse populations and encouraged participant referrals, our sample may have unintentionally excluded survivors not affiliated with such organizations or those relying on offline or culturally specific support systems. Future research should employ more inclusive recruitment strategies, including outreach through hospital registries, partnerships with African American survivor networks or community centers, and targeted social media campaigns or accounts that have higher number of African American followers. Addressing these structural and digital inequities is essential to advancing equity and representation in digital cancer survivorship research.

Future Directions

Future intervention research and clinical practice should focus on improving the accessibility and sustainability of online cancer communities through both structural support and individual capacity-building.

At the system level, oncology social workers have long played a critical role in connecting patients with fragmented resources [38], and our findings further confirmed this essential function. However, many social workers, particularly those outside of large cancer centers, were not well-versed in the availability of online cancer communities and virtual support groups for minority YA survivors on various scattered platforms [31]. While social support from family, peers, and health care providers can facilitate access to online communities, the active involvement of health care professionals or trained moderators in online health communities enhances trust, reduces the spread of misinformation, and mitigates risks such as cyberbullying and communication breakdowns [39,40]. Expert-led moderation has been associated with improved emotional safety, greater engagement, and more supportive peer interactions [41]. This underscores the importance of digital literacy training with health care professionals to strengthen their competencies in navigating and moderating different online cancer communities, so they can more effectively refer, prepare, and support YA survivors.

At the individual level, private or peer-led groups typically rely on YA survivors themselves to establish norms and maintain boundaries, placing added emotional and relational burdens on those already coping with cancer. Our findings indicated that many YA survivors not only passively join a group but actively take part in building or contributing to their own communities. One promising approach is to train YA cancer survivors who are interested in leadership roles in online communities on skills to identify harmful content, establish group norms, and manage conflict. Additionally, while the prevalence of cyberbullying and emotional risk in online communities has been documented [42], few interventions exist to prepare survivors for these challenges. Education around safe storytelling, self-care, and

XSL•FO
RenderX

managing online engagement fatigue should be integrated into survivorship support programming [35]. This includes guidance on when to disengage, how to set personal boundaries, and how to respond to toxic interactions.

Conclusion

This study highlights that YA cancer survivors navigate online communities through multiple pathways but face significant barriers to sustained engagement, highlighting the need for provider training and peer moderator support. To foster safer and more inclusive online environments, health care providers should be trained to guide survivors toward reliable support resources; community moderators should be trained to manage emotional labor and maintain healthy group boundaries; and YA cancer survivors should receive survivorship support to navigate online spaces effectively. Strengthening these multilevel supports can enhance the sustainability and psychosocial benefits of online cancer communities for YAs.

Funding

QC was supported by the American Cancer Society Social Work Doctoral Training Grant (134807-DSW-20-086-01-SW).

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the sensitive and potentially identifiable nature of qualitative interview data and the absence of participant consent for open sharing, but are available from the corresponding author on reasonable request.

Authors' Contributions

QC contributed to conceptualization, data collection, project administration, data analysis, and original draft writing. ED was responsible for conceptualization, methodology, review, and editing of the manuscript. LZ contributed to data analysis. LN contributed to methodology and review and editing. BJ was involved in conceptualization, supervision, and funding acquisition.

Abstract

Background: Individuals undergoing cancer treatment often face a high symptom burden that impairs quality of life. Exercise and mind-body therapies have been shown to reduce symptoms but are underused. We developed a digital exercise and mind-body therapy program that effectively reduces symptoms while overcoming in-person delivery barriers. Understanding patient experiences can inform treatment mechanisms and guide digital health interventions in cancer care.

Objective: This study aimed to explore patient experiences with Integrative Medicine at Home (IM@Home), a 12-week live digital program delivering exercise and mind-body therapies tailored to the needs of individuals undergoing cancer treatment.

Methods: This qualitative study was embedded in a randomized clinical basket trial (NCT05053230) evaluating the effects of IM@Home versus enhanced usual care on symptoms and acute health care utilization in adults with solid tumors undergoing active treatment and experiencing moderate or greater fatigue. Using maximum variation sampling, 20 participants were selected for semistructured interviews. Interviews explored participants' experiences with the program, its impact on outcomes, unmet needs, and suggestions for improvement. Transcripts were analyzed using a combined inductive and deductive thematic analysis.

Results: Twenty participants (mean age 63, SD 9.6 years; 18/20, 90% female) were interviewed. Five major themes emerged: (1) IM@Home alleviated symptom burden and supported symptom self-management; (2) IM@Home facilitated social support and information exchange; (3) IM@Home offered a flexible, tailored program in a group setting; (4) IM@Home facilitated accessible, cost-effective support; and (5) recommendations for program enhancement. IM@Home was perceived as an accessible, flexible, and supportive program that promoted physical and emotional well-being during treatment.

Conclusions: IM@Home demonstrates a promising model for delivering integrative supportive care during cancer treatment. Findings highlight patient-valued features such as real-time guidance, tailored content, and community support. These insights can inform future implementation, integration into clinical care, and efforts to enhance digital mind-body interventions in oncology.

Introduction

In 2024, an estimated 2,001,140 new cancer cases were expected in the United States [1], with most individuals undergoing systemic therapy or radiation [2]. While these treatments have significantly improved survival rates, people with cancer often experience a high symptom burden, including fatigue, pain, and insomnia, which can lead to reduced quality of life and, in some cases, treatment discontinuation [3,4]. A recent systematic review found that up to 90% of patients undergoing active cancer treatment reported unmet needs, with psychological (eg, anxiety and fear) and physical (eg, tiredness and lack of energy) challenges being most prevalent [5]. Exercise and mind-body therapies (eg, meditation, yoga) are endorsed by leading oncology organizations, including the American Society for Clinical Oncology, the Society for Integrative Oncology, and the National Comprehensive Cancer Network, as effective strategies for managing cancer treatment-related symptoms [6-10], therefore, improving treatment adherence and survival rates [11-13]. However, clinical implementation remains limited due to barriers, such as limited access, restricted modality options, and logistical challenges (eg, travel) [14-19]. Innovative delivery methods are urgently needed to address these barriers and integrate these therapies into oncology care.

Digital health technologies, including remote delivery of clinical or supportive care via telecommunications (telehealth), health services delivered through mobile health devices, and internet-based health services (eHealth), show promise for improving access [19-22] and are widely used in cancer care for symptom management [23-27], treatment supervision [28,29], and clinical trials [30-33]. Examples relevant to cancer care include mobile apps for symptom tracking and medication [34,35] and wearable activity monitors to promote physical activity and exercise [36,37]. However, their adoption for delivering exercise and mind-body therapies during cancer treatment remains limited, with concerns including ensuring safety when patients engage remotely, tailored patient-centered program design for online group formats, and addressing technical barriers [19]. To address these gaps, at Memorial Sloan Kettering Cancer Center (MSK), we developed a novel Integrative Medicine at Home (IM@Home), a 12-week live, digital telehealth program delivering group-based exercise and mind-body therapies [38,39], designed specifically for individuals with cancer. IM@Home combines multiple evidence-based modalities—including yoga, meditation, and fitness—with intensity and activities tailored to participants' needs and treatment-related limitations. Patients have unlimited access to classes, allowing them to choose sessions based on their preferences, providing flexible and ongoing support. A randomized clinical trial (NCT05053230) of 200 patients in active treatment demonstrated IM@Home is safe and effective in reducing fatigue, anxiety, and depression, while lowering acute health care utilization [40].

While quantitative data support IM@Home's clinical benefits, understanding the end user experience is essential to inform broader implementation and patient-centered refinement, particularly in oncology, where patient safety and care needs are heightened [41-43]. To fully understand how complex interventions such as IM@Home lead to change in outcomes, it is important to examine the broader context in which these interventions operate. This includes moving beyond standardized outcome assessments to actively include the voices of individuals directly targeted by the intervention, whose experiences and perspectives are crucial to refining the delivery and ensuring real-world relevance [44]. Yet, few studies have examined patient perspectives on synchronous digital mind-body interventions during active treatment, a period marked by significant physical, psychological, and logistical challenges [41,43]. This study addresses that gap by exploring participants' views on the program's digital delivery, usability, and impact on symptom relief and quality of life. The findings offer insights to support the safe, effective, and accessible integration of digital integrative oncology interventions into routine cancer care.

Methods

Study Design

This qualitative study was conducted as part of the Integrative Medicine for Patient-reported Outcomes, Values, and Experience (IMPROVE; NCT05053230) trial, a randomized clinical basket trial assessing the effects of the IM@Home program on symptoms and acute health care utilization in patients with moderate or greater fatigue undergoing active treatment for melanoma, head and neck, lung, gynecological, or breast cancer. From October 2021 to March 2023, a total of 200 participants were randomized to 12 weeks of either IM@Home intervention (live exercise and mind-body classes via Zoom [Zoom Video Communications]) or enhanced usual care (standard of care plus on-demand meditation resources). Study design, primary results, and detailed program description have been published elsewhere [38,40].

The IM@Home program offers 23 live classes per week, including movement-focused classes (eg, fitness and dance), mind-body classes (eg, yoga and tai chi), and mind-focused classes (eg, meditation and music therapy). Classes are delivered synchronously (in real time) via Zoom, each lasting 30-60 minutes, and led by licensed MSK Integrative Medicine Service clinicians—including certified fitness trainers, yoga and mindfulness instructors, and licensed music therapists with experience in oncology—who guided participants, offered modifications, and provided verbal cues and encouragement to support engagement and safety. Upon randomization, a member of the research team contacted participants by phone to introduce the program, provide an overview of class types, and assist with registration. Participants could attend as many classes as desired each week, select any combination of classes, and modify their selections as needed.

Participants

We used maximum variation sampling, targeting approximately 20% of IM@Home participants to capture diverse experiences across cancer types and different stages of program participation (study time points: Weeks 4-7, Weeks 8-12, or after study completion). The sampling framework, including the number of participants selected from each cancer type and time point, can be found in Multimedia Appendix 1. Selected participants were contacted by a member of the research team via phone to

XSL•FO
RenderX

invite them to participate in the qualitative interviews. All participants approached for interviews agreed to participate.

Data Collection

We conducted semistructured interviews with 20 IM@Home participants, led by 2 trained qualitative researchers with backgrounds in integrative therapies and psychology (KS and KB). Interviewers had previously briefly interacted with some participants during their participation in the IM@Home program, either during consent or later while providing assistance with class registration. At the start of each interview, participants were informed of the interviewers' professional roles. The research team developed and used an interview guide to explore key aspects of participants' experiences while allowing flexibility in responses (Multimedia Appendix 2). To ensure participant-driven insights, interviewers used open-ended probing questions and adapted them in real time to explore emerging topics.

Interviews were scheduled according to participant preference and availability, conducted via HIPAA (Health Insurance Portability and Accountability Act)-compliant Zoom, lasted up to 20 minutes, and were audio-recorded with the participant's consent using the Zoom recording function. Audio files were securely stored on an encrypted, password-protected institutional server accessible only to the study team. The audio recordings were transcribed verbatim (KS), reviewed for accuracy (KB), and de-identified by both coders (KS, KB) prior to analysis. Reflexive journaling and team debriefings were used to minimize interviewer bias.

Data Analysis

We analyzed all interview transcripts using a 2-phase approach that combined inductive and deductive thematic content analysis [45,46]. Our analytic process followed the 6-phase reflexive thematic analysis framework described by Braun and Clarke [46] familiarization with the data; generating initial codes; searching for themes; reviewing themes; defining and naming themes; and producing the final report.

In Phase 1, two researchers (KS and KB) independently read 5 transcripts to identify key narrative content and determine the unit of analysis (eg, sentences or full passages) (Phase 1: familiarization). Through an inductive, open coding process, they developed descriptive and interpretive codes (Phase 2: generating initial codes), allowing themes to emerge from the data. The researchers then met to discuss coding and emerging themes and iteratively refined and grouped codes into higher-order categories, forming thematic units (Phase 3: searching for themes; Phase 4: reviewing themes). Analytic memo writing supported the identification of emerging patterns and conceptual relationships. This iterative process ensured that findings were grounded in participant experiences rather than predetermined categories.

In Phase 2, using a deductive approach, the finalized coding scheme was applied across all transcripts by 2 researchers (KS and KB) to assess coding consistency and intercoder agreement. A third researcher (KD) reviewed coded transcripts to enhance credibility, with any discrepancies resolved through discussion. Once coding was completed, the final themes, categories, and representative quotes were reviewed and discussed with the broader research team (Phase 4: reviewing themes**;** Phase 5: defining and naming themes; and Phase 6: producing the report). To further enhance confirmability, an independent reviewer (SC) examined the coding and interpretation for potential bias or inconsistency. NVivo software (version 14; QSR International) was used to support data management and analysis. Thematic saturation was evaluated continuously throughout the analysis.

Strategies to Ensure Trustworthiness

Credibility was supported through researcher triangulation (3 coders participated in data coding, analysis, and interpretation), peer debriefing with the broader research team, and reflexive memo writing. Transferability was addressed through purposeful sampling and thick description of the context, participants, and findings. Dependability was ensured via a detailed audit trail documenting all stages of data collection, coding, and analysis, along with intercoder agreement among coders.

Confirmability was enhanced by maintaining an audit trail, practicing reflexivity, and conducting an external audit by an independent reviewer (SC) to assess for bias or inconsistency.

Ethical Considerations

The study was approved by the Institutional Review Board (IRB) at MSK (IRB# 21-369), registered at ClinicalTrials.gov (NCT05053230). The ethics approval for the qualitative interviews was part of the original IRB approval. Participant confidentiality was maintained; data were collected and stored in secure, password-protected systems and analyzed in deidentified form. Participants did not receive compensation for study participation. All participants provided written informed consent. Findings are reported per the Standards for Reporting Qualitative Research guidelines [47] and COREQ (Consolidated Criteria for Reporting Qualitative Research) extension [48]. The COREQ checklist is provided as a Multimedia Appendix 3.

Results

Participant Characteristics

All participants approached for interviews agreed to participate. Of the 20 participants interviewed (mean age 63, SD 9.6 years), a majority were female (18/20, 90%), White (17/20, 85%), and had breast cancer (9/20, 45%). Table 1 summarizes the demographic and clinical characteristics of the 20 participants included in the qualitative interviews. This qualitative study sample was broadly reflective of the overall IMPROVE trial population (N=200) and the IM@Home arm (n=99) with respect to gender, age, and cancer type, although there was a slightly higher proportion of White and Asian participants and a slightly lower proportion of Black participants compared with the IM@Home arm.

Head and neck	4 (20)
Lung	3 (15)
Melanoma	1 (5)
Time of the interview, n (%)	
After study completion	2 (10)
Week 4-7	7 (35)
Week 8-12	11 (55)

Qualitative Findings

Saturation was achieved by the 17th transcript; however, all 20 interviews were coded to capture potential nuances and ensure comprehensive representation. Ultimately, 5 major thematic units were identified. These thematic findings are summarized in a narrative account below, while detailed theme descriptions, including definitions, categories, subcategories, and additional illustrative quotes, are provided in Table 2.

XSL•FO
RenderX

Table 2. Qualitative findings.

Themes and their definitions, and categories and subcategories	Example quotes
Theme 1. IM@Home alleviated symptom burden and supported symptom self-management: *IM@Home helped participants manage cancer-related symptoms by improving physical strength, reducing fatigue, alleviating stress and anxiety, and providing accessible self-coping strategies to enhance overall well-being.*	
Reduced treatment-related symptom burden	• "The thing that definitely did help was also, you know, in terms of trying to sleep the guided part of getting you to relax, because I've always been a bit of an insomniac, and I think this one didn't. This whole episode of going through all this didn't help in that one. So that part definitely helped just being able to kind of visualize every part of you, relaxing and going to sleep." [P003] • "It's hard to explain, I know it's good for me and I do it. My back hurts and my neck hurts, and whatever I'm doing…I don't know if it's the Chair yoga or one of the other things, but my back feels better. The neck, I think, got a little worse. But the back feels better, so I know, whatever I'm doing it is helpful in the long run." [P002] • "I really like it. I feel like a different person. I feel so much looser. I just feel like 'wow', and it's not like you're sweating, and it's really tough, but you can really feel these small movements, and I just feel good. I feel so much better like it gives me quite a bounce to my day." [P017] • "I do feel that it was um I do feel like it did give me a greater range of motion, and I do feel that I slept better." [P010]
Enhanced symptom self-management and sense of control	• "I would describe it [IM@Home program] as a tool for coping. Because I think being able to figure out how to um move in the world emotionally and physically with the illness, or the recovery from an illness is coping and coping and adapting is critical." [P010] • "I think it's such a stressful time in your life, because you really don't know what to what to expect. What you're going through and all, you don't know how you're physically the physically going to be reacting to anything, and it's such a stressful time. I think if you can plug that [IM@Home] into your day in some way, even, maybe a couple of times a day to help you kind of get yourself grounded, and I think that that would be helpful. I think you just have to try and stay focused as much as you can, even though it's quite difficult." [P011] • "I definitely feel more like myself […] where I'm not so consumed with cancer and treatments, like I almost feel like I can. I feel mentally better. That's one thing I would definitely say, I don't feel as upset all the time. I don't feel as down, because it was definitely getting, like, as the as the radiation went through like definitely emotional and teary and sort of feeling sorry for myself. So I definitely feel that I do feel more positive and just mentally like a bit more clear and like a bit more positive and going forward." [P017] • "Yes, actually, psychologically better because I finished it. Finally, you got up off the couch from watching TV or something on a day when I was doing that. Not as good as I felt if I could get out shopping for three hours. That is the ultimate kick in the pants. Yeah that [IM@Home] gets me going." [P005]
Theme 2. IM@Home facilitated social support and information exchange: *the program fostered a sense of community, offering emotional support, reducing isolation, and enabling peer-to-peer learning through shared experiences and instructor guidance.*	
Building a sense of community	• "There's also a sense of community because usually in the beginning, at the end there's little discussion, a talk, and you hear people talking giving little advices, there is a little community there and I like it." [P004]
Feeling seen and supported	• "Beyond the exposure to something that can provide comfort and health benefits, there is a certain companion ability among people if you attend the same class. There are some of the same people in those classes, and they do talk to the instructor primarily after the class. […] And you know, in the chat function afterwards, somebody will mention [personal stories] and just a nice kind of things that people would say, or someone talks about something they're having a hard time with, or something that went well. And there are all these other people don't know, but who are saying, you know congratulations, or you know that's tough, or maybe throw out a resource they've heard of. So it's not a big bulletin board, it's not a big chat, but there's a little bit of a sense of community I think, is nice." [P012]
Knowledge and resource sharing	• "I think it's very good for that [sharing personal experiences] it seemed like a lot of the conversations and the chats and the things that they [patients] were talking to each other. You know this is the best speaker [platform] to use. You know, I think, all that neighborliness is very useful too. I think a sense of community is always good." [P010] • "I don't have my camera on but some people do and it builds a camaraderie, which some people might need. Thank God, I have a lot of support from friends, from family members, you know, but some people might not have that. And to get a support from the group of people, I think that that would be very beneficial." [P002]

XSL•FO
RenderX

Themes and their definitions, and categories and subcategories	Example quotes
Theme 3. IM@Home offered a flexible, tailored program in a group setting: *participants valued the program's safe, flexible, and personalized approach within a group format, allowing them to engage in oncology-tailored exercises suited to their needs, schedules, and symptom burdens.*	
Ensuring safety and personalization	• I think the most helpful was just the fact that the instructors were clear […] they made it very clear like 'Well, here's our warm-up,' and they really did make sure, like I've been to some fitness classes where there's really no emphasis on the warm-up or on the stretching afterwards. And that's such an important part of the program. So I thought that that was probably the most beneficial. And, in my opinion, is that they really did look at this holistically and say, like, here are people who are recovering and or bring in something so let's make sure that they stretch appropriately before we dive into the program, and then let's make sure at the end." [P020] • "Well, I've been sick, for almost two years, I'm getting better now, and it makes me feel good. I mean after yoga, gentle yoga it's very gentle but it's just my speed, my level and I can't believe how good it is for me and then like its wow that feels so easy, then I feel the stretches, I feel the muscles that I haven't used for a while. So [the classes] make me feel good." [P004] • "There was a large group of people of varying levels. And so instructors wanted to make sure that everybody was able to participate. I like the emphasis on breathing. I like the emphasis on just moving, being able to do what you know. Just move. Just do whatever you can to move." [P020] • "It's something that's very good for you, and you don't need like a lot of equipment, either, because that's the other thing that people find discouraging is oh, like I don't have weights. Well, you could use water bottles, or you could use towels, or you could use. I think what she said was, you could use your thumb and your index finger, like those types of modifications, were very helpful. So I think that's how I would sell it to her judgment-free, all activity levels the privacy of your own home with instructors that give you different options for your fitness, level." [P010]
Offering variety and flexibility	• "There are abundant resources through the program for it [symptoms], access to, particularly to mind, body experiences that are interesting to explore if you've never done them before, and if you've done them before they're a way to maintain a practice […] It's good for you. It feels good to do it, and it can help you step outside yourself a little bit." [P012] • "You can choose which ones you want, and there's a variety and different levels." [P015] • "I think that's what I liked best about this program that it was just at a level and at a pace where you can kind of ease into it and then modify as you got stronger." [P020] • "I didn't find it difficult or challenging, because I think people provided enough guidance to say, 'Hey, here, if you are a beginner, here's where you could do it.' This is, for example […] push-ups right, you could use a wall or a chair or the floor or do a full-on push-up. So, there's different types of push-ups you can do depending on your level. I didn't really think it was all that challenging. And then there was always the caveat that if you weren't comfortable doing that, then, you know, and just keep moving or do something else." [P020] • "It was a good variety. It gave you just different the different chances to do the different types of classes. Also, for the length of time that I had on my schedule so that I was able to do it. I thought the variety was good. Having them [classes] at the different time sequences, also the different types they had, where they kind of had you going you know mentally and all that. That was also very good, because it gave some variety." [P011]
Role of instructors	• "And the most helpful is because the instructors also say you can do this, keep going and they motivate you to go, and that helps me. It's just a way that they, I can't explain it, it's just the way that they do the classes that I enjoy and it's like, you know, like when I get tired, I just keep going." [P018] • "I think the other positive was that there was pretty good instruction, like sometimes when you do online classes. and you know, and the cameras aren't turned on for most of the people like you don't know if they're going to do something that might injure themselves, but they manager themselves. But I feel like people were, you know, in a pretty good... they gave pretty good instruction. But I know that's always a challenge with online classes, especially when you're when you have a group of people of varying levels. Making sure that no one gets hurt." [P020]
Theme 4. IM@Home facilitated accessible, affordable, and ongoing support: *the digital format removed barriers such as cost, travel, and infection risk, making exercise and mind-body therapies accessible to diverse patients while supporting long-term wellness beyond active treatment.*

Themes and their definitions, and categories and subcategories	Example quotes
Improving accessibility and convenience	• "I would be concerned about going to the gym and even though that don't have to have a mask for indoors now I'll continue wearing a mask because I don't need to catch anything else, and a lot of people that are basically homebound at this point either because of the situation, because of COVID, or because of the way they feel. It's good to have something that they could do at home due to their fitness level. That's not difficult and is enjoyable. I would recommend it." [P002] • "Especially after surgery and radiation, when you're tired and you want to regain your energy, it's most people aren't self-motivated to join a gym or do anything like that, but just the fact that it's in privacy of your home that there are people that are there that are just like you. And that it's geared and tailored for patients." [P020] • "I was a very regular gym goer and I always would go in, lift weights and do some cardio, and would always take a yoga class. I probably did like 4 or 5 a week […] since the pandemic, I'd stopped going to the gym, for fear of infection. And because of the pandemic I'm still not there, I'm not going to a gym. I'm just not going to be in a big building with people breathing hard and no masks. So that that's the biggest benefit that it's just the ability to get back into some sort of fitness routine." [P015] • "It was simple. I mean I just chose a class clicked on it got a registration form put in my name, address phone number whatever and then the next day or I got a link to the class the simple." [P002]
Providing structure and motivation	• "Sometimes the treatment can have a very demotivating effect, and having something to look forward to, I feel helped so much, mentally." [P016] • "Even though I get tired I can keep going better than before I was doing the classes, so I really think that they're starting to help build me up again, […] which is a good thing, because I was almost to the point where I was just sitting in my chair and said, 'Forget this, I'm tired' So now I'm actually looking forward to doing the classes." [P018] • "And the most helpful is because the instructors also say you can do this, keep going and they motivate you to go, and that helps me. It's just a way that they, I can't explain it, it's just the way that they do the classes that I enjoy and it's like, you know, like when I get tired, I just keep going." [P018]
Theme 5. Recommendations for program enhancement: *participants provided several suggestions for optimizing the program's implementation and maximizing its benefits.*	
Need for additional guidance	• "I think the one thing that can be a little difficult, which maybe in-person would have helped, is the Tai chi. I tried doing it, and it's so hard to, because you have like a mirror image, and the instructor is telling you to twist your body a certain way. It's hard to figure out exactly how to do that. So I think that was the only class that I was very confusing in terms of doing it online." [P016] • "One thing I will say about the course description, that I read before I went to each class, was I didn't feel that they were very clear on the type of material you should bring to the class […] I don't recall now what they said but it's like some classes, we use stretchy bands and I know [instructor], would talk a lot about what you could use to substitute and maybe you don't want to discourage people from coming you know joining thinking that they don't have all the materials that are maybe used in the class." [P006]
Expanding delivery methods	• "Let me just say this, if you could record the classes and rerun them in the evening, right the same class. So, for example, you know [instructor's name] does a tai chi class in the morning, and then you ran a recording of it at night where people couldn't attend in the morning. I mean it's I know it's a whole technological issue to get that set up and to do it, but you wouldn't have the instructor having to instruct again in the evening, you could replay a class." [P006]
Timing considerations for the program introduction	• "Having the program being offered to patients in conjunction with we start treatment and have someone help us come up with a training and exercises plan from the beginning would help to be active." [P008] • "Why can't the doctors mention it to the patients when they do like the five week follow up from their surgery and say, 'Oh, we have an Integrative program. I think it would be good for you to have exercise in your healing process to recover better.' And maybe you have to like kind of coordinate it with the doctors." [P009]

Theme 1. IM@Home Alleviated Symptom Burden and Supported Symptom Self-Management

Participants reported that the IM@Home program was valuable for managing cancer-related symptoms during treatment, offering physical, mental, and social benefits.

Reduced Treatment-Related Symptom Burden

Participants highlighted significant improvements in physical and mental health, including reductions in cancer treatment-related symptoms, particularly radiation-related fatigue, overall stress, and anxiety. Fatigue reduction led to increased muscle strength, flexibility, and mobility, while decreased stress and anxiety enhanced their motivation to stay active.

> *It really helped. I feel like my muscles are stronger, my walking is a lot easier, and I'm not as tired as I used to be.* [P006]

> *What I noticed was with the radiation fatigue, I think about week three, I was like, 'Wow, I'm good.' I've got my normal energy back, like there's no more fatigue. That was probably the biggest benefit, just like flipping a switch, 'I'm good!'* [P015]

These improvements collectively increased their ability and willingness to continue classes and carry out daily activities and further contributed to the reduction of comorbid symptoms such as insomnia. Yoga and fitness classes were frequently mentioned for fatigue management and meditation classes for reducing stress.

Enhanced Symptom Self-Management and Sense of Control

Many participants described the challenges they faced during treatment, particularly after leaving the hospital. This was when treatment-related symptoms emerged, requiring them to manage these difficulties on their own, often leading to a sense of lost control. In this context, participants noted that IM@Home provided valuable, accessible, and easy coping skills, such as breathing techniques, to help them navigate symptoms or manage difficult moments at home. Additionally, completing classes provided participants with a sense of control, giving them the courage and confidence to continue their ongoing treatments.

> *With all the stress of the diagnosis and treatment that's one [breathing and relaxation] that I realized is a good thing for the stress release […] there were days when things were happening to me, and my ability to just lay there and count my breaths or breathe through things was really a great thing.* [P015]

The anticipation of classes also provided mental relief, with one participant noting, "Having something to look forward to helped so much mentally" (P016). Another participant highlighted the program's impact on self-commitment and achievement.

> *At the conclusion of each class, there is a feeling of accomplishment. I did something for me, I kept a commitment to myself. I showed up and got through the whole thing. I feel good about doing it.* [P012]

Theme 2. IM@Home Facilitated Social Support and Information Exchange

The program fostered a sense of community, helping participants feel less isolated. As one participant noted, "There is a feeling that you're doing this together" (P012). Another described class interactions as feeling like "a friend came into their home" (P005).

Participants valued the emotional support of being seen and not feeling alone.

> *You see the other people that are in the class with you, that's comforting not to be alone, because a lot of us are alone.* [P013]

Receiving support and encouragement from peers and instructors contributed to a more positive experience during the treatment process.

> *It's comforting seeing the instructor and hearing them acknowledge you makes a difference.* [P013]

Participants described how postclass discussions provided opportunities to exchange advice and learn from others' experiences, further enriching the program's social aspect.

> *I learned a lot from the instructor's comments about the effects of radiation on muscles and fascia, which came from an exchange with another class participant […] It was enlightening for me, and it was what I was experiencing.* [P012]

Theme 3. IM@Home Offered a Flexible, Tailored Program in a Group Setting

Participants described their experience with IM@Home as safe, patient-centered, and flexible. They noted differences compared to other general fitness classes they had attended, expressing that IM@Home felt safe and comfortable. The activities were tailored to fitness levels and the unique physical and mental needs of cancer patients, including those with metastatic disease and a high symptom burden.

With good tolerance and noticeable benefits, they continued engaging with IM@Home and used it as a valuable tool for maintaining their quality of life. As one participant explained,

> *Exercise and [being active] can keep things from reoccurring, maximize your lifestyle and functionality, and help you regain skills you've lost. When you're living with an illness, dealing with something chronically, you need as many tools as you can to alleviate pain and symptoms and to continue to live as fully as you can, even though you're still sick.* [P010]

Participants also noted the key contributions of instructors specialized in oncology care.

> *The instructors were really top-notch, and they were specifically tailoring the exercises and the activity levels.* [P010]

Additionally, even in a group setting, patients felt that the program was individualized to their preferences, schedules, and daily routines. IM@Home offered a variety of classes, including

XSL•FO
RenderX

yoga, meditation, and fitness, empowering participants to choose activities aligned with their preferences and physical needs. Its flexibility allowed them to continue participating in the face of such challenges as scheduling conflicts with treatment appointments, changes in symptoms or needs, or concerns about monotony.

> *I thought it was great that it would be in my own home, and with little to no equipment. All those things they thought were fantastic because when you have ongoing illness you there are things like side effects, where you might have to run to a bathroom and to physically be in a class it would make all those things difficult, whereas here you had some latitude as to when you could attend or leave the class or come back to the class, and so I thought I was primed for success at it.* [P010]

Theme 4. IM@Home Facilitated Accessible, Affordable, and Ongoing Support

Participants appreciated the program's digital format for increasing accessibility in several ways: (1) compared to in-person classes, the digital format was more cost-effective, which was important given the financial burden of cancer treatments; (2) the digital format eliminated the need for travel, reducing barriers for those with mobility limitations; and (3) it minimized infection risks for patients who could not safely attend in-person sessions, particularly those who were immunocompromised. They emphasized that the digital format allowed not only the general cancer population but also those facing significant barriers to in-person attendance to receive support and stay active.

> *I don't have to go anywhere, I don't have to travel, I turn on my computer.* [P003]

> *While you're going through this process and can't get out and do some of the things you used to, or that you thought about doing […] This is a productive and psychologically healthy way to spend some of that extra time. It feels good to do it.* [P011]

Additionally, participants emphasized the importance of having resources to maintain healthy behaviors despite treatment side effects and even after completing cancer treatments. They appreciated the online program provided ongoing access, allowing patients to engage whenever needed and supporting their commitment to long-term wellness.

> *Knowing there is an interface out there I can go to any time, if I want to do some meditation or some light exercises like chair yoga, it really helps that there is something out there I can lean on.* [P016]

> *I was not exercising at all. I was becoming very lethargic. Having this program helped me on a daily basis. I signed up, I keep signing up for more and more classes, and it keeps me starting my day with exercise and it made me feel better.* [P003]

Theme 5. Recommendations for Program Enhancement

Participants provided several suggestions for optimizing the program. Some suggested offering more detailed guidance alongside the classes to help them understand complex movements or better prepare for class participation.

> *It's so hard to figure out exactly how to do [movement]. It was very confusing in terms of doing it online.* [P016]

They also recommended incorporating additional delivery methods, besides live online classes, to benefit patients without reliable internet access or devices. Furthermore, participants proposed introducing the program earlier in the cancer care journey, such as during consultation, to maximize its benefits.

> *Could there be a consultation where, after meeting your surgeon, you also meet your oncologist and learn about programs like IM@Home to help you along the road?* [P017]

Discussion

Overview

This qualitative study explored the experiences of patients undergoing active cancer treatment who participated in a 12-week cancer-specific digital exercise and mind-body program, IM@Home. Participants described a broad range of benefits, including improved symptom management and enhanced social support, and reflected on the program's novel, patient-centered, group-based online delivery. They also identified opportunities for improvement, such as adding real-time feedback, peer mentorship, and recorded sessions to complement live classes. Taken together, the findings suggest a preliminary program model in which digitally delivered, flexible integrative medicine programming promotes symptom relief and peer connection, mechanisms that supported patients during treatment. These mechanisms appear shaped by contextual factors (eg, treatment-related fatigue, mobility limitations, and scheduling barriers) and can inform refinements to optimize delivery. Overall, these findings provide timely insights into how live, structured, digitally delivered integrative care can address supportive care needs during active treatment and reinforce prior evidence on the value of synchronous, patient-centered digital interventions in oncology.

Principal Findings

Exercise and mind-body therapies are well-documented for managing cancer-related symptoms [7,40,49-53] and for improving quality of life during treatment [40,54-60]. Our interviews' findings on symptom management (ie, reduced fatigue and mental stress) align with previous trials and are consistent with results from our randomized clinical trial [40]. This suggests these symptoms may be primary targets for online exercise and mind-body therapies in cancer care. Additionally, our findings indicate that symptom relief came not only from the interventions but also from patients' own continued efforts, as they learned self-coping strategies and received encouragement and support from other participants. Existing literature underscores the importance of self-coping in symptom management and healing [61-63], highlighting its role not only in managing symptoms during treatment but also in supporting long-term survivorship.

XSL•FO
RenderX

Our study provides valuable insights into the design and delivery of digital interventions. The increasing popularity of digital health reflects its ability to overcome traditional barriers to care such as accessibility and scheduling [64]. Remote delivery of clinical or supportive care via telecommunications (ie, telehealth) is particularly beneficial for immunocompromised patients, offering privacy and reduced infection risks [65]. However, many digital programs face implementation challenges in cancer care, such as balancing intervention effects with patients' tolerance, delivering the program in a group setting while maintaining patient-centered care, and engaging patients in routine participation without adding to their burden [19,50,66,67]. Participants indicated that IM@Home successfully addressed these challenges by integrating multiple evidence-based therapies tailored to patients with cancer, accommodating different exertion levels to ensure safety and align with patient tolerance, and allowing flexible access to various treatment modalities. This flexibility enabled participants to select activities based on preferences, symptoms, and schedules, while maintaining regular engagement. These features enhanced safety, improved adherence, and expanded access, ultimately increasing the effectiveness of the interventions.

A distinctive feature of IM@Home was its live, group-based delivery format, which fostered community, reduced feelings of isolation, and created a safe, supportive environment, crucial for maintaining quality of life and coping during cancer treatment [68,69]. Participants emphasized the unique value of real-time interaction with instructors and peers, describing the experience as supportive and empowering. This structure stands in contrast to many digital interventions that rely on asynchronous content and may lack opportunities for interpersonal connection or individualized guidance. Social support was repeatedly cited as a motivating factor, as participants found validation in shared experiences and encouragement from others. These relational aspects, often overlooked in digital health design, are critical for sustained engagement and psychological support during cancer care [70]. This finding aligns with broader calls for a "patient revolution" in the health care system, emphasizing the need to empower patients to take a more active role in their care [71]. A key component of this shift is enabling patients to seek advice and support from others who have faced similar challenges. Based on patient feedback, they received empathy, insight, and practical strategies from both peers and instructors, fostering a greater sense of control and satisfaction with care and alleviating pressure on the health care system.

Our findings underscore the need to integrate digital exercise and mind-body programs like IM@Home into standard oncology care. Early incorporation into treatment planning, perhaps during initial consultations, could maximize benefits by establishing wellness routines before treatment-related symptoms worsen. Participants also highlighted the need for additional guidance or on-demand resources to complement online classes. Potential solutions, such as enhancing real-time feedback, incorporating peer mentorship, and providing recorded sessions, should be considered in future program development. Additionally, multicenter trials are needed to assess program effectiveness across diverse populations, alongside cost-effectiveness and scalability. Furthermore, improving patient education and clinician-patient communication about the benefits of digital interventions could promote adoption and adherence. By addressing current gaps, digital exercise and mind-body programs like IM@Home can be optimized to meet the complex needs of patients with cancer and expand access to effective, comprehensive care. These insights offer actionable strategies for future program refinement and broader clinical integration.

From an implementation perspective, IM@Home demonstrates a scalable model for integrating digital exercise and mind-body therapies into routine oncology care. By reducing barriers related to cost, travel, and immunocompromise, the program has the potential to increase access and address equity gaps in supportive care. Embedding such interventions early in the cancer care trajectory—and ensuring they are adaptable to individual needs—may help improve adherence and patient-centered outcomes and promote more equitable access to evidence-based supportive care. Future adaptations might include multilingual content, device-lending strategies, or hybrid models to serve patients with limited digital access.

Limitations and Future Directions

This study has several limitations. First, the small, predominantly female and White sample limits the transferability of findings. While we used maximum variation sampling to capture a range of experiences across cancer types and study time points, the demographic homogeneity may have influenced the range of perspectives reported. Future research should aim to recruit more diverse participants to enhance the transferability of findings. Second, we did not include participants who dropped out or conduct interviews at earlier time points. Including these participants could have provided additional insights into barriers and facilitators of engagement. Third, although formal member checking—returning preliminary themes to participants to assess whether the interpretations resonate with their experiences—was not conducted, casual interactions with participants supported the credibility of the findings. Finally, future studies should also explore long-term outcomes and implementation strategies (eg, integration into routine clinical workflows and program scalability) to advance equitable integration of digital integrative care into cancer treatment pathways.

Conclusions

IM@Home represents a novel, patient-centered, and scalable model for digital integrative care. Participants viewed the program as supportive, empowering, and effective in managing treatment-related symptoms. These findings lay the foundation for refining and scaling IM@Home to benefit diverse cancer populations and inform the development of future digital health interventions.

Abstract

Background: Hyperthermic intraperitoneal chemotherapy (HIPEC) has been integrated into the management of gastric cancer (GC) as a combined approach for addressing peritoneal metastasis, serving both prophylactic and therapeutic roles following GC surgery. The pivotal decision regarding HIPEC administration typically arises intraoperatively, creating a complex clinical scenario where family caregivers must act as surrogate decision-makers under substantial time constraints. This decision-making process proves particularly challenging due to limited understanding of the procedure's risk-benefit profile and long-term outcomes among nonmedical surrogates, challenges often exacerbated by the acute stress of the surgical environment.

Objective: This qualitative study aims to explore how family caregivers of patients with GC navigate the HIPEC decision-making process, specifically examining the facilitators, challenges, and the role of information acquisition that shape the shared decision-making mode.

Methods: This study adopted a qualitative approach using semistructured interviews; 15 family caregivers of patients with GC in a major tertiary hospital in Guangxi Province were selected as research objects through a purposive sampling method. Participants were asked to comment on their experience of surrogate decision-making for the HIPEC process. The Colaizzi 7-step method was used to analyze and summarize the themes.

Results: The mean age of the 15 participants was 39.8 (SD 13.29, range 20-68) years, and all patients were on average aged 56.7 (SD 10.78, range 36-74) years. The relationship to the patient was distributed as follows: 33% (5/15) spouses, 60% (9/15) children, and 6% (1/15) other relatives. Four major themes emerged from the data analysis: (1) shared decision-making participation mode (doctor-led passive decision-making and doctor-family shared decision-making); (2) decision-information sources (decision-making information came from medical-care personnel, decision-making information came from the internet, and decision-making information came from acquaintances); (3) challenges in the decision-making process (financial burden and anticipated therapeutic efficacy); and (4) facilitator in the decision-making process (positive health beliefs and cultural dimensions of perceived responsibility: a Confucian perspective).

Conclusions: HIPEC decision-making by family caregivers of patients with GC was primarily passive decision-making, and many obstacles and facilitators were encountered in the process. Medical staff should share information and encourage and guide family caregivers to participate in the decision-making process through decision assistance or decision support.

Introduction

Gastric cancer (GC) is 1 of the 5 most common malignant tumors in the world [1], and the cumulative risk of peritoneal metastasis (PM) is nearly 30%. It is the most common form of GC metastasis [2,3]. Systemic chemotherapy drugs have difficulty penetrating the peritoneal barrier; PM treatment is difficult, and the disease progresses rapidly. Once PM occurs, the mortality of patients is very high, which has become the main cause of death in the literature.

Developments have been made in the field of peritoneal tumors over the last decade, and hyperthermic intraperitoneal chemotherapy (HIPEC) is an emerging treatment technique. It heats an infusion-containing chemotherapy drug to the therapeutic temperature and is reinjected into the patient's abdominal cavity for a certain period of time. The main principle of HIPEC is hyperthermia, chemotherapy, and mechanical scour, which can break through the plasma-peritoneal barrier, remove the residual tissue, and free cancer cells after surgery [4,5]. HIPEC prevents PM based on radical gastrectomy and can also be combined with cytoreductive surgery to treat selected patients with resectable primary or secondary peritoneal malignancy [6,7]. The median survival of patients with advanced GC can reach 18.1 months after HIPEC [8]. However, there is some controversy about the safety and effectiveness of HIPEC. A meta-analysis reported that HIPEC failed to improve the 1-3 year overall survival and gastrointestinal complication rates, but improved long-term overall survival [9]. From the perspective of health literacy popularization, a small percentage of the public has heard of or understood HIPEC, which is a complex operation [10]. Treatment decisions in HIPEC are individualized and require patient and physician involvement. Therefore, the difficulty for patients is to question whether the disease can be successfully treated, as HIPEC is unknown. These concerns and questions can run from decision-making to treatment.

Surrogate decision-makers are more common in intensive care units, ignoring the fact that patients with cancer may also need family caregivers to make surrogate decisions [11,12]. Family caregivers often participate in decision-making, and even become the main decision-maker, when some patients with GC may have adverse psychological conditions, physical discomfort resulting in reduced decision-making ability, or surgeons need to put forward HIPEC-related treatment recommendations according to intraoperative conditions. Although the safety of HIPEC has been proven, it is associated with higher mortality, lower overall treatment morbidity, and reduced quality of life in the short term [13]. People sometimes make different medical decisions for others than they would make for themselves [14]. Family caregivers are usually concerned that surrogate decision-making will influence the patient's prognosis and lack of HIPEC experience, thus they may fall into decision-making difficulties and conflicts, resulting in possible psychological pressures such as regret, anxiety, contradiction, and unease [11]. Negative emotions will again affect the implementation of decision-making and reduce the satisfaction of patients and caregivers with medical treatment, forming a vicious circle [15].

Previous studies have been conducted to explore the surrogate decision-making process from diagnosis to treatment in patients' relatives with digestive tract tumors because their lack of understanding of treatment information leads to passive decision-making [16]. HIPEC is a special treatment for gastrointestinal tumors, and most studies focus on prognosis and adverse reactions [13]. Conversely, relatively few studies have focused on the surrogate decision-making experience of HIPEC, which may be due to the underrepresentation of families of patients with GC in HIPEC clinical trials. Different surrogate decision-makers have different views on health, disease, and participation mode of treatment, which are important for whether patients can obtain better treatment plans in time [12].

This study aims to identify the decision-making participation mode of surrogate decision-makers for patients with GC considering HIPEC, particularly their stance on the spectrum of paternalistic, physician-led decision-making and collaborative, shared decision-making, while elucidating the multilevel challenges and facilitators underlying this process. Our results can serve as a reference for formulating targeted decision-support strategies and guiding doctor-patient communication, thereby improving HIPEC decision-making efficiency, safeguarding patients' physical and mental health, and enhancing patient satisfaction with medical treatment.

Methods

Design

An exploratory qualitative study involved semistructured interviews with family caregivers of patients with GC treated with HIPEC who acted as the primary decision-makers. From January to April 2024, family caregivers of patients with GC undergoing abdominal HIPEC after gastrointestinal gland surgery in a major tertiary hospital in Guangxi were selected as the research subjects. We used face-to-face interviews to understand the real experience of family caregivers' HIPEC decision-making process. This study followed the comprehensive criteria for the reporting of qualitative research guidelines (Multimedia Appendix 1) [17].

Study Setting

This study was conducted in the Gastrointestinal Surgery Department of the First Affiliated Hospital of Guangxi Medical University, a national key clinical construction specialty, a key medical and health discipline of Guangxi, and the chief unit of the Guangxi Gastric Cancer Alliance, focusing on the diagnosis and treatment of GC. Through the combination of multiple disciplines, the department carries out accelerated rehabilitation surgery for GC and promotes the rapid rehabilitation of patients with GC. The related technology of accelerated rehabilitation surgery is in a leading position in the country. Doctors evaluate the need for HIPEC before or during surgery, and the patient or family decides whether to proceed with HIPEC after surgery. All patients underwent HIPEC within 48 h after closing the abdominal cavity. The perfused temperature was 43 °C, and each operation time was 60-90 minutes.

Research Team and Interviewer Characteristics

This study's team comprised 6 health care providers, namely, 3 postgraduate students (ZKKT, DNL, and XC), 2 specialists in gastrointestinal surgery nursing (KJ and WZT), and 1 expert in the field of oncology nursing (LY). All interviews were conducted by 2 primary researchers (ZKKT and DNL), both are female and holding MSc Nursing degrees, with over 3 years of dedicated research and academic training in oncology. Before data collection, the interviewers completed formal training in qualitative methodology, including specialized instruction in interview techniques, probing strategies, and ethical considerations. To minimize potential bias, neither researcher had established clinical relationships with any of the participants' families. This absence of prior therapeutic engagement was explicitly disclosed to all participants at the commencement of each interview session [17]. This study was supervised by KJ, a professor of nursing with extensive research experience in gastrointestinal oncology. The project was led by author LY, Director of Nursing at a major tertiary hospital in Southern China.

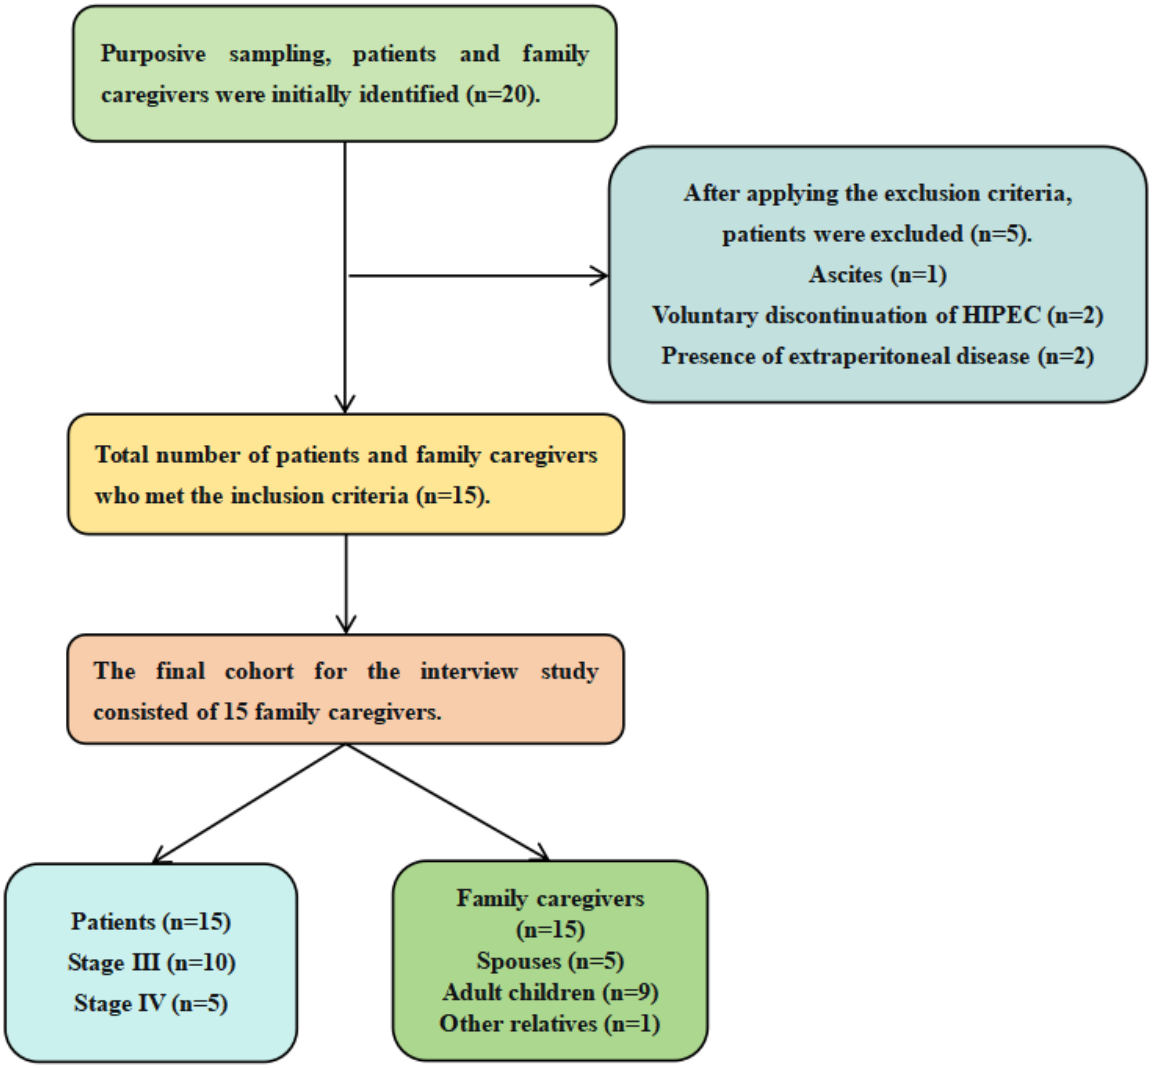
Recruitment and Sample

The purposive sampling method was used to recruit the participants. Participants were surrogates of adult patients with GC. We approached surrogates of nondecisional patients who required or were expected to require HIPEC after surgery. To be eligible to participate, surrogates needed to be at least 18 years of age, be fluent in the Chinese language, have clear awareness with sufficient communication skills, and self-identify as a primary decision-maker for the patient. Exclusion criteria included extraperitoneal disease, ascites >500 mL, physiologic inability to undergo HIPEC [5], surrogates of patients with recurrent disease, or those who were not involved in the treatment decision. This approach ensured that all participants had direct experience with the phenomenon of interest. Potential eligible surrogates were screened through electronic health records. After the patient completed the HIPEC treatment, the primary nurses of the patients in charge invited the respondent and confirmed eligibility. Participants were informed that their participation was entirely voluntary and that they could opt out at any time. All participant records were kept confidential.

Sample size was based on data saturation, and the calculation and evaluation methods included 3 elements, namely, base size, run length, and new information threshold [18]. Recruitment was stopped when the 2 researchers considered that the content was saturated and without new aspects emerging. Base size as denominator, the run length was the number of interviews within which we looked for and calculated new information. The new information threshold represents the proportion of new information. We will prospectively calculate saturation using a base size of 4 interviews and a run length of 2 interviews. We have selected a new information threshold of ≤5% to indicate that we have reached adequate saturation.

Data Collection

Interviews were conducted in a quiet hospital room, a doctor's office, or a classroom. The interviewers first introduced the purpose, significance, and content of the interview to the interviewees and obtained their consent. Before the interview, interviewees were required to fill in a self-made questionnaire, which included demographic variables (age, gender, education level, occupation, relationship between family caregivers, and patients) of patients and their families, as well as disease-related information (HIPEC protocol and tumor stage) of patients.



They conducted a one-to-one semistructured interview with the interviewees according to the final guide of the interview (Textbox 1), which was developed and tested in 2 preinterviews whose interview data were not included in the data analysis. During the process, they paid attention to observe and record the changes in the nonverbal communication of the interviewees. They were encouraged to express their real thoughts and ask questions. All interviews were audio recorded, transcribed verbatim, and compared with digital audio recordings to ensure the accuracy of the content [17]. Unclear or doubtful contents expressed by the interviewees were confirmed through retelling, questioning, and other ways. Induction, intervention, or judgment was prohibited. The interview duration was limited to approximately 30 minutes per participant. A recruitment diagram appears in Figure 1.

Textbox 1. Qualitative interview guide.

- I'd like to start by asking how did you decide to receive hyperthermic intraperitoneal chemotherapy (HIPEC) on behalf of the patient.
- Can you recall the process of treatment decision?
- What do you know about HIPEC?
- What made you decide to receive HIPEC?
- What concerns did you have during the decision-making process?
- Is there anything you'd like to know or want the medical staff to help you with?

Figure 1. Study enrollment diagram. HIPEC: hyperthermic intraperitoneal chemotherapy.

Data Analysis

The audio recordings from each interview were transcribed verbatim. Within 24 h after the interview, 2 researchers (ZKKT and DNL) independently organized the interview data, transcribed it into text, coded transcripts, and analyzed the data with the Colaizzi 7-step analysis method [19]: The interview data were read repeatedly to deeply understand the content information; code recurring, meaningful statements; form a categorized coded view; write a detailed description; have sublimation view as the theme; and then to return the written text to the interviewee for verification. The 2 researchers were fully immersed in the interview content, independently reading and coding in detail. It was summarized after completion, and if any objection was raised, they were discussed and determined within the team (ZKKT, DNL, XC, and WZT). During this process, the research team adopted triangulation, randomly selected 20% transcripts and codes, and then submitted them to the noninterviewers for reviewing and improving the codes [20]. Then, regular meetings were held within the team to generate initial themes (ZKKT, DNL, XC, and WZT).

Ethical Considerations

This study was approved by the Ethics Committee of the First Affiliated Hospital of Guangxi Medical University (2024-E055-01). Before the interview, the interviewer introduced the purpose, significance, and content of the research to the subjects. All data were used only for research purposes. All participants signed informed consent forms after expressing their willingness to participate. During the interview, participants were free to interrupt the experiment if they chose to do so. Immediately following data collection, the interviewer engaged all participants in a standardized debriefing process to disclose the sham trial. Participants were not provided compensation for participation. All personal identifiers of the participants were removed before analysis to ensure privacy. This study strictly adheres to Beauchamp and Childress's Four Principles of Biomedical Ethics [21] to establish the theoretical framework for our ethical approach, recognizing that decision-making during a patient's surgical procedure inherently precludes the preservation of their decision-making capacity.

Results

Patient and Surrogate Decision-Maker Characteristics

The analysis sample for data saturation included 15 patients and their surrogate decision-makers. All participants were on average 39.8 (SD 13.29, range 20-68) years of age at the time of interview. The majority were male (11/15, 73%), and 27% (4/15) were female. The relationship to the patient was distributed as follows: 33% (5/15) spouses, 60% (9/15) children, and 6% (1/15) other relatives. All patients were on average 56.7 (SD 10.78, range 36-74) years of age at the time of interview. The demographic and clinical characteristics of these participants and patients are presented in Table 1.

Table 1. Characteristics of participants.

Number	Surrogate decision-maker					Patient					
	Gender	Age (years)	Education	Occupation	Relationship with patients	Gender	Age (years)	Medical insurance	HIPEC[a], n	Stage	Chemotherapeutics drugs
1	Male	43	Middle school	Farmer	Husband	Female	46	Medical insurance for residents	3	III[b]	Lobaplatin
2	Female	36	Junior college	Office clerk	Wife	Male	36	Medical insurance for residents	3	III	Docetaxel
3	Male	20	College	Student	Son	Male	53	No medical insurance	5	IV[c]	Lobaplatin
4	Male	55	Middle school	Farmer	Husband	Female	51	Medical insurance for residents	3	III	Oxaliplatin
5	Male	45	Master	Construction industry manager	Son	Female	67	Medical insurance for residents	3	IV	Lobaplatin
6	Male	32	College	Office clerk	Son	Male	60	Medical insurance for residents	3	IV	Docetaxel
7	Male	33	College	Civil servant	Son	Male	60	Medical insurance for residents	2	III	Oxaliplatin
8	Female	45	Primary school	Farmer	Wife	Male	47	Medical insurance for residents	3	IV	Docetaxel
9	Male	26	Junior college	Office clerk	Son	Male	54	Medical insurance for residents	1	III	Docetaxel
10	Female	49	College	Civil servant	Daughter	Male	74	Medical insurance for urban employees	3	III	Docetaxel
11	Male	51	High school	Worker	Son	Male	73	Medical insurance for residents	3	III	Docetaxel
12	Male	45	Junior college	Individual	Full brother	Male	51	Medical insurance for residents	3	III	Lobaplatin
13	Male	26	High school	Farmer	Son	Male	58	Medical insurance for residents	1	IV	Oxaliplatin
14	Female	24	Junior college	Individual	Daughter	Male	51	Medical insurance for residents	3	III	Oxaliplatin
15	Male	68	Junior college	Retiree	Husband	Female	70	Medical insurance for urban employees	1	III	Docetaxel

[a]HIPEC: hyperthermic intraperitoneal chemotherapy.

[b]III: stage III gastric cancer is categorized as locally advanced disease. In this stage, the primary tumor has invaded deeply through the gastric wall (potentially involving the serosa) and has extensively metastasized to the regional lymph nodes.

[c]IV: stage IV represents the most advanced phase of gastric cancer. It is defined by the presence of distant metastasis (M1), regardless of the extent of the primary tumor (Any T) or the involvement of regional lymph nodes (Any N).

Topic

The researchers identified four themes through their analysis: (1) shared decision-making participation mode, (2) decision-information sources, (3) challenges in the decision-making process, and (4) facilitators in the decision-making process. The themes and subthemes derived from the analysis are shown in Table 2.

XSL•FO
RenderX

Table 2. Themes and subthemes.

Themes	Subthemes
1. Shared decision-making participation mode	• Doctor-led passive decision-making • Doctor-family sharing decision-making
1. Decision-information sources	• Decision-making information comes from the medical-care personnel • Decision-making information comes from the internet • Decision-making information comes from acquaintances
1. Challenges in the decision-making process	• The financial burden • Anticipated therapeutic efficacy
1. Facilitator in the decision-making process	• Positive health beliefs • Cultural dimensions of perceived responsibility: a Confucian perspective

Theme 1: Shared Decision-Making Participation Mode

Overview

The way of shared decision-making was primarily based on the level of information mastery and education of decision-makers.

Doctor-Led Passive Decision-Making

Nine surrogate decision-makers expressed a preference for physician-dominated decision-making, indicating that their role was primarily to adhere to the physician's recommended treatment course.

The adoption of this decision-making approach demonstrates a significant correlation with educational attainment. Surrogates with limited formal education exhibited a substantial knowledge gap regarding HIPEC compared to clinical professionals, while simultaneously expressing stronger deference to hierarchical medical authority.

> *All of us live in rural areas. I, my wife, my younger brother and my younger sister all have only a middle school education. They seldom go to the hospital for medical treatment. I had never heard of HIPEC and had to rely on the doctor to make the decision. I'm at a loss right now.* [Number 4, aged 55 years, farmer, husband of patient]
>
> *I never considered challenging the doctor's decision. Since the treatment method they proposed was effective, I followed the expert's advice. After all, he was respected authorities whose opinions are widely accepted.* [Number 13, aged 26 years, farmer, son of patient]

From a cognitive perspective, many surrogates reported experiencing significant feelings of inadequacy and information overload. When participants acquired information but demonstrated either an unwillingness to engage in multisource verification or an inability to synthesize information from disparate channels, they consistently reverted to physician-dependent decision-making as a default strategy.

> *Several doctors came and told me a lot of information. I managed to understand a little bit, but it was too complicated. Without knowledge of HIPEC, the patient was lying on the bed, unable to move, unable to make decisions. We do what the doctor recommends completely at this time.* [Number 11, aged 50 years, worker, son of patient]
>
> *Although the doctor is obligated to inform us of this information, I don't think I can fully understand it. I don't worry about whether I can understand it or not. All I need to know is that the doctor's decision is correct, and I just need to follow his decision.* [Number 1, aged 43 years, farmer, husband of patient]

Doctor-Family Shared Decision-Making

Six surrogate decision-makers combined information obtained from various sources. Family caregivers who engaged in doctor-family shared decision-making typically possessed higher educational attainment, demonstrating not only comprehension of complex HIPEC information but also the capacity to critically evaluate disparate information sources, including both physician-provided guidance and internet-acquired content.

> *At the beginning, after being informed of HIPEC by the clinical doctor, first checked the Internet, but also asked acquaintances, to understand the thermal perfusion technology can prevent metastasis, avoid risk effect, we decided to carry out HIPEC.* [Number 5, aged 45 years, construction-industry manager, son of patient]
>
> *On the premise of knowing a lot about the principle, knowledge and effect of thermoperfusion, I took the initiative to choose the best hospital recognized for surgery and HIPEC.* [Number 6, aged 32 years, office clerk, son of patient]

These surrogate decision-makers did not passively await information but rather demonstrated a proactive communication stance, exemplified by actively seeking clarifications during consultations and engaging in iterative questioning with physicians. They perceived clinicians as collaborative partners in problem-solving rather than unidirectional authorities.

> *After consulting with acquaintances, I repeatedly confirmed with the doctor whether changing the treatment plan could cure gastric cancer and also determined whether the quality of life would change in the future.* [Number 5, aged 45 years, construction-industry manager, son of patient]

XSL•FO
RenderX

After I came to this hospital now, I will also ask the doctor to check the information I found online. Even though they urged me, I couldn't make up my mind easily. [Number 6, aged 32 years, office clerk, son of patient]

Theme 2: Decision-Information Sources

Decision-Making Information Came From Medical Care Personnel

All participants indicated that medical personnel were the initial source of information for their HIPEC decision-making. As a new therapeutic modality, HIPEC has a low popularity among the public, with less access, and obtaining relevant information initially in daily life was difficult for patients and their families.

I've never heard of HIPEC, and I don't know how it works. The first time I heard HIPEC, it was introduced by the surgeon. [Number 2, aged 36 years, office clerk, wife of patient]

I usually read disease-related information on social platforms, but rarely mention HIPEC, and only know it from doctors. [Number 10, aged 49 years, civil servant, daughter of patient]

The main source of HIPEC information for 10 (10/15, 66.6%) surrogate decision-makers of patients was medical staff. A total of 6 surrogate decision-makers did not subsequently seek information in other ways, so this became their only access to information. In particular, older decision-makers living in rural areas lack the competence and access to information.

We rural people do not know this, only through the doctor's recommendation, and do not look up other information. [Number 1, aged 43 years, farmer, husband of patient]

Born in a rural area and an elderly person, I rarely use a smartphone, so I only know about it from my doctor. [Number 4, aged 55 years, farmer, husband of patient]

Decision-Making Information Came From the Internet

Some surrogate decision-makers indicated that they actively sought information and confirmation through internet channels, these being by those with higher education or high internet usage. The primary information sought by participants concerned 3 key areas: the mechanism of HIPEC treatment, its efficacy in GC, and potential adverse effects.

After the doctor first told me HIPEC, I searched on the Internet myself to simply understand what therapeutic effect it has on GC. I looked it up through wechat public account and Baidu. [Number 2, aged 36 years, office clerk, wife of patient]

I searched for side effects (of HIPEC) through Baidu. There are other doctors on Baidu, they might give me different advice. [Number 7, aged 33 years, civil servant, son of patient]

Furthermore, the field of HIPEC is highly specialized, and some of the family caregivers of patients have difficulties understanding it.

But I have no knowledge reserve, even if I find relevant information, I cannot understand. [Number 7, aged 33 years, civil servant, son of patient]

Decision-Making Information Came From Acquaintances

In addition to seeking information through the internet, 3 decision-makers consulted expert acquaintances. For unknown professional treatment information, patients' families tended to consult other doctors through trusted relatives and friends. Surrogate decision-makers find it easier to hear the truth from close friends, to obtain better judgment, and ensure information credibility.

I have relatives and friends who are doctors, they asked someone who is an expert in the field of stomach cancer to know if HIPEC can help my mother's condition. [Number 5, aged 45 years, construction-industry manager, son of patient]

I asked the doctor at our local hospital about the effect of HIPEC and whether it was harmful to the patient's health. After all, it was the first time I heard about this treatment, and I was still a little afraid. [Number 6, aged 32 years, office clerk, son of patient]

Theme 3: Challenges in the Decision-Making Process

Financial Burden

An overarching theme from the interviews was that the significant economic pressure associated with postoperative HIPEC presented a major decisional impediment for nearly all participants. This financial strain was frequently cited as a direct barrier to completing the full course of recommended therapy.

As ordinary people, the economic pressure is relatively large, the thermoperfusion drainage tube is completely self-funded with thousands of yuan each time. I hope the society can be helpful in this respect. [Number 11, aged 51 years, worker, son of patient]

The price is very expensive and the medical insurance is not reimbursed, our average family salary is not high. what if the treatment results are not proportional to our efforts? [Number 9, aged 26 years, office clerk, son of patient]

Anticipated Therapeutic Efficacy

First, a notable uncertainty was noted among some participants concerning the expected benefits of HIPEC, particularly pertaining to the therapeutic protocol and its effectiveness in preventing metastasis and recurrence. This ambiguity was rooted in their nonprofessional background, which consequently hindered their comprehension of the proposed HIPEC regimen and led to profound decisional uncertainty.

The doctor and I have discussed whether to do it three times or four times before, but we still don't know what effect the number of times has on the efficacy, and we are not sure whether the patient can complete the radical cure or prevent metastasis after completing HIPEC, This makes me quite unsure

XSL•FO
RenderX

whether I really need it. [Number 2, aged 36 years, office clerk, wife of patient]

I mainly want to know what effect can be achieved by doing three times, although the doctor always said that the effect is not guaranteed, I hope you can take the initiative to give us a clear answer. [Number 5, aged 45 years, construction-industry manager, son of patient]

Second, some participants, after an in-depth understanding of HIPEC, were concerned that the new technology in chemotherapy had unknown risks of damaging health or aggravating conditions.

HIPEC is also a form of chemotherapy that kills cancer cells and seems to kill healthy cells, raising concerns that patients may suffer weakened immunity and other after-effects. [Number 2, aged 36 years, office clerk, wife of patient]

I'm still worried about any adverse reactions or accidents with this new technology. [Number 10, aged 49 years, civil servant, daughter of patient]

Theme 4: Facilitator in the Decision-Making Process

Positive Health Beliefs

The participants showed a desire to assist patients in their recovery and were the most important facilitators in decision-making. Such participants indicated that they would be more willing to consent to HIPEC, particularly for patients with GC at high risk of PM. They perceived the procedure as offering a promising therapeutic approach, citing its potential to prevent and treat metastatic dissemination, improve survival outcomes, and maintain a few side effects profile. Surrogate decision-makers considered that health was more important than wealth.

I know that the patient is not in good condition now. As long as the curative effect is good, the treatment should be treated, do not think about the problem of money, health is the most important. [Number 14, aged 24 years, individual, daughter of patient]

Health is the most important thing. I understand that HIPEC as early as possible after surgery can more thoroughly identify cancer cells, and then prolong life. As long as there is a effective treatment, we must actively coordinate. [Number 6, aged 32 years, office clerk, son of patient]

Cultural Dimensions of Perceived Responsibility: Confucian Perspective

A total of 60% (9/15) of surrogate decision-makers were children of patients who had the Chinese Confucian cultural values that maintained the integrity of the family and honored their parents. Having a parent with cancer triggered feelings of guilt, and participants felt it was their responsibility to help patients choose the best treatment. They were concerned that making the decision to forgo HIPEC would lead to adverse health outcomes for their parent.

My dad's situation of cancer was bad, but my parents have worked so hard for us since childhood, and as long as there is any hope, I want to try. [Number 10, aged 49 years, civil servant, daughter of patient]

My father knew that the cost of HIPEC was very expensive in a huff, and he wanted to give up the treatment. But he had worked hard all his life, and I, as a son, certainly would not give up the treatment easily. Now we comfort him every day and advise him to actively cooperate. [Number 9, aged 26 years, office clerk, son of patient]

Discussion

Principal Findings

In this qualitative study, 15 family caregivers of patients with GC as surrogate decision-makers were preliminarily studied in China. Applying thematic analysis to those that met our study inclusion criteria, we identified 4 themes, including the mode, facilitators, challenges, and decision-information sources of surrogate HIPEC decision-making.

Our findings identified 2 predominant modes of shared decision-making among HIPEC surrogate decision-makers. Those with lower educational attainment demonstrated reduced health literacy and stronger deference to hierarchical medical authority, making them more likely to rely on a health care provider for decision-making. This appears rooted in their limited capacity to comprehend medical concepts, compounded by inherent information asymmetry that predisposes clinical dominance. Lacking the ability and confidence to navigate this entrenched power structure, they often transferred final decision-making authority to clinicians, thereby mitigating the burden of decisional conflict [22]. Additionally, these decision-makers lack the foundational cognitive skills to assess information reliability and weigh risks against benefits—a finding consistent with Robertson et al [23]. This deficit impedes their ability to process highly specialized information. When confronted with unfamiliar and complex decisions, they frequently experience cognitive and informational overload. Such overload precipitates decisional conflict, characterized by internal contradiction and profound uncertainty, ultimately precluding meaningful participation in either independent or shared decision-making.

Surrogate decision-makers who used diverse information sources were more likely to engage in doctor-family shared decision-making, a finding consistent with Bakke et al [24]. From a personal capacity perspective, their cognitive and educational foundations translated into superior health literacy, enabling them to evaluate the credibility of web-based information and synthesize disparate sources into a coherent cognitive framework. This capacity fostered greater autonomy in assessing treatment efficacy and survival rates through independent verification [25]. Notably, during our interviews, these individuals voluntarily demonstrated their understanding of HIPEC specifics. Regarding behavioral strategies, these surrogates proactively managed information flow to ensure comprehensive understanding and approached decision-making as a process requiring their ultimate accountability. When

XSL•FO
RenderX

physicians and patients communicated effectively, they collectively arrived at treatment decisions [26].

The participation of patients and their families in decision-making conformed to the ethical principle of autonomy and should not play a passive decision-making role in this process [27]. Our findings underscore that facilitating effective shared decision-making requires the integrated provision of essential information alongside careful consideration of patient and family values throughout the decision-making continuum. Patient decision AIDS (PDAs) are popular tools in recent years that help patients make the best choices in health care options based on their personal values and goals, based on evidence-based medicine [28]. Online PDA provides treatment options according to the preferences of patients and their families, including related benefits, risks, and diagrams [29]. PDA can realize centralized information and effectively reduce decision-making conflicts in patients with cancer. From the health care team's perspective, we recommend establishing a dedicated HIPEC decision-support team comprising surgeons and specialized oncology nurses to provide structured decision guidance. This team would be responsible for implementing and systematically evaluating surrogate decision-makers' comprehension and use of decision aid materials [30]. Whole-process and dynamic decision-making support was provided to improve the health literacy of patients and their families and thus reduce decision-making difficulties and conflicts.

We found that participants lacked the basic knowledge of HIPEC and the ability to identify and understand information. Consistent with the result of Hart et al [31], surrogate decision-makers spent more time understanding decision information, with less information, they often misinterpret and undermine decisions. We found that participants with low education indicated that they were not interested in researching decision information. Xie et al [32] similarly found that caregivers' desire for information was lower than for decision-making participation. When the family caregivers, as nonprofessionals, were faced with highly specialized information such as HIPEC, they had difficulty understanding it. This inability even destroyed the positive degree of surrogate decision-makers who obtain further information, especially among the less educated [33]. These findings underscore that health care providers must prioritize the dissemination of HIPEC knowledge and enhance health education for patients with GC and their families, as this constitutes a fundamental prerequisite for facilitating informed decision-making. First, implementation should begin by advancing health care providers' understanding of current HIPEC evidence, enabling them to coherently translate and disseminate updated research insights to surrogates during decision-making consultations. Second, a supportive environment should be created. We recommend that health care institutions implement PDAs containing structured educational modules, which should provide an overview of GC natural history for HIPEC, comparative outcomes of treatment options, and so on. As demonstrated by Jayakumar et al [34], PDAs with professional guidance yield superior decision quality compared to merely distributing educational materials passively. With guidance from health care providers, these tools help laypersons establish fundamental disease and treatment knowledge, creating essential cognitive foundations for decision-making. Furthermore, providing educational videos at hospital admission significantly enhances engagement and health literacy among patients and their families, thereby improving both the decision-making experience and overall satisfaction with care [35].

The participants expressed diverse challenges facing HIPEC decisions. Financial burden emerged as the primary and most formidable challenge during the decision-making process. Consistent with the result of Graves et al [36], the lower-income patients and caregivers with HIPEC were associated with higher rates of decision regret. Some participants said that the single-use perfusion catheters required for HIPEC were a substantial out-of-pocket expense. During initial discussions of HIPEC, clinicians informed patients of the treatment costs but did not sufficiently underscore the substantial financial implications. As a result, families proceeded with the procedure only to discover—after 1 or 2 cycles—that the cumulative expenses far exceeded their anticipated financial burden. Consistent with reports from Western health systems [37], it was compounded in China as HIPEC was currently not reimbursable through national health insurance, representing a significant financial burden borne directly by families. Consequently, most treatment costs must be borne directly by families rather than through social insurance mechanisms. This financial burden compromises the ability of surrogate decision-makers to pursue clinically optimal decisions and develop treatment plans aligned with optimal clinical guidelines [38]. Uninsured patients with PM will be less likely to consider HIPEC or adjuvant chemotherapy, resulting in people with low economic and social status still at a disadvantage in terms of health [37]. Hamilton et al [39] proved that although the cost of HIPEC for patients was higher than that of systemic chemotherapy, the quality and the overall cost-effectiveness are better. Therefore, according to China's medical conditions, the medical security system should be improved, and the compensation ratio related to HIPEC should be refined to accurately solve the economic burden of patients with GC.

Moreover, the unpredictability of treatment outcomes significantly contributes to this complex decision-making situation. First, most significantly, while the combination of cytoreductive surgery and HIPEC demonstrates efficacy in both treating and preventing peritoneal metastases in advanced GC, this approach remains controversial and continues to evolve within the oncology community [40]. Based on their concern for the patient, participants were concerned about whether a previously unknown treatment can actually improve the cancer situation and inflict new damage to the patient. A joint multicenter study from the United Kingdom and Australia demonstrated significant variations in post-HIPEC survival outcomes and length of hospital stay across different geographic populations [41]. As highlighted by Marano et al [42], even within high-volume specialized institutions, the application of cytoreductive surgery with HIPEC varies substantially in terms of indication, technical execution, and outcome expectations, underscoring the need for clearer communication strategies with patients and their families. Second, our findings indicate that

XSL•FO
RenderX

participants who engaged with multiple information channels and possessed some prior understanding of HIPEC experienced particularly pronounced uncertainty, often stemming from encountering conflicting or inconsistent information across these sources. Different from the results of Crijns et al [26], higher health literacy and satisfaction with the decision of decision-makers were associated with sufficient information support for them. We analyzed that the possible cause was cancer information overload, which can be defined as feeling overwhelmed by the amount of cancer-related material in the information environment. Shi et al [43] show that cancer information overload is associated with perceived perception of illness and treatment uncertainty can lead to anxiety, depression, and emotional fatigue, and, in turn, impaired decision-making ability [30,44]. Effective clinician-family communication serves as a fundamental prerequisite for mitigating therapeutic uncertainty among decision-makers, aiming to support their psychological well-being and maintain alignment with treatment goals. In this context, physicians should engage in transparent dialogue with surrogate decision-makers, recognizing that artificial intelligence-based decision aids cannot substitute for essential human interaction [45].

Regarding the facilitator underlying the surrogate decision-making process for HIPEC, participants indicated their choices were informed by positive health perceptions as well as socioculturally informed perceived responsibilities. First, a participant believed that the “hope” brought by HIPEC can restore a healthy life status. Consistent with the results of Boegle et al [46], when decision-makers perceive that HIPEC is meeting their needs, evoked hope and trust, it benefits the adherence to their treatment. To be precise, they are decision-makers who may care more about longer survival and relapse in the future [45]. Second, consistent with Nissen et al [47], family functionality support is also conducive to improving the disease pressure of patients with cancer and their families and to reducing the physical and psychological burden on caregivers. Furthermore, within traditional Chinese cultural norms, adult children serving as surrogate decision-makers typically adhere to the Confucian virtue of filial piety. This ethical framework mandates comprehensive care for elderly parents, and such filial behavior has been associated with mitigated caregiver burden among adult children [48,49]. Seeking aggressive treatment modalities is often viewed as an expression of loyalty and familial responsibility. However, as demonstrated by Wu et al [50], children with strong filial values may feel compelled to pursue intensive treatment options even when facing substantial financial costs, which can paradoxically lead to decision-making conflicts and psychological distress. In summary, we recommend implementing family centric support protocols for individuals considering HIPEC, delivered through multidisciplinary shared decision-making teams that integrate specialized psychotherapists and oncology nurses to provide sustained psychosocial support. This structured approach enhances decision-making quality by systematically leveraging family caregivers’ capacity for optimism as a constructive psychological resource [30,44]. Given the significant role of filial piety in surrogate decision-making, health care providers should cultivate a balanced understanding of Confucian cultural values among adult children and proactively identify decision-making conflicts during clinical consultations.

Strengths and Limitations

Strengths and limitations of our study warrant discussion. First, our study focuses on the decision-making process of family caregivers of patients with GC, considering HIPEC, an understudied population (to the best of our knowledge). By adopting a qualitative approach, we delve into their lived experiences, addressing a frequently overlooked dimension of patient-centered care. Second, the systematic methodology used enhances the methodological rigor of the inquiry.

Our study has several limitations that should be considered when interpreting the findings. First, our application of a purposive sampling strategy, recruiting participants from a single health care institution in Southern China, means our findings may not be fully representative of all family caregivers of patients with GC considering HIPEC. Second, our cohort consisted predominantly of male participants, reflecting the sociocultural context in China where male family caregivers often assume the role of primary decision-maker. Yet, the framework of culture could also be a strength: this research is contextualized within the framework of Chinese culture, examining the underlying logic and sensitivities of relevant sociocultural norms for the understanding of decision-making processes. Finally, this study was limited by its exclusive focus on the perspectives of surrogate decision-makers. The findings do not incorporate the views of treating clinicians, the patients themselves, or direct observation of clinical interactions, which represent critical avenues for future research to triangulate and enrich our understanding of the decision-making dynamics.

Future Directions

Regarding future research, we propose several directions. Subsequent studies should aim to disentangle the specific factors involved in both information acquisition and the decision-making process for HIPEC. This includes investigating how individuals receive and process information from various channels and how they navigate psychosocial challenges during decision-making. We further propose large-scale, multicenter studies that use a mixed methods approach engaging multiple stakeholders—including surgeons, oncologists, and patients—to develop an integrated model of HIPEC decision-making. Finally, we recommend that future research intentionally enroll more female surrogate decision-makers to facilitate a gender-based analysis and elucidate its influence on decision-making outcomes.

Conclusions

This qualitative study explored the real experiences of GC patients’ family caregivers in making decisions about surrogate HIPEC treatment, including the participation mode, decision-making information sources, facilitators, and challenges. Our findings suggested that providing necessary and sufficient information support with regard to HIPEC was the key to achieving shared decision-making by surrogate decision-makers and improving the decision-making experience. Our findings highlighted areas that have not been previously addressed. Health care providers must intensify their efforts to

XSL•FO
RenderX

refine the shared decision-making framework for HIPEC and develop culturally sensitive PDA tailored to the sociocultural and health care context. Such instruments are essential to support GC families in achieving optimal surrogate decision-making aligned with patient values and clinical evidence.

Funding

Funding for LY was provided by Guangxi Medical and Health Appropriate Technology Development and Promotion Application Project (S2022069) and the First Affiliated Hospital of Guangxi Medical University (YYZS2020030).

Abstract

Background: Digital health platforms have become increasingly important sources of health information for cancer survivors. Cancer survivors frequently rely on digital resources to obtain information related to diagnosis, treatment, survivorship, and follow-up care. In this study, cancer information burden is defined as the perceived challenges associated with seeking, understanding, and evaluating cancer-related information, including the effort required to obtain information, frustration during information seeking, difficulty understanding information, and concern regarding information quality. As the online health information environment becomes increasingly complex, some survivors may experience difficulty locating, evaluating, and understanding cancer-related information. However, limited nationally representative research has examined how cancer information burden differs across demographic and socioeconomic groups.

Objective: This study examined cancer information burden and associated demographic and socioeconomic factors among US cancer survivors using nationally representative data from the Health Information National Trends Survey (HINTS) 2022 and 2024.

Methods: Data were drawn from pooled cycles of the HINTS conducted in 2022 and 2024. Survey-weighted regression analyses were used to evaluate factors associated with cancer information burden among cancer survivors. Outcomes included the perceived effort required to obtain cancer information, frustration during information seeking, difficulty understanding cancer information, and concerns regarding information quality. Composite measures of cancer information burden were also examined. Models were adjusted for demographic and socioeconomic characteristics, including age, sex, race and ethnicity, educational attainment, household income, geographic region, and survey cycle.

Results: Hispanic cancer survivors reported a significantly greater cancer information burden, including higher levels of perceived effort and frustration associated with obtaining and understanding cancer-related information, compared with non-Hispanic White survivors. Non-Hispanic Asian survivors also demonstrated elevated levels of information burden, although estimates were less precise because of smaller subgroup sample sizes. Postbaccalaureate education was associated with lower frustration during cancer information seeking. Female survivors reported lower levels of difficulty understanding cancer-related information and lower overall information burden than male survivors. Differences between the 2022 and 2024 survey cycles were not statistically significant after adjustment.

Conclusions: Differences in cancer information burden persist among US cancer survivors. Hispanic and non-Hispanic Asian survivors, and individuals with lower educational attainment, may experience greater challenges obtaining and navigating cancer-related information. These findings support the development of accessible, culturally responsive, and health literacy–sensitive cancer communication strategies.

Introduction

Cancer survivors are increasingly turning to online health resources to manage diagnosis, treatment, survivorship, symptoms, and long-term care. Digital health tools like patient portals, educational websites, telehealth services, and search engines have become essential parts of today's cancer information landscape [1-3]. As health care systems expand their digital communication infrastructure, survivors are likely to encounter more complex online information environments. Emerging technologies, including conversational agents and algorithmically supported search tools, represent 1 component of the changing digital information environment [4,5]. However, the present study did not assess awareness, use, or exposure to these technologies.

Cancer survivors may be especially vulnerable to these changes because cancer-related information is often medically complex, emotionally distressing, and hard to interpret. Previous studies have shown that survivors commonly face information overload, frustration, and uncertainty when looking for cancer-related information online [6-11]. In this study, cancer information burden is defined as the perceived difficulty associated with seeking, understanding, and evaluating cancer-related information, including effort, frustration, difficulty understanding, and concern regarding information quality. Differences in digital access, education levels, health literacy, and trust in health information sources can further affect individuals' capacity to take advantage of changing digital health environments [12-14].

Prior studies have documented demographic and socioeconomic differences in cancer information seeking, information-source preferences, patient-centered communication, and digital information use among cancer survivors. Earlier Health Information National Trends Survey (HINTS)–based and population-based studies found that age, race and ethnicity, educational attainment, income, cancer history, and perceived health were associated with information-seeking behaviors and experiences [15-18]. These studies establish that cancer information experiences are not uniform across survivor populations. However, less is known about whether these patterns remain evident in the most recent HINTS cycles and how multiple dimensions of perceived information-seeking burden perform when examined separately and as a validated composite measure. Older, Black, and Latino seniors, and seniors from other minority groups have less access to digital tools, less online experience, and are less confident using web-based health resources, making them less likely to use eHealth or mobile health tools [19-21]. Nonetheless, limited nationally representative research has examined cancer information burden among survivors during the 2022 and 2024 period or identified the population groups most likely to report difficulty obtaining and understanding cancer information. Identifying population groups that report greater difficulty accessing and understanding cancer information may inform the development of more accessible digital communication strategies. It may also provide a baseline for future studies that directly assess how emerging digital technologies affect information access and navigation.

Using pooled HINTS 2022 and 2024 data, this study provides an updated, nationally representative assessment of cancer information-seeking burden among US cancer survivors. The analysis examined 4 related but distinct experiences: effort in obtaining information, frustration during information seeking, difficulty understanding information, and concern regarding information quality. We also evaluated the internal consistency and dimensional structure of a composite burden measure and examined its demographic and socioeconomic correlates. The study was intended to update and extend prior evidence rather than attribute observed patterns to emerging technologies. The primary research question was as follows: which demographic and socioeconomic characteristics are associated with perceived effort, frustration, difficulty understanding, concern regarding information quality, and overall cancer information-seeking burden among US cancer survivors? As a secondary analysis, we asked the following: does the association between age and cancer information-seeking burden differ between HINTS 2022 and HINTS 2024? Age was selected because older and younger cancer survivors may differ in digital access, familiarity with online health information, and experience navigating digital health resources.

This study was informed by the Comprehensive Model of Information Seeking, which proposes that health information-seeking experiences are shaped by antecedent characteristics, including demographic factors, personal experience, salience, and beliefs, as well as characteristics of information channels and sources [22-25]. In the context of cancer survivorship, age, sex, race and ethnicity, educational attainment, household income, geographic context, and prior cancer-related experience may influence how individuals seek, understand, and evaluate information. The present analysis focused on demographic and socioeconomic antecedents available consistently in HINTS 2022 and 2024. Because the dataset did not include all constructs required for a complete test of the framework, including detailed cancer characteristics, digital access, eHealth literacy, prior health care experiences, information-source characteristics, and trust, the framework was used to guide interpretation rather than to test the full model.

Methods

Data Source and Study Population

This study used pooled cross-sectional data from the 2022 and 2024 cycles of the HINTS, a nationally representative survey conducted by the National Cancer Institute that explores health communication behaviors, health information seeking, and digital health engagement among US adults. These were the 2 most recent publicly available nationally representative HINTS datasets at the time of analysis. A standard HINTS survey cycle was not conducted in 2023; therefore, no nationally representative HINTS 2023 dataset was available for inclusion. Cancer survivors were identified using the HINTS question that asked whether a doctor or other health professional had ever told the respondent that they had cancer. Respondents who answered "yes" were classified as cancer survivors. This definition captured a self-reported cancer diagnosis at any time and was not restricted to diagnoses occurring within the previous

XSL•FO
RenderX

year. Respondents who answered "no" were excluded from the cancer-survivor sample. No additional cancer-specific eligibility criteria were applied based on cancer type, stage, treatment status, recurrence, or time since diagnosis. Pooling the 2 survey cycles yielded 1972 cancer survivors. For outcome-specific descriptive analyses, respondents were required to have a valid response to the corresponding cancer information burden item. The composite score was calculated as the mean of available responses across the 4 burden items. Fully adjusted regression models were further restricted to respondents with complete data for the relevant outcome and all included covariates. Survey cycle was not treated as a measure or proxy of generative AI (GenAI) exposure because HINTS did not assess respondents' awareness, use, or exposure to GenAI tools.

Measures

Cancer Information Burden Outcomes

Four HINTS items were used to assess cancer information-seeking burden, defined as the perceived effort, frustration, difficulty understanding, and concern regarding information quality experienced during the search for cancer-related information. Respondents were asked, "based on the results of your most recent search for information about cancer, how much do you agree or disagree with each of the following statements?" The statements were as follows: "it took a lot of effort to get the information you needed," "you felt frustrated during your search for the information," "you were concerned about the quality of the information," and "the information you found was hard to understand." These items represent perceived effort, frustration, concern regarding information quality, and difficulty understanding cancer information, respectively. The original HINTS response options were strongly disagree, somewhat disagree, somewhat agree, and strongly agree.

Each item was coded on a 4-point ordinal scale ranging from 0 (strongly disagree) to 3 (strongly agree), with higher values indicating greater perceived cancer information burden. Responses that were coded as inapplicable, filter missing, not ascertained, or answered in error in the original HINTS data were treated as missing. The 4 items were analyzed separately as ordinal outcomes.

An overall cancer information burden score was calculated as the arithmetic mean of the available responses across the 4 coded burden items. The resulting score ranged from 0 to 3, with higher scores indicating greater overall perceived cancer information burden.

The 4-item composite demonstrated high internal consistency, with a Cronbach α of 0.881. Exploratory factor analysis supported a single-factor structure. The first factor had an eigenvalue of 2.948 and explained 73.7% of the total variance. Factor loadings were 0.876 for perceived effort, 0.898 for frustration, 0.820 for concern regarding information quality, and 0.838 for difficulty understanding. These findings support combining the 4 items into a composite score while retaining the individual items for dimension-specific analyses.

Covariates

Covariates were selected using a theory-informed approach based on the Comprehensive Model of Information Seeking and prior cancer communication literature. Demographic and socioeconomic variables were treated as antecedent characteristics that may shape cancer information-seeking experiences. Demographic and socioeconomic covariates included age, sex, race and ethnicity, educational attainment, household income, geographic census division, and survey cycle. Race and ethnicity categories included non-Hispanic White, non-Hispanic Black, Hispanic, non-Hispanic Asian, and non-Hispanic Other populations. Educational attainment was categorized as less than high school, high school graduate, some college, bachelor's degree, and postbaccalaureate degree. Household income was categorized into 6 groups ranging from less than US $20,000 annually to US $100,000 or greater. Geographic variation was assessed using US census divisions. Survey cycle was included as a temporal covariate to evaluate whether cancer information burden differed between HINTS 2022 and HINTS 2024; it was not interpreted as a proxy for GenAI exposure.

Missing Data and Analytic Samples

Of the 1972 cancer survivors in the pooled HINTS 2022 and 2024 samples, the number of respondents with valid data differed across the cancer information burden outcomes. Valid outcome data were available for 1373 respondents for perceived effort in obtaining cancer information, 1366 for difficulty understanding cancer information, 1367 for frustration during information seeking, and 1368 for concern regarding information quality. The composite cancer information burden score was available for 1389 respondents because it was calculated as the mean of available responses to the 4 burden items.

Adjusted regression models used complete-case estimation. Respondents were included in a given model only when they had valid data for the corresponding outcome and all covariates included in that model. Therefore, respondents with valid outcome data could contribute to descriptive analyses but were excluded from adjusted analyses when age, sex, race and ethnicity, education, household income, census division, or survey-cycle information were missing. Household income had the largest amount of missing covariate data and accounted for much of the reduction in analytic sample size.

The final complete-case regression samples included 957 respondents for perceived effort, 952 for difficulty understanding, 953 for frustration, 956 for concern regarding information quality, and 969 for the composite score. No values were imputed in the primary analyses.

Statistical Analysis

Survey-weighted analyses were conducted to account for the complex HINTS sampling design, including stratification, clustering, and sampling weights. Covariates were selected using the Comprehensive Model of Information Seeking and prior cancer communication literature. Age, sex, race and ethnicity, educational attainment, household income, US census division, and survey cycle were included as antecedent demographic and socioeconomic characteristics potentially

XSL•FO
RenderX

associated with cancer information-seeking burden. Missing data were handled using complete-case analysis. Each regression model included only respondents with complete data for the outcome of interest and all covariates. Consequently, analytic sample sizes varied slightly across outcomes because of differences in item nonresponse. No imputation procedures were performed.

Survey-weighted proportional-odds ordinal logistic regression models were estimated for the 4 ordinal cancer information burden outcomes. Results are presented as odds ratios (ORs) with 95% CIs. An OR greater than 1 indicates higher odds of reporting a greater level of cancer information burden, whereas an OR below 1 indicates lower odds.

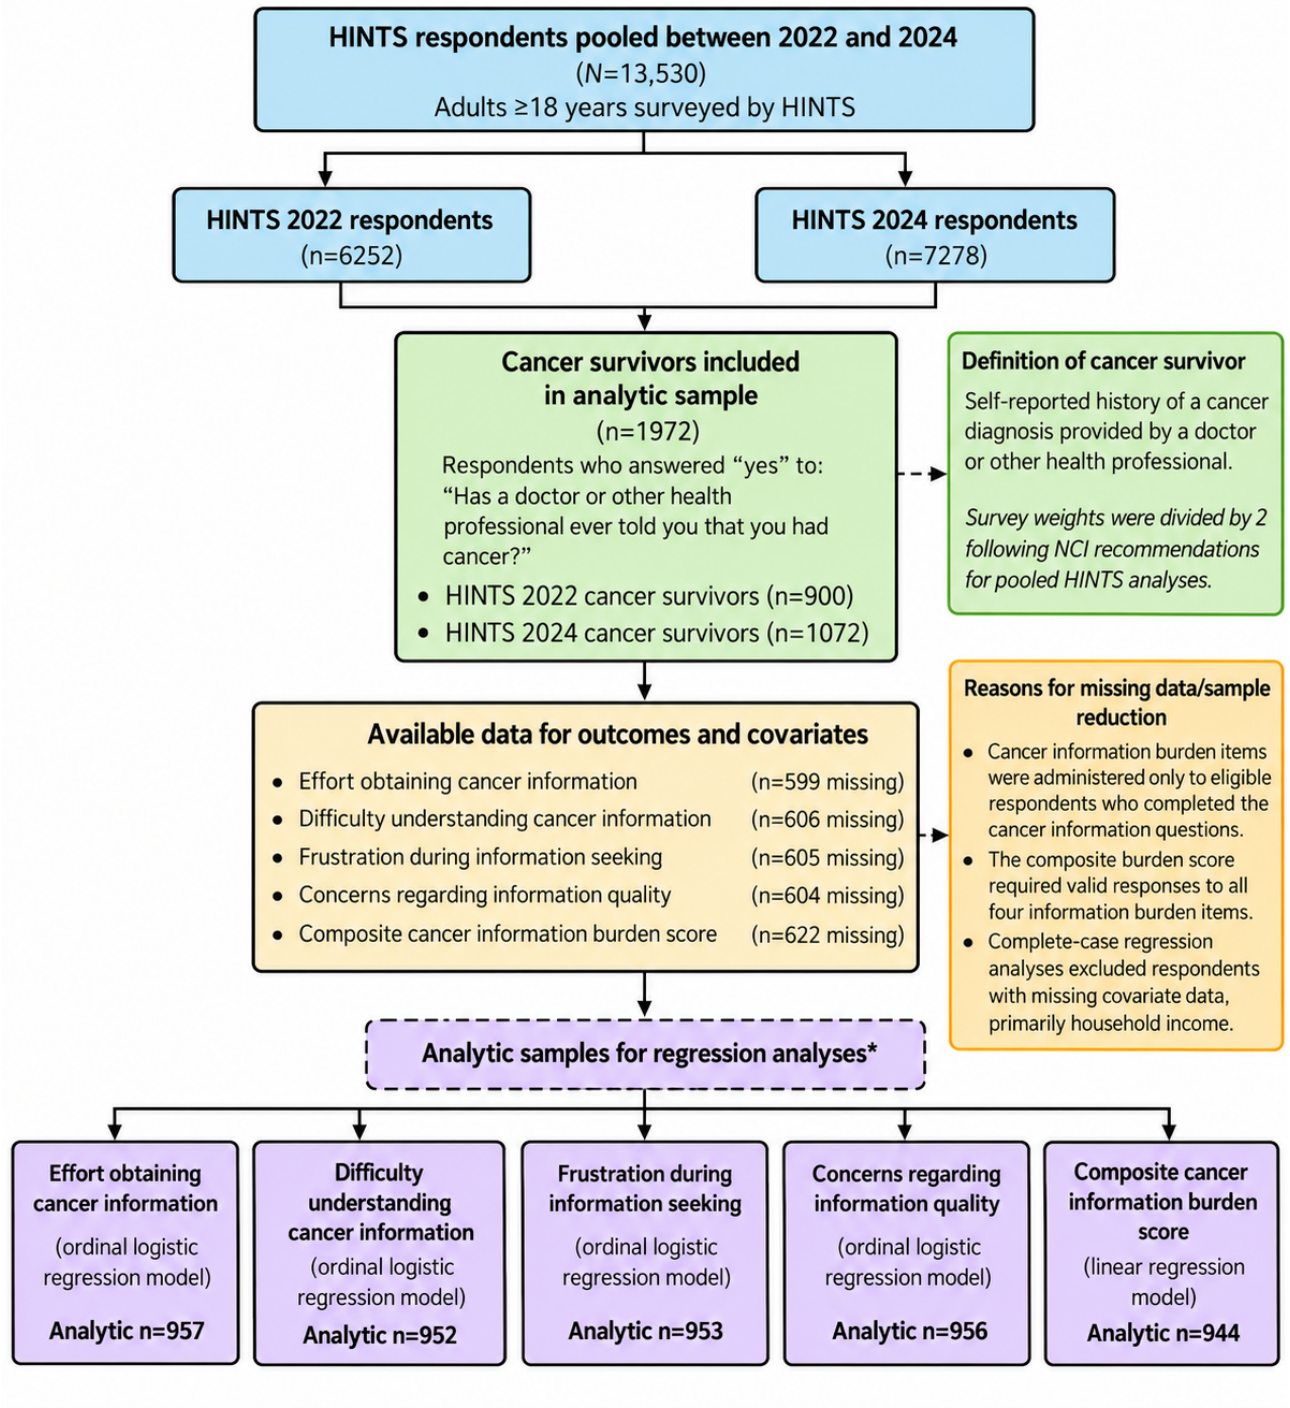
The proportional-odds assumption was assessed for each ordinal outcome using parallel-lines diagnostic tests. Evidence of nonproportionality was identified for perceived effort in obtaining cancer information and concern regarding information quality, while findings for difficulty understanding cancer information were mixed across tests. No evidence of nonproportionality was identified for frustration during information seeking. For outcomes showing evidence of assumption violations, generalized ordered logistic regression models with partial proportional odds were estimated as sensitivity analyses, allowing selected coefficients to vary across outcome thresholds. These sensitivity analyses yielded conclusions that were substantively consistent with the primary models.

Survey-weighted linear regression was used to examine the composite cancer information burden score. Cronbach α and exploratory factor analysis were used to assess the internal consistency and dimensional structure of the 4-item composite measure.

As a secondary analysis, an age × survey cycle interaction term was added to each model to assess whether age-related associations with cancer information burden differed between HINTS 2022 and HINTS 2024. Age was selected as the interaction of interest because it may be associated with access to, familiarity with, and navigation of digital health information environments. Additional interactions were not systematically examined because the available sample size limited statistical power for multiple subgroup analyses, and extensive interaction testing could increase the likelihood of chance findings. Statistical significance was assessed using 2-sided tests with an α level of .05. All analyses were conducted using Stata (version 19.5; StataCorp LLC).

Ethical Considerations

This study was a secondary analysis of publicly available, deidentified data from the National Cancer Institute's HINTS. Because the dataset is publicly available and contains no identifiable participant information, a separate institutional review board review was not required for this study. The original HINTS data collection protocols were reviewed and approved by the Westat Institutional Review Board, and all participants provided informed consent before participating.



Results

Sample Characteristics

Figure 1 presents the study population selection process, while Table 1 summarizes the weighted descriptive characteristics of US cancer survivors included in the analytic sample. The pooled analytic sample included 1972 US cancer survivors from the 2022 and 2024 HINTS cycles. The unweighted sample included 900 (45.6%) respondents from HINTS 2022 and 1072 (54.4%) from HINTS 2024. After application of survey weights, the corresponding population estimates were 50.5% (n=997) for HINTS 2022 and 49.5% (n=976) for HINTS 2024. The weighted mean age of respondents was 65.8 (95% CI 64.5-67.1) years. Approximately 52.1% (95% CI 48.4%-55.6%) of respondents were female survivors. The sample was predominantly non-Hispanic White (77.8%, 95% CI 74.6%-80.7%) survivors, although Hispanic (8.4%, 95% CI 6.7%-10.5%), non-Hispanic Black (7.3%, 95% CI 5.7%-9.2%), non-Hispanic Asian (2.0%, 95% CI 1.3%-2.9%), and non-Hispanic Other (4.6%, 95% CI 3.1%-6.8%) populations were also represented. Educational attainment varied substantially across respondents. Approximately 42.3% (95% CI 39.2%-45.6%) reported some college education, while 16.9% (95% CI 14.8%-19.2%) reported a bachelor's degree and 16.8% (95% CI 14.7%-19.3%) reported postbaccalaureate education. Approximately 6.0% (95% CI 4.5%-7.8%) of respondents reported less than a high school education. Household income levels also varied across the sample. Approximately 22.0% (95% CI 18.7%-25.7%) of respondents reported annual household incomes between US $50,000 and US $74,999, while 21.6% (95% CI 18.6%-25.0%) reported incomes of at least US $100,000 annually. Approximately 16.3% (95% CI 13.8%-19.3%) reported annual household incomes below US $20,000. Of the 1972 cancer survivors included in the pooled dataset, between 1366 and 1373 respondents provided valid responses to the individual cancer information burden items. The composite cancer information burden score was available for 1389 respondents because it was calculated as the mean of available responses across the 4 burden items. After complete-case exclusion of respondents with missing covariate information, primarily household income, the final regression samples ranged from 952 to 957 participants. The composite burden analysis included 969 respondents.

[a]Unweighted counts are presented alongside survey-weighted percentages or means and their 95% CIs. Survey-weighted estimates account for the complex HINTS sampling design. Percentages may not sum to 100% because of rounding.

[b]HINTS: Health Information National Trends Survey.

Regarding measures of cancer information burden, approximately 39.8% of respondents somewhat or strongly agreed that obtaining cancer information required substantial effort. Similarly, 35.0% somewhat or strongly agreed that cancer information was difficult to understand, while 36.0% somewhat or strongly agreed that seeking cancer information was frustrating. Concerns regarding cancer information quality were also common, with approximately 50.8% somewhat or strongly agreeing that they were concerned about the quality of cancer-related information. The 4 cancer information burden items demonstrated high internal consistency (Cronbach α=0.881). Exploratory factor analysis identified 1 dominant factor with an eigenvalue of 2.948, accounting for 73.7% of the total variance. All 4 items loaded strongly on this factor, with loadings ranging from 0.820 to 0.898. These findings supported the use of the mean of the 4 items as an overall cancer information burden score.

Factors Associated With Cancer Information Burden

Parallel-lines diagnostics indicated evidence of nonproportionality for perceived effort in obtaining cancer information and concern regarding information quality. Diagnostic findings for difficulty understanding cancer information were mixed, whereas no evidence of nonproportionality was identified for frustration during information seeking. Partial proportional-odds sensitivity models were therefore estimated for outcomes showing evidence of assumption violations. These sensitivity analyses produced conclusions that were substantively consistent with those of the primary proportional-odds models. Table 2 presents survey-weighted regression models examining factors associated with cancer information burden among US cancer survivors. Several significant demographic and socioeconomic differences emerged across perceived effort in obtaining cancer information, difficulty understanding cancer information, frustration during information seeking, concern regarding information quality, and the composite cancer information burden score.

Hispanic cancer survivors experienced greater cancer information burden than non-Hispanic White survivors for selected outcomes. Hispanic respondents had significantly higher odds of reporting greater effort in obtaining cancer information (OR 2.611, 95% CI 1.387-4.913, P=.003) and greater frustration during cancer information seeking (OR 2.087, 95% CI 1.154-3.773, P=.02). Hispanic survivors also had higher composite cancer information burden scores, although this association did not reach statistical significance after adjustment for covariates (β=0.265, 95% CI −0.002 to 0.532, P=.051). These findings indicate that Hispanic cancer survivors reported greater cancer information burden for selected outcomes. Because the data are cross-sectional, the observed associations do not establish why these differences occurred.

[a]ORs greater than 1 indicate higher odds of reporting a higher level of cancer information burden. The proportional-odds assumption was evaluated using parallel-lines tests, and partial proportional-odds sensitivity models were estimated for outcomes showing evidence of nonproportionality.

[b]OR: odds ratio.

[c]β: unstandardized linear regression coefficient.

[d]*P*<.01.

[e]*P*<.05.

[f]HINTS: Health Information National Trends Survey.

[g]N/A: not applicable.

Non-Hispanic Asian cancer survivors also demonstrated elevated cancer information burden for selected outcomes. In particular, Asian survivors had significantly higher odds of reporting greater effort in obtaining cancer information than non-Hispanic White survivors (OR 5.495, 95% CI 1.543-19.568, *P*=.009). Estimates for frustration and the composite burden score were

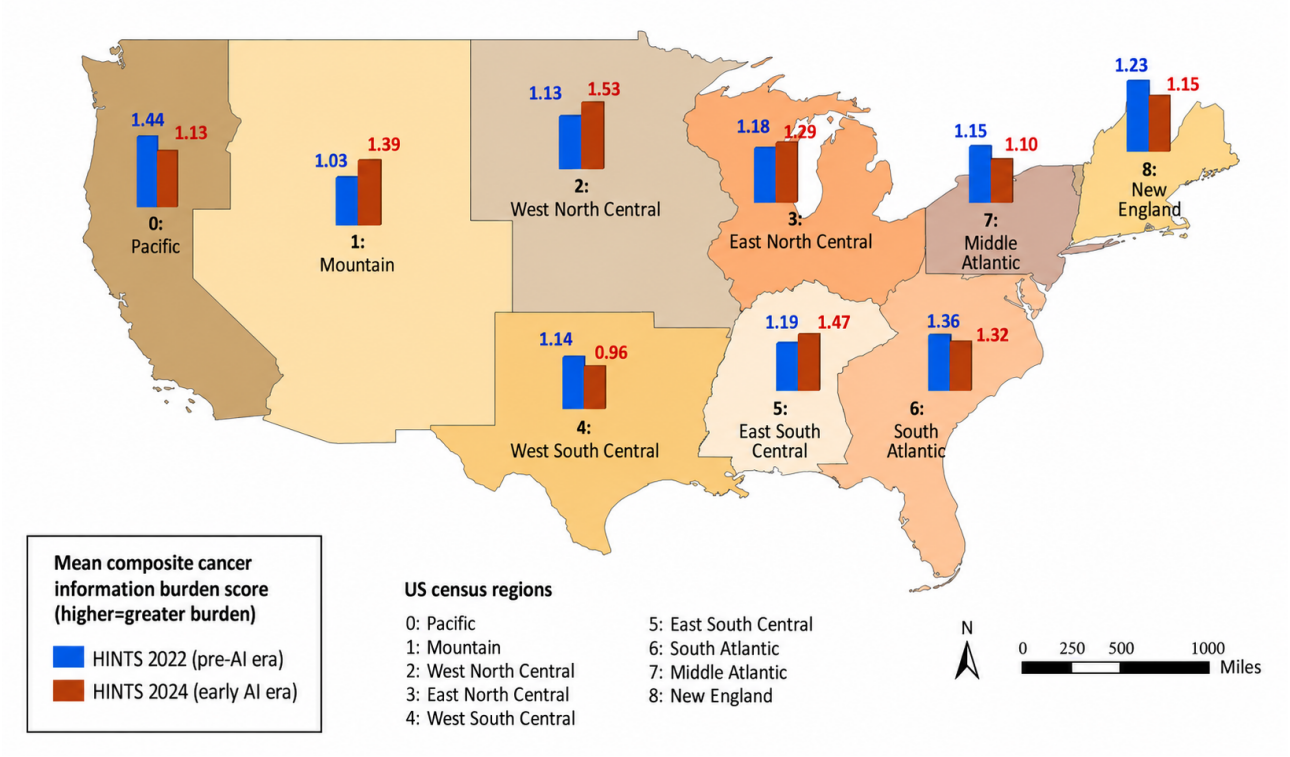
XSL•FO
RenderX

higher, but these associations did not reach statistical significance. The wide CIs likely reflect the smaller number of non-Hispanic Asian respondents in the analytic sample.

Female cancer survivors generally reported a lower cancer information burden than male survivors. Female survivors had significantly lower odds of reporting difficulty understanding cancer information (OR 0.562, 95% CI 0.383-0.824, P=.003) and greater frustration when seeking cancer information (OR 0.683, 95% CI 0.489-0.954, P=.03). They also had significantly lower overall cancer information burden scores (β=−0.177, 95% CI −0.313 to −0.041, P=.01). These associations may be related to differences in health information-seeking experience or familiarity with health care navigation, although these potential explanations were not directly measured in HINTS.

Educational attainment was associated with frustration during cancer information seeking. Respondents with postbaccalaureate education had significantly lower odds of reporting greater frustration than respondents with less than a high school education (OR 0.256, 95% CI 0.069-0.951, P=.042). Respondents with a bachelor's degree showed a similar pattern, although the association narrowly missed statistical significance (OR 0.270, 95% CI 0.072-1.016, P=.053). Other education-related estimates generally suggested lower cancer information burden among respondents with higher educational attainment, but the CIs included the null value.

Non-Hispanic respondents classified in the Other racial and ethnic category had significantly higher odds of reporting greater concern regarding cancer information quality than non-Hispanic White respondents (OR 2.798, 95% CI 1.222-6.408, P=.02). This estimate should be interpreted cautiously because of the heterogeneity and likely small sample size of this category.



Age was not significantly associated with the cancer information burden outcomes after covariate adjustment. Household income and US census division also demonstrated limited associations across the models. Differences between the 2022 and 2024 HINTS cycles were not statistically significant for any outcome. These findings indicate that the measured associations did not differ significantly between the 2 survey cycles.

Figure 2 presents exploratory, survey-weighted mean cancer information burden scores across US census divisions. Certain divisions appeared to have higher or lower mean scores for selected burden measures, but the patterns were not uniform across outcomes or survey cycles. No formal pairwise or omnibus comparisons were conducted for this figure; therefore, these descriptive differences should not be interpreted as statistically significant geographic variation. Because the number and weighted distribution of cancer survivors differed across census divisions and survey cycles, some of the visual variation may reflect differences in regional sample composition. Multimedia Appendix 1 reports the unweighted sample sizes and weighted percentages of cancer survivors by census division and survey cycle.

The regional distribution of cancer survivors did not differ significantly between HINTS 2022 and HINTS 2024, based on a survey-weighted design-adjusted Pearson test ($F_{7.48,2594.52}$=0.943, P=.48). Thus, the descriptive differences shown in Figure 2 were not accompanied by evidence of a significant change in the geographic composition of the cancer-survivor sample across survey cycles.

RenderX

Figure 2. Exploratory, survey-weighted mean cancer information burden scores across US census regions (Health Information National Trends Survey [HINTS] 2022 vs HINTS 2024). Values represent descriptive survey-weighted means for perceived effort in obtaining cancer information, difficulty understanding cancer information, frustration during information seeking, concern regarding information quality, and the composite burden score across the US census divisions. No formal pairwise or omnibus statistical comparisons were conducted. Regional patterns should therefore be interpreted as exploratory. Unweighted sample sizes and weighted distributions by census division and survey cycle are reported in Multimedia Appendix 1. Data source: HINTS 2022 and 2024 survey-weighted means estimated using linearized variance.

Secondary Analysis of the Interaction Between Age and Survey Cycle

Table 3 presents the secondary interaction analyses examining whether age-related associations with cancer information burden differed between HINTS 2022 and HINTS 2024. Across all 5 outcomes, the age × survey-cycle interaction terms were not statistically significant, indicating no evidence that the association between age and cancer information burden differed between HINTS 2022 and HINTS 2024. For effort in obtaining cancer information, the interaction between age and HINTS 2024 was not statistically significant (β=−0.004, 95% CI −0.034 to 0.025, *P*=.77). Similarly, no significant age-by-cycle interaction was observed for difficulty understanding cancer information (β=−0.019, 95% CI −0.058 to 0.020, *P*=.33), frustration during cancer information seeking (β=−0.012, 95% CI −0.043 to 0.020, *P*=.47), concerns regarding cancer information quality (β=−0.012, 95% CI −0.047 to 0.024, *P*=.52), or the composite cancer information burden score (β=−0.005, 95% CI −0.018 to 0.008, *P*=.45).

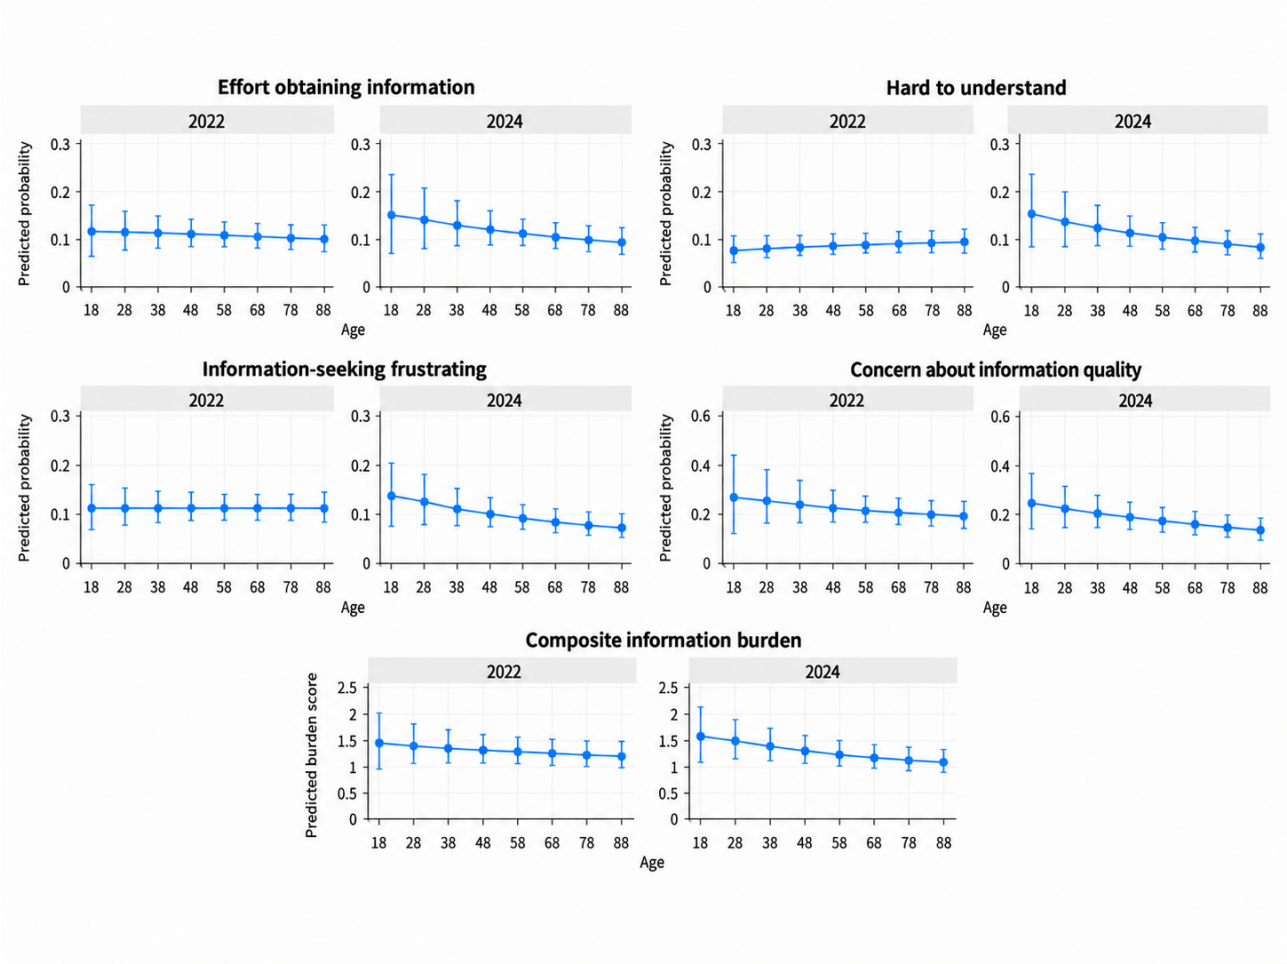
Table . Interaction between age and survey year in models of cancer information burden among US cancer survivors[a].

Outcome	Age, β (95% CI)	HINTS[b] 2024, β (95% CI)	Age × HINTS 2024, β (95% CI)	*P* value	Observations
Effort in obtaining cancer information	−0.003 (−0.025 to 0.018)	0.296 (−1.811 to 2.402)	−0.004 (−0.034 to 0.025)	.77	957
Difficulty understanding cancer information	0.003 (−0.030 to 0.035)	1.364 (−1.376 to 4.104)	−0.019 (−0.058 to 0.020)	.33	952
Frustration during information seeking	0.000 (−0.026 to 0.026)	0.644 (−1.596 to 2.885)	−0.012 (−0.043 to 0.020)	.47	953
Concerns regarding information quality	−0.006 (−0.036 to 0.025)	0.422 (−2.165 to 3.009)	−0.012 (−0.047 to 0.024)	.52	956
Composite cancer information burden score	−0.001 (−0.011 to 0.010)	0.288 (−0.613 to 1.188)	−0.005 (−0.018 to 0.008)	.45	969



[a]Survey-weighted proportional-odds ordinal logistic regression models were estimated for the 4 ordinal cancer information burden outcomes. For these models, β estimates are unexponentiated coefficients expressed on the log-odds scale. Survey-weighted linear regression was used for the composite cancer information burden score, for which β estimates are unstandardized linear regression coefficients. Models were adjusted for sex, race and ethnicity, educational attainment, household income, and US census division. The age × survey-cycle interaction term indicates whether the association between age and each outcome differed between HINTS 2022 and HINTS 2024. HINTS 2022 was the reference survey cycle.

[b]HINTS: Health Information National Trends Survey.

Figure 3 presents predictive margins that illustrate age-specific trends in cancer information burden across the 2022 and 2024 survey cycles. Overall, predicted probabilities and burden scores were broadly comparable between survey years, with overlapping CIs across most age groups. Across several outcomes, younger cancer survivors demonstrated modestly higher predicted levels of cancer information burden compared with older survivors, particularly in 2024. This pattern was most apparent for difficulty understanding cancer information, concerns regarding cancer information quality, and the composite cancer information burden score. However, CIs were wider at younger ages, indicating greater uncertainty in these estimates. Collectively, these findings indicate that age-related associations with cancer information burden did not differ significantly between the 2022 and 2024 survey cycles. Because HINTS did not measure GenAI use or exposure, these findings cannot be attributed to changes in AI-enabled health information environments.

Figure 3. Predicted cancer information burden by age and survey year among US cancer survivors.

Discussion

Principal Findings and Interpretation

This study provides an updated, nationally representative assessment of cancer information-seeking burden among US cancer survivors using HINTS 2022 and 2024 data. The findings were broadly consistent with earlier HINTS-based and population-based studies showing that cancer information-seeking behaviors and experiences differ across demographic and socioeconomic groups [15-18]. The present analysis extends this literature by examining 4 burden dimensions separately, evaluating a 4-item composite measure, and assessing whether these associations were evident in recent HINTS cycles. Accordingly, the findings should be interpreted primarily as a contemporary and confirmatory update rather than as evidence of entirely new demographic patterns. In contrast, adjusted differences between the 2022 and 2024 survey cycles and age × survey-cycle interactions were not statistically significant. These findings should be interpreted as evidence regarding cancer information burden during 2022 and 2024 and not as evidence of GenAI effects because HINTS did not assess AI use, awareness, or exposure. Viewed through the Comprehensive Model of Information Seeking, the observed associations may reflect differences in antecedent characteristics that shape information-seeking experiences. However, the current study did not measure several constructs central to the framework, including the salience of current information needs, beliefs, prior cancer experience, information-channel characteristics, trust, digital access, and eHealth literacy. The findings therefore support a theory-informed interpretation but should not be considered a formal test of the model. The secondary age × survey-cycle analyses did not identify statistically significant interactions for any outcome. These results indicate that the association between age and cancer information burden did not differ significantly across the 2 survey cycles, although the analyses may have had limited power to detect modest interaction effects.

One of the most notable findings was the elevated cancer information burden reported among Hispanic cancer survivors. Hispanic respondents consistently demonstrated higher perceived effort associated with obtaining cancer information and greater frustration during cancer information seeking compared with non-Hispanic White survivors. Non-Hispanic Asian respondents also demonstrated significantly higher perceived effort in obtaining cancer information. These findings are consistent with prior research documenting differences in health literacy, access to culturally tailored information, and digital navigation experiences across population groups [20,26-28]. The associations remained after adjustment for education, income, and geographic region. However, the present study did not directly measure health literacy, structural barriers, digital navigation skills, or exposure to AI-generated health content. These factors therefore represent possible areas for future investigation rather than established explanations for the

XSL•FO
RenderX

observed associations. Overall, these findings are consistent with prior HINTS-based and population-based research. Davis et al [15] identified demographic correlates of cancer information-seeking experiences among US cancer survivors, while Elkefi and Matthews [16] documented differences in information-seeking behaviors and source preferences across a diverse survivor sample. Mahmood et al [17] further showed that patient-centered communication was associated with cancer information-seeking experiences, and Benzo et al [18] reported associations between digital information-seeking behaviors and sociodemographic characteristics, cancer history, and perceived health. The present study extends this literature by showing that selected demographic differences remain evident in recent HINTS data and vary across specific dimensions of cancer information-seeking burden.

The descriptive patterns shown in Figure 2 suggest possible geographic variation in cancer information burden, but these observations are exploratory. The figure was not accompanied by formal pairwise or omnibus testing, and the number and weighted distribution of cancer survivors varied across census divisions and survey cycles. Consequently, some visual differences may reflect regional sample composition rather than independent geographic effects. Census division was included as a covariate in the adjusted regression models, but most division-specific estimates were not statistically significant. Future studies with larger geographic samples should formally test regional differences and examine whether survey-cycle changes vary across areas.

Educational attainment also demonstrated a protective relationship with several dimensions of cancer information burden. Cancer survivors with bachelor's or postbaccalaureate degrees reported lower levels of frustration during cancer information seeking and generally lower composite burden scores. These associations may be related to differences in digital literacy, familiarity with health systems, or the ability to evaluate complex health information. However, these potential mechanisms were not directly measured in the present study. Prior research has consistently demonstrated that health literacy and digital literacy strongly influence the ability to effectively navigate online health information environments [29,30]. Earlier HINTS-based studies have also linked educational attainment and socioeconomic characteristics with cancer information-seeking experiences and source use [15,17]. The current findings therefore reinforce prior evidence that educational resources may shape how survivors experience the effort and frustration associated with obtaining cancer information. The present findings indicate that educational attainment was associated with selected dimensions of perceived cancer information burden. The study cannot determine whether this association was influenced by the increasing availability of AI-enabled information tools.

Interestingly, female cancer survivors reported significantly less difficulty understanding cancer information and less frustration during information seeking than male survivors. Prior HINTS-based and population-based studies have also identified sex differences in health information-seeking behaviors, preventive service use, and engagement with health care systems [31,32]. Female survivors may have greater prior experience seeking health information, communicating with health professionals, and managing health care for themselves or family members. These experiences may provide context for the observed associations. However, the present study did not directly measure prior information-seeking frequency, caregiving roles, digital literacy, or health care navigation experience, and these factors should not be interpreted as established explanatory mechanisms. Future studies should directly evaluate whether these characteristics account for sex differences in cancer information-seeking burden.

Age was examined as a potential modifier because digital access, online information-seeking experience, and familiarity with digital health tools may differ across age groups. However, the absence of statistically significant interactions suggests that age-related patterns were not detectably different between the 2022 and 2024 cycles. Because HINTS did not directly measure digital literacy, technology use, or AI exposure, the mechanisms underlying age-related information experiences could not be evaluated. Future studies with larger samples and direct measures of digital engagement should further assess whether age modifies the relationship between changing information environments and cancer information burden.

Although AI was not evaluated in this study, the findings provide a baseline for future research on cancer communication in changing digital environments. GenAI tools may offer opportunities to simplify medical terminology, tailor educational materials, and support patient engagement, but they may also introduce concerns related to information accuracy, bias, and unequal access. Because HINTS did not measure AI use, exposure, or reliance on AI-generated information, the present results cannot determine whether AI-enabled systems influenced cancer information burden. Future studies should directly assess the use of these tools and evaluate their associations with comprehension, trust, and information burden.

The incremental contribution of this study lies in its use of recent pooled HINTS cycles, its simultaneous evaluation of 4 specific burden dimensions, and its psychometric assessment of a composite cancer information burden measure. The high internal consistency and single-factor structure supported the use of the composite, while the item-specific models showed that associations were not uniform across all dimensions. This outcome-specific pattern provides more detail than treating cancer information seeking as a single behavior or experience.

Limitations

This study has several limitations. First, the cross-sectional design precludes causal inference. Second, the study relied on self-reported perceptions of cancer information burden rather than objective measures of information-seeking behavior or comprehension. Third, the analyses did not account for cancer-specific characteristics, including cancer type, time since diagnosis, treatment status, disease stage or severity, recurrence, or survivorship phase. These factors may influence information-seeking needs and perceived burden and could contribute to residual confounding. Future studies should examine whether the observed associations vary across cancer types and phases of care. The analyses also did not adjust for factors more directly related to digital information access and

XSL•FO
RenderX

navigation, such as internet use, frequency of online health information seeking, digital literacy, eHealth literacy, or access to digital technologies. These factors may influence perceived cancer information burden and could partly explain the observed associations. Future studies should incorporate these measures to better understand the pathways through which demographic and socioeconomic characteristics are associated with cancer information burden. Fourth, HINTS 2022 and 2024 did not measure GenAI awareness, use, chatbot engagement, AI-assisted search behavior, or exposure to AI-generated health information. Survey cycle therefore cannot be interpreted as a proxy for AI exposure, and neither differences nor the absence of differences between 2022 and 2024 can be attributed to GenAI. References to changes in the digital information environment are intended only to provide broader temporal context. Fifth, some subgroup analyses, particularly among non-Hispanic Asian respondents, were limited by relatively small sample sizes, resulting in wider CIs. Finally, although the study examined several dimensions of cancer information burden, additional factors such as trust in online information, patient portal engagement, and exposure to AI-generated misinformation warrant further investigation. Complete-case analysis reduced the adjusted analytic samples, primarily because of missing household income data. If missingness was systematically related to information burden, some selection bias may remain.

Despite these limitations, this study provides nationally representative evidence regarding cancer information burden in 2022 and 2024. The findings identify demographic and socioeconomic characteristics associated with selected dimensions of information burden during this period. Because the survey did not measure AI-related exposures, the study cannot determine whether technological developments influenced these associations or whether AI-enabled communication systems affected information burden. Future research should directly measure AI tool use and examine its longitudinal associations with patient understanding, trust, well-being, and cancer information burden.

Implications for Cancer and Digital Health Communication

Digital health information systems may create opportunities to improve access to understandable and personalized cancer information. However, their effects on cancer information burden were not evaluated in this study. The observed associations by race and ethnicity, sex, and educational attainment underscore the importance of accessibility, cultural responsiveness, readability, and health literacy–sensitive design in cancer communication. Future evaluations of AI-enabled communication tools should examine whether their benefits and limitations differ across population groups.

Conclusions

These findings reinforce and update prior HINTS-based evidence that cancer information-seeking experiences differ across survivor populations while showing that associations vary by the specific dimension of burden examined. The validated composite measure may support future studies seeking to monitor cancer information burden over time or across communication environments. Hispanic and non-Hispanic Asian survivors, and individuals with lower educational attainment, may experience greater difficulty obtaining, understanding, and evaluating cancer information. Cancer communication strategies should prioritize accessibility, readability, cultural responsiveness, and health literacy. Future studies should directly measure the use of GenAI and other emerging digital tools before evaluating their relationship with cancer information burden.

Acknowledgments

The authors would like to thank the UTHealth Houston School of Public Health for its support of this research.

Generative AI Use

During the preparation of this manuscript, the authors used OpenAI's ChatGPT (model: GPT-6) to assist with language editing, improving clarity, and refining the organization of the manuscript and responses to reviewers. The authors critically reviewed and edited all AI-assisted content and take full responsibility for the accuracy, integrity, and originality of the manuscript. Generative AI was not used to generate, analyze, or interpret study data or to make scientific conclusions.

Funding

This work was supported by startup funds provided by the University of Texas Health Science Center at Houston. The funder had no role in the study design; data collection, analysis, and interpretation; manuscript preparation; or the decision to submit the manuscript for publication.

Data Availability

The data used in this study are publicly available from the National Cancer Institute's Health Information National Trends Survey (HINTS) website.

Authors' Contributions

JG conceived and designed the study, conducted the statistical analyses, interpreted the findings, and wrote the original draft of the manuscript. SVM, YZ, and JHW contributed to the conceptual development of the study, reviewed the manuscript, and provided critical revisions and intellectual input. All authors have read and agreed to the published version of the manuscript.

Abstract

Background: As the number of cancer survivors continues to grow, optimizing long-term survivorship care models has become increasingly important. Telehealth has the potential to improve access to health care for survivors; however, studies evaluating telehealth in this population remain limited. Additionally, concerns persist regarding equity in technology access and digital literacy.

Objective: This study aimed to examine demographic factors and patient attitudes influencing telehealth use among cancer survivors compared to the general population.

Methods: Adult participants were identified from the nationally representative database Health Information National Trends Survey 6 (HINTS 6). Multivariable logistic regression was used to calculate the predictors of telehealth use among cancer survivors. χ^2 tests compared the prevalence of reported reasons of not using telehealth in the last 12 months between cancer survivors and the general population.

Results: A total of 5793 (weighted n=239,557,883) individuals were included in this study, 7.7% (weighted n=18,545,434) who are cancer survivors. 5092 individuals from the general population and 701 cancer survivors were included. Older age was associated with lower telehealth use (adjusted odds ratio [aOR] 0.11; 95% CI 0.02 - 0.59 for patients aged ≥65, compared to those under 40 y old). Higher education (aOR 2.55; 95% CI 1.24 - 5.27) and heart disease history (aOR 2.52; 95% CI 1.20 - 5.28) were associated with increased telehealth use. Employed (aOR 0.46; 95% CI 0.22 - 0.97) and retired (aOR=0.37; 95% CI: 0.18 - 0.77) cancer survivors were less likely to use telehealth than unemployed individuals. Of the nonusers, over 60% reported that telehealth options were not offered, and 80% preferred in-person visits. Technical issues and privacy concerns were not major factors in utilizing telehealth.

Conclusions: Despite greater telehealth use among cancer survivors, a negative association between older age and telemedicine utilization persists. Efforts should focus on improving access for older cancer survivors and addressing employment-related factors, patient attitudes, and telehealth availability. Future studies should explore personalized approaches to enhance cancer survivors' health care experiences. Our findings emphasize the need to address specific factors including age and employment related disparities, patient preferences and telehealth availability to optimize equitable access to telehealth and enhance the delivery of cancer survivorship care.

survivorship; telehealth; digital health; internet; disparities; healthcare delivery; cancer

Introduction

Cancer survivors represent approximately 5.4% of the US population, and the number of survivors is expected to increase by 7.9 million by 2040 [1]. As the number of cancer survivors grows, the need to optimize long-term survivorship care models is imperative. Cancer survivors face unique health challenges, as they require continued monitoring for risk of recurrence, assessment for long-term physical and psychosocial effects of both the disease and its treatments, management of comorbidities, screening for new malignancies, and health promotion. Moreover, cancer survivors may face considerable economic burden for myriad reasons, including the inability to work and the rising costs of cancer therapies [2-4]. Patients with cancer and cancer survivors represented a vulnerable population during the rise of the COVID-19 pandemic, and fear associated with contracting the virus significantly affected all aspects of medical care [5-7]. As a result, telehealth offered potential health care delivery solutions for all socially distanced patients [8].

XSL•FO
RenderX

Telehealth is defined as the delivery of health and health-related services via telecommunication technologies [9] and has been successfully implemented over the last two decades in noncancer contexts including diabetes care, hypertension, mental health, and chronic pain [10-13]. Telehealth for cancer patients was evaluated before the COVID-19 pandemic and was shown to be as effective at improving quality of life as in-person care [14]. Although prior studies have examined telehealth use among cancer survivors, these have largely been limited to specific cancer types [15,16]. Data on telehealth utilization among cancer survivors, particularly relative to the general population, remain limited. In our analyses, the general population serves as the reference group, enabling assessment of whether cancer survivorship is independently associated with the outcomes of interest.

While telehealth is a powerful tool with the potential to improve health care outcomes, inequities remain regarding access to the technologies required for successful telehealth interactions. This is exemplified by a decrease in telehealth utilization by adults who are uninsured, have lower incomes, and are without high school degrees [17]. Older adults may have less digital literacy as well, and a small qualitative study found older cancer survivors made use of online platforms for general health concerns but preferred in-person visits for major issues [18,19]. Further research regarding the use of and potential barriers to telehealth services is imperative to continued improvement of survivorship-care. Our study aims to analyze demographic factors and patient attitudes that influence telehealth uptake among cancer survivors compared to the general population.

Methods

This study was a retrospective cross-sectional analysis of publicly available data from the Health Information National Trends Survey 6 (HINTS 6) [20]. HINTS data were assessed from the National Cancer Institute HINTS website. which collects nationally representative data about how adults use different communication channels to obtain health information. Telehealth visits were defined in HINTS 6 as a telephone or video appointment. Telehealth data was extracted for adult patients from March 7, 2022, to November 8, 2022. A total of 5793 individuals were included in this study, 5092 individuals from the general population and 701 cancer survivors. Our outcome of interest was overall telehealth utilization rates, reasons for having telehealth visits, and patient perceptions of telehealth utilization.

Outcome Variables

Participants were first asked whether they had used telehealth (defined as a telephone or video visit with a health care provider) in the past 12 months and whether they had been offered a telehealth option for care. Telehealth was assessed using items from section D of HINTS 6 [20].

Among those who used telehealth, additional questions assessed reasons for choosing telehealth (eg, provider recommendation, convenience, infection avoidance, or ability to include caregivers). Participants were also asked about their experiences and perceptions of telehealth, including preferences for in-person versus telehealth visits, concerns about privacy, perceived difficulty using the technology, technical problems encountered, and whether the quality of care was comparable to in-person visits.

Among those who did not use telehealth, items assessed whether telehealth was offered and reasons for nonuse (eg, preferred in person, privacy concerns, perceived difficulty using the technology)

Statistical analysis included a χ^2 test to compare the prevalence of telehealth use in the last 12 months between cancer survivors and the general population. Additionally, multivariable logistic regression was used to calculate the adjusted odds ratio (aOR) of telehealth use in cancer survivors compared to the general population. Our model was adjusted for multiple variables — age, sex, race/ethnicity income, education, marital status, BMI, employment status, insurance status, physical activity, diabetes, hypertension, lung disease, heart disease and smoking status.

All analyses incorporated the HINTS complex survey weights, and variance estimates were calculated using the Taylor series linearization method to account for the survey's stratified sampling design. Listwise deletions were used to treat missing values across these variables. All statistical analyses were performed with SAS 9.4. A 2-sided *P* value of <.05 was considered statistically significant.

Ethical Considerations

HINTS is deidentified, publicly available data, and has been designated as exempt research and approved by the Westat IRB [21].

Results

Patient Characteristics

A total of 239,557,883 individuals were included in the weighted sample, of which 7.7% (weighted n=18,545,434) were cancer survivors. 5092 individuals from the general population and 701 cancer survivors were included. Cancer survivors differed from the general population across multiple sociodemographic and clinical characteristics (Table 1). As expected, cancer survivors were more likely to be older (*P*<.001) and retired (*P*<.001). Cancer survivors were also more likely than the general population to be female (*P*<.001), non-Hispanic White (*P*<.001), married (*P*=.01), and have insurance (*P*<.001). Clinically, cancer survivors were more likely to be smokers (*P*<.001) and have additional medical comorbidities including diabetes (*P*=.002), hypertension (*P*<.001), heart disease (*P*<.001), and lung disease (=.003).

[a]Values are presented as unweighted n with weighted percentages and 95% confidence intervals. Percentages and confidence intervals were calculated using survey weights and therefore may not correspond directly to the unweighted counts.

[b]NHW: Non-Hispanic White.

[c]NHB: Non-Hispanic Black.

[d]P-values are not reported because these variables were collected exclusively in the cancer cohort and were not compared between groups.

Telehealth use was more common among cancer survivors than the general population (n=320, 48.2% vs n=2042, 38.4%; *P*=.01, aOR 1.48; 95% CI 1.07 - 2.04) (Table 2). Among cancer survivors who utilized telehealth, older age was associated with a lower likelihood of using telehealth compared to those under 40 years old (aOR 0.11; 95% CI 0.02 - 0.59 for age ≥65). Additionally, telehealth usage among cancer survivors was greater among those with higher education levels (aOR 2.55; 95% CI 1.24 - 5.27) and a history of heart disease (aOR 2.52; 95% CI 1.20 - 5.28). However, cancer survivors who were employed (aOR 0.46; 95% CI 0.22 - 0.97) or retired (aOR 0.37; 95% CI 0.18 - 0.77) were less likely to use telehealth than those who were unemployed (Table 3).

[d]NHW: Non-Hispanic White.

[e]NHB: Non-Hispanic Black.

Among those utilizing telehealth, avoiding infection was a more frequent motivator for the general population compared to cancer survivors (n=947, 51.5% vs n=114, 36.9%; *P*=.008, aOR 0.63; 95% CI 0.40 - 0.996). No significant differences were observed between cancer survivors and the general population in other reasons for telehealth use, including provider recommendation, convenience, or the ability to include family and friends. Similarly, there were no significant differences in perceptions of telehealth, including perceived difficulties, or equivalence to in-person visits (Table 2). Although privacy concerns were significantly less likely among cancer survivors after adjustment for covariates (aOR 0.43; 95% CI 0.21 - 0.89) (Table 2), the unadjusted comparison did not reach statistical significance (*P*=.07).

Among individuals who had not used telehealth in the past 12 months, over 80% (general population, n =411 and cancer survivors, n=68) did not use telehealth because they preferred in-person visits, and over 60% (general population, n=1875 and cancer survivors, n=231) of both groups reported that their health care providers did not offer telehealth services (Table 4). There were no significant differences in privacy concerns or technical difficulties as reasons for not utilizing telehealth (Table 2).

Discussion

Principal Results

Our study retrospectively analyzed telehealth utilization in both the general population and cancer survivors, using the HINTS 6 data. We identified several factors that may affect the likelihood of cancer survivors utilizing telehealth.

We found older age and lower education level in cancer survivors to be associated with decreased use of telehealth, which is consistent with results from prior research [17-19,22-24]. Chen et al [25] found that prostate cancer survivors with less than a high school education had lower use of telehealth than those who had received any college education. Moreover, there is evidence that cancer patients with higher education levels have more positive perceptions of telemedicine with regards to satisfaction and privacy [26]. Along these same lines, Kjeldsted et al [27] noted that cancer patients with lower education levels reported less positive experiences with telemedicine, specifically with regard to comfort and confidence levels in teleconsultations.

Cancer survivors in our study with a history of heart disease were more likely to use telehealth. Inglist et al [28] published a Cochrane systematic review identifying 41 randomized controlled trials and found telehealth interventions reduced the relative risk of all-cause mortality by 20%. Consequently, various telehealth interventions have been used in heart disease management including structured telephone or video support for monitoring risk factors monitoring such as hypertension, and remote monitoring or wearable implantable devices including arrhythmia detection. These types of interventions familiarize many patients to telehealth technologies, therefore they may be more willing to engage in them in other settings like oncology [29].

Unlike previous research, we did not find privacy concerns or technical difficulties as major factors associated with reduced telehealth use [30]. Lower odds of older cancer survivors using telehealth may support prior evidence regarding the digital divide; this indicates the need to investigate other potential barriers for older cancer patients and use of telehealth including access to the internet and technology. A study from a primary care setting found that patient portal use was 28%, and patients with the lowest broadband access were less likely to utilize their patient portal [31].

Among the patients who had not utilized telehealth services over the prior 12 months, our study found that 60% of both cancer survivors and the general population were not offered this option.

This may be a result of system-level factors such as medical licensure, payment models and lack of training for implementation of telehealth interventions [32]. However, telehealth regulatory changes during the pandemic led to payment parity and equal reimbursement for telehealth visits as well as elimination of previous licensure requirements [33,34]. Furthermore, patient privacy regulations, particularly certain HIPAA (Health Insurance Portability and Accountability ACT of 1996) requirements, including the use of various video conferencing platforms, were waived during the pandemic [34]. Sequentially, a US Department of Health and Human Services report found a 63-fold increase in telehealth utilization [35]. Hopefully this trend in increased uptake will continue.

Preceding research has established potential benefits of telehealth compared to in person care, including improved quality of life, decreased costs [36,37], and improved access to health care for patients in rural communities [38]. However, research also suggests that telehealth may exacerbate inequities by further increasing the digital divide [39]. To mitigate this risk, specific guidelines and personalized care will need to be implemented. The Journal of the National Cancer Institute has recently published the Framework for Integrating Telehealth Equitably (FITE), which is intended to guide equitable implementation of telehealth [40]. Potential interventions, such

XSL•FO
RenderX

as the Telehealth Task Force described by Worster et al [41], have demonstrated that providing tailored digital support can successfully engage older, racially diverse, and socioeconomically disadvantaged cancer patients, thereby helping to reduce the digital divide. A designated task force or telehealth navigators may similarly assist in addressing the needs of older cancer survivors, and those with low health literacy. The lower telehealth utilization observed among employed cancer survivors compared to their unemployed counterparts may reflect scheduling constraints inherent to the working population, such as limited availability during standard clinic hours or difficulty finding a private setting for a telehealth visit during the workday. To address such barriers, the Multinational Association for Supportive Care in Cancer (MASCC)–ASCO standards and practice recommendations for survivorship care emphasize flexible scheduling and the inclusion of both video and audio-only appointment options to increase accessibility across diverse patient populations [42].

Limitations

Our study does have limitations, as it focuses on data from a snapshot of time in 2022. It should also be noted that this data was collected during the COVID-19 pandemic, which had a large impact on the utilization of telehealth, and it is unclear how telehealth is being used in the post-pandemic setting. The strengths of our study include the inclusion of all cancer types, the large sample size, and the use of a model adjusted for multiple variables—age, sex, race/ethnicity income, education, marital status, BMI, employment status, insurance status, physical activity, diabetes, hypertension, lung disease, heart disease and smoking status—which allowed us to more directly compare the cancer survivor population to the general population.

Conclusion

As the health care delivery landscape continues to transform, understanding the factors that influence telehealth utilization among cancer survivors is imperative for ensuring equity and access to care, as well as tailoring interventions to meet the unique needs of this population.

Although cancer survivors in our study were significantly more likely than the general population to use telehealth, fewer than half did so. Digital literacy may not be a barrier to telehealth use in cancer survivors as they did not experience more difficulties in their telehealth visits.

The results of our study highlight the need for further efforts to mitigate barriers to telehealth uptake by cancer survivors. Health care providers also need to consider patients' specific concerns and preferences when promoting telehealth. Future studies are needed to explore and develop personalized approaches to health care delivery, with the goal of optimizing cancer survivors' outcomes and experiences.

Funding

The authors declare that no funds, grants, or other support were received during the preparation of this manuscript.

Data Availability

The datasets generated and analyzed during the current study are available in the nationally representative database, Health Information National Trends Survey 6 (HINTS 6) [43].

Abstract

Background: Cardiovascular disease is a leading noncancer cause of morbidity and mortality among individuals diagnosed with cancer. Although modern cancer therapies have improved survival, many are associated with cardiotoxic effects that increase the risk of cardiovascular complications. Early identification of cardiovascular symptoms and signs may support timely clinical management. However, tracking cardiovascular health during cancer care can be complex for both patients and medical team participants, and important indicators, such as blood pressure changes, heart rate variability, fluid retention, chest pain, or new-onset fatigue, may be missed between clinic visits. Mobile health technologies offer potential tools to facilitate remote monitoring, yet behavioral factors influencing cardiovascular tracking in cardio-oncology remain insufficiently understood.

Objective: This study aimed to identify barriers and facilitators influencing cardiovascular symptom tracking among patients with cancer and medical team participants using the capability, opportunity, motivation–behavior (COM-B) framework.

Methods: This qualitative descriptive study included adult patients with cancer (n=12) receiving cardiotoxic therapies and members of their health care teams (n=12), including oncologists, nurses, advanced practice providers, and allied health professionals. Participants were recruited from a cardio-oncology clinic. Semistructured interviews explored perceptions of tracking cardiovascular symptoms and signs. Data were analyzed using rapid qualitative analysis and organized according to COM-B domains. The study received ethical approval, and participants provided informed consent.

Results: Patients with cancer and medical team participants described cardiovascular symptom tracking as a shared responsibility. Capability-related themes included uncertainty regarding which symptoms to monitor, appropriate thresholds for concern, and variability in communication practices. Opportunity-related themes included time pressures, competing clinical demands, and the influence of patient-medical team participant relationships and social support. Motivation-related themes reflected perceived benefits of tracking, including reassurance for patients and improved clinical insight for medical team participants, alongside concerns about information burden and unclear actionability. Both groups expressed interest in digital tools that provide clear guidance, defined response pathways, and integration within health care workflows.

Conclusions: Cardiovascular symptom tracking in cancer care is shaped by interrelated behavioral and contextual factors affecting both patients and medical team participants. Digital systems intended to support tracking should address knowledge clarity, workflow integration, and actionability of reported information. Understanding these determinants may inform the design and implementation of cardiovascular monitoring strategies in cardio-oncology settings.

Introduction

Cardiovascular disease (CVD) is a leading noncancer cause of mortality in populations with cancer and an important contributor to morbidity. A recent systematic review and meta-analysis of 136 studies across 16 countries reported that individuals with cancer experience a 55% higher risk of cardiovascular mortality compared with the general population (standardized mortality ratio=1.55, 95% CI 1.40 - 1.72), with increased risk observed for both heart disease and cerebrovascular conditions [1]. Similarly, a study in the United States shows that patients with cancer remain at increased risk of CVD-related death from the time of diagnosis forward into survivorship, where risk is particularly elevated during the first year following diagnosis [2]. Contemporary cardio-oncology reviews further emphasize that cardiovascular and oncologic conditions are biologically and clinically interconnected, underscoring the need for systematic attention to cardiovascular risk throughout the cancer continuum [3]. Collectively, these findings support the concern for CVD risk in survivorship rather than as a secondary complication in cancer care.

Beyond mortality differences, new cardiovascular events are common during cancer treatment. In a cohort of 17,389 Australian patients treated with chemotherapy, nearly half developed CVD requiring hospital admission during follow-up [4]. More than 50% of these events occurred within 12 months of starting treatment. Patients who developed CVD during follow-up had higher subsequent all-cause mortality [4]. In a population-based cohort study conducted in Alberta, Canada, more than 4.5 million adults were followed for a median of 11.8 (IQR 6.4-11.8) years [5]. Among 224,016 individuals with a new cancer diagnosis, adjusted analyses showed a higher risk of cardiovascular mortality, stroke, heart failure, and pulmonary embolism compared with participants without cancer, while myocardial infarction risk was not increased. Together, these findings suggest that cardiovascular complications frequently arise early in the cancer trajectory and are strongly linked to adverse outcomes, underscoring the need for proactive cardiovascular risk identification and monitoring during and after cancer therapy.

Despite the high incidence of cardiovascular events during and after cancer treatment, early cardiovascular symptoms, such as dyspnea, fatigue, palpitations, or peripheral edema, may emerge between scheduled oncology encounters and may be missed or underdetected [6]. Because these symptoms overlap with common cancer- or treatment-related effects, they may not always prompt cardiovascular evaluation. Systematic electronic monitoring of patient-reported outcomes (PROs) has been linked to positive outcomes in oncology settings. In the multicenter patient-reported outcomes to enhance cancer treatment (PRO-TECT) cluster-randomized trial conducted across 52 community oncology practices, weekly electronic symptom reporting among patients with metastatic cancer significantly reduced emergency department visits and delayed deterioration in physical function, symptom burden, and health-related quality of life (HRQoL) compared with usual care [7]. Similarly, implementation of electronic medical record (EMR)–integrated symptom and needs monitoring in a large ambulatory oncology population at an academic cancer center was associated with reduced emergency department usage and hospitalizations [8]. These findings highlight that systematic symptom tracking can enhance early detection and improve patient-centered and usage outcomes, yet cardiovascular-specific symptom monitoring has not been well-studied in or implemented in cardio-oncology practice.

Digital PRO monitoring and mobile health (mHealth) tools may help address gaps in cardiovascular risk and symptom tracking across the cancer continuum by extending monitoring beyond episodic clinic visits. In a systematic review of mHealth technologies used to study cardiovascular health in populations with cancer, the most commonly captured measures were physical activity and heart rate, primarily via mobile apps and commercial wearables, and integration with EMRs was limited, representing a significant implementation barrier to translating patient-generated data into clinical action [9]. Complementing this landscape, EMR-integrated symptom and needs monitoring in ambulatory oncology has demonstrated that workflow-embedded PRO systems are feasible and associated with reductions in emergency department visits and hospitalizations, while also revealing variability in patient engagement [8]. Qualitative work focused specifically on symptom-tracking for cardiotoxicity, demonstrating that both patients and medical team participants perceive value in a patient-facing mHealth application to facilitate earlier recognition of treatment-related cardiotoxicity. However, medical team participants emphasized the need for simple design, clear triage and escalation pathways for urgent symptoms, and integration with existing clinical workflows and EMR constraints to ensure a safe and feasible implementation [10]. Together, these findings suggest that although digital tools for symptom monitoring are increasingly available, cardiovascular-specific tracking in cardio-oncology remains underdeveloped and insufficiently integrated into routine practice.

Cardiovascular symptom tracking to support cancer care ultimately depends on the behaviors of both patients and medical team participants. In this context, relevant behaviors include patients actively monitoring and reporting cardiovascular signs and symptoms, and medical team participants promoting, reviewing, and responding to that information within routine care. The capability, opportunity, motivation–behavior (COM-B) model, which is central to the Behavior Change Wheel framework, conceptualizes behavior as arising from the interaction of capability, opportunity, and motivation [11]. Capability refers to an individual's ability to engage in a behavior and includes both physical skills and psychological

XSL•FO
RenderX

capacity (eg, knowledge and understanding). Opportunity refers to external factors that enable or constrain behavior, including physical opportunity (eg, time and resources) and social opportunity (eg, support and norms). Motivation encompasses processes that energize and direct behavior, including reflective processes (eg, intentions and beliefs) and automatic processes (eg, habits and emotional responses).

The framework was developed to identify determinants of behaviors and to inform intervention design and has been widely applied to organize barriers and facilitators in implementation research. Applying COM-B to cardiovascular symptom and sign tracking in the cardio-oncology setting provides a structured approach to understanding determinants of these interrelated patient and medical team participant behaviors. In this study, COM-B was used as an analytic framework to classify barriers and facilitators to cardiovascular symptom tracking.

Methods

Study Design

We used a descriptive qualitative design guided by the COM-B model. Qualitative data were collected through semistructured interviews focused on identifying barriers and facilitators to tracking symptoms and signs relevant to cardiovascular health (eg, fatigue, chest pain, palpitations, and blood pressure) in the context of cancer treatment and survivorship. Interviews also explored participants' perspectives on desirable features of digital health solutions to support cardiovascular symptom monitoring, with these features subsequently mapped to COM-B domains.

The target behavior in this study was tracking cardiovascular symptoms and signs between clinical appointments. This behavior involves complementary roles for patients with cancer and medical team participants. Patients engage in tracking using available tools and strategies and report this information during or between visits. The medical team often inquires about cardiovascular health during appointments and may ask patients to monitor specific signs or symptoms between visits to support clinical care discussions and decisions. Because tracking involves actions and expectations on both sides of the clinical relationship, both patients with cancer and medical team participants were interviewed.

The COM-B framework guided both the development of the interview guides and the analysis of qualitative data. The model conceptualizes behavior as the interaction of capability (physical and psychological), opportunity (physical and social), and motivation (reflective and automatic). In this study, the framework was used to classify participant-reported barriers and facilitators related to tracking behaviors.

Participants and Recruitment

Medical team participants (n=12) and patients with cancer (n=12) who were currently undergoing or had previously undergone cardiotoxic anticancer therapy as defined by established cardio-oncology guidelines [12] (eg, tyrosine kinase inhibitors, chemotherapy, immune checkpoint inhibitors, and radiation) participated in one-on-one semistructured interviews to discuss their experiences and perspectives related to tracking symptoms and signs relevant to cardiovascular health. Eligible medical team participants were (1) aged 18 years or older, (2) English-speaking, (3) currently practicing as a licensed health care professional or allied health professional involved in cancer or cardio-oncology care (eg, physician, advanced practice provider, nurse, or allied health discipline such as physical therapy, exercise physiology, or nutrition), (4) employed within an oncology or cardio-oncology care setting, and (5) involved in the care of patients who were receiving or had received cardiotoxic anticancer therapy.

Eligible patients were (1) aged 18 years or older; (2) English-speaking; (3) diagnosed with cancer; (4) currently undergoing or had previously undergone a cancer regimen that includes a targeted, biologic, radiation, or immune-based therapy (eg, tyrosine kinase inhibitors or immune checkpoint inhibitors); (5) able to engage in physical activity (self-report); and (6) interested in symptom or sign tracking or increasing physical activity levels to improve health (self-report). Although physical activity was discussed during interviews, this analysis focuses on tracking symptoms and signs relevant to cardiovascular health; physical activity–related findings are reported separately.

Medical team participants were recruited through word of mouth and professional referrals. Potential patients were recruited via medical team participant-based referrals within the cardio-oncology clinic. Medical team participants introduced the study to eligible patients during routine medical appointments. If patients expressed interest, members of the research team contacted them via telephone or email to provide additional study information and confirm eligibility. The telephone was the primary mode of contact unless the participant preferred email. If a potential participant could not be reached by phone, a voicemail was left. Research staff followed a 3-call limit protocol when attempting contact. Eligible participants who provided informed consent were enrolled and scheduled for a semistructured interview with a trained member or members of the research team.

Of the 32 patients with cancer screened through the EMR, 7 were ineligible. The remaining 25 preliminarily eligible patients were approached by the clinical study team during medical appointments in the cardio-oncology clinic and asked whether they were interested in speaking with the research study team. The research team attempted to contact all 25 patients by telephone or email. Of the total, 5 patients were unreachable despite repeated contact attempts, and 4 were not contacted after the recruitment target had been met. Moreover, 16 patients were successfully screened by the research team; of these, 2 were ineligible and 2 declined to participate. In total, 12 patients with cancer were enrolled and completed interviews.

Data Collection

Semistructured interviews were conducted remotely via videoconferencing (eg, Zoom [Zoom Communications] and Microsoft Teams) between December 12, 2023, and July 29, 2024. Interviews were facilitated by the lead author (RMB), one of the research team members (MKT), or both, who were trained in qualitative interviewing techniques and followed a semistructured guide designed to promote open discussion.

XSL•FO
RenderX

The interview guides were developed based on the COM-B model domains, including motivation, opportunity, and capability [11]. Open-ended questions were structured to elicit participants' perspectives related to tracking symptoms and signs relevant to cardiovascular health. Patients were asked about their experiences tracking their own symptoms and signs, whereas medical team participants were asked about their perspectives on patients' tracking behaviors. Topics included current tracking practices, contextual factors influencing tracking (eg, available tools and time constraints), motivational factors, and perceptions of potential digital tools to support tracking. Example prompts included: "How do you currently keep track of your own/your patients' signs and symptoms?" (capability), "Can you describe any opportunities or external factors that help you track signs and symptoms?" (opportunity), and "Can you describe your reasons for tracking signs and symptoms?" (motivation). The full interview guides are provided in Multimedia Appendix 1.

Interviews lasted approximately 60 - 90 minutes. All interviews were audio- and video-recorded with the participant's permission, transcribed using the auto-generated transcript from Zoom or Teams, and reviewed and corrected, when necessary, by a research team member (MKT). Participants were given the option to turn their camera on or off. Participants were assigned unique identifiers not associated with personal identifying information. Participants received an electronic US $25 gift card delivered via email upon completion of the interview.

Sociodemographic information from patients (age, sex, race, ethnicity, education, employment, income, height, and weight) was collected via REDCap surveys. Similar demographic information was collected verbally from medical team participants before interviews, including age, sex, race, ethnicity, job position, and years of experience in their current role.

Data Analysis

Demographic and medical characteristics were analyzed using descriptive statistics. Rapid qualitative analysis (RQA) was applied to analyze the one-on-one interviews [13-15]. RQA is a team-based qualitative approach in which research team members review audio recordings and transcripts, summarize key points, and identify patterns across interviews to generate themes.

A total of 5 study team members (RMB, MKT, SMSG, VPA, and AG) were involved in transcript review, data summarization, and were adequately trained in RQA. Research assistants first reviewed and corrected auto-generated transcripts for accuracy. Following this step, a researcher (RMB) reviewed each transcript and interview recording and identified segments corresponding to the COM-B domains and subdomains. Relevant excerpts were grouped according to these domains and further categorized as facilitators or barriers.

Each transcript was then independently reviewed by a second researcher (MKT), who repeated the process while having access to the initial coding for comparison. After double review, identified themes and supporting quotes were entered into a structured database to allow for comparison across participants. The research team met regularly to reconcile interpretations and ensure consistency.

Themes were finalized by examining patterns across participants and grouping similar concepts within COM-B subdomains. Because each subdomain is inherently aligned with a COM-B domain, themes were organized accordingly within capability, opportunity, or motivation and illustrated with representative quotes, with subcomponents (eg, physical or psychological capability; physical or social opportunity; and automatic or reflective motivation) used for classification.

Ethical Considerations

This study was approved by The Ohio State University Institutional Review Board (IRB #2021C0018). All participants provided informed consent before participation. Interviews were audio-recorded with participant permission. Identifying information was removed and replaced with unique identifiers to maintain confidentiality.

Results

Participant Characteristics

Participant demographic and clinical characteristics are summarized in Table 1.

[a]Not applicable.

[b]% value not applicable.

In total, 12 patients with cancer participated in interviews. The mean age was 65.3 (SD 12.6) years, and participants were evenly distributed by sex (6/12, 50% female). Most identified as White and non-Hispanic (10/12, 83.3%). The mean BMI was 26.9 kg/m² (SD 4.53), with 41.7% (5/12) classified as overweight and 33.3% (4/12) classified as obese. The majority had completed a graduate or professional degree (7/12, 58.3%) and were retired or disabled (10/12, 83.3%). The most frequently reported annual household income category was US $100,000-US $199,999, representing 41.7% (5/12) of participants. Cancer diagnoses included acute myeloid leukemia (3/12, 25%), breast cancer (2/12, 16.7%), and a range of other malignancies represented in smaller frequencies. Participants reported receiving multiple cancer-directed therapies, including chemotherapy (6/12, 50%), radiation (5/12, 41.7%), tyrosine kinase inhibitors (4/12, 33.3%), stem cell transplant (4/12, 33.3%), hormonal therapy (3/12, 25%), surgery (3/12, 25%), immune checkpoint inhibitors (1/12, 8.3%), and other therapies (4/12, 33.3%).

A total of 12 medical team members were interviewed. Most participants were female (7/12, 58.3%). The mean age was 37.8 (SD 6.4) years, and participants had been in their current position for a mean of 4.5 (SD 2.78) years. Participants identified as White and non-Hispanic (6/12, 50%), Asian (3/12, 25%), White and Hispanic (1/12, 8.3%), Black or African American (1/12, 8.3%), or multiple races or ethnicities (1/12, 8.3%). Professional roles included cardio-oncologists (4/12, 33.3%), oncologists (3/12, 25%), radiation oncologists (1/12, 8.3%), and allied health professionals, including a nurse practitioner, physical therapist, exercise physiologist, and dietitian (each 1/12, 8.3%).

Qualitative Themes

Themes were organized by COM-B domain and categorized as facilitators or barriers. Table 2 summarizes the themes identified among patients and medical team participants, along with the number of participants who endorsed each theme. Illustrative quotes can be found in Multimedia Appendix 2.

[a]COM-B: capability, opportunity, motivation–behavior.

[b]Not applicable.

Within the capability domain, 3 facilitator themes and 4 barrier themes were identified among patients, compared with 2 facilitator themes and 1 barrier theme among medical team participants. Opportunity included 3 facilitator themes and 2 barrier themes among patients, and 4 facilitator themes and 3 barrier themes among medical team participants. Within the motivation domain, 4 facilitator themes and 3 barrier themes were identified among patients, while 4 facilitator themes and 2 barrier themes were identified among medical team participants.

Digital health solution features were also described and mapped to COM-B domains. Among patients, 5 motivation-related, 3 opportunity-related, and 3 capability-related features were identified. Among medical team participants, 2 motivation-related features and 1 feature related to opportunity and capability were identified.

Domain: Capability

Overview

In the COM-B framework, capability refers to an individual’s capacity to engage in a behavior. Capability includes psychological capability, such as knowledge, cognitive skills, and memory processes, and physical capability, such as the physical ability to perform the behavior. In the context of cardiovascular symptom tracking, capability reflects whether patients with cancer and medical team participants possess the knowledge, skills, and abilities necessary to monitor and interpret signs and symptoms. We identified 3 facilitator themes and 4 barrier themes among patients, and 2 facilitator themes and 1 barrier theme among medical team participants. Patients described varying levels of awareness of cardiotoxicity risks and challenges with real-time documentation, while medical team participants noted difficulty attributing symptoms specifically to cardiotoxicity.

XSL•FO
RenderX

Psychological Capability

The first theme related to knowledge of cardiovascular risk. Medical team participants described awareness that certain cancer treatments increase the risk of CVD. In contrast, although patients described awareness of their symptoms, just over half reported being aware that their cancer treatment could increase cardiovascular risk. Some patients reported that they had not been informed about the potential cardiac effects of cancer treatment. As some patients described:

> *They tested my heart before I was allowed to have the transplant, but I don't believe they said anything about the risk to my heart causing any heart problems.*
>
> *I never really thought to ask about well, how will this affect my heart, or will this affect my heart in a bad way, or whatever.*
>
> *No, we didn't discuss that [increased cardiovascular risk]. I don't remember. Well, I don't, I don't remember them discussing that, but I guess if I had looked at the papers that come with all the drugs that one drug that they took me off of definitely can impact the heart can be a side effect.*

Medical team participants described obtaining information about signs and symptoms during clinical encounters and noted difficulty determining whether symptoms were related to cardiotoxicity, given the variability in patient presentation. As one medical team participant stated:

> *They're not always related to cardiotoxicity, it could just be coincidental…but then, other times, it's clearly due to their cardiotoxicity of their cancer therapy.*

Most patients reported that their medical team had asked them to track signs and symptoms, and some described already monitoring select measures. However, several patients expressed uncertainty about which information to track and reported challenges documenting symptoms in real time. Some patients also reported relying on memory to recall symptoms between appointments rather than documenting them in real time. Only a subset of patients described using systematic tools, such as journals or applications, to record cardiovascular symptoms over time.

> *I don't know what else would be important to track of the, you know, what's being tracked. Blood pressure, all this other stuff.*
>
> *You know, [oncologist name] has been asking me, and once again this is my recall. I could not be remembering correctly. But he, you know, he mainly asked, "Do you have chest pain? Do you have this? Do you have that?" But I haven't been able to like, pull out a notebook and say, "On February third I had this and February second…"*

Finally, some patients noted that their lack of tech-savviness was a barrier to digital tracking. As one patient noted:

> *Oh, you gotta, you gotta keep in mind, I'm a bit technologically challenged.*

Physical Capability

Physical capability refers to the physical capacity to perform a behavior. In the context of tracking cardiovascular signs and symptoms, this includes whether patients feel physically able to consistently monitor and document symptoms in their daily lives.

Some patients described that severe symptoms, such as fatigue or feeling unwell, limited their ability to consistently track signs and symptoms. When symptoms were most burdensome, tracking was sometimes deprioritized or not completed at all.

Domain: Opportunity

Overview

In the COM-B framework, opportunity refers to external factors that make a behavior possible or prompt it. Opportunity includes both social (interpersonal influences, cultural norms, and professional roles) and physical (environmental resources, tools, time, and system-level structures) opportunities. In the context of cardiovascular symptom tracking, opportunity reflects the extent to which the clinical environment, social networks, and available tools support or constrain tracking behaviors for both patients with cancer and medical team participants. We identified 3 facilitator themes and 2 barrier themes among patients, and 4 facilitator themes and 3 barrier themes among medical team participants. Both groups highlighted patient–medical team participant encounters, social support, and tool access as facilitators, while time constraints and limited standardized resources emerged as key barriers.

Social Opportunity

The first theme identified by both patients and medical team participants was the role of patient–medical team encounters in shaping tracking behaviors. Most medical team participants described obtaining information about signs and symptoms during follow-up visits. Similarly, most patients reported that tracking was more likely to occur when their medical team explicitly asked them to monitor specific signs and symptoms between appointments. Conversely, some patients described that when tracking was not requested, they were less likely to engage in monitoring. For example, as 2 participants noted:

> *…during treatment for radiation for like esophagus cancer, for example, it's a five and a half week long treatment. So, we see them every week. They, you know, they kind of report what's going on every week.*
>
> *…I think my doctors definitely help, obviously. But they they've been awesome, and even in terms of explaining like, why, it's important. I think that's like a huge thing that sometimes providers miss, is explaining why specifically we're tracking these things and why it's important that we're kind of tracking them for ourselves, what they could in indicate in the future. And then they've also been very good at kind of explaining everything, and the process of how to do that.*

Another theme identified by both groups was the role of social support (ie, family, friends, and social support groups) in tracking signs and symptoms. Medical team participants

XSL•FO
RenderX

described that family members and friends could contribute additional information about patients' symptoms and help reinforce monitoring behaviors (eg, medications and blood pressure). For example, 1 medical team participant stated:

> *So, their family and friends are huge in getting the full picture of the patients a lot of times… So, getting all the information and, or, tracking like you said, tracking symptoms, making sure they're taking their medication, making sure they're taking their blood pressures, not downplaying their blood pressures if there's something that should be concerned.*

Patients also described family members and friends as providing support for tracking, including encouragement and concern when symptoms occurred. One patient stated:

> *My husband has been great cause he wants me to feel good. So, I think, having like a support system of people that want you to feel as good as you can and are concerned when you don't feel good and kind of want to mark that, that's important.*

A related theme among medical team participants involved staff roles in communication and follow-up. Participants described nurses as frequently serving as a point of contact between patients and oncologists. Some medical team participants also described workload and staffing constraints that affected their ability to follow up on patients' signs and symptoms outside of scheduled visits. For example, 1 medical team participant stated:

> *I don't have the bandwidth to call every patient and check on them and the patients I see here on Wednesday. [Nurse's name] helps with that.*

Physical Opportunity

Among both patients and medical team participants, most reported using physical and digital tools to track signs and symptoms. Most patients reported using paper-based tools (eg, notebooks, binders, or written logs). Patients also described using digital tools (eg, note-taking applications, meditation or glucose monitoring apps, blood pressure cuffs, and KardiaMobile) and device features (eg, alarms) to monitor signs and symptoms. A few patients reported not using any applications to track signs or symptoms. Some patients reported that having physical or digital tools organized in a single location helped with tracking. For example, 1 participant noted:

> *I found in life that it helps to be a little more organized. You know I mentioned. I try to always have the blood pressure cuffs in a one place, and it's taken me a long time in life to realize that being organized really helps.*

Most medical team participants described limited availability of paper-based or digital tools to provide to patients for tracking. Participants on the medical team reported lacking standardized resources to monitor patients between visits. For example, 1 medical team participant stated:

> *I think leveraging, like, 21st century technology to help patients, like, better identify and capture their symptoms, and then to also help them kind of engage in the preventative, or, you know, meaningful cardiac preservation or survivorship activities is really kind of a big part of the future.*

Another theme identified among both the medical team and patients was the time barrier. Most medical team participants consider time constraints to be a major barrier to understanding trends in patients' signs and symptoms. Similarly, many patients mentioned that finding time to track their signs and symptoms was a common obstacle.

> *So, I think cause sometimes, especially when I was working full time and also trying to like manage treatments and stuff, it just felt like there was such a limited amount of time and memory to do those things [tracking].*

Domain: Motivation

Overview

Motivation within the COM-B model refers to processes that direct and energize behavior. It includes reflective motivation, which involves conscious decision-making, planning, and evaluation of outcomes related to tracking behaviors, and automatic motivation, which involves emotional responses and habitual processes that influence engagement in tracking cardiovascular symptoms and signs. Themes were identified within both reflective and automatic motivation among patients and medical team participants. We identified 4 facilitator themes and 3 barrier themes among patients, and 4 facilitator themes and 2 barrier themes among medical team participants. Patients described reassurance and a sense of control as motivating tracking, while survivorship demands and emotional distress could diminish engagement; medical team participants valued tracking for clinical decision-making but expressed concern about information volume and actionability.

Reflective Motivation

Patients identified the perceived value of monitoring for health management and planning. Patients reported recognizing the importance of tracking their cardiovascular symptoms and described this recognition as motivating their engagement in tracking behaviors. Participants reported that monitoring contributed to a clearer understanding of their symptoms and allowed them to observe patterns or changes in symptoms over time. For example, 1 patient stated:

> *The one thing that I enjoy is being able to look at the data. I mean, that's just my thing. I like being able to look and see my trends where I've been, where I'm going.*

Another patient shared:

> *Honestly, I think that knowledge and data are kind of like a huge piece of mind for me personally like being to look able to look at trends especially like makes me think about chemo both with, you know, the signs of like my blood pressure, my heart rate, but also with the symptoms being able to kind of plan how I'm going to feel, I know on Day 5. I'm going to feel, you know, the most tired, and things like that. Allows me to kind of find the best way to live my life to the max, you know.*

XSL•FO
RenderX

However, some patients reported that when the medical team participants did not emphasize the importance of monitoring, they were less likely to prioritize tracking. Participants described reduced urgency or engagement when tracking was not explicitly discussed during clinical encounters. One patient noted:

> *I think that's like a huge thing that sometimes providers miss, is explaining why specifically we're tracking these things and why it's important that we're kind of tracking them for ourselves, what they could in indicate in the future.*

The second theme identified among patients was the use of tracking signs and symptoms to inform planning of daily activities and life events (eg, travel, holidays, and family events). Patients described using tracked information to guide their activities, adjusting plans based on how they felt or anticipated feeling. One patient described avoiding travel during treatment due to anticipated side effects and stated:

> *If I know when I'm going to be tired, I'm not going to make plans for those days. I'm going to try to give myself rest. But then, on the days where I know I start ticking up, then I know that I can start making plans with people, or we can choose to take a trip at that time.*

Some patients also described feeling overwhelmed by the demands of managing their health, which they reported affected their engagement in tracking. One participant shared:

> *I think it gets to be just a lot sometimes. Both logistically, in terms of like, there's so many appointments, there's so many medications. There are so many points, again, of like data, of like taking care of yourself, that sometimes you're just like, I want to sit on this couch all day. I don't want to think about any of this crap, like I need a day or 2 or 3, you know.*

The first theme identified among medical team participants was the use of signs and symptom data to inform clinical decision-making. Medical team participants described using PROs and other tracking data (eg, EMR data) to guide treatment adjustments and medication management. Participants also described tracking data as important for monitoring and identifying changes in cardiovascular health status. For example, 1 medical team participant stated:

> *But having better kind of updates on their symptom progression will allow us to better manage their cardiotoxicity or cardiovascular disease that may be independent from their cancer, cancer therapy.*

Medical team participants also described using symptom-tracking data to address specific patient complaints and inform clinical management decisions. Participants noted that tracking data provided additional context when evaluating symptoms. For example, 1 medical team participant stated:

> *You ask them whether they're doing okay, whether they're having any symptoms. If they're having any symptoms, then you try to make adjustments to the medications.*

In contrast, some medical team participants described information overload as a potential barrier to encouraging tracking. Participants noted concerns about receiving large volumes of patient-generated data and the time required to review it. For example, 1 medical team participant stated:

> *You like run the risk of collecting too much information, and, you know, kind of overburdening… You know, everybody's busy nowadays. And so, like sorting through you know, like reams of paperwork is not necessarily gonna be super helpful.*

The second theme identified among medical team participants was encouraging tracking to obtain information about patients' health outside the clinic, in their real-world environments. Participants described that clinical measurements may differ from those recorded at home and that tracking between visits provides additional context about patients' status. For example, 1 medical team participant stated:

> *Usually, I ask them, you know, "When you go home over the next, you know, month or so before I see you next, I want you to write down your blood pressure at different times of the day and make sure that you bring that back. So I know, you know, is your blood pressure really high at home, or is it just high in clinic because you're anxious?"*

Medical team participants described patient motivation as influencing engagement in tracking, noting variability in how consistently patients monitored and reported symptoms. Participants also described that asking patients to track signs and symptoms could add to patients' responsibilities, which, in some cases, limited engagement. At the same time, medical team participants reported encouraging patients to track their health between visits and emphasized the importance of patients being aware of changes in their health status. Some participants described prompting patients to take an active role in monitoring their health. For example, 1 medical team participant noted:

> *The big thing is for them to be self-aware of what's going on… So, being more self-sufficient and taking control of their health is the biggest goal, because, like so, we can't hold their hand forever.*

Automatic Motivation

Medical team participants described routinely asking about signs and symptoms during patient encounters, characterizing this practice as part of standard workflow. Similarly, several patients described tracking as part of their daily routine. Patients reported that engaging in routine tracking was reassuring and associated it with feeling more in control of their health. One patient shared:

> *It's just kind of a routine. I guess it just kind of reassures me that I know what's right. I just feel like it's probably, you know, a lot psychological, but it feels like I'm keeping track of something, my body, you know, and I've got control of something right?*

The second theme among patients revealed that emotional processes can influence the tracking of signs and symptoms. Patients mentioned concerns about their health and the potential

XSL•FO
RenderX

for worsening conditions, which may motivate them to monitor their symptoms closely, as they seek to anticipate changes and mitigate negative outcomes.

> *I probably subconsciously was more apt to worry about the cancer coming back. I probably worried more about any symptoms or anything and contributing to that.*

In contrast, some patients described that frequent or intense tracking became distressing or anxiety-producing. One participant shared:

> *Sometimes I see myself as going overboard with tracking so much that you become too somatically focused, and it starts becoming anxiety-producing. Because you're always tuned into every breath, and this and that, rather than living your life and having fun and doing things that are fun.*

Digital Health Solution Features

Both patients and medical team participants described specific features that could support cardiovascular symptom tracking.

Among medical team participants, the most frequently endorsed feature was reminders, alerts, or triaging capabilities (7/12). Medical team participants described the value of automated prompts to encourage patient logging, as well as alert systems that would highlight abnormal values and help prioritize review. One participant noted:

> *I will say reminders and things like keeping track of the blood pressure log, etc., through the phone, that works.*

Another medical team participant emphasized the importance of triaging information efficiently:

> *... like you only get the red flag if it's a lab that's abnormal or it's an imaging say, that's abnormal. So, in theory, when you're going through your inbox, you kind of triage, what's what I really need to like open up and look at versus it's probably normal.*

Of the 12 medical team participants, 6 highlighted the importance of tracking functionality that allows visualization of trends over time. Medical team participants described wanting both patients and medical team participants to see symptom progression and recovery patterns:

> *I've often thought like how nice it would be to, to, you know, kind of keep track of patients when they're not in my clinic to make sure that everything's going okay, and they're not in trouble, but then also to for the patient to kind of log things and kind of see their progress and see whether you know how they've progressed and how they're recovering. So, I think it'd be, you know, valuable in multiple aspects.*

Moreover, 4 medical team participants emphasized the potential benefit of incorporating reward systems or positive reinforcement to promote long-term tracking behaviors. One participant explained:

> *If they have some other commendation for whatever they're done in an app then they're more likely to do… and that's supposed to reinforce and something like that would definitely help people start doing or sticking onto the habit.*

Finally, 5 medical team participants stressed that any digital solution must be simple and user-friendly, with clear and actionable outputs:

> *I think if the app is simple, I think it could be helpful, that the app is simple and captures relative symptoms that are, that are useful, and that can be turned into actionable items that would be useful.*

Discussion

Principal Findings

This qualitative study examined barriers and facilitators to cardiovascular symptom and sign tracking from both patient and medical team perspectives, in a cardio-oncology setting, using the COM-B framework. We found that tracking behaviors related to cardiovascular health were shaped by interrelated factors across capability, opportunity, and motivation domains. Patients described variability in knowledge regarding cardiovascular health during and after cancer treatment, including uncertainty about which symptoms or signs to monitor and when to communicate changes. Medical team participants similarly identified gaps in standardized processes for cardiovascular symptom tracking and expressed concerns about time constraints and information burden. At the same time, both groups identified various motivational drivers, including perceived value of monitoring for maintaining cardiovascular health, reassurance, and improved clinical decision-making. Social opportunity, particularly patient–medical team participant communication and family involvement, also emerged as central to supporting tracking behaviors.

These findings suggest that cardiovascular symptom tracking in cancer care is not limited by awareness of cardiotoxicity alone but is influenced by clarity of expectations, workflow integration, and alignment between patient and medical team participant roles.

Comparison With Previous Literature

Randomized trials in oncology have demonstrated that structured electronic symptom monitoring can improve some clinical and PROs. For example, in the PRO-TECT cluster-randomized trial, weekly electronic symptom reporting reduced visits to the emergency department and delayed deterioration in physical function and HRQoL among patients with metastatic cancer [7]. Similarly, the use of an EMR-integrated symptom and needs monitoring in an ambulatory, racially, ethnically, and linguistically diverse oncology population (My Wellness Check [American Heart Association]) has been associated with reductions in emergency department usage and hospitalization [8]. These findings are consistent with broader evidence that PRO monitoring enhances symptom detection and clinical communication, supporting improved system-level outcomes in oncology care [16].

These studies establish the potential clinical impact of systematic symptom monitoring but do not examine the behavioral mechanisms influencing long-term engagement in symptom

XSL•FO
RenderX

tracking, particularly for cardiovascular risk in cardio-oncology contexts.

Our findings extend this literature by identifying capability-, opportunity-, and motivation-related determinants influencing the adoption and implementation of cardiovascular symptom tracking. Whereas previous trials primarily evaluate downstream clinical outcomes, our qualitative data illuminate upstream behavioral and contextual factors (including knowledge gaps, workflow constraints, uncertainty about symptom attribution, and perceived role boundaries) that may influence the feasibility of structured cardiovascular monitoring.

Our findings align with the qualitative work on cardiotoxicity-focused mHealth tools, where both patients and medical team participants expressed interest in digital cardiovascular symptom tracking but stressed the importance of clear reporting guidance for urgent symptoms, integration with existing clinical systems, and minimal workflow disruption [10]. Additionally, a recent systematic review of mHealth tools for cardiovascular health in patients with cancer found a fragmented array of technologies and measures, limited integration with electronic health records (EHRs), and few studies specifically addressing structured cardiovascular symptom collection [9]. More broadly, mHealth technologies enable continuous monitoring of both physiological and patient-reported data, but their implementation is often constrained by variability in engagement and limited integration into clinical care workflows [9], aligning with recent implementation-focused reviews demonstrating that the effectiveness of remote symptom monitoring depends on patient engagement, workflow integration, and actionable use of reported data [16].

Together, these studies suggest that although digital monitoring tools are increasingly available, implementation may depend less on technological capability alone and more on alignment with behavioral determinants and system-level structures. This aligns with findings from previous work on EHR-integrated interventions, which highlight that successful implementation depends on alignment with clinical workflows, defined roles, and manageable data flows rather than technology alone [17,18]. By applying the COM-B framework, our study provides a behavioral lens to inform the design and integration of cardiovascular symptom-tracking approaches in oncology settings. Notably, cardiovascular symptom tracking may differ from general oncology symptom monitoring in several respects: the overlap between cardiotoxicity-related and cancer- or treatment-related symptoms, the evolving nature of cardiovascular risk across the cancer care continuum, and the need for coordination across oncology and cardiovascular specialties.

Implications for Behavioral Determinants and Implementation

Cardiovascular symptom tracking in cancer care emerged as a shared behavior shaped by capability, opportunity, and motivation among both patients and medical team participants. Patients were often unsure which cardiovascular symptoms or signs should be tracked and when changes should prompt communication, suggesting that education alone may be insufficient without clear expectations for monitoring and reporting. Although patients generally recognized the relevance of cardiovascular health, many described ambiguity about expectations for monitoring and reporting. Medical team participants similarly described variability in how cardiovascular monitoring was addressed and incorporated into routine care. Such variability likely reflects differences in clinical context, patient complexity, and workflow demands, underscoring the importance of clarifying expectations and responsibilities when considering strategies to support consistent tracking practices. These challenges highlight the importance of clearly defining which cardiovascular symptoms should be tracked and when reporting is warranted, particularly in contexts where symptom attribution is uncertain. They also suggest that effective tracking approaches may need to be integrated into existing workflows and support coordination across oncology and cardiovascular care teams, agreeing with broader systematic reviews identifying knowledge gaps, workflow constraints, and variability in perceived value as central barriers to PRO implementation [19].

Opportunity constraints were prominent. Time limitations, competing priorities, and concerns about information burden shape whether tracking can be integrated into routine workflows. Previous implementation research in oncology has shown that monitoring systems are more likely to be adopted when embedded within existing clinical processes, supported by defined triage pathways, and aligned with established roles rather than added as an additional task [7-9]. EMR-integrated monitoring programs that include automated alerts and predefined response workflows have been described as feasible in ambulatory oncology settings when these structural supports are in place [20]. Observational analyses have also reported associations between participation in such programs and health care usage outcomes [8]. More broadly, implementation science literature emphasizes that long-term adoption of digital monitoring systems depends on minimizing disruption to clinical workflows and reducing cognitive and time burden on medical team participants [21], along with recent umbrella reviews highlighting workflow disruption, limited integration with EHRs, and time and resource constraints as key barriers to implementing patient-generated health data systems in oncology care [19]. The findings of this study add to this literature by identifying behavioral factors that may influence uptake of cardiovascular-specific tracking within cardio-oncology settings.

Motivational influences were equally apparent. Patients described reassurance and a sense of control as reasons for engaging in monitoring, whereas uncertainty about symptom meaning sometimes contributed to inconsistent reporting. Medical team participants were more inclined to engage with monitoring data when it was perceived as clinically meaningful but expressed concern when data volume was high or when response expectations were unclear. This aligns with previous real-world implementation studies demonstrating that long-term engagement with electronic PRO systems may vary over time and is influenced by reminder systems, medical team participant reinforcement, perceived relevance to care, and integration into clinical workflows [22]. These findings are also consistent with previous research showing that perceived usefulness and ease of use are central determinants of engagement with digital health

XSL•FO
RenderX

and self-monitoring tools in chronic disease management [23]. These perspectives indicate that perceived usefulness and manageable data flow may be important for long-term engagement over time.

Taken together, these findings indicate that knowledge clarity, workflow integration, and perceived value operate in combination. Introducing a digital tool without addressing expectations or integrating tracking into existing care processes may offer limited benefit.

Implications for Digital Health Design

Our findings inform the design of digital tools intended to support cardiovascular symptom tracking in cancer care. For patients, tools may benefit from providing clear guidance on which symptoms and signs to monitor and when changes should prompt communication with the medical team. Educational components embedded within the tracking process may help address gaps in psychological capability while avoiding additional burden during clinical encounters. Tools should also account for the overlap between cardiovascular, cancer-related, and treatment-related symptoms to avoid excessive data collection that increases patient burden or generates information that is not clinically actionable.

Medical team participants emphasized that digital tracking must be integrated into existing EMR systems and supported by clear triage processes. Previous implementation work in oncology indicates that feasibility is strengthened when monitoring systems include defined response workflows and designated roles for follow-up [20]. Broader implementation-oriented scholarship in digital oncology similarly emphasizes the importance of integrating patient-generated health data into existing clinical infrastructure and aligning digital tools with established workflows [21].

Broader mHealth research in populations with cancer has documented limited integration of patient-generated data into clinical systems and substantial variability in measures captured across platforms [9], echoing findings from recent reviews that emphasize the need for integrating patient-generated health data into clinical workflows and ensuring data are actionable at the point of care [19]. Participants emphasized that tracking is useful only when incoming information can be interpreted and acted upon efficiently. However, actionability may depend not only on data integration, but also on the availability of clinical resources, referral pathways, and support services that allow medical teams to respond to identified needs. For example, symptom or risk data may be more actionable in settings where patients can be referred to embedded supportive care, rehabilitation, behavioral health, nutrition, or cardiovascular services. In contrast, when follow-up services are unavailable, poorly coordinated, or associated with additional patient costs, tracking may generate information that is difficult to act on and may increase the burden for patients and medical team participants. This reflects broader challenges in translating patient-generated data into actionable clinical insights, particularly when data streams are not standardized or integrated with existing decision-support systems [9]. From an informatics perspective, this underscores the importance of systems that support interpretation within clinical workflows rather than treating data as isolated data entries [21].

In summary, digital cardiovascular symptom tracking systems should prioritize clarity, workflow alignment, and actionable outputs rather than simply increasing data volume. Participants' perspectives also indicate that minimizing cognitive burden and time constraints for both patients and medical team participants may be central to feasibility. Clear expectations regarding symptom relevance and defined response processes may support more consistent engagement over time.

Strengths and Limitations

This study has several strengths. First, it included perspectives from both patients and medical team participants, allowing examination of cardiovascular symptom tracking as an interdependent behavior rather than a unidirectional patient responsibility. Second, use of the COM-B framework provided a structured approach to organizing barriers and facilitators across psychological, social, and environmental domains while maintaining analytic transparency. Third, interviews focused specifically on cardiovascular symptoms and signs tracking in the cardio-oncology context, contributing to a growing body of research that has largely examined symptom monitoring more broadly in oncology.

Several limitations should be considered. Participants were recruited from a single, specialized cardio-oncology clinic and were predominantly highly educated and White, which may limit transferability to other institutions with different workflow structures or to more diverse and underserved populations. These findings may not reflect the experiences of individuals with lower health or digital literacy, limited access to technology, or those receiving care outside of specialized clinic settings. As with all qualitative studies, findings reflect self-reported perceptions and experiences rather than directly observed behaviors. We did not measure actual tracking adherence or clinical outcomes and therefore cannot draw conclusions regarding the effectiveness of specific tracking approaches. Additionally, because all interviews were conducted with participants who had access to videoconferencing capability, they may have been more interested in cardiovascular health or digital tools than nonparticipants, potentially introducing selection bias. Finally, while the COM-B framework provided a useful organizing structure, alternative theoretical approaches may have highlighted different aspects of tracking behavior. Future studies should include more diverse and community-based populations to better understand how cardiovascular symptom tracking can be implemented across different health care settings.

Conclusions

Cardiovascular symptom tracking in cancer care is a shared behavior requiring coordinated engagement between patients and medical team participants. The use of the COM-B framework allowed identification of capability, opportunity, and motivation factors that shape how cardiovascular symptoms and signs are monitored and communicated in cardio-oncology settings. Participants described ambiguity regarding expectations across both groups. Patients emphasized uncertainty about which

XSL•FO
RenderX

symptoms warranted tracking and about expectations for communicating symptom information, whereas medical team participants described time pressures, concerns about information burden, and limited standardized processes for reviewing and responding to symptom information. Medical team participants expressed concern about receiving large volumes of symptom information without clear mechanisms for prioritization or response, while patients described reassurance and a greater sense of control as benefits of tracking. Efforts to strengthen cardiovascular symptom tracking may benefit from addressing behavioral determinants alongside technological considerations. Digital systems that provide clear guidance, align with clinical workflows, and support actionable interpretation of symptom reports may facilitate engagement and perceived value. Future studies should examine how these behavioral insights inform implementation strategies and evaluation of cardiovascular monitoring approaches in routine cancer care.

Acknowledgments

Abstract

Background: Mobile health (mHealth) apps offer new opportunities to support cancer survivors in managing their health, adopting healthier lifestyles, and increasing awareness of recurrence symptoms. However, despite their potential, little is known about survivors' use of such tools in routine follow-up care, or which factors are associated with their engagement.

Objective: The aim of the present study was to identify survivor characteristics associated with the use of the Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology (LETSGO) app. In addition, we aimed to describe engagement patterns among gynecologic cancer survivors during the first year of follow-up after treatment.

Methods: App data from 378 participants in the intervention group of the LETSGO multicenter clinical trial were included in the analysis. Using multiple logistic regression, we analyzed app data from the first year of LETSGO app use to identify participant characteristics associated with use. In addition, we described the frequency of user interactions with app features and identified the most frequently used features during the first year of the intervention in a subset of 49 participants with complete app log data.

Results: Of the 378 participants in the intervention group, 267 (70.6%) used the LETSGO app at least twice and were defined as app users. The median age of app users was 63 (53-70) years vs 70 (60-78) years among app nonusers (P<.001). App use was associated with younger age (odds ratio [OR] 0.96 per year, 95% CI 0.93 - 0.99; P=.003), higher education (OR 2.2, 95% CI 1.1 - 4.6; P=.03), and having ovarian cancer (OR 2.9; 95% CI 1.1 - 7.5; P=.03). The LETSGO app included a monthly reminder for symptom self-registration, and monthly peaks in the symptom monitoring feature corresponded with the timing of this reminder. App log data from the full first year of the intervention were available for 49 participants. Among these, user engagement was highest for the physical activity and activity goal-setting features, whereas the disease information feature showed steady but less frequent use.

Conclusions: Our findings indicate that LETSGO app use was associated with survivor characteristics such as age, education level, and cancer type. Considering user characteristics when tailoring mHealth apps may support user engagement in digital follow-up care and inform the development of mHealth tools that better align with survivors' needs and preferences. Engagement with the LETSGO app during the first year of follow-up among a subset of participants with complete app log data was highest for the physical activity and activity goal-setting features. The pattern of symptom registration following reminders indicates that scheduled prompts may support regular app engagement, while steady use of the disease information feature suggests an ongoing need for accessible health information during follow-up.

Introduction

Gynecologic cancer and its treatment can have a profound impact on survivors' well-being, with many women experiencing physical and psychosocial late effects [1-3]. As life expectancy following cancer treatment continues to improve, the focus of care has shifted from survival alone to promoting long-term well-being and quality of life [4-7]. Consequently, follow-up care has become an important component of survivorship, not only for monitoring recurrence but also for managing late effects and providing psychological support [8-10]. At the same time, the growing population of cancer survivors places increasing pressure on the outpatient clinics, where most patients are monitored for years after treatment. This underscores the need for more sustainable follow-up strategies that meet survivors' needs and are resource-efficient [10-12].

In this context, empowering cancer survivors to take an active role in managing their own health is increasingly recognized as a key component of future follow-up care. Such empowerment may help reduce the burden on outpatient clinics by enhancing survivors' ability to cope with cancer-related challenges and regain control over everyday life [13]. A central aspect of empowerment is strengthening the self-management skills of cancer survivors to promote self-care, address ongoing needs after treatment, and contribute to more efficient use of health care services [13-16].

Digital interventions, particularly mobile health (mHealth) apps, have shown promise in promoting empowerment and improving quality of life among cancer survivors [17-20]. The mHealth apps are internet-based apps on mobile devices that support health-related activities. Over recent years, an increasing number of mHealth apps have been developed to meet the specific needs of patients with cancer [21-23]. These mHealth technologies can complement health care professionals by providing tailored information, enabling self-monitoring, simplifying access to health care services, supporting behavior and lifestyle changes, and thereby reducing long-term health care costs [24,25]. They can also serve as platforms for collecting patient-reported outcomes, offering valuable insights into symptoms, functional status, and overall well-being without requiring in-person visits [26,27].

The effectiveness of mHealth apps in cancer survivorship for supporting behavior and lifestyle changes, as well as symptom monitoring, depends not only on their design and content but also on regular and sustained user engagement. Research indicates that digital health interventions, including mHealth apps, are effective only when users interact with them as intended [28,29]. Nonadherence, when users fail to use the digital intervention as intended, and attrition, when they discontinue use over time, remain common challenges [30,31]. Therefore, understanding user engagement and user perspectives is essential to improve the effectiveness of mHealth apps [30,32]. Although mHealth apps are increasingly used in cancer survivorship, knowledge regarding how users interact with these technologies over time and which factors influence sustained use remains limited [29]. As mHealth apps usually include more than one feature, it is important to identify which features are most used by cancer survivors because their needs may vary depending on diagnosis and individual characteristics [33].

In the Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology (LETSGO) multicenter clinical trial, we evaluated a new follow-up model involving nurse-led patient education, reinforced with the LETSGO app [16]. The comprehensive LETSGO app was designed to educate patients on late effects after cancer treatment, motivate physical activity, encourage healthier lifestyle changes, facilitate symptom monitoring for recurrence detection, and provide reminders to support physical activity goals in gynecologic cancer survivorship [16].

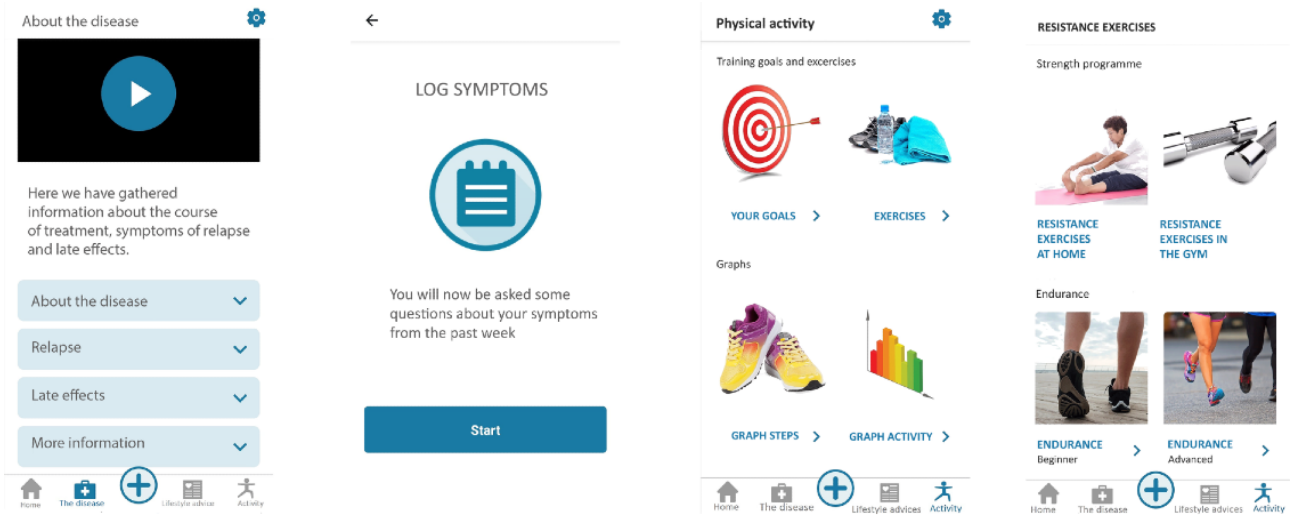
To improve our understanding of user engagement and to support the design and development of future digital follow-up interventions that better meet survivors' needs, this study's primary aim was to examine associations between selected demographic and clinical characteristics and the use of the LETSGO app among gynecologic cancer survivors in follow-up care. A secondary aim was to describe 1-year use patterns, including frequency of use and the most frequently used features.

Methods

Study Setting and Participants

The LETSGO multicenter clinical trial recruited women (N=741) from 12 Norwegian hospitals between December 2019 and February 2023 to test a new follow-up model for routine survivorship care after treatment for gynecological cancer, aimed at enhancing health-related empowerment through education and self-management strategies, as described in the study protocol [34]. Eligible women were aged 18 years or older, had a histologically confirmed diagnosis of ovarian, endometrial, cervical, or vulvar or vaginal cancer, were able to understand Norwegian, and had no cognitive impairments. Patients were assigned to their respective group (intervention group or standard follow‐up group) based on their hospital of residence. At the intervention hospitals, women received alternating nurse-led and physician-led follow-up consultations. The nurses focused on coaching participants in empowerment techniques, reinforced by the multifunctional LETSGO app, which was introduced to the women at the initial nurse-led consultation [34]. This substudy was conducted among 378 (51%) participants in the intervention group and is based on app registration data and app log data from the first year of LETSGO app use.

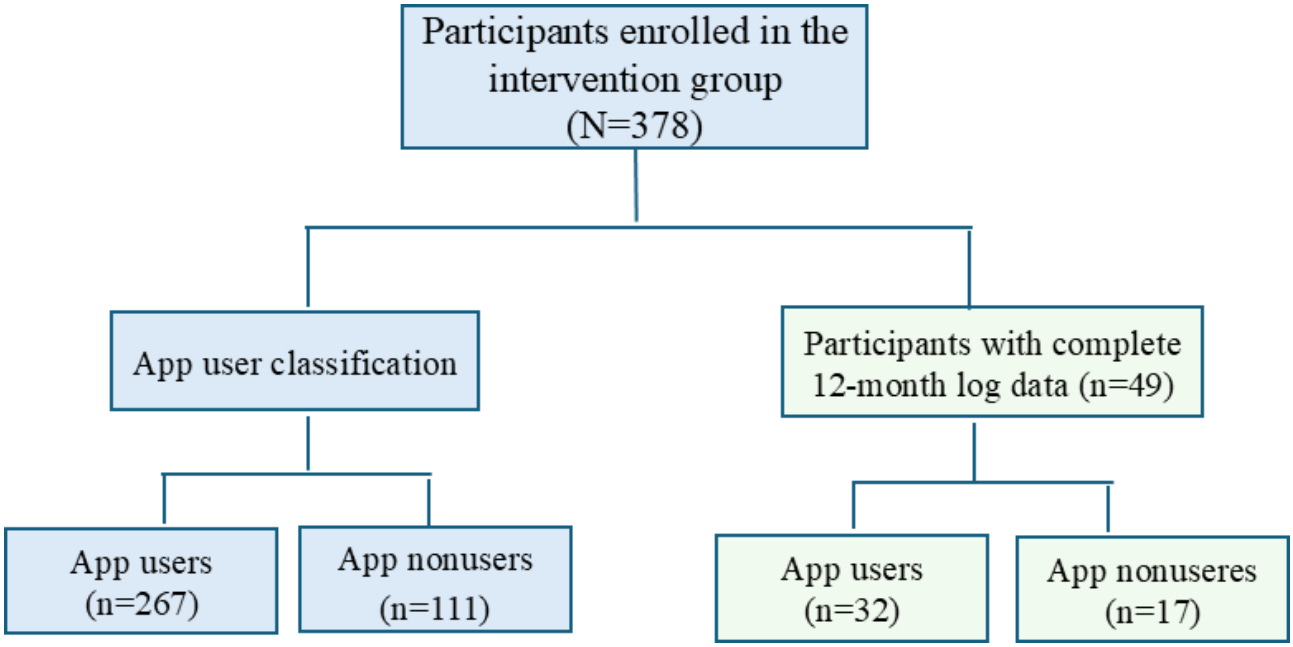
XSL•FO
RenderX



The LETSGO App

The LETSGO app was developed by a multidisciplinary team of experts in the field of gynecological cancer, behavior change, exercise oncology, and IT, alongside user representatives [34]. Its primary goal was to empower women to take a more active role in their own health by providing education and motivation. Pilot testing of the LETSGO intervention and study procedures provided valuable feedback on the app's functionality [35]. In response, technical improvements were made prior to its use in the intervention study. At the first nurse-led consultation, participants received a personal login code for the LETSGO app along with use instructions. Participants could also discuss app-related questions during follow-up consultations with nurses, including receiving help with technical or practical issues related to app use. Each participant registered their cancer type in the app to access diagnosis-specific information and saved the phone number of their outpatient clinic with direct access to the responsible nurse. The LETSGO app, accessible on smartphones and tablets, featured multiple modules, written content, links to external resources, and videos for additional guidance, as shown in Table 1 and Figure 1. Furthermore, the app offered users the option to log their own physical activities and set activity goals. Additionally, they received a wearable activity tracker to monitor their physical activity level (walking steps) [34].

Table . Content of the Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology (LETSGO) app.(Figure 2)



Features	Written content and videos
Contact information	• Telephone number to the responsible nurse
Disease information (ovarian, endometrial, cervical, or vulvar or vaginal cancer)	• Treatment • Signs of recurrence • Late effects • Links to external information
Lifestyle information and coaching	• Dietary guidance • Smoking cessation • Stress management • Yoga and mindfulness instructions
Physical activity	• Physical activity instructions • Resistance exercises • Endurance • Activity goal setting
Electronic reminder	• Electronic reminder to register physical activity • Electronic reminder to register symptoms
Symptom monitoring for recurrence	• 10 items related to cancer recurrence

Figure 1. Screenshots illustrating the core features of the Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology (LETSGO) app (Multimedia Appendices 1-4).

XSL•FO
RenderX

Figure 2. App user classification and availability of complete 12-month app log data.

The monthly monitoring of self-evaluated symptoms potentially indicating a recurrence included 10 items. These items were selected from the European Organisation for Research and Treatment of Cancer (EORTC) item library based on the most frequently reported recurrence symptoms for each type of gynecologic cancer [36]. The app sent users monthly reminders to complete the symptom monitoring questionnaire while also allowing them to complete the same questionnaire whenever needed. If their responses exceeded a predetermined threshold, an alert was triggered in the app, indicating a potential recurrence and advising them to contact the outpatient clinic. The phone number of the nurse at their outpatient clinic was automatically displayed on the screen for easy access.

Data Collection

At baseline in the LETSGO trial, participants completed patient-reported outcome measures, including sociodemographic characteristics (ie, age, BMI, education level, and employment status). Clinical information (ie, diagnosis and treatment modality) was obtained from medical records. These data were stored in the Viedoc software (Viedoc Technologies AB), a secure electronic data capture system, and extracted for inclusion in the analysis dataset. In this study, participants' education level was categorized as primary (≤10 years), secondary (11 - 13 years), or medium or high (≥14 years), and employment status was categorized as 0=no or 1=yes. Cancer diagnosis was categorized as endometrial, ovarian, cervical, or vulvar cancer. Treatment modality was categorized into three groups: (1) surgery only, (2) surgery plus chemotherapy, and (3) chemotherapy plus radiotherapy (with or without surgery) and other treatment combinations. Because of the low number of participants receiving chemotherapy and radiotherapy and other treatment combinations, these were combined into a single category.

All app data included in this study (app registration data and app log data) from the first year of the intervention were retrieved from the Services for Sensitive Data (TSD) platform at the University of Oslo, a secure system for handling sensitive research data. The app data included participant registrations in the physical activity, activity goal setting, and symptom monitoring features.

In addition, app log data capturing use frequency, measured as the number of clicks, were available for the physical activity, activity goal setting, disease information, and lifestyle information and coaching features. However, due to a miscommunication between the research team and the app developers regarding data storage, app log data were not stored from the beginning of the intervention period. Once this was identified, app log data collection was implemented. Consequently, app log data covering the full 12-month intervention period were available for only 49 participants. The analysis of app-use frequency over 12 months was limited to this subset of 49 participants.

App users were defined as those participants who, during the first year of the intervention, registered symptoms (symptom monitoring) at least twice and reported weekly physical activity (physical activity) and/or activity goals (activity goal setting) at least twice. There is currently no consensus on how engagement thresholds in digital health interventions should be operationalized, and our definition was pragmatically chosen to distinguish participants with repeated use of both features from those who did not meet this threshold, while also avoiding unnecessary exclusion of participants with low-frequency engagement [28,30].

Statistical Analyses

All statistical analyses were performed using SPSS Statistics (version 30; IBM Corp).

Participant characteristics were described using descriptive statistics. Continuous variables were presented as medians and ranges, while categorical variables were presented as counts and percentages. Group differences were assessed using the

XSL•FO
RenderX

Mann-Whitney *U* test for continuous variables and the Pearson chi-square test for pairs of categorical variables.

Multiple logistic regression analyses were conducted to identify participant characteristics associated with app use and to examine which groups were more likely to use the app. App use (coded as 0=no and 1=yes) was the dependent variable. Variables considered clinically relevant and potentially associated with app use, including demographic (eg, age, education level, and employment status) as well as clinical characteristics (ie, diagnosis and treatment modality), were entered as possible predictive factors. These independent variables were entered into the analysis simultaneously and treated as covariates, allowing the association between each variable and app use to be estimated while controlling for the others. Multicollinearity between independent variables was assessed, and no evidence of problematic multicollinearity was identified. Odds ratios (ORs) with 95% CIs were calculated to assess the strength of association.

Weekly symptom registrations over the first year of the intervention for all participants (N=378) were summarized to describe overall engagement with the symptom monitoring feature.

A subanalysis of the 49 participants with complete app log data covering the full 12-month intervention period was conducted to assess the frequency of user interactions with the key app features (physical activity, activity goal setting, disease information, and lifestyle information and coaching), and to identify which app features were most frequently used.

The app log data captured the number of user clicks within each feature. Results are presented as bar and line graphs. Differences in demographic and clinical characteristics between participants with complete app log data covering the full 12-month intervention period and those without were assessed using the Mann-Whitney *U* test for continuous variables and the Pearson chi-square test for categorical variables. All tests were 2-sided, and $P<.05$ was considered statistically significant. All results are considered exploratory; therefore, no correction for multiple testing was applied.

Ethical Considerations

The LETSGO study (ClinicalTrials identifier NCT04122235) was approved by the Regional Committee for Medical and Health Research Ethics (REK 2019/11093) and the data protection officers at participating hospitals. Written informed consent covering all aspects of the LETSGO study was obtained from the participants prior to inclusion. The data from the LETSGO app were stored on the TSD platform at the University of Oslo, and sociodemographic and clinical data were stored in Viedoc software.

Results

Characteristics of the Participants

Of the 378 participants included in the analysis, 267 (70.6%) were defined as app users. An overview of participant classification and availability of complete 12-month app log data is presented in Figure 2. Some baseline variables were missing for 39 participants. There were no statistically significant differences between those with and without missing data regarding age ($P=.23$), treatment modality ($P=.38$), and type of diagnosis ($P=.26$). Of those with missing data, 33.3% (13/39) were app users. The median age of all participants was 65 years, and app users were significantly younger than app nonusers (median age 63 vs 70 years). App users had significantly higher education and were more often employed compared with app nonusers (Table 2). Endometrial cancer was the most common diagnosis (221/378, 58.5%).

[a]App users: ≥2 registrations of symptoms and ≥2 registrations of weekly physical activity or activity goals during the first year of follow-up.

[b]App nonusers: Participants who did not meet the definition of app users.

[c]Not applicable.

[d]Participants receiving chemotherapy plus radiotherapy and other treatment combinations were grouped due to low numbers.

Factors Associated With App Use

Participants with missing data on variables included in the logistic regression model were excluded from the analysis, resulting in 337 complete cases included in the adjusted model.

Women with vulvar cancer were excluded from the regression analysis due to the low number of participants in this diagnosis group.

In the multiple logistic regression analysis, adjusted for age, education level, employment status, type of diagnosis, and treatment modality, increasing age was associated with lower odds of app use. For each additional year of age, the odds for app use were approximately 4% lower (OR 0.96 per year, 95% CI 0.93 - 0.99; *P*=.003). Younger participants had higher odds of app use, with a 10-year decrease in age being associated with approximately 50% higher odds of using the app. Participants with secondary education had more than 2-fold higher odds of app use compared with those with primary education (OR 2.23, 95% CI 1.09 - 4.56; *P*=.03). Participants diagnosed with ovarian cancer had higher odds of app use compared with those diagnosed with cervical cancer (OR 2.93, 95% CI 1.14 - 7.53; *P*=.03). Similarly, participants diagnosed with endometrial cancer had higher odds of app use compared with those diagnosed with cervical cancer (OR 3.31, 95% CI 1.16 - 9.49; *P*=.03). Other variables, including treatment modality and employment status, were not associated with app use (Table 3).

Registration in the Symptom Monitoring Feature

Of the 378 participants, 310 (82%) registered symptoms using the symptom monitoring feature at least once, including participants who did not meet the predefined criteria for app use. Symptom registration was most frequent in the first weeks after inclusion, followed by a decline and stabilization over the 1-year period (Figure 3). We observed monthly peaks in registrations that corresponded to the app reminder being sent once per month. However, participants also registered symptoms between reminders, indicating engagement with the feature outside the scheduled prompts.

XSL•FO
RenderX

Figure 3. Weekly number of symptom registrations over the 52-week follow-up period.

App Feature Use Over 12 Months for 49 Participants With Complete Log Data

A subanalysis of frequencies of app use among 49 participants over the first year of intervention showed that the proportion of users who interacted with each feature at least once per month was the highest for physical activity (n=39, 79.6%), followed by activity goal setting (n=29, 59.2%), while disease information and lifestyle information and coaching showed lower but relatively consistent engagement (n=10-20, 20.4% - 40.8%) over time (Figure 4). The median number of uses per month, defined as the number of individual participant registrations within app features, also indicated that physical activity and activity goal setting features were used most frequently (Figure 5). Among the 49 participants with complete log data, the median of app-use frequency was 104 (IQR 54 - 301; range 16 - 10,767). There were no statistically significant differences between participants with app log data covering the full intervention period (n=49) and those without (n=329) regarding age, BMI, education level, employment status, diagnosis, and treatment modality (data not shown).

XSL•FO
RenderX

Figure 4. Proportion of users engaging with each app feature at least once per month during the 12-month follow-up period (n=49).

XSL•FO
RenderX

Together, Figures 2 to 4 illustrate different aspects of app engagement during the first year of the intervention, including symptom registrations over time, the proportion of users engaging with different app features, and monthly use frequency.

Discussion

Principal Findings

In this observational study of 378 gynecologic cancer survivors participating in the LETSGO trial who had access to the LETSGO app as part of the intervention, app use was more common among younger women, those with secondary education, and women diagnosed with ovarian cancer. Symptom registration was highest shortly after inclusion and stabilized over time with monthly peaks corresponding to the app's reminder schedule. In a subanalysis of 49 app users with complete log data, engagement was highest for physical activity and activity goal setting features, while use of the disease information feature remained steady but less frequent.

The inverse association between age and app use aligns with previous studies showing that age may influence engagement with digital technologies, including mHealth technologies [37-40]. An umbrella review of 46 systematic and scoping reviews found that most digital interventions were effective regardless of age, whereas results on actual use and engagement showed greater variation [41]. Our findings align with this, indicating that although digital interventions may be effective across age groups, their uptake and engagement still differ by age. This may reflect differences in digital skills, familiarity with technology, or digital health literacy [42]. Older individuals may experience barriers related to digital health interventions, including lower digital competence, reduced confidence in using technology, lower digital health literacy, and less encouragement from health care providers [43,44].

Previous research [41] has highlighted that education has often been overlooked in existing research, even though it may contribute to the digital gap. Educational level may reflect both digital skills and general health awareness, which are important factors for engaging with digital health interventions. Earlier studies have reported higher app use among individuals with higher (tertiary) education [45,46]. In our study, however, app use was higher among women with secondary education compared with those with primary education. Among women with higher education, there was also a tendency toward higher app use compared with those with primary education, although this difference was not statistically significant. A possible explanation for the lack of a stronger association could be that women with higher education already have greater access to digital health technologies in general, which could reduce their need for this specific app [47]. However, this hypothesis was not directly examined in our study. This disparity underlines the importance of examining how education levels influence both use and sustained engagement with digital interventions in future research.

We found that women diagnosed with ovarian and endometrial cancer had higher odds of app use compared with women with cervical cancer. This finding may reflect differences in the disease trajectory, treatment intensity, and follow-up needs across diagnostic groups. One possible explanation for the observed association among women with ovarian cancer, suggested by previous research, is that ovarian cancer is often associated with greater symptom burden, longer treatment trajectories, and a perceived need for closer follow-up [48,49], which could make digital tools for symptom tracking and support more relevant and useful in their care routines [50].

Regular symptom monitoring may indicate that participants found the feature useful, which is supported by findings from a study reporting higher engagement when patients perceived symptom monitoring as relevant and meaningful for managing their symptoms [51]. In our study, the monthly peaks following reminders suggest that scheduled prompts support sustained engagement among participants. Some symptom registrations occurred outside the immediate monthly reminder pattern. However, the available data do not allow us to determine whether these registrations were self-initiated or delayed responses to reminders.

This finding aligns with previous research showing that structured symptom monitoring can encourage sustained app use over time [52]. Nevertheless, the distinction between reminder-driven and self-initiated use may be important to consider when designing future digital follow-up apps. Balancing structured guidance, such as reminders, with the opportunity for users to engage when they find it relevant could help maintain user engagement over time while ensuring that users feel supported without becoming dependent on reminders.

Although the impact of patient-directed alerts in the LETSGO app was not examined in our study, such alerts may still play a role in shaping how patients engage with and respond to the symptom monitoring feature. In the LETSGO app, patient-directed alerts are generated when symptom reports exceed predefined threshold values and prompt patients to take action, such as contacting a health care provider. Unlike many mHealth apps that notify clinicians, alerts in the LETSGO app are one-way and directed only to patients. Previous studies have shown that patient-directed symptom alerts can support earlier action and enhance patient self-management [26]. Sending alerts to patients rather than clinicians may also reduce the burden on health care providers [26]. This design supports patient empowerment approaches that encourage patients to take a more active role in their own health, which is one of the goals of mHealth interventions [32].

The high engagement with physical activity–related features in the subanalysis of 49 app users may indicate that physical activity and goal setting are particularly important for some participants in this subgroup. However, because this analysis was based on a small sample, these use patterns should be interpreted with caution and not generalized to the entire intervention group. Within these limitations, our findings are consistent with previous work highlighting the central role of physical activity features in digital interventions for cancer survivors [53,54], and they may reflect that such features foster feelings of progress, help users regain a sense of control, and support self-management during recovery [55]. This is further supported by a study [56] that found that physical activity

XSL•FO
RenderX

tracking and goal-oriented features were important drivers of motivation and engagement in physical activity in a mHealth intervention for breast cancer survivors.

The steady use of the disease information feature indicates an ongoing need for accessible and reliable information that supports participants' understanding of their condition. This observation should be interpreted in light of previous research showing that digital health literacy is often limited and influenced by factors such as age, gender, and education level [57]. This underscores the need to develop cancer-related information that is easily accessible and user-friendly across digital health platforms, including mHealth apps.

Study Strengths and Limitations

Strengths of this study include a large sample size (N=378), which allowed for robust analysis and increased the precision of the estimated associations between app use and participant characteristics. Because Norway ensures equal access to health care and consistent cancer treatment nationwide, our unselected, multihospital sample strengthens the external validity of the findings. Finally, app use was measured based on app log data rather than self-reports, thereby reducing possible recall bias.

However, the study has several limitations. The criteria for app use were defined by the minimum user threshold and therefore reflected minimal active use rather than sustained long-term engagement. Definitions of engagement in digital health research vary and are measured in different ways, with no clear standard for how engagement thresholds should be operationalized [28,30]. The results of this study reflect only 1 year of access to the LETSGO app, and engagement patterns over a longer period may differ. Although analyses were adjusted for demographic and clinical variables, unmeasured factors such as digital literacy or attitudes toward technology may have influenced app use. Missing data in some baseline variables may have affected the findings and introduced potential bias, as the logistic regression analyses were based on complete cases only. In addition, women with vulvar cancer were too few to be included in the regression analysis, precluding the possibility of drawing any conclusions for this diagnosis group. Analyses of app-use frequency over 12 months were limited to the 49 participants with complete log data. Although participants with and without complete log data did not differ in measured baseline characteristics, unmeasured technical or implementation-related factors may still have influenced log data availability. The small number of participants with complete log data also limited the precision of the estimates. Therefore, findings related to app feature use and use frequency should be interpreted with caution.

Implications for Practice

The observed variation in app use across demographic and clinical groups indicates that a one-size-fits-all digital intervention may not be sufficient. Addressing these factors when developing interventions can help promote equitable and sustained use across diverse user groups and enhance engagement among groups less likely to use the app. In clinical practice, this highlights the need for targeted onboarding and user support, such as motivational guidance and technical assistance, tailored to the needs of different patient groups to ensure equal access to and benefit from app-based support in follow-up care.

Although app log data for the full first year were available only for a subset of the participants, the highest engagement with the physical activity and activity goal setting features among these participants suggests that encouraging regular physical activity and goal setting may be perceived as supportive by survivors, helping them monitor their activity levels and maintain a sense of control during recovery. Symptom alerts delivered directly to survivors may support earlier self-initiated contact with health care providers, thereby potentially facilitating timely clinical assessment when needed.

Conclusions

App-use patterns indicate differences in engagement across app features and participant characteristics. Findings from this study underscore the need to consider demographic and clinical characteristics when implementing digital tools in follow-up settings to ensure equal participation and avoid disparities in follow-up care. Overall, this study provides insight into the potential relevance of the LETSGO app in routine follow-up after cancer treatment, suggesting that such mHealth approaches may be applicable across different gynecologic cancer diagnoses. These findings may also inform the development and implementation of future mHealth tools designed to support cancer survivors in routine follow-up care.

Acknowledgments

The authors would like to express their sincere appreciation to all participants for their contributions to this study. They also thank Anette Strømsbø Gjørv for assistance in improving the visual content of the LETSGO (Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology) app used in this manuscript.

During the preparation of this work, the authors used ChatGPT (GPT-4o; OpenAI) and Microsoft Copilot, which were available to students at the University of Oslo, to improve the readability and language of the Introduction and Discussion sections, without altering the content. After using these tools, the authors reviewed and edited the content as needed and take full responsibility for the final publication.

Abstract

Background: Cardiovascular disease and cancer are leading causes of morbidity and mortality worldwide, with cancer survivors facing elevated cardiovascular risk due to shared risk factors and cardiotoxic treatments. Physical activity (PA) is a well-established strategy to improve cardiovascular health and survivorship outcomes; however, most cancer survivors do not meet recommended PA guidelines. Understanding multilevel influences on PA engagement and promotion is essential to improving implementation in cardio-oncology care.

Objective: This study aimed to examine barriers and facilitators to PA engagement and promotion in cancer survivorship from both survivor and medical team perspectives using the Capability, Opportunity, Motivation-Behavior (COM-B) framework.

Methods: A descriptive qualitative study was conducted with 12 cancer survivors and 12 medical team members involved in oncology care. Semistructured interviews explored experiences, perceptions, and practices related to PA across the cancer care continuum. Rapid qualitative analysis was used to identify themes, which were mapped to COM-B domains. Participants also completed surveys assessing PA, cardiovascular health (Life's Essential 8 [LE8]), and sociodemographic factors.

Results: Survivors had a mean age of 65.3 (SD 12.6) years and were evenly distributed by sex. PA engagement varied, with 42% (5/12) of survivors meeting recommended guidelines. The mean modified LE8-derived cardiovascular health score was 71.3 (SD 11.9), reflecting a standardized 6-domain composite (diet, PA, nicotine exposure, sleep, BMI, and blood pressure) calculated identically for all 12 participants. Across COM-B domains, physical limitation was the most commonly reported capability barrier (12/12 survivors), while current engagement in PA was the most prevalent capability facilitator (12/12 survivors). Opportunity was shaped by access to PA resources and social support, with social environment being the most frequently cited facilitator (12/12 survivors; 9/12 medical team members) and lack of access to PA resources being the most common barrier among medical team members (9/12). Motivation reflected perceived health outcomes as the most prevalent facilitator across both groups (12/12 survivors; 7/12 medical team members), alongside competing concerns such as safety and emotional responses. Medical team members' ability to promote PA was influenced by survivor readiness, clinical context, and resource availability.

Conclusions: PA engagement in cardio-oncology is shaped by dynamic interactions among capability, opportunity, and motivation across survivor and medical team member contexts. Although PA is widely valued, sustained engagement remains limited due

XSL•FO
RenderX

to fluctuating symptoms, environmental constraints, and clinical uncertainties. Interventions should prioritize flexible, survivor-centered approaches and incorporate supportive clinical communication and resource alignment to enhance PA across the survivorship trajectory.

Introduction

Background

Cardiovascular disease (CVD) and cancer are the 2 leading causes of death worldwide, highlighting the need for strategies to improve health among individuals affected by both conditions [1]. Compared with individuals without cancer, people with a cancer diagnosis experience a significantly higher risk of CVD, attributable to shared cardiometabolic and behavioral risk factors, cancer-related physiological changes, and exposure to cardiotoxic therapies [2,3]. As cancer survival has improved over recent decades, CVD has emerged as a leading cause of morbidity and mortality among cancer survivors, with noncancer deaths, particularly cardiovascular-related deaths, surpassing cancer-related deaths between 1973 and 2012 [4,5].

Cardiotoxic cancer therapies (eg, anthracyclines, chest radiation, and immune-based agents) significantly contribute to both short- and long-term cardiovascular morbidity and mortality [6]. As a result, CVD has become a major determinant of survivorship outcomes, with cancer survivors who develop CVD experiencing significantly worse survival and greater morbidity over time [7]. Consequently, the 8-year overall survival rate was 60% among those who developed CVD compared with 81% among those who did not, highlighting the critical role of cardiovascular health in long-term cancer survivorship [7].

Given the central role of cardiovascular health in long-term cancer survivorship, identifying effective and scalable strategies to mitigate cardiovascular risk is a clinical priority. Physical activity (PA) represents one such strategy, with well-established benefits for cardiovascular health, functional capacity, and quality of life among individuals with cancer [8]. In a meta-analysis of controlled PA interventions in cancer survivors, PA was associated with significant improvements in cardiorespiratory fitness both during and after cancer treatment, with weighted mean effect sizes (Cohen *d*) of 0.51 and 0.65, respectively ($P<.01$) [9]. Regular engagement in PA among cancer survivors improves cardiorespiratory fitness and reduces cardiovascular risk, helping to counteract treatment-related deconditioning and loss of aerobic capacity. This is clinically important given that cardiorespiratory fitness is a strong and independent predictor of cardiovascular and all-cause mortality [8,10]. In addition to cardiometabolic benefits, the American College of Sports Medicine has published PA recommendations that have been linked to improvement in common cancer-related symptoms, including fatigue, anxiety, depression, poor health-related quality of life, lymphedema, and poor physical function [11].

Clinical guidelines from the American Cancer Society (ACS) and the American Institute for Cancer Research (AICR) recommend regular PA before, during, and after cancer treatment, with adults advised to engage in a minimum of 150 minutes of moderate-to-vigorous physical activity (MVPA) per week, alongside muscle-strengthening activities [8,12]. Despite these recommendations, population-based data demonstrate that the majority of survivors do not meet recommended PA guidelines [13]. Despite ample evidence supporting the benefits of PA, engagement and promotion remain inconsistent, shaped by factors operating at the survivor, medical team member, and health care system levels [14,15]. Together, these findings suggest that the role of PA in cancer care is shaped by a range of factors that can act as both barriers to and facilitators of participation and promotion.

Compared with general oncology populations, patients receiving cardio-oncology care face actual or potential cardiovascular complications of cancer treatment in addition to cancer-related morbidity. PA may therefore be relevant to both cancer survivorship and cardiovascular health. Survivors may also have difficulty determining whether symptoms reflect cardiotoxicity, cancer treatment effects, or normal exertion, creating uncertainty about safe PA participation [16]. Further, promoting PA in cardio-oncology may require coordination between oncology and cardiology teams for counseling, safety guidance, and referral to exercise services [17]. These features make cardio-oncology a clinically distinct setting for examining the multilevel influences on PA engagement and promotion.

These multilevel influences highlight the need for a behavioral framework capable of integrating survivor, medical team member, and health care system determinants of PA engagement in cancer care. The Capability, Opportunity, Motivation-Behavior (COM-B) model provides a comprehensive framework for understanding and influencing health-related behaviors by explicitly identifying modifiable conditions required for a behavior to occur. Within this model, behavior is conceptualized as the result of interactions among individuals' physical and psychological capabilities, the social and environmental opportunities available to them, and both reflective and automatic motivational processes [18]. Applied to PA in cancer care, the COM-B framework offers a structured way to examine how survivor-level factors (eg, symptoms and beliefs), medical team member factors (eg, knowledge and time), and health care system factors (eg, access and resources) shape whether PA is initiated, sustained, and promoted.

Few studies have examined the influences of both survivor and medical team member factors in an integrated, theory-informed manner or explored how they are experienced and navigated

XSL•FO
RenderX

within clinical interactions. Limited qualitative work has simultaneously incorporated survivor and medical team perspectives to understand how PA engagement and promotion unfold across survivorship. As a result, there remains an incomplete understanding of the specific barriers, facilitators, and contextual conditions that shape PA as both a survivor behavior and a clinical practice.

Prior research suggests that PA engagement in cancer survivorship is shaped by not only individual factors but also clinical and system-level influences. Although clinicians widely endorse PA, gaps remain in how it is assessed, discussed, and supported in practice, with uncertainty regarding roles, time constraints, and available referral pathways limiting consistent promotion. Survivors also report interest in receiving guidance from their care teams, yet counseling and support vary across settings [19]. Existing qualitative work has largely focused on survivor experiences alone, with less attention to how survivor and medical team member perspectives intersect within clinical care. As a result, there remains limited understanding of how PA is both experienced by survivors and operationalized in clinical interactions.

Objectives

To address this gap, this qualitative study uses the COM-B framework to examine PA engagement and promotion in cancer survivorship from both survivor and medical team perspectives. By exploring how capability, opportunity, and motivation interact across roles and contexts, this study aims to generate actionable insights to inform more responsive clinical practice and intervention design for promoting and supporting PA throughout the survivorship trajectory.

Methods

Study Design

We conducted a descriptive qualitative study guided by the COM-B framework to examine PA engagement and promotion in the context of cancer treatment and survivorship. Semistructured interviews were used to explore perceived barriers and facilitators influencing PA behaviors among cancer survivors and medical team members involved in cancer care. The COM-B framework was used as an organizing lens to structure the examination of barriers and facilitators of PA behavior across medical team personnel (in terms of promotion) and cancer survivors (in terms of engagement).

In addition, cancer survivor participants completed a brief survey to capture self-reported sociodemographic characteristics, PA, and overall health measures. PA was assessed using the Rapid Assessment of Physical Activity (RAPA), a validated self-report measure of PA levels in adults [20]. The RAPA includes a series of yes/no items reflecting increasing levels of aerobic PA, with scores ranging from 1 (sedentary) to 7 (active). The final RAPA score was assigned based on the highest affirmed item. Consistent with the validated scoring criteria, participants with scores of 6 or higher were classified as "active." Item 6 of the RAPA indicates engaging in at least 30 minutes of moderate PA on 5 or more days per week, whereas item 7 indicates engaging in at least 20 minutes of vigorous PA on 3 or more days per week. The RAPA also includes items assessing strength and flexibility activities, asking whether participants engage in muscle-strengthening activities (eg, lifting weights and calisthenics) and flexibility activities (eg, stretching and yoga) at least once per week. These items are scored separately from the RAPA aerobic score and were not incorporated into the aerobic score or the study's classification of "active" status, which was based solely on the aerobic component. They are reported here descriptively. In addition to the RAPA, survivors reported weekly minutes of moderate or greater intensity activity as part of the PA domain of the Life's Essential 8 (LE8) cardiovascular health assessment (described below). This continuous self-report item was classified against the ACS/AICR guideline of 150 or more minutes per week, providing a second, independently derived measure of guideline-consistent PA. Because the RAPA and this continuous minutes-based measure use different item formats and scoring approaches, the resulting classifications may differ for some participants.

Select social determinants of health, including income, education, and employment status, were assessed using the Protocol for Responding to and Assessing Patients' Assets, Risks, and Experiences (PRAPARE) [21]. The full PRAPARE domain set was not analyzed for this manuscript.

Cardiovascular health was assessed using the American Heart Association's LE8 framework, which results in a composite score based on 8 health behaviors and factors: diet, PA, nicotine exposure, sleep health, BMI, blood lipids, blood glucose, and blood pressure [22]. The diet component was operationalized using a Mediterranean diet–based scoring approach, consistent with the Modified Mediterranean Eating Pattern for Americans (MEPA) recommended within the LE8 framework [22,23]. When individual LE8 components were missing, composite scores were calculated using the 6 domains available for all participants (diet, PA, nicotine exposure, sleep, blood pressure, and BMI). Blood glucose was not included in the survey instrument and therefore was not assessed. Blood lipid data were available for only 4 of 12 participants (33%) due to missing responses. Both domains were therefore excluded from the primary composite and are reported descriptively where available. Given the small sample size, validated imputation approaches were not considered appropriate to address missing domain data. Because some participants were unable to report clinical measures, survey-derived health measures were analyzed descriptively to characterize overall health status within the sample.

All 12 survivor participants completed the full survey battery. Blood lipid values were collected via self-report. Some participants left this item blank or did not respond, resulting in missing data for this domain. Blood glucose was not included in the survey instrument and was therefore not assessed for any participant.

The target behavior for this analysis was engagement in and promotion of PA throughout cancer survivorship. Because PA behaviors are shaped by complementary roles within the clinical relationship (survivors engaging in PA and medical team members providing encouragement and guidance), both survivor and medical team perspectives were included.

XSL•FO
RenderX

Participants and Recruitment

Survivor participants (n=12) were adults aged 18 years or older who had received a cancer diagnosis and were currently undergoing or had previously undergone cancer treatment involving cardiotoxic therapies, including targeted, biologic, radiation, or immune-based treatments. Medical team members (n=12) were health care professionals involved in the care of oncological survivors. Eligible survivor participants were required to have access to a device capable of supporting remote interviews (eg, smartphone, computer, or tablet) and to self-report interest in tracking cardiovascular symptoms and engaging in PA. Individuals who were pregnant, incarcerated, or unable to complete the interview in English were excluded.

Survivors were recruited through clinician referrals within a cardio-oncology clinic. Clinicians introduced the study to eligible survivors during routine appointments, and interested individuals were contacted by the research team to provide additional information and confirm eligibility. Medical team participants were recruited via professional referrals and word of mouth. All participants provided informed consent prior to enrollment.

Data Collection

Semistructured interviews were conducted with research staff members remotely via videoconferencing platforms (eg, Zoom and Microsoft Teams) between December 2023 and July 2024. Interviews were conducted by the lead author (MKT) and/or the study's principal investigator (RMB). Both were trained in rapid qualitative analysis (RQA) and qualitative interviewing techniques. Neither interviewer had a prior relationship with survivor or medical team participants. All participants were referred to the research team by the cardio-oncology clinic rather than recruited directly by the interviewers. Reflexivity was supported through regular team meetings in which interpretations were discussed and reconciled collaboratively rather than by a single analyst. While each interview followed the semistructured interview guide, interviewers remained flexible and allowed participants to elaborate on relevant topics as they arose to ensure complete data capture.

The semistructured interview guides used to conduct both survivor and medical team member interviews are available in Multimedia Appendix 1. Survivor interview questions explored experiences engaging in PA before, during, and after cancer treatment; reasons for being physically active or not being physically active; and external factors that may help or hinder PA engagement. Medical team participants were asked about their roles, confidence, and approaches to encouraging PA among survivors. Prompts were aligned with COM-B domains, including capability (eg, symptoms and knowledge), opportunity (eg, time, access, and social support), and motivation (eg, beliefs and priorities). Survivor participants received a US $25 gift card upon interview completion.

Interviews lasted approximately 60 - 90 minutes and were audio-recorded with participant consent. Most interviews were also video-recorded, although participants were given the option to keep their cameras off. Interviews were transcribed verbatim using a Zoom- or Teams-generated transcript and edited by a research team member when necessary. Survey data were analyzed descriptively to summarize participant characteristics, PA levels, cardiovascular health, and self-rated general health status.

Data Analysis

Analysis followed the RQA approach by Hamilton and Finley [24], with attention to best practices for rigor and validity [25,26]. RQA, used to analyze interview data, is a team-based approach that emphasizes systematic review and synthesis of qualitative data to identify actionable themes [24,25]. This study used a hybrid, deductive-dominant analytic approach: the COM-B framework was applied a priori to structure both the interview guides and the RQA summarization process. Research team members were trained in the RQA process. One researcher completed an initial review of each transcript, summarizing key points directly into structured templates organized by the COM-B domain and subdomain. A second researcher subsequently reviewed the same transcript, with access to the initial summary, to compare interpretations. Because reviewers were not blinded to one another's summaries, a formal interrater agreement statistic was not calculated. Discrepancies were resolved through team discussion and consensus. Within this deductively structured framework, the specific content of facilitator and barrier themes was generated inductively from participant data. Summaries were then organized into analytic matrices to enable comparison across participants and facilitate theme development. A template of the analytic matrix structure used for theme development is provided in Multimedia Appendix 2. Data collection and analysis occurred concurrently over approximately 1 year, with transcripts reviewed and summarized in a rolling manner as interviews were completed. As data collection and analysis progressed, the team observed that later interviews increasingly reinforced previously identified themes rather than introducing substantially new ones, consistent with thematic redundancy. Formal saturation metrics were not applied as a stopping criterion. Sample size was determined a priori based on the scope of the study. Final themes were mapped to the COM-B framework and categorized as barriers or facilitators within the overarching domains of capability, opportunity, and motivation. Consistent with the COM-B model, these domains were further specified as physical and psychological capability, physical and social opportunity, and reflective and automatic motivation. Representative quotations were selected to illustrate each theme. Sociodemographic characteristics of survivor participants were collected via a survey and summarized descriptively.

Ethical Considerations

This study was approved by The Ohio State University Institutional Review Board (IRB #2021C0018). All participants provided informed consent prior to participation. Interview recordings and transcripts were deidentified, assigned a unique study ID, and stored securely in accordance with institutional policies.

Results

Participant Characteristics

Participant demographic and clinical characteristics derived from both survey and interview data are presented in Table 1. A total of 12 cancer survivors participated in interviews and completed surveys. Survivor participants had a mean age of 65.3 (SD 12.6) years, with an equal representation of women and men. Most survivors identified as White and non-Hispanic (10/12, 83%). BMI values indicated that the majority of survivors were either overweight (5/12, 42%) or obese (4/12, 33%), with a mean BMI of 26.9 (SD 4.53) kg/m². Educational attainment was generally high, with 58% (7/12) of participants reporting completion of a graduate or professional degree. Most survivors (10/12, 83%) were retired or receiving disability benefits, and annual household income most frequently fell between US $100,000 and $199,999 (5/12, 42%). Cancer diagnoses were heterogeneous. The most commonly represented diagnosis was acute myeloid leukemia (3/12, 25%), followed by breast cancer (2/12, 17%), with several other malignancies represented in smaller numbers. Most survivors reported exposure to multiple cancer-directed therapies, reflecting complex treatment histories. These included chemotherapy (6/12, 50%), radiation therapy (5/12, 42%), tyrosine kinase inhibitors (4/12, 33%), stem cell transplantation (4/12, 33%), hormonal therapy (3/12, 25%), and surgery (3/12, 25%), with fewer participants reporting exposure to immune checkpoint inhibitors (1/12, 8%) or other treatment modalities (4/12, 33%).

[b]Complete education, employment, and annual income data are provided in Table S2 in Multimedia Appendix 3.

In addition, 12 medical team members involved in the care of survivors with cancer completed interviews. Medical team members had a mean age of 37.8 (SD 6.4) years and reported an average of 4.5 years in their current professional roles. Of the 12 medical team members, 7 (58%) identified as female, and the team represented a range of racial and ethnic backgrounds, including White and non-Hispanic (6/12, 50%), Asian (3/12, 25%), White and Hispanic (1/12, 8%), Black or African American (1/12, 8%), and multiple racial or ethnic identities (1/12, 8%). Professional disciplines included cardio-oncology physician (4/12, 33%), medical oncologist (3/12, 25%), and radiation oncologist (1/12, 8%), as well as allied health professionals such as nurse practitioner (1/12, 8%), physical therapist (1/12, 8%), exercise physiologist (1/12, 8%), and dietitian (1/12, 8%).

Self-Reported PA

Based on self-reported weekly PA minutes collected as part of the LE8 PA domain, 42% (5/12) of survivor participants met recommended PA guidelines (≥150 min per week of MVPA), while 58% (7/12) did not. Using the separate, categorical RAPA instrument, 50% (6/12) of participants were classified as active, while 50% (6/12) were classified as underactive. Of the 12 participants, 9 (75%) were classified concordantly across the 2 measures: 4 met both criteria and 5 met neither; the remaining 3 were classified differently. These 2 measures rely on different item structures and scoring algorithms and are not expected to yield identical classifications for all participants.

For descriptive purposes only, and independent of the RAPA aerobic score reported above, 67% (8/12) of survivor participants reported engaging in strength training activities at least once per week, and 50% (6/12) reported engaging in flexibility activities at least once per week. Categorized jointly, 42% (5/12) reported both, 33% (4/12) reported one only, and 25% (3/12) reported neither.

The mean cardiovascular health score (modified LE8-derived score) was 71.3 (SD 11.9). Descriptive details, including LE8 domain-level scores, are provided in Table S1 in Multimedia Appendix 3.

COM-B Themes

The results are organized according to the COM-B framework, capturing themes related to capability, opportunity, and motivation across both survivor and medical team member perspectives. Themes and subthemes identified within each domain are summarized in Table 2. In the text below, we describe these themes in greater detail, using representative quotations to illustrate how participants experienced and interpreted PA engagement and promotion in cancer survivorship. A table of additional quotes representing each theme can be found in Multimedia Appendix 4.

[a]COM-B: Capability, Opportunity, Motivation-Behavior.

[b]PA: physical activity.

[c]Not applicable or not available.

Domain: Capability

Overview

In the COM-B framework, capability refers to an individual's capacity to engage in a behavior and encompasses (1) physical capability (eg, physical strength, stamina, and symptom burden) and (2) psychological capability (eg, knowledge, understanding, and cognitive processes required to perform the behavior) [18]. In this study, capability captured factors influencing whether survivors were physically able and cognitively prepared to engage in PA, as well as whether medical team members felt equipped to assess and support PA participation.

Physical Capability

We identified 1 theme under physical capability: the *ability to engage in PA*. Every survivor mentioned their current engagement in activities and their ability to perform activities of daily living, such as household chores, which demonstrated their physical capability to stay active. One survivor mentioned:

XSL•FO
RenderX

> *I'm more of a person that takes on the chores of life. And that's where I get a lot of my physical activity in.*

For some, this baseline level of PA served as a foundation for further engagement in PA. At the same time, all survivor participants noted physical limitations, such as symptom burden and decreased fitness levels, that presented significant barriers to their ability to regularly engage in PA. One survivor noted:

> *There's been incidences during the whole time where I couldn't be very active… I've seen a lot of muscle atrophy set in. I've got very weak and things like that.*

If survivors were capable and self-driven to engage in PA, it facilitated medical team members' ability to promote PA. However, symptom-driven limitations also shaped medical team members' approaches, as they could only prescribe PA that aligned with what survivors' physical conditions allowed. One medical team member explained:

> *Every cancer patient is so different, and they have their own limitations and physical limitations.*

Psychological Capability

We identified 1 theme under psychological capability: the role that *knowledge and awareness* play in PA from survivors' and medical team members' perspectives. Many survivors mentioned their previous experience with PA, facilitating them with the cognitive tools to plan and engage in PA. Similarly, most medical team members emphasized that their knowledge of the benefits of PA and tips and tricks to help promote PA were key facilitators. On the other hand, some medical team members noted that a lack of knowledge regarding individual survivors' current PA levels and activity history hindered their ability to tailor and promote PA effectively. One medical team member stated:

> *People are super inexperienced on exercise, so the more information they have, the more successful they'll be with sticking with it.*

Domain: Opportunity

Overview

Within the COM-B framework, opportunity refers to external factors that enable or prompt behavior and includes (1) physical opportunity, such as environmental resources, access, time, and contextual constraints, and (2) social opportunity, including interpersonal influences, social norms, and support systems [18]. In this study, opportunity captured how features of survivors' physical environments and social contexts shaped their ability to engage in PA, as well as how these same conditions influenced medical team members' ability to promote PA.

Physical Opportunity

The first theme identified was the importance of *PA resources* for both medical team members and survivors regarding PA. Most survivors made note of access to public environments (eg, parks and gyms) along with tools, such as home PA equipment, online resources (eg, apps and YouTube), workout plans, and fitness trackers, as facilitators to engage in PA. Despite the availability of PA resources described by some participants, self-reported findings indicated that a majority of participants (7/12, 58%) did not meet recommended PA levels. Medical team members also identified access to online tools as a key facilitator for promoting PA among cancer survivors, noting that these resources expand accessible and flexible options for engaging in PA. One survivor mentioned:

> *I do think that like having things that you can do from the comfort of your own home is very important, because sometimes you don't feel like…looking like a normal person…on the flip side…gym accessibility would be awesome.*

However, several medical team participants also discussed that a *lack of access* to these resources is a barrier to promoting PA among survivors. Medical team members recognized that a lack of access to public parks or gyms, or tools and digital resources, reduces the opportunities for survivors to engage in regular PA. One medical team member noted:

> *…you want appropriate people doing the videos, not just someone,…that's a star on YouTube…Someone that's qualified is really important because our survivors are…receiving chemotherapy. They may not be in the best shape, and it's important to have the right…movements and things like that.*

Another medical team member stated:

> *You can only do so much. I mean, I can't get them a pair of running shoes. I can't get them a membership at the gym, or make it warmer outside to run, or whatever it is that would actually work for them.*

Another theme identified was *weather and time* regularly engaging in PA. Lack of time and poor weather conditions can be limiting factors in engaging in PA. One survivor stated:

> *I mean, it's harder in the winter time to walk and stuff like that…That's the hard time. It's hard to walk.*

Social Opportunity

Social support emerged as an integral facilitator for PA from both survivor and medical team member perspectives. For patients, access to local *classes, events, and support groups* created a sense of community and accountability, ultimately making engaging in PA more enjoyable. Many survivors also emphasized the supportive role that *their family, friends, pets, and medical team* provide in engaging in regular PA. Medical team members similarly highlighted the importance of supportive social environments to facilitate promoting PA among survivors. One medical team member mentioned:

> *Their families are the biggest cheerleaders…I have a lot of survivors…who are part of exercise groups or walking groups…and their goal is to get back to being with those people.*

Domain: Motivation

Overview

Within the COM-B framework, motivation refers to the internal processes that direct and sustain behavior and includes (1)

XSL•FO
RenderX

reflective motivation, such as conscious intentions, beliefs about outcomes, and evaluations of risk, and (2) automatic motivation, including emotional responses, habits, and routines [18]. In this study, motivation captured how survivors' beliefs, intentions, emotions, and habitual patterns influenced their engagement in PA, as well as how medical team members' perceptions of survivor motivation shaped their approaches to promoting PA.

Reflective Motivation

The first theme identified was the relationship between PA and *perceived health*. Both survivors and medical team members noted that the benefits of PA (eg, symptom relief and appearance) served as a motivating factor for engaging in and promoting PA. However, both groups also identified barriers to PA. Survivors reported that physical limitations, such as fatigue and discomfort, reduced their motivation to engage in regular PA. Medical team members echoed these concerns, noting that survivor-specific limitations related to treatment and disease often constrained their motivation to promote PA. One survivor noted:

> *Today, coughing and breathing is tough…I was thinking about getting on the bike…maybe trying for… 10 minutes or so. But usually, I'd like to go 30 minutes on the bike, if I can, but we'll see…if I get things moving and agitated then I start coughing a lot.*

Another survivor explained:

> *I feel like even in terms of physical appearance, again, there's so many things that change, but being able to still feel good about my body and like how I present myself is important to me.*

One medical team member stated:

> *It's extremely important. It's directly linked to their cardiovascular outcomes and their oncology outcomes…the physical activity is critical. I try to encourage all my survivors to be as physical as they can be.*

A second theme identified was the factors associated with PA-related resources. Several survivor participants reported that having access to at-home workouts and digital health tools was motivating. Many participants appreciated the flexibility that home workout options provided. This approach reduced logistical barriers, allowing them to engage in PA. At the same time, PA tracking tools provided motivating metrics, such as step count, that allowed survivors to understand and manage their PA. One survivor highlighted:

> *I have a lot of apps on my iPad about exercise and different things, so those kind of help a little bit. I will open up one and say, "Okay, let me see if I can get a 10-minute workout in or a 5-minute workout in."*

However, the positive influence of PA-related resources was tempered by *resource preferences and safety concerns*, which limited motivation to engage in PA. Few survivors were reluctant to use digital resources, such as online PA programs or tracking apps, due to discomfort with technology or a preference for more traditional methods. Moreover, some survivors expressed caution about the risks associated with PA, such as potential injury or the possibility of exacerbating symptoms, increasing their apprehension about engaging in PA. This focus on safety reflects survivors' conscious assessments of their physical limitations and the potential health consequences of PA. One survivor noted:

> *…during treatment, you're really afraid that you might hurt something or break something, that you're fragile and frail. It's pretty easy to say, "I'll wait till after treatment…"*

Several survivor participants also highlighted their *intentions* to engage in PA, which included a positive outlook toward PA and creating strategies to maintain accountability. Survivors noted that their motivation to engage in PA was influenced by the setting of goals and plans. Medical team members also observed this inclination in some survivors, stating that a survivor's motivation (eg, intentions, perceived beliefs, and consequences) to engage in PA serves as a key facilitator in promoting PA in survivors. One survivor explained:

> *Before that, I could bench press the 25 pounds. It's like, I wanna get back to that. I can do 20 now, but I can't do 25 yet.*

Automatic Motivation

The first theme identified was the positive and negative influence that a survivor's *emotions* have on their PA behaviors. On one hand, some survivors described experiencing positive feelings associated with engaging in PA, which was a facilitating factor. On the other hand, some survivors described negative feelings associated with engaging in PA, thus acting as a barrier. Aligned with this finding, medical team members also noted that the association of survivors' emotional relationship with PA influenced their motivation to promote PA. One medical team member noted:

> *…the biggest thing is their own motivation, like if they're not motivated to exercise or to do any physical activity, they're not gonna do it.*

One survivor mentioned:

> *When I'm achy and stiff, I'll go to a stretching type class, and I'll just feel better. I also feel when I'm kind of groggy, I'll go to some of these classes and just getting my blood flowing…my mood improves. I just feel better.*

The second theme identified was the *importance of a routine or habit* as a positive influence on motivation. Survivors noted that once PA became part of their daily routine, it required less conscious decision-making, which reinforced their ability to maintain regular PA. One survivor stated:

> *Just doing it as part of a routine. Say, this is my routine. I get up. I find the class that I want to go to at the center. I click on it and I go to it.*

Discussion

Principal Findings

In this qualitative study informed by the COM-B framework, findings indicate that although PA is widely valued, consistent

XSL•FO
RenderX

engagement remains limited. Although participants frequently described access to PA resources, less than half (5/12, 42%) met the recommended PA guidelines, suggesting a disconnect between available resources and sustained engagement. Rather than reflecting a lack of interest or intent, this pattern highlights the conditions under which PA requires adaptation, reassurance, and contextual support.

Capability-related factors included fluctuating symptoms, knowledge and awareness of PA, and readiness for PA, which shaped both survivors' ability to engage and medical team members' approaches to promoting PA. Opportunity-related influences reflected access to resources and supportive environments, where availability of PA options and social support facilitated engagement, while practical constraints, such as time and environmental barriers, limited feasibility. Motivation operated through both reflective processes, including weighing perceived health benefits alongside safety concerns and intentions to be active, and automatic processes, such as emotional responses and established routines.

The COM-B model conceptualizes behavior as arising from an interacting system of capability, opportunity, and motivation, with capability and opportunity also influencing motivation [18]. Participants' accounts illustrated these cross-domain relationships. Medical team members described family support and peer exercise groups as strengthening survivors' motivation by connecting PA with valued relationships and social roles, illustrating how social opportunity could support reflective motivation. Survivors described treatment-related physical vulnerability as contributing to perceived risk and fear-based avoidance, suggesting that limitations in physical capability could also weaken reflective motivation. These interactions varied across participants rather than reflecting a single, uniform pathway.

Descriptive survey findings complemented these themes by demonstrating variability in PA engagement, with fewer than half of participants (5/12, 42%) meeting recommended PA guidelines and only half (6/12, 50%) classified as active based on the RAPA. Many participants expressed motivation to engage in PA, suggesting that motivation alone may be insufficient to sustain engagement in some contexts, particularly in the absence of supportive conditions or resources. This aligns with prior evidence showing that adherence to PA guidelines among cancer survivors remains low, with previous studies reporting that only 20% meet aerobic PA guidelines [27]. Self-reported health status similarly varied, reinforcing heterogeneity in overall health. Together, these results underscore that PA engagement among survivors and promotion from medical team members represent complex, role-specific behaviors shaped by interacting influences.

Comparison With Prior Literature

These patterns are consistent with prior research suggesting that PA engagement across cancer survivorship is shaped by interrelated conditions that influence feasibility and support. Prior survivorship studies have similarly emphasized that engagement in health-promoting behaviors following a cancer diagnosis is influenced by dynamic and context-dependent situations. For example, qualitative reviews of survivor perspectives describe PA engagement as contingent on a range of factors, including symptoms, environmental conditions, and the variability of reassurance and guidance from health care professionals [28]. With most cancer survivors not achieving recommended PA levels, this reflects ongoing challenges related to clinical practice, resource availability, and behavior change across both survivor and medical team member contexts [19].

Several specific themes identified in our study closely align with those reported in qualitative syntheses of cancer survivors' experiences with PA. Among adults (n=12) with cancer seen in the cardio-oncology clinic, treatment-related side effects, particularly fatigue, emerged as major barriers to PA participation. This finding is consistent with prior research identifying treatment-related symptoms, including fatigue, as predominant barriers to engaging in PA [28,29]. Similarly, environmental concerns were identified as barriers, aligning with findings from qualitative syntheses and systematic reviews, including weather conditions, lack of suitable or adapted PA environments, and financial constraints [28,30]. Psychological concerns were prominent, with fears of worsening symptoms or disease and reduced self-esteem or motivation shaping survivors' willingness to engage in PA, consistent with prior literature describing emotional and cognitive barriers to PA [30]. Support-related factors also emerged as key facilitators, as participants emphasized the value of encouragement, structure, guidance from health care professionals, and group-based settings in supporting PA engagement, alongside frustration when such support was absent, which has been similarly reported in qualitative studies and mixed-method reviews of cancer survivors [28,30].

Prior literature has documented that clinicians' promotion of PA in cancer care is shaped by multiple professional and contextual considerations, rather than by endorsement of PA alone. Qualitative studies of oncology care medical team members indicate that, although clinicians widely recognize the benefits of PA, promotion is influenced by factors such as role clarity, confidence and training, time constraints, availability of referral resources, and concerns related to survivor symptoms and safety [31]. Complementing these findings, Schmitz et al [19] indicated that clinicians often lack clarity regarding their role in assessing, advising, and referring patients for PA, alongside system-level barriers such as limited referral pathways, insufficient resources, and challenges integrating PA promotion into routine care. Importantly, this work emphasizes that oncology clinicians are not expected to provide detailed PA prescriptions but instead play a key role in encouraging PA and directing survivors to appropriate professionals and programs (eg, cancer rehabilitation services, exercise physiologists, and community-based programs), highlighting the need for accessible referral pathways within cancer care [19].

Collectively, prior work shows that both survivor engagement and clinician promotion of PA are shaped by aligned, or misaligned, conditions within the clinical encounter. This is consistent with a recent qualitative study applying the COM-B framework and Theoretical Domains Framework to examine PA integration in breast cancer care from both patient and health care professional perspectives, which similarly found that

patient-level barriers (eg, misconceptions and fatigue) and professional-level barriers (eg, need for clearer protocols and training) shape integration of PA into routine oncology care [32]. By integrating survivor and medical team member perspectives, this study shows that PA engagement is not simply an individual survivor behavior but a negotiated clinical behavior that is jointly experienced and navigated throughout the survivorship journey.

Implications for Intervention Design

Findings from this study indicate that promoting PA in cancer survivorship may benefit from flexible, responsive approaches rather than relying on standardized or one-time recommendations, as both survivors and medical team members described PA engagement as fluctuating over time. These findings highlight the potential value of interventions that facilitate ongoing communication between survivors and medical team members, allowing recommendations to be tailored and revisited as clinical circumstances change. Such approaches may be particularly relevant in clinical contexts where PA has the potential to influence patient outcomes, including treatment tolerance, recovery, and rehabilitation.

For survivors who face symptom burden, safety concerns, or environmental barriers, future intervention development could examine adapted home-based programs that provide feasible alternatives to traditional PA settings. This approach is supported by evidence that home-based PA interventions can provide accessible alternatives for cancer survivors facing feasibility barriers and that interventions incorporating frequent counseling are associated with larger improvements in fatigue, suggesting the importance of pairing flexible PA resources with ongoing support that can be revisited and adapted [33]. These results indicate that interventions should support clinicians in translating general PA guidance into feasible, individualized recommendations that account for survivors' potential barriers. Consistent with this approach, evidence from implementation research suggests that strategies incorporating individualized and interactive elements, such as tailored counseling and active survivor-medical team member communication, are more effective at increasing PA uptake during and after cancer treatment than one-time or generic recommendations [34]. However, the feasibility of delivering individualized counseling in routine oncology care may be limited by time constraints, staff availability, and variability in referral resources. To address this gap, future interventions should examine low-burden implementation strategies that preserve individualized support while fitting within existing clinical workflows.

Access to resources also emerged as an important factor shaping PA engagement. Survivors frequently described community spaces, home-based options, and digital tools as facilitating adaptation and continuity of PA, while medical team members noted variability in survivors' access to such resources as a consideration during promotion. Both survivors and medical team members described the supportive role that survivors' social environments, including family, friends, and their medical team, can play in facilitating physical engagement. This aligns with qualitative evidence demonstrating that social support functions as a key facilitator of PA among cancer survivors, enabling both adoption and maintenance of PA through mechanisms such as encouragement, accountability, and companionship [35]. In this context, clinicians may play a supportive role by helping survivors identify and make use of feasible, accessible resources, both material and social, that align with their circumstances. Framing PA promotion as an adaptive clinical process that incorporates individualized guidance and practical support may enable more sustained engagement without increasing burden within routine care. Future interventions should examine how resource-matching strategies, including digital PA tools, wearable-supported self-monitoring, group-based remote programs, and curated community referral options, can be tailored to survivors' needs and integrated into survivorship care without increasing burden on survivors or medical team members.

The findings also point to important considerations for the design of PA interventions in cancer survivorship. Interventions that focus exclusively on modifying survivor behavior may be limited if they do not also account for the clinical interactions through which PA is discussed and supported. The results suggest that intervention approaches should allow for flexibility, recognizing that survivor capacity and circumstances often change over time rather than remaining stable. Given that participants described clinical encounters as key settings where PA is discussed and negotiated, future intervention development should examine approaches that account for the barriers identified in our study, including symptom burden, safety concerns, competing demands, environmental constraints, social support needs from family and medical team members, and variability in clinical guidance. Population-based evidence indicates that fewer than half of cancer survivors report receiving PA counseling from a medical team member, yet those who do receive counseling are more likely to engage in higher levels of PA, highlighting the survivor-medical team member interaction as a meaningful opportunity for intervention [36].

Intervention approaches may also benefit from attending to how counseling is translated into action, including connection to feasible PA resources and tools, such as home-based options, community spaces, and digital supports. Additionally, leveraging survivors' existing social environments may further support engagement and align with evidence that social support facilitates adoption and maintenance of PA among cancer survivors [35]. Overall, interventions that align survivor experiences, clinician guidance, and available supports are more likely to be effective than those targeting any single element in isolation.

Implications for Future Research

Future research should continue to examine PA engagement and promotion as dynamic, context-dependent processes that unfold throughout survivorship. Longitudinal qualitative or mixed-methods studies may be particularly valuable for understanding how survivors' and clinicians' assessments of feasibility, support needs, and priorities shift over time in response to changing symptoms, treatment phases, and life circumstances. Studies that intentionally integrate survivor and medical team perspectives within shared care contexts could further illuminate how clinical interactions shape PA

XSL•FO
RenderX

engagement. Larger-scale qualitative or mixed-methods studies, including those conducted across multiple clinical settings or health systems, would be useful for assessing the transferability and generalizability of these findings to more diverse survivorship populations. In addition, research that evaluates strategies designed to support survivor-medical team member PA counseling within routine care may help strengthen translation of evidence into practice. Greater attention to variability across care settings, resource availability, and survivor populations will also be important for informing equitable and scalable approaches to PA promotion in survivorship.

Implications for Digital Health and Referral Pathways

Given the relevance of digital health approaches to supporting PA in survivorship, several implications for digital tools and referral pathways emerged from this study. Both survivors and medical team members described interest in accessible referral pathways connecting survivors to appropriate professionals and programs (eg, cancer rehabilitation services, exercise physiologists, and community-based programs) [19]. Recent feasibility studies offering PA interventions provide examples of such approaches, including brief PA communication and clinician referral pathways involving exercise professionals, as well as electronic triage tools paired with brief counseling and referral to PA or rehabilitation services [37,38]. For survivors facing symptom burden, safety concerns, or environmental barriers, digital and technology-supported PA resources, including group-based videoconference (tele-exercise) programs, wearable technology–based interventions, and app-based tracking tools, offer feasible and scalable alternatives to traditional PA settings [39,40]. Future interventions should examine how resource-matching strategies, including digital PA tools, wearable-supported self-monitoring, group-based tele-exercise programs, and curated community referral options, can be tailored to survivors' needs and integrated into survivorship care without increasing burden on survivors or medical team members.

Strengths and Limitations

This study has several strengths. First, it incorporated both survivor and medical team perspectives from a single setting, providing a more comprehensive view of PA engagement and promotion in cancer survivorship than studies focused on a single group. Examining these perspectives together enabled the identification of shared challenges and complementary insights within clinical interactions. Second, the focused, theory-informed interview structure supported in-depth exploration of PA engagement and promotion within a cardio-oncology setting, where PA may be shaped by not only cancer survivorship concerns but also cardiovascular risk, treatment-related symptoms, and perceptions of safety. The use of the COM-B framework to guide data collection and analysis supported systematic examination of capability, opportunity, and motivation as interacting influences on PA engagement and promotion. Although the interview guide also addressed symptom tracking, those findings are reported separately in another manuscript. Additionally, descriptive survey data provided useful context regarding participants' self-reported PA behaviors and cardiovascular health characteristics, although these data were not intended to validate or explain individual qualitative themes. Lastly, conducting interviews remotely helped reduce logistical and health-related barriers to participation, potentially increasing accessibility for individuals who may have had difficulty attending in-person interviews.

The interpretation of these findings should consider several limitations. First, the study relied on self-reported perceptions and experiences, which reflect participants' accounts of PA engagement and promotion rather than directly observed behaviors or objectively measured outcomes. PA measures were self-reported and descriptive in nature, which may be subject to recall or reporting bias. The cardiovascular health composite reported here reflects a modified, 6-domain adaptation of the American Heart Association's LE8 framework, excluding blood glucose (unavailable for all participants) and blood lipids (available for only 4 of 12 participants), and should not be interpreted as equivalent to the validated 8-domain LE8 score. A sensitivity analysis among the subset of participants with lipid data indicated that including this domain did not shift composite scores uniformly (mean change=1.0 points; range −3.1 to +4.4), suggesting that the original variable-denominator approach could have introduced variability tied to data availability rather than true cardiovascular health status. All interviews were conducted remotely, which may have shaped the nature of participant responses and introduced selection bias favoring individuals with greater comfort using technology or access to remote communication platforms. The modest gift card incentive (US $25) provided to survivor participants, while intended to offset time and participation burden, may have also influenced recruitment speed or introduced a degree of selection bias toward individuals more motivated by the incentive or with greater flexibility to participate. This potential influence was not formally assessed. The sample size was relatively small and, while appropriate for qualitative inquiry, may not capture the full range of perspectives across cancer types, treatment stages, or sociodemographic backgrounds. This diagnostic, treatment, and professional heterogeneity strengthened our ability to identify behavioral themes that generalize across clinical contexts, though it also precluded stratified analysis by diagnosis, treatment type, or professional role. Theme prevalence may vary across these subgroups. Survivor participants tended to have higher levels of income and educational attainment and were predominantly White and non-Hispanic, which may limit the transferability of the findings to more socioeconomically and racially or ethnically diverse survivorship populations. Barriers, such as weather, time, and gym access, reflect this relatively affluent sample. Structural social determinants of health barriers common in marginalized populations (eg, transportation, neighborhood safety, cost, and job flexibility) were unlikely to be captured and warrant a dedicated study. In addition, participants were recruited from a single clinical setting, which may limit transferability to other survivorship care environments with different resources, workflows, or practice norms. Relatedly, because participants were recruited from a specialized cardio-oncology clinic rather than a general oncology setting, both survivors and medical team members may have had greater baseline awareness of and engagement with lifestyle interventions than would be expected

XSL•FO
RenderX

in general oncology populations, which may have influenced the prominence of themes related to knowledge, motivation, and support for PA. Finally, although the COM-B framework provided a useful structure for organizing data collection and analysis, its application may have highlighted certain behavioral influences while de-emphasizing others. Alternative approaches could have yielded different interpretive themes.

Conclusion

This qualitative study explored how PA engagement and promotion are experienced and navigated in cancer survivorship from both survivor and medical team perspectives. Across interviews, PA was widely recognized as valuable, yet participation and promotion were influenced by changing symptoms, competing priorities, perceived safety, available resources, and the circumstances of clinical encounters. Patterns of PA were not static; instead, engagement reflected ongoing adjustment to health status and life context rather than simple adherence to recommendations. These findings highlight PA as a behavior that evolves over time within survivorship rather than one that can be adequately supported through singular or standardized guidance.

By applying the COM-B framework, this study offers insight into how capability, opportunity, and motivation interact across survivor and clinical contexts to shape PA engagement and promotion. The findings underscore the importance of clinical conversations, social and material supports, and adaptive approaches that accommodate fluctuation rather than expecting consistency. Attention to how PA is discussed, supported, and resourced may help bridge the gap between evidence and sustained engagement in daily life. Collectively, these insights contribute to a growing emphasis on flexible, context-aware strategies to support PA throughout the survivorship trajectory and may inform more responsive approaches to clinical practice, intervention design, and future research.

Acknowledgments

We thank the participants who shared their time and insights and the American Heart Association for allowing us to use the Life's Essential 8 approach to evaluate cardiovascular health. The authors would also like to thank the Lifestyles Lab team members for their contributions to data management and administrative coordination.

During the preparation of this manuscript, the authors used CoPilot (Microsoft 365) as a writing support tool to proofread the text for grammar. All content was written, critically reviewed, and edited by the authors, who take full responsibility for the final manuscript.

Funding

This study was supported by discretionary research funds provided to RMB through the Ohio State University Comprehensive Cancer Center (OSUCCC).

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

MKT and RMB conceived and designed the study, conducted interviews, and coordinated the primary interpretation of findings. MKT led manuscript writing. MKT and RMB oversaw data collection and conducted the final analysis. MKT, RS, SMSG, and VP coordinated data management, performed preliminary analyses, and assisted with manuscript writing. All authors contributed to study design, interpretation of the results, and critical revision of the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Melanoma, a highly aggressive form of skin cancer, is the second most common type of cancer for adolescent and young adult (AYA, ages 15-39 years) patients. AYA patients with melanoma may turn to internet sources, especially artificial intelligence (AI) chatbots, to manage uncertainty about prognosis and treatment.

Objective: This study aims to evaluate the quality, empathy, and readability of responses generated by leading AI chatbots when addressing the top unmet needs of AYA patients with melanoma receiving treatment.

Methods: Our research team recently surveyed 152 AYA patients with melanoma using the Needs Assessment Service Bridge, a validated instrument that assesses psychosocial needs for AYA patients with cancer. The survey identified the top 5 needs for advanced AYA patients with melanoma receiving treatment. Each need was reframed into a question and brief clinical history, then entered into each chatbot by 5 individuals who cleared their prequestion and postquestion history. Chatbot responses were evaluated to assess information quality (Global Quality Score [GQS] and DISCERN), accessibility and readability (GQS, Flesch Kincaid Grade Level, Flesch Reading Ease), and perceived empathy (Perceived Empathy of Technology Scale [PETS], including domains of Emotional Responsiveness [PETS-ER], Understanding and Trust [PETS-UT]).

Results: Across 75 chatbot responses, ChatGPT achieved the highest average quality (mean GQS 4.42, SD 0.32; mean DISCERN 3.24, SD 0.31) and empathy (mean PETS-ER 5.35, SD 1.85; mean PETS-UT 6.36, SD 1.83), though with greater variability. Copilot produced the lowest quality and empathy scores, while Gemini responses were consistently midrange. PETS-UT exceeded PETS-ER across all models, suggesting stronger cognitive empathy than emotional responsiveness. Readability analysis showed outputs exceeded the average US reading level (mean Flesch Kincaid Grade Level 11.82, SD 1.44; mean FRE 38.60, SD 9.00), limiting accessibility. The most readable responses were found in question 2, which also scored higher in quality and empathy, whereas questions 4 and 5 produced the most complex, difficult-to-read responses corresponding with lower quality and empathy ratings.

Conclusions: AI chatbots can provide moderately accurate and supportive responses to needs of AYA patients with melanoma, but outputs are inconsistent, written above the recommended reading level for health information, and limited in empathy. Question framing strongly influenced chatbot performance, with more emotional prompts drawing greater empathy, and readability aligning with both quality and empathy. Chatbot use in this population should remain adjunctive, with further research needed to standardize quality, improve readability, and enhance empathetic communication.

Introduction

Melanoma, a malignant tumor of melanocytes, is an aggressive form of skin cancer due to its high metastatic potential and associated mortality. Despite being most frequently diagnosed in older adults, cutaneous melanoma accounts for approximately 7% of newly diagnosed cancers among adolescents and young adults (AYAs, age 15 - 39 years) [1]. A melanoma diagnosis and subsequent treatment can be highly disruptive for AYA patients, with implications for physical health, emotional well-being, and social function. The severity of the disease, coupled with the uncertainty of treatment outcomes, often introduces feelings of fear and isolation [2]. In seeking clarity in this uncertainty, patients may turn to the internet and social media for answers, education, and support. When seeking answers through internet interfaces, patients are likely to leverage artificial intelligence (AI)–driven chatbots, such as Chat GPT, Microsoft Copilot, and Google Gemini [3].

AI chatbots use natural language processing to generate conversational responses to user queries and have been shown to provide health information in an accessible and interactive manner [4]. Their availability, objectivity, and capacity to adapt personalized responses to diverse communication styles make them appealing to patients navigating difficult diagnoses [5]. While some studies have evaluated the most frequently asked chatbot questions regarding specific forms of cancer (ie, breast, leukemia, prostate), no published research to our knowledge has systematically examined their ability to address AYAs' specific concerns regarding melanoma treatment and survivorship [6].

A recent survey study of AYAs with melanoma identified several unmet needs for patients in different phases of cancer care using the validated Needs Assessment Service Bridge (NA-SB) questionnaire [7]. This survey represents a separate study and included 152 AYA respondents, 20 of whom were actively receiving systemic treatment at the time of participation; detailed methods and results are reported elsewhere [7]. For AYA patients with melanoma currently undergoing systemic treatment, the top 5 unmet needs included the following: (1) what happens after treatment, (2) fear of cancer recurrence, (3) long-term hormonal side effects, (4) long-term systemic side effects, and (5) genetic implications on diagnosis and treatment [7]. In this study, survey findings were used solely to identify patient-prioritized unmet needs for chatbot evaluation.

Building on these empirically derived patient priorities, this study anchors chatbot prompts in validated unmet needs rather than search-derived queries; evaluates perceived empathy using the Perceived Empathy of Technology Scale (PETS), a recently validated instrument not previously applied in oncology chatbot research; and examines how readability, empathy, and information quality interact. Together, this novel approach enables a patient-centered and multidimensional evaluation of chatbot suitability for AYA melanoma care, further building on previous chatbot-oncology research. With these established unmet needs and the increasing use of AI chatbots for AYA patient support, we evaluated the unique response of 3 chatbots to patient-centered questions to determine if these resources are safe and valid for use by AYA patients with melanoma.

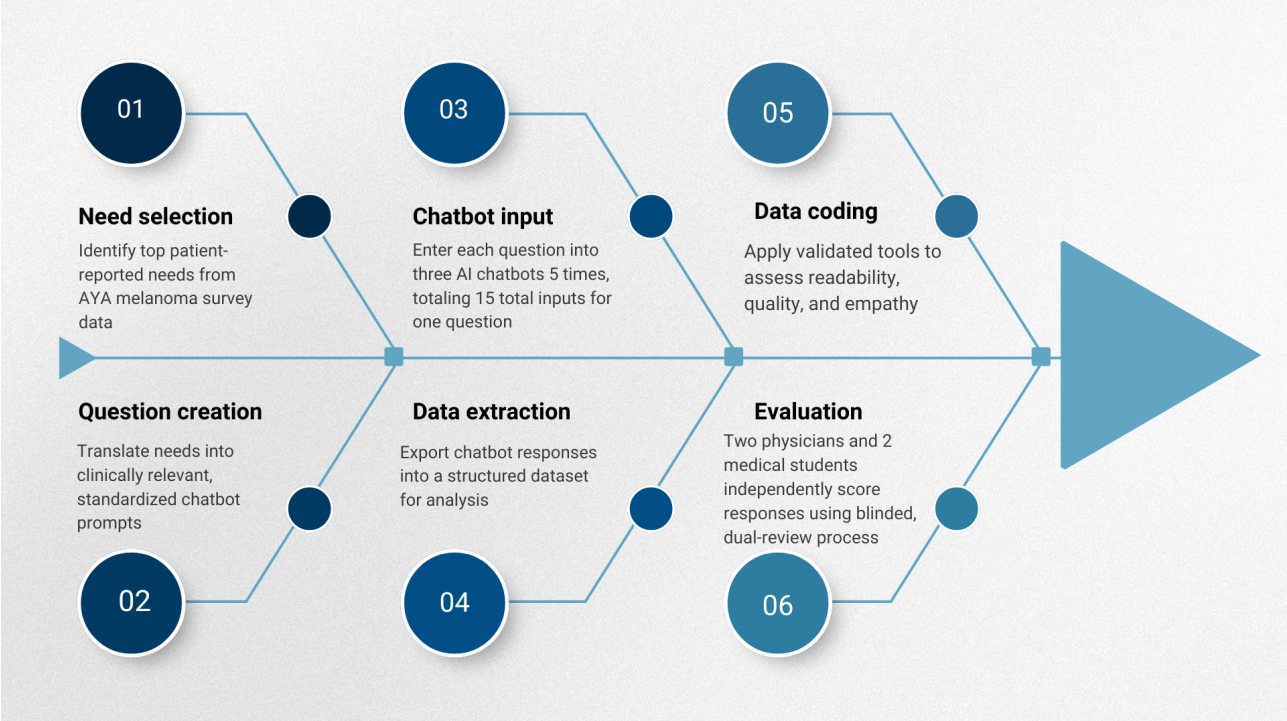
Methods

Need Selection and Question Creation

The top 5 most frequently reported needs for AYA patients with melanoma receiving systemic treatment were identified through the NA-SB survey. Once identified, each NA-SB prompt was slightly modified into a question format with a standardized and appropriate brief clinical history (Textbox 1). All questions shared a common stem that identified the patient as an AYA with metastatic melanoma, with tailored follow-up questions added to reflect the specific need category.

Textbox 1. Questions input into each chatbot, based on the 5 most frequently reported needs.

Questions from the perspective of patients currently on treatment:



1. I am an adolescent/young adult patient with metastatic melanoma and am currently receiving treatment. I want more information about what will happen when treatment finishes.
2. I am an adolescent/young adult patient with metastatic melanoma and am currently receiving treatment. In the last month, I have become more worried about my cancer spreading. What do I need to know and what steps can I take to cope with this fear?
3. I am an adolescent/young adult patient with metastatic melanoma and am currently receiving treatment. How will my treatment affect long-term hormone changes?
4. I am an adolescent/young adult patient with metastatic melanoma and am currently receiving treatment. I want more information about how my genetics may or may not have impacted my diagnosis and treatment.
5. I am an adolescent/young adult patient with metastatic melanoma and am currently receiving treatment. I want more information about the long-term side effects of treatment.

Study Design

This study evaluated the quality of responses generated by AI chatbots to needs frequently reported by AYA patients with melanoma receiving treatment. Our methodologic approach included six components: (1) need selection, (2) question creation, (3) chatbot input, (4) data extraction, (5) data coding, and (6) evaluation (Figure 1).

XSL•FO
RenderX

Figure 1. Study design workflow. AI: artificial intelligence; AYA: adolescent and young adult.

Ethical Considerations

This study relied exclusively on publicly available chatbot outputs and did not involve interaction with human participants, collection of identifiable private information, or intervention. As such, it did not meet the definition of human participant research and did not require institutional research board approval.

Chatbot Input and Data Extraction

Chat GPT 4.0 (Open AI), Copilot (Microsoft), and Gemini (Google) were selected for evaluation based on their increasing usage among AYAs and advancements in their technology. The free, publicly accessible versions of all chatbots were used to reflect the most accessible chatbot platforms available to patients. The resulting need–related questions, outlined in Textbox 1, were entered into each chatbot 5 times by 4 individuals (RPM, ALO, KMR, and SZ) during a single study period (April 8, 2025, to August 8, 2025). To minimize bias, these team members did not participate in question selection, and AI personalization was avoided through memory clearing between each input, ensuring that responses did not draw on prior prompts or stored contextual data, thus replicating a true AYA patient experience. Responses were copied and exported into an Excel spreadsheet where a separate team completed data coding and evaluation.

Data Coding and Evaluation

Responses were evaluated and coded to assess information quality (Global Quality Score [GQS] and DISCERN), perceived empathy (Perceived Empathy of Technology), and readability (Flesch Kincaid Grade Level [FKGL], Flesch Reading Ease [FRE]; Table 1). Four team members, 2 medical students (JLJ and PLH) and 2 physicians (KCN and MHS), completed evaluations independently, with results hidden until completion to minimize bias. Quality metrics (GQS and DISCERN) were evaluated by physician reviewers due to their clinical expertise, while empathy (PETS) was evaluated by medical student reviewers to approximate a patient-facing perspective. Score interpretation for all tools is provided in Table 1. Reviewers met prior to scoring to align on scale interpretation. Any discrepancy in scores between the raters is a product of the qualitative nature of the rating and is representative of different physicians' interpretation. All analyses are exploratory and descriptive. Duplicate independent scoring with averaging was used to mitigate individual subjectivity, which was considered sufficient for this evaluation using previously validated instruments. Formal interrater reliability statistics (eg, intraclass correlation coefficient or Cohen κ) were not calculated, as estimates based on only 2 raters per domain may be unstable and potentially misleading, particularly for perceptual constructs such as empathy. The results are presented as means, standard deviations (SD), and visual comparisons. No inferential statistical testing was performed, and no claims of statistical significance or superiority were made.

XSL•FO
RenderX

Table . Evaluation metrics for chatbot responses, detailing assessed domains and score interpretation.

Assessment tool	Evaluated domains	Scale	Score interpretation
Global Quality Score [8]	• Accessibility • Quality • Flow • Usefulness	• 5-point Likert scale	• 1=Poor quality, flow, and missing information • 2=Fair • 3=Moderate • 4=Good • 5=Excellent quality, flow, and information
DISCERN [9]	• Accuracy • Quality	• Items 1 - 8 (5-point Likert scale) • Item 16 (summary 5-point Likert scale)	• Low quality information ≤2 • Medium-quality information=2 - 4 • High-quality information ≥4
Perceived Empathy of Technology Scale [10]	• ER[a], UT[b]	• 10 items, 2 domains. Each item is assessed with a 10-point scale and then averaged across 5 items for each domain score (ER and UT)	• 1 - 3=Low empathy • 4 - 6=Moderate empathy • 7 - 10=High empathy
Flesch Kincaid Grade Level [11] (FKGL)	• Comprehension	• Automated formula estimating US school grade level required to understand text	• Numeric grade level (eg, 8=8th-grade reading level)
Flesch Reading Ease [11] (FRE)	• Readability • Flow	• Automated formula producing a score from 0 to 100, with higher value indicating easier reading	• 0 - 30=Very difficult to read • 31 - 50=Difficult to read • 51 - 60=Fairly difficult to read • 61 - 70=Plain English • 70 - 100=Easy to read

[a]ER: Emotional Responsiveness.

[b]UT: Understanding and Trust.

Quality (GQS and DISCERN)

Chatbot answer quality was evaluated using the GQS and DISCERN scales. The GQS scale evaluates quality, accessibility, flow, and perceived usefulness of information for patients, as judged by a physician (Table S1 in Multimedia Appendix 1). The DISCERN scale assesses the quality of written health information, focusing on reliability, clarity, and explanations of risks and benefits (Table S2 in Multimedia Appendix 1). Two physicians (KCN and MHS) evaluated each response with the QGS and DISCERN scales. The results were then averaged into a final score.

Empathy (PETS)

The PETS, a 10-item instrument designed to assess emotional responsiveness and understanding in human-technology interactions, was used to evaluate perceived empathy in chatbot responses. The PETS was applied without modification. The PETS tool is divided into 2 sections: PETS-ER (6 items) and PETS-UT (4 items; Table S3, Multimedia Appendix 1). The PETS-ER (Emotional Responsiveness) focuses on emotional engagement and support. PETS-UT (Understanding and Trust) measures “cognitive empathy” or the ability of the Chatbot to understand the user’s perspective. Each item was individually scored, then averaged to give domain-specific scores for each input. Two medical student reviewers (JLJ and PLH) performed scoring and highlighted key examples for qualitative evaluation.

Readability (FKGL, FRE, and Word Count)

To evaluate each output’s readability, the FKGL and FRE were utilized. FKGL estimates the US grade level required to comprehend a response, while FRE scores readability from 0 to 100 (higher=easier to read). Scores for both instruments were calculated in Microsoft Word’s spelling and grammar tool.

Results

Descriptive metrics of chatbot performance are reported in Table 2, stratified by question with overall summary statistics for each chatbot. Individual input scoring is available in Multimedia Appendix 2.

[a]GQS: Global Quality Score.

[b]PETS-ER: Perceived Empathy of Technology Scale-Emotional Responsiveness.

[c]PETS-UT: Perceived Empathy of Technology Scale-Understanding and Trust.

[d]FRE: Flesch Reading Ease.

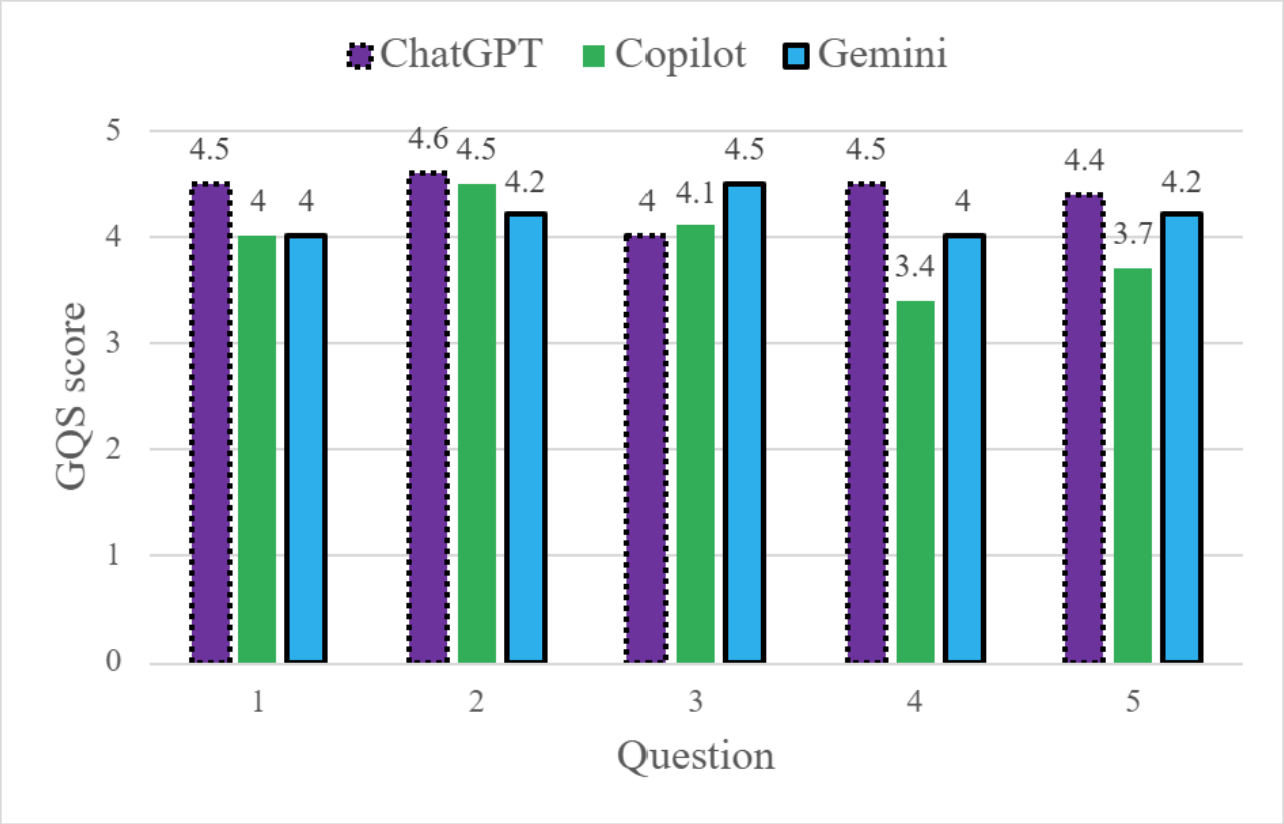
[e]FKGL: Flesch-Kincaid Grade Level.

Quality (GQS and DISCERN)

ChatGPT demonstrated the highest average information quality scores, achieving the highest GQS and DISCERN ratings for 4 out of the 5 questions (Figures 2 and 3). Copilot responses showed the lowest average quality scores, while Gemini responses generally fell between the 2 other models.

XSL•FO
RenderX

Figure 2. Global Quality Score (GQS) scores comparing each chatbot by question input.



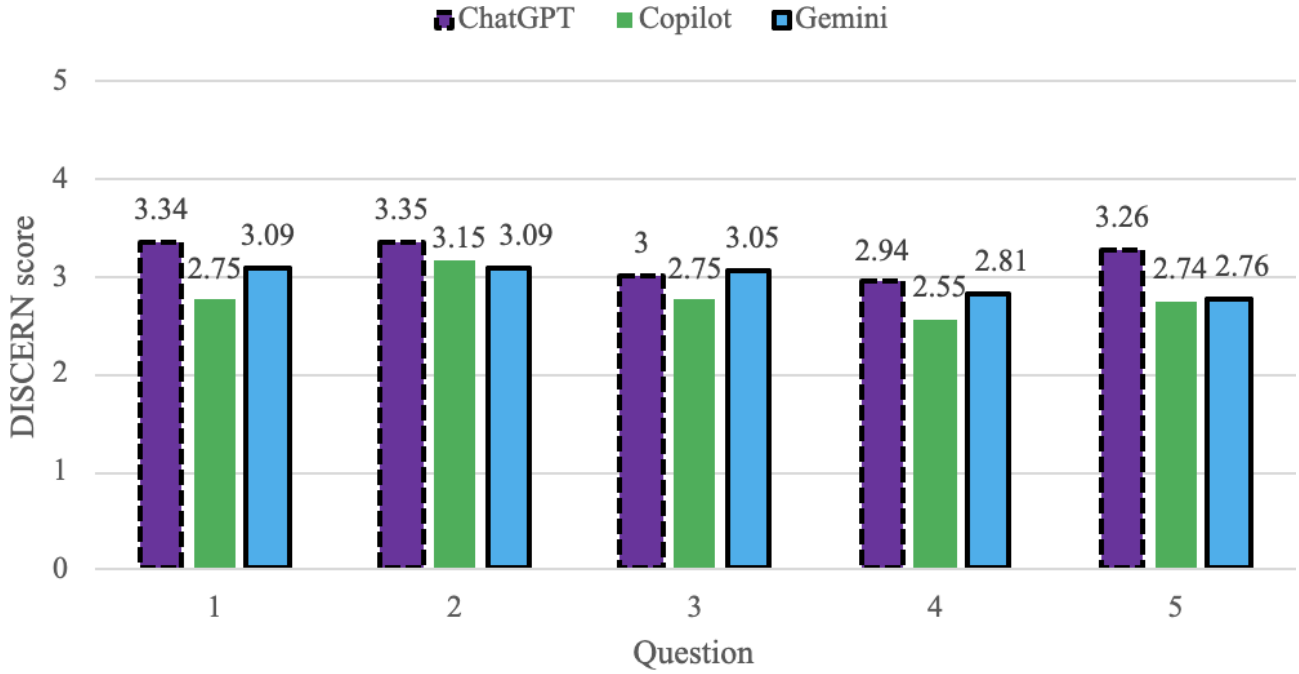


Figure 3. DISCERN scores comparing each chatbot by question input.

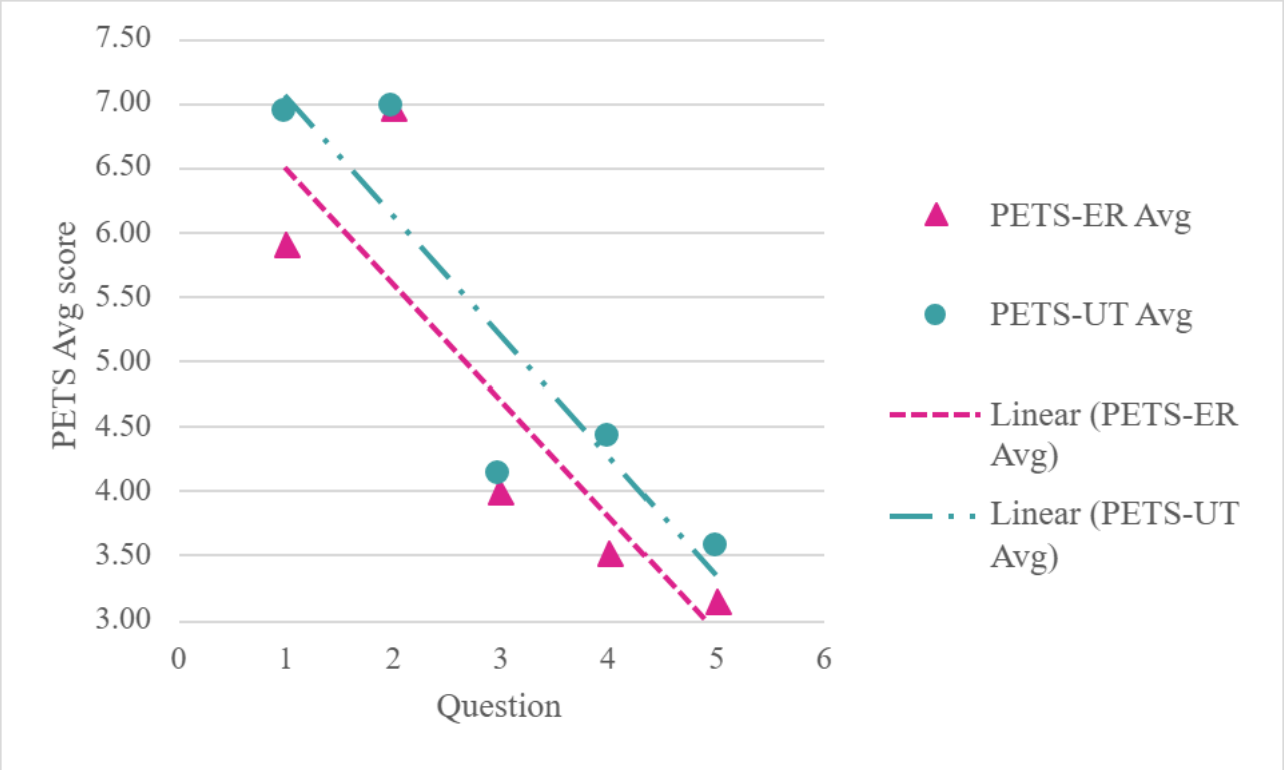
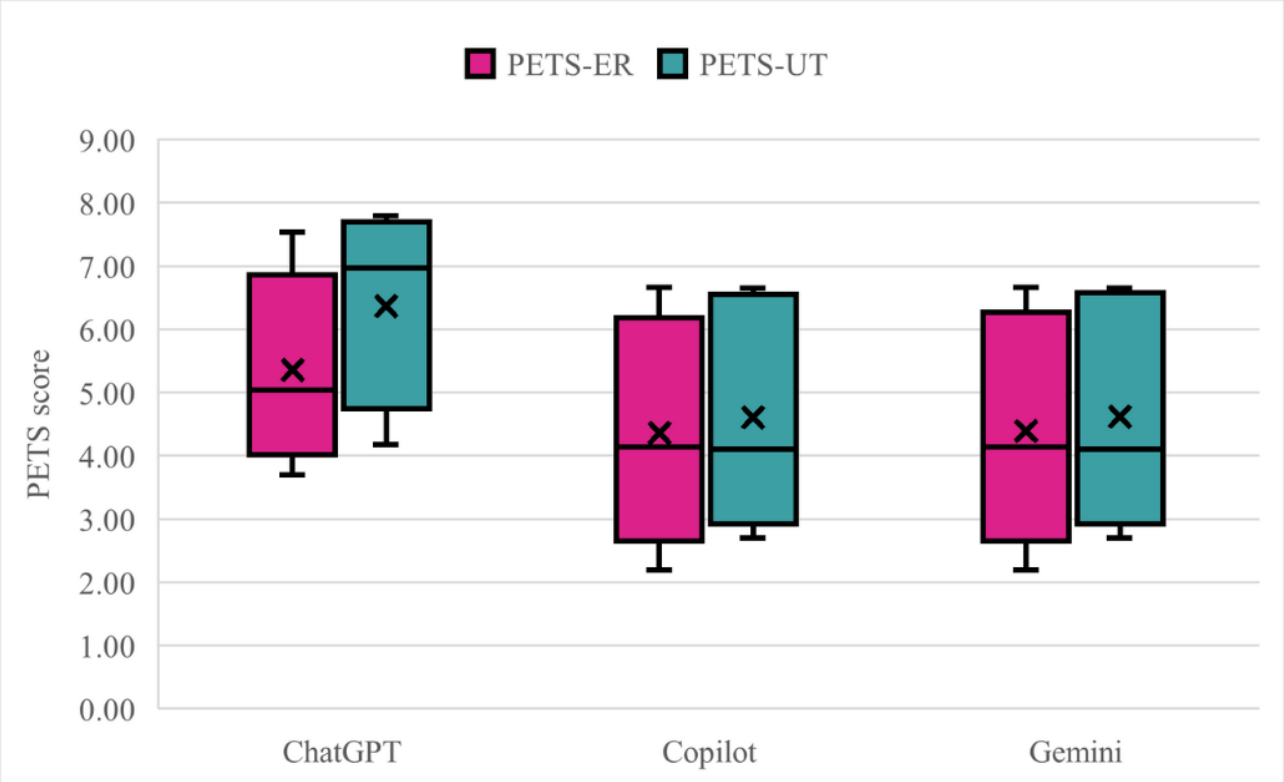


Quality variability differed across chatbots (Table 2). Copilot responses demonstrated greater variability in quality scores across question, while Gemini responses showed more consistent quality patterns. ChatGPT exhibited moderate variability for quality metrics. At the question level, Questions 4 and 5 were associated with greater variability in quality scores across chatbots, while Questions 2 and 3 yielded more similar scores across models (see Multimedia Appendix 3 for all SD). Overall, descriptive rank ordering based on average scores and variability suggests differences in consistency and distribution of information quality across chatbots.

Empathy (PETS-ER and PETS-UT)

PETS scores varied at the question and chatbot level (Table 2). Questions 1 and 2 are associated with the highest perceived empathy, and Question 5 demonstrates the lowest empathy scores (Figure 4).



XSL•FO
RenderX

Figure 4. Average Perceived Empathy of Technology Scale (PETS) across chatbot by question. Avg: average; ER: Emotional Responsiveness; UT: Understanding and Trust.

When empathy scores were summarized by chatbot, descriptive differences in average perceived empathy were observed across models (Figure 5). ChatGPT responses demonstrated higher average empathy scores compared to Copilot and Gemini, which demonstrated lower averages. Across all models, PETS-UT scores exceeded PETS-ER scores, suggesting stronger cognitive empathy and perspective taking rather than emotional expression.

Figure 5. Box and whisker plots showing Perceived Empathy of Technology Scale-Emotional Responsiveness (PETS-ER) and Perceived Empathy of Technology Scale-Understanding and Trust (PETS-UT) scores across chatbots, illustrating limited overall perceived empathy compared to understandability.

XSL•FO
RenderX

ChatGPT showed the largest UT-ER gap (mean 6.36, SD 1.83 vs 5.35, SD 1.85), indicating moderate-to-high levels of understanding, but only moderate emotional connection. Copilot and Gemini had similar low-moderate ER and UT averages, with limited perceived empathy overall. Variability patterns further distinguish AI models (Figure 5). ChatGPT produced the widest variation in empathy scores. In contrast, Gemini and Copilot showed slightly more predictable patterns of empathy.

Readability (FRE, FKGL, and Word Count)

All outputs were written at an eighth-grade reading level or higher (range 8.2 - 14.6, mean 11.82, SD 1.44, equivalent to high school senior level). The average FRE score across all AI chatbot responses was 38.60, SD 9.00, indicating difficult readability overall. Gemini tended to produce the longest but most readable responses. Copilot consistently produced shorter responses associated with lower average readability. ChatGPT produced responses with the most variability in readability and word count. Question 5 responses were the least readable (mean grade level 12.76, SD 0.71), while question 2 responses were the most readable (mean grade level 9.9, SD 1.01).

Discussion

Quality

ChatGPT responses were associated with higher average quality scores and moderate variability across multiple questions. Gemini responses demonstrated moderate quality scores with greater consistency, while Copilot responses exhibited greater variability and the lowest quality scores, even producing a factually incorrect answer regarding genetic mutations and the associated risk of developing melanoma (see Copilot 4_1 in Multimedia Appendix 4). In health communication, information quality standardization is critical because it allows for less confusion and increases patient-provider trust [12].

Quality is not only model dependent but also question reliant. Questions 1 and 2 received the highest quality evaluations, whereas Questions 4 and 5 produced lower quality scores. This pattern suggests that chatbots tend to provide more consistent responses to straightforward or well-established topics. In contrast, questions regarding more complex science with sparse and/or unclear literature, such as recurrence risk, long-term treatment effects, and genetic implications, produced less reliable responses, often without communicating their limitations. These complex topics often represent areas of greatest concern for AYA patients with melanoma, which underscores the importance of cautious interpretation of chatbot-generated information.

The review of lower-quality outputs revealed common pitfalls. Responses with low-quality scores were often oversimplified, incomplete, or presented in bullet-point style responses, with insufficient detail to address the question. The lack of actionable information was most apparent in discussions of treatment, side effects, and hormone changes. For example, when a patient asked how treatment would affect hormones, responses accurately identified potential consequences, such as adrenal insufficiency, but failed to describe symptoms. From a patient perspective, clinically beneficial communication translates these answers into recognizable manifestations at home (ie, fatigue, dizziness, or other changes). Accuracy was further undermined by the lack of transparent source citation and inconsistent use of safeguards, such as disclaimers. Instead, statements were presented as definitive, risking patient confusion when conflicting with other resources or provider guidance.

Conversely, higher-quality responses demonstrated more complete and organized content. They cited credible resources, gave disclaimers, and emphasized the importance of deferring to the health care team for individualized guidance. These responses were detailed and well-tailored to the questions, without an overwhelming word count, which improved readability and digestion of information. They had clear directions to access specific resources for further support and actionable suggestions for the patient. These qualities serve as a reference standard for future versions of AI-generated health information.

Although the overall quality scores across all chatbot responses were moderate to high, persistent gaps in sourcing and uncertainty disclosures raise serious patient safety concerns. For AYA patients with melanoma undergoing treatment, inconsistent quality can undermine trust and lead to confusion at a vulnerable stage of care. To be reliable in clinical contexts, AI systems must deliver outputs that are not only accurate and detailed but also verifiable, transparent, and responsibly framed.

Empathy

Across the 3 chatbot platforms, a central pattern emerged: systems struggled to balance clinical accuracy with emotional support. ChatGPT comparatively showed the highest empathetic capacity, while Gemini and Copilot tended to be neutral and lacking emotion. The qualitative review of responses identified a set of best practices that distinguished qualities of higher-empathy outputs from weak ones (Textbox 2). Detailed examples supporting these best practices are provided in Multimedia Appendix 5.

XSL•FO
RenderX

Textbox 2. Key best practices for artificial intelligence (AI) chatbot responses to express empathy.

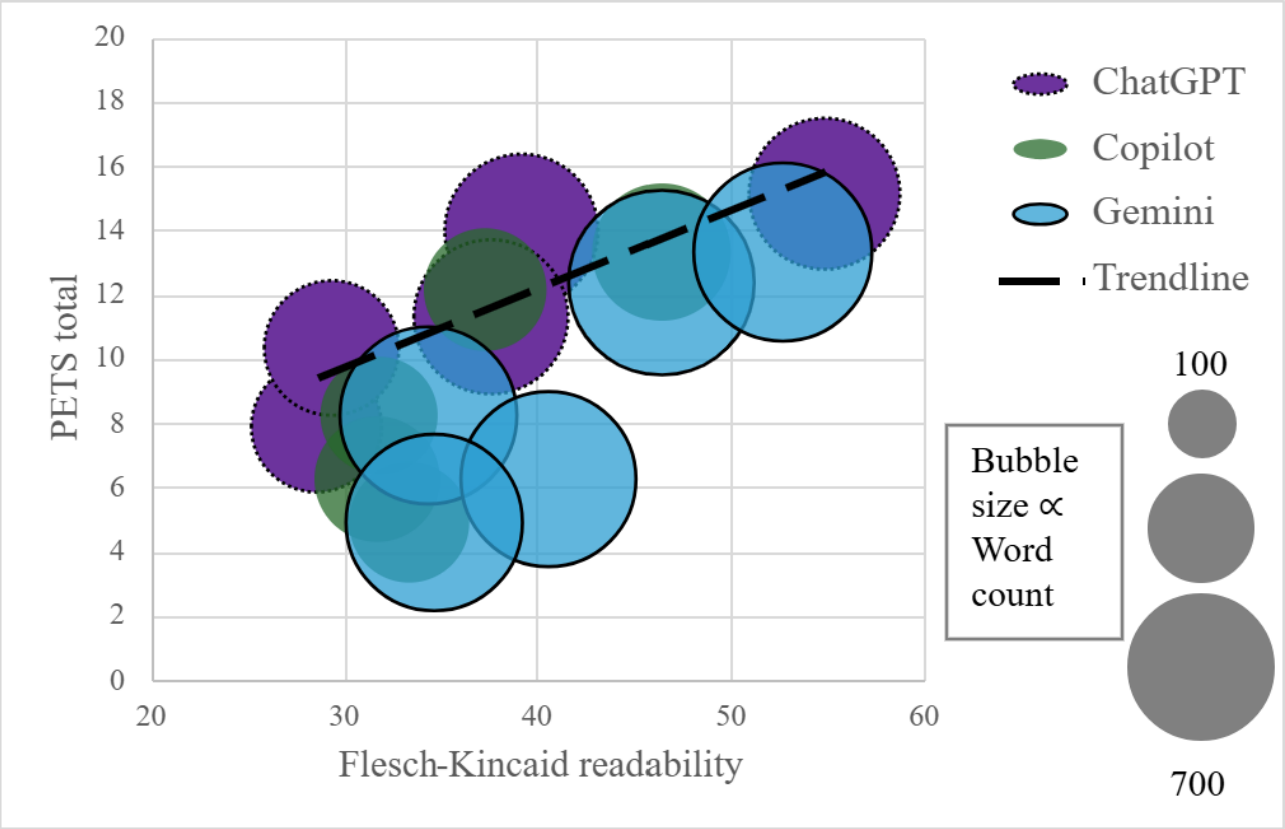
Best practices (Perceived Empathy of Technology Scale [PETS] scores)

- Open with empathy and understanding
- Asks follow-up and clarification questions
- Symptoms and side effects in plain language
- Medical disclaimers and boundaries
- Cites credible resources
- Specific actionable coping strategies
- Adolescents and young adults–specific
- Demonstrates interest in the patient
- Provides empathy in all contexts

Common pitfalls (↓ PETS scores)

- Robotic or purely clinical tone
- One-way information delivery
- Lists of side effects or clinical jargon
- Overstep scope
- Lack citations or specific resources
- Generic or overwhelming advice
- Adult-centric or generic framing
- Lack of interest or personalization
- Overlooks unspoken emotional needs

AYA patients with melanoma have unique needs compared to adults; however, chatbots often default to general or even pediatric framing [13]. When AYA patient-specific needs were addressed, it was often with a surface-level list rather than a meaningful explanation. Systems were better equipped to name emotions rather than express them, as demonstrated by higher UT than ER scores, and empathy was also prompt-dependent. Chatbot responses generally failed to infer patient distress if not explicitly stated (as seen in questions 3-5), unlike a human clinician who can use nonverbal cues and proactively address unspoken emotional needs even in the face of an analytical question. The chatbot lacks the emotional intelligence to deliver difficult news and interpret patient reactions. Responses receiving low PETS scores risk coming across as dismissive or cold, which may invalidate patient concerns and discourage them from seeking support or adhering to care recommendations in the future when they most need it.



Human providers naturally contextualize information based on patient age, life stage, current treatments, and psychosocial needs, a skill beyond a chatbot's reach. Since our 5 questions represent domains of greatest emotional and informational needs of AYAs with melanoma, the irregularity of empathy suggests that current AI systems may not adequately support this unique patient population.

Readability

Response length and readability varied across chatbots. Gemini responses were longer on average with higher readability scores, whereas ChatGPT responses demonstrated wider variability, and Copilot responses were shorter with lower average readability scores. Responses that were easier to read tended to be perceived as higher quality (GQS/DISCERN) and more empathetic (PETS) as seen in Figure 6.

XSL•FO
RenderX

Figure 6. The relationship between Flesch-Kincaid readability and total Perceived Empathy of Technology (PETS) (empathy) scores across all chatbot responses. Each bubble represents a chatbot, with size proportional to overall word count. While word count shows little association with either readability or empathy, responses with higher readability tend to receive higher empathy scores.

Readability analysis revealed that all chatbot responses exceeded the US average reading level (7th-8th grade), with outputs averaging at the 11th-12th grade level. This creates a barrier for accessibility. These findings echo prior research that health care documents are often written at a level too high for general populations, reducing inclusivity and comprehension [14]. Unlike clinicians, who are trained to use strategies such as follow-up questions and the "teach-back" method, chatbots do not check understanding unless prompted. This may highlight a key limitation of AI chatbots for medical communication. They draw primarily from online sources, which are often already written at inflated reading levels, and thus lead to reproduced complexity by AI outputs [15]. Clinicians, by contrast, are trained to adapt explanations to patient literacy, developmental stage, and clinical context.

Readability is particularly important for AYAs, whose health literacy may be affected by education disruption, treatment-related cognitive impairment, and emotional distress. Cancer-related cognitive impairment affects approximately 25% to 28% of AYA survivors and may affect attention, memory, and processing speed, increasing the cognitive burden of complex medical information [16]. The National Comprehensive Cancer Network Guidelines for AYA Oncology emphasize that information should be delivered in an age-appropriate and developmentally appropriate manner, particularly in the context of disrupted education and psychosocial stressors [17]. While no evidence-based guidelines specify an optimal reading level for AYA oncology populations, the commonly cited 8th-grade target is extrapolated from general health literacy recommendations and represents a pragmatic benchmark rather than an AYA-specific threshold.

AI may therefore generate content that is technically accurate but inaccessible, potentially leading to confusion or disengagement. For proper implementation, chatbots should aim to target their output responses of health care information to an 8th-grade level and incorporate interactive strategies that mimic provider feedback loops. Without these adjustments, the use of AI to answer the needs of AYA patients with melanoma remains limited.

Patient Safety and Clinical Implications

Although AI chatbots may provide AYA patients with adequate education, support, and resources regarding their diagnosis, they cannot replace clinician input and should be used cautiously. The potential dangers associated with patients using AI in health care are multifaceted, with key risks including misinformation, unsafe recommendations, lack of understanding of the questions being asked, and insensitivity. Given that AYAs are the primary users of AI compared to other age groups, they may be particularly vulnerable to these risks due to their vulnerability to algorithmic bias and variable access to clinical guidance [18]. These risks are inferred from content characteristics of chatbot responses and were not measured as patient outcomes in this study.

AI use in health care has been shown to spread misinformation [19]. In our study, we found that chatbot explanations regarding the causes of metastatic melanoma and recommendations for next steps may include inaccurate or misleading information.

XSL•FO
RenderX

Responses across all 3 platforms often focused on sun avoidance and using sun protection factor to prevent melanoma recurrence or secondary malignancy. Although this advice may be relevant for certain patient populations, it is not applicable to all patients, particularly for individuals with skin of color. As a result, responses lack inclusivity for diverse patient communities. Additionally, some chatbot responses encouraged AYA patients to explore clinical trials available for their conditions. While well-intended, this response is particularly unsafe to AYA patients, as it may increase the risk of false hope or confusion if patients are encouraged to consider trials that are not medically appropriate. Some responses even offered to interpret lab and genetic testing results. While AI chatbots have the potential to explain pathology reports and simplify medical jargon to patients, their interpretations are not flawless and should be used carefully with clinician oversight [20]. Encouraging vulnerable patients to input their private health information to AI systems may expose them to breaches of data privacy and security, potentially leading to unauthorized access or misuse of sensitive medical information [21].

Limitations

This study evaluated a limited number of single-turn responses (5 question and 75 single-turn responses), which may not fully capture chatbot performance. AI chatbots can refine responses through follow-up prompts, so the single-turn design does not reflect extended, multiturn conversations. This limitation may influence the perceived quality, empathy, and readability of chatbot responses. Studies testing multiturn chats may be beneficial in the future. In addition, chatbot responses are sensitive to prompt phrasing and contextual detail, and the use of subjective scoring instruments introduces potential variability in interpretation. Each response was independently evaluated by 2 reviewers per domain, with scores averaged to reduce individual rater bias. For transparency, we have included all outputs in Multimedia Appendices 4, 6 and 7 as well as an example of the grading process with score justifications in Multimedia Appendix 8. Formal interrater reliability statistics were not calculated, which limits quantitative assessment of scoring consistency. Although duplicate independent scoring with averaging was used to reduce subjectivity, future studies with larger and cross-disciplinary reviewer pools should incorporate formal reliability testing to further strengthen methodological rigor. Additionally, the separation of reviewer roles by domain may introduce systematic differences in scoring interpretation.

Future Directions

Moving forward, we aim to use responses from this dataset to develop resources within melanoma oncology clinics that answer these questions and provide higher-quality and safer responses for AYA patients with melanoma. By providing age-appropriate education and support tools, we hope to improve the treatment experience and the overall well-being for AYAs navigating melanoma care. This will help expand the currently limited resources available for AYAs currently receiving treatment and hopefully bring more attention to the unaddressed survivorship needs of patients. Future clinic-integrated resources would be developed with clinician oversight and human evaluation to ensure accuracy, safety, and appropriateness for patient use, rather than relying on autonomous AI fine-tuning. If this study were to be replicated or expanded upon, it would be helpful to incorporate intraclass correlation coefficient or Cohen κ into the data analysis to correct for discrepancies in the grading system. Additionally, this study establishes a patient-centered framework that can be applied to future research evaluating AI chatbot communication around emerging and experimental melanoma therapies, including novel immunotherapies and mRNA-based cancer vaccines. Our findings suggest that chatbot performance declines in areas with limited or evolving scientific literature, indicating that AI responses on new treatments or clinical trials may be particularly vulnerable to misinformation or oversimplification. Future studies should specifically assess this phenomenon to generate realistic expectations for AYAs navigating the rapidly evolving melanoma therapeutic landscape.

Conclusion

This study provides an evaluation of the utility of AI to answer the most pressing needs of AYA patients with melanoma currently receiving treatment. Overall, chatbot responses were often informative but demonstrated persistent gaps in quality, empathy, and readability. Patient safety may be at risk due to the inability of AI systems to integrate patient context, emotional nuance, and conversational reciprocity into answers. Question wording, emotional phrasing, and clarity were predictive of the responses received. When questions addressed topics covered by multiple publications, AI responses were more consistent, with higher quality. However, when questions addressed controversial or rapidly changing topics, AI responses were often vague. Quality, empathy, and readability were all interconnected, as higher-rated responses incorporated clear and concise wording, showed interest in the patient's medical status, provided tangible resources and references, and recognized the limits of AI, encouraging further conversation with medical providers. This research should be replicated and can provide a reference standard for future AI chatbot responses for AYA patients with melanoma.

Acknowledgments

The authors declare the use of generative artificial intelligence (GAI) in the research process. According to the GAIDeT taxonomy (2025), data collection was delegated to GAI tools under full human supervision. The GAI tools used were ChatGPT (GPT-4o), Gemini, and Copilot. Responsibility for the final manuscript lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Data Availability

The dataset generated during this study, including all chatbot outputs and scoring, is available in the Multimedia Appendices. No human participant data were collected.

Authors' Contributions

JLJ and PLH are co-first authors and contributed equally to this work. JLJ, PLH, and KCN contributed to conceptualization and methodology; JLJ and PLH contributed to question development, empathy, readability scoring, and manuscript writing. RPM, SZ, ALO, and KMR performed question input and data collection. MR provided project oversight and expert clinical opinion. MHS contributed to manuscript writing and editing, quality scoring, and response review. KCN served as principal investigator; provided project oversight, conceptualization, methodology, contributed to data collection; and participated in manuscript writing and editing. All authors reviewed and approved the final manuscript.

Abstract

Background: About 4 in 10 people in Sweden get cancer during their lifetime, and approximately half of them will be diagnosed during their working life. As cancer survival rates improve, a growing number of individuals face challenges in returning to work following treatment. This increases the demand for effective return-to-work (RTW) strategies. Despite existing rehabilitation frameworks, cancer survivors often encounter barriers to sustainable work reintegration.

Objective: This study aimed to investigate stakeholders' perceptions of facilitators and barriers to RTW among cancer survivors, including factors promoting work-related well-being during the RTW process.

Methods: During the development phase of a work-oriented rehabilitation intervention, semistructured interviews were conducted, with 25 stakeholders involved in the RTW process: health care professionals (n=12), social insurance officers (n=7), employers (n=5), and an employment service agency officer (n=1). Data were analyzed using qualitative content analysis.

Results: Five overarching themes were identified that influenced RTW: collaboration and clear division of responsibilities, balancing individual adaptations, reducing structural barriers through support, views and expectations of the individual regarding RTW, and the emotional significance of work. Key facilitators included flexible work arrangements, individualized adaptations, a strong desire to work, and the emotional value of work. Barriers comprised lack of collaboration among stakeholders, particularly the absence of a clear division of responsibilities, as well as structural barriers, such as sick leave bureaucracy and financial obstacles. The role of rehabilitation coordinators was highlighted as pivotal in bridging gaps between stakeholders and ensuring continuity in care.

Conclusions: RTW for cancer survivors is a complex, multifactorial process requiring coordinated efforts across health care, insurance, and employment sectors. Enhancing collaboration, clarifying stakeholder responsibilities, and implementing flexible, individualized support structures are essential to facilitating cancer survivors' RTW. Additionally, including a designated coordinator in the process is proposed. More support during the early phase of RTW is necessary to reduce the risk of long-term labor market exclusion. To help cancer survivors' RTW, clear role definitions and shared responsibilities among stakeholders are essential. Flexibility in the RTW process helps individuals reintegrate at their own pace, reduces isolation, and promotes social connection. These are key considerations for future policies and support measures.

Introduction

When developing work-oriented rehabilitation interventions, it is crucial to consider the experiences of stakeholders in their working life. Understanding barriers and facilitators can enhance successful implementation of such interventions into practice [1,2]. Over the past 30 years, the global incidence of cancer among individuals younger than 50 years has risen by 79%. This trend is particularly pronounced in high-income countries, influenced by lifestyle factors and enhanced diagnostic methods [3,4]. Concurrently, advancement in cancer treatment has markedly improved survival rates for many cancer types, especially those affecting working-age populations [5]. In Sweden, it is noteworthy that almost half of all cancer cases are diagnosed during people's working years [6]. Consequently, cancer survivors, individuals diagnosed with cancer who are still alive, are likely to remain active on the labor market for many years to come [7]. This reality underscores the importance of facilitating return to work (RTW) postdiagnosis [8-11]. Furthermore, cancer diagnoses have significant economic consequences for both individuals and society. Patients frequently experience considerable financial strain due to lost income from prolonged sick leave or reduced working hours [9]. On a societal level, the economic impact of cancer-related work absence in Sweden is substantial, estimated at approximately US $4 million annually, which is comparable with the cost associated with outpatient cancer care [12].

Although cancer treatment has improved survival, many survivors experience long-term physical, cognitive, and psychological effects that can hinder individuals' work ability. Although more cancer survivors return to work [13], many face functional limitations [14,15], and about 25% of cancer survivors did not return even 14 years postdiagnosis [16]. Among those who do not return, many work part-time [17] or attribute their absence to mental illness, chronic pain, or musculoskeletal disorders [18]. In the Nordic countries, 14% of cancer survivors received disability pension 7 years after diagnosis [7], and many reported reduced work ability (K Tödt et al, unpublished data, 2026). Previous studies of common cancer types in Sweden, including breast, colorectal, and prostate cancer, have demonstrated that many survivors experience prolonged work absence following diagnosis and treatment. More recent evidence from a nationwide registered-based prospective cohort study showed that, even after returning to work, cancer survivors had a substantially higher risk of future labor market marginalization [19]. Specifically, they exhibited a 1.6-fold increased risk of new sick leave episodes, a 2-fold higher risk of receiving a disability pension, and a 1.3-fold increased risk of unemployment compared with matched individuals with no cancer [19]. These findings underscore the need for a comprehensive rehabilitation approach, viewing RTW as a complex process requiring coordinated medical, psychosocial, and work-oriented rehabilitation [20].

Prior research has shown that many cancer survivors are motivated to maintain or resume employment during and after treatment [13,21]. Prolonged absence from work is associated with reduced quality of life [22] and may erode dignity, social identity, and financial security [23,24]. These challenges have intensified calls for more effective multiple-stakeholder interventions to support occupational reintegration [8-11].

Motivation to return to work is shaped by both personal and contextual factors. Social support from family, peers, colleagues, and employers reinforces a sense of belonging and security, thereby facilitating labor market reintegration [8,11]. Equally critical are workplace conditions: flexible work arrangements, task modifications, and organizational cultures oriented toward inclusivity and health promotion, which are consistently identified as facilitators of RTW [7,9]. Collectively, the evidence underscores the importance of supportive networks and enabling organizational structures to reclaim their professional role following treatment.

Theories concerning cancer and work emphasize the importance of tailoring rehabilitation interventions to the individual cognitive and emotional resources of survivors, as well as to the specific demands they face related to their illness, treatment, work, and personal circumstances [20]. In non–cancer populations with, for example, musculoskeletal or mental illness disorders, the most promising interventions for RTW were found to be multidisciplinary, involving several stakeholders [11,25]. Reviews have shown positive effects of cancer rehabilitation in general, but several areas remain underdeveloped, particularly regarding RTW [15,26]. Cancer rehabilitation seeks to prevent and alleviate cancer-related consequences [15,26], while work-oriented rehabilitation specifically addresses those affecting work participation [10].

Approaches to cancer rehabilitation and RTW vary considerably across European countries. Differences in health care and social insurance systems, as well as in the distribution of responsibilities among stakeholders, shape both the design of interventions and how they are perceived by employers, health care providers, and insurance agencies [16,27,28]. Research highlights the importance of adapting rehabilitation strategies to each sociopolitical and institutional context, while also addressing the specific needs of cancer survivors and involved stakeholders [8,9,11]. The Swedish context illustrates this well. Employers are liable for wage compensation during the first initial 14 days of sick leave, after which financial benefits are administered by the Swedish Social Insurance Agency. Employers are responsible for workplace-related interventions, whereas the Swedish Social Insurance Agency coordinates actions among relevant authorities and stakeholders.

Important stakeholders regarding work participation include health care professionals in cancer, primary and occupational health care, managers, and social insurance officers [29-31]. Previous research has stressed that cancer survivors often require more comprehensive support from these diverse working-life stakeholders to facilitate a sustainable RTW process [21].

To enhance intersectoral collaboration, the Act on Coordination of Rehabilitation Efforts (Act no. 2019:1297) mandates the establishment of rehabilitation coordination. These professionals, commonly occupational therapists, physiotherapists, social workers, or registered nurses, serve as intermediaries between patients and key actors within the RTW process [32]. Their responsibilities include providing individualized support, ensuring communication across organizational boundaries, and

XSL•FO
RenderX

facilitating the development of personalized rehabilitation plans [33]. At the core of the Swedish RTW system lie systematic assessments of work ability and structured measures aimed at promoting workplace reintegration. Collectively, these arrangements are intended to provide a coordinated and equitable approach to supporting individuals on sick leave.

Although the Act on Coordination of Rehabilitation Efforts requires regions to provide coordinated rehabilitation, these are often delivered through rehabilitation coordinators whose roles and visibility vary across settings [32,33]. Research suggests that coordinators may support RTW processes through continuity and coordination [20], but evidence of their effectiveness in improving RTW outcomes is inconsistent [10]. Although rehabilitation coordinators represent one important stakeholder in RTW processes, this study adopts a broader perspective to capture how facilitators and barriers emerge across multiple interacting actors.

Previous research has identified various facilitators and barriers to RTW after cancer [9,34,35], but much of this evidence is based on heterogeneous contexts [9] and overlooks how institutional conditions shape the RTW processes [16,36]. This is particularly relevant in Sweden, where RTW involves multiple actors across health care, workplaces, and the social insurance systems [17,19]. Key stakeholders' perspectives also remain underexplored [23,31,37], especially regarding how these actors interact in practice [38], an important gap given that RTW is a multiactor process. Recent structural changes, such as the introduction of rehabilitation coordinators, have further reshaped RTW processes [32,33], yet limited empirical knowledge exists about how stakeholders experience these changes [21,39]. Against this backdrop, this study was conducted to generate context-specific, empirical insights into facilitators and barriers to RTW after cancer from a multistakeholder perspective. The study contributes by (1) integrating multiple stakeholder perspectives, and (2) informing the development of a tailored intervention.

Hence, it is essential to further explore and describe the perspectives of stakeholders themselves, as their roles, perceptions, and interactions are central to shaping the conditions under which cancer survivors attempt to resume working life. The aim of this study was to investigate working-life stakeholders' perceptions of both facilitators and barriers to RTW among cancer survivors, including factors for work-related well-being during the RTW process.

Methods

Study Design

This qualitative study was a part of the development phase of a complex intervention following the updated Medical Research Council framework [40] regarding work-oriented rehabilitation. A qualitative interview design was chosen to gain an in-depth understanding of stakeholders' experiences and perceptions of cancer survivors' RTW process. Semistructured interviews were conducted with 25 stakeholders representing various roles in the RTW context during spring 2023. The qualitative interview approach provided flexibility and allowed participants to elaborate on issues of personal and professional relevance [41].

Sample participants were recruited using purposive sampling to ensure variation in characteristics, geographic locations, and work settings (specialized care, primary care, and public and private sector). Purposive sampling involves the intentional selection of information-rich cases to capture diverse experiences related to the studied phenomenon [42]. The sampling aimed to capture variation both between stakeholder groups and within groups comprising multiple roles. For example, the health care professional group included several relevant clinical disciplines (physicians, nurses, occupational therapists, and physiotherapists). The sampling strategy also reflected the stakeholders commonly involved in RTW processes for cancer survivors, resulting in higher representation of health care professionals and representatives from the Swedish Social Insurance Agency, while representation from Employment Agency officers was more limited (n=1). Rehabilitation coordinators were included as one of several stakeholder groups; however, the study was not designed to specifically examine their role but rather to explore facilitators and barriers to RTW across multiple stakeholders.

Participants represented 3 regions in central Sweden, involved in a larger research program developing an intervention to support cancer survivors' RTW. Stakeholders included health care practitioners (registered nurse, occupational therapist, physician, counselor, and rehabilitation coordinator), social insurance officers, employment service agency representatives, and first-line managers from private and public employers. Selection was based on experience supporting cancer survivors in maintaining or returning to work during cancer treatment. Inclusion criteria were employment within a stakeholder group relevant to RTW processes (ie, health care professionals, social insurance officers, employment service officers, social workers, or first-line managers) and experience of supporting cancer survivors in RTW. No specific exclusion criteria were applied; however, all participants were required to be able to participate in an interview conducted in Swedish. The study followed COREQ (Consolidated Criteria for Reporting Qualitative Research) [43].

Setting

The study was conducted within the Swedish RTW system, a tax-funded framework involving health care services, employers, and the Swedish Social Insurance Agency. Employers provide sick pay during the initial 2 weeks of sick leave, after which the Swedish Social Insurance Agency assesses work capacity, administers benefits, and coordinates rehabilitation in collaboration with health care providers. Employers are also responsible for workplace-based rehabilitation, while additional support, such as rehabilitation, may be provided by the Swedish Public Employment Service (Act no. 2019:1297).

RTW processes typically involve ongoing interaction between these stakeholders, where health care providers assess work ability, employers implement workplace adjustments, and the Social Insurance Agency coordinates measures and monitors eligibility for benefits. For individuals with cancer, the system includes specific regulations and coordinates efforts intended

XSL•FO
RenderX

to support a gradual and individualized RTW process, although the level of coordination may vary.

Data Collection

A study coordinator recruited participants in 2 stages. First, brief study information was emailed to key organizational contacts relevant to the study, who were asked to forward the invitation to potential participants. Interested individuals contacted author SLF for further information. Subsequently, comprehensive information was provided, eligibility criteria were verified, and participants were informed about the purpose of the study. Initially, 26 individuals expressed interest in participating; however, 1 participant withdrew prior to the interview due to personal reasons, resulting in 25 completed interviews. Participants provided informed consent and, immediately before the interview, completed a brief web-based survey describing their demographic characteristics (Table 1). Participants' age ranged from 39 to 65 years, and those who were employers had between 8 and 46 employees (median 43).

Table . The participating working-life stakeholders.

Variable	Participants (n=25)

[a]Their occupations were nurse (n=3), occupational therapist (n=3), physician (n=3), counselor (n=1), and rehabilitation coordinator (n=2). The health care settings were specialized care (n=9) (eg, oncology: n=4), primary care (n=2), and occupational health care (n=1).

[b]The employers worked in the public sector (n=3), private sector in a middle-sized company (n=1), or private sector in a big company (n=1).

[c]In their present occupation.

[d]Being health care professionals within primary care or rehabilitation clinics.

[e]Being employers.

[f]Distributed by the Confederation of Regional Cancer Centres [44].

The authors SLF, LE, PF, and MF interviewed the stakeholders individually, one-on-one in a video meeting. The interviewers comprised a district nurse, an occupational therapist, and 2 oncology nurses; 3 were women and 1 was a man. The interviewers had both professional experience in clinical cancer care and experience in conducting qualitative interviews. A semistructured interview guide was followed (Textbox 1), asking follow-up questions as needed to deepen or expand responses, in line with qualitative interview methodology [41]. Interviews were audio-recorded, lasting between 20 and 71 minutes (median 42 minutes).

XSL•FO
RenderX

Textbox 1. The semistructured interview guide.

At the beginning of the interview, the interviewer introduced themselves and briefly described their professional background. The interviewer presented a case study based on a fictional patient "Kim" on whom the informants were asked to base their reasoning. The first questions were connected to this case, and the case description formed the basis for the interview. In the last questions of the interview, we moved away from the Kim case and asked interviewees to talk more generally about the questions. When necessary, field notes were made. A detailed description of the case used during the interviews is provided in Multimedia Appendix 1.

Interview questions

- What challenges do you anticipate regarding work in relation to having cancer?
- Could you tell me if you have a role in supporting individuals' work and occupational health during or after cancer treatment, and if so, what does this involve?
- Can you tell me which other actors have roles here?
- What do you believe could promote work and health here, and what do you believe could hinder work and health?
- Does Kim, in this example, need any support regarding work and health? If so, please describe it.

Moving beyond the case of Kim

- If anything were possible, what kind of support would need to exist to support people's work and health during and after treatment?
- As a final question, we have now discussed...(your role, other stakeholders, collaboration, and support related to work and health). Is there anything else you would like to add regarding work or health in relation to work for individuals during or after cancer treatment?

Data Analysis

According to Elo and Kyngäs [45], the interviews were transcribed verbatim and analyzed using qualitative content analysis. Initially, transcripts were read several times by authors SLF, KW, and MF to gain familiarity. No dedicated qualitative analysis software was used. Instead, data were managed in Microsoft Excel to organize transcripts, track codes, and collate categories. Data handling followed strict standards of integrity and confidentiality.

Transcripts were evenly distributed among these authors, who independently extracted meaning units relevant to the study aim and generated initial categories and subcategories. Subsequently, these authors collaboratively reviewed their analyses, refined categories and subcategories, and reached consensus on findings. All 25 interviews were analyzed as a single dataset. No separate analyses were conducted by stakeholder groups; instead, themes were developed based on patterns identified across the entire material. During coding, sector-related nuances were noted and considered in the interpretation, but no formal comparison between stakeholder groups was performed. An example of the analytic structure is illustrated by the data unit "Most people want to work. I have to say it's an extremely exciting experience working with people, that everyone is so eager to get back to work. I think so." which was coded as "Most people want to work," grouped into the subcategory "Desire to work," and further abstracted into the category "Emotional significance of work." Trustworthiness was ensured through analyst triangulation to enhance credibility and reduce interpretative bias [42]. Dependability and confirmability were supported through transparent documentation and regular discussion within the research team [46]. Reflexivity and methodological transparency were emphasized to strengthen credibility and transferability, in line with qualitative research standards [41]. The research team included members with backgrounds in nursing, health-related research, and occupational therapy, which contributed to multiple professional perspectives during data interpretation. Reflexive discussions throughout the analytic process increased awareness of potential preunderstandings and supported interpretative rigor.

Ethical Considerations

The study was approved by the Swedish Ethical Review Authority (registration numbers 2022-03686-01, 2023-05671-02) and conducted in compliance with the Declaration of Helsinki (World Medical Association, 2013). Informed consent was obtained from all participants. Participants did not receive any financial or material compensation for their participation.

Results

Overview

Barriers and facilitating factors regarding RTW were identified not only in the individual adaptations made by cancer survivors but also in cooperation among stakeholders. Structural issues, including financial obstacles and sick leave regulations, also influenced RTW outcomes. Highlighted factors promoting work-related well-being were flexibility and personalized adaptations. Categories and subcategories are presented in Table 2.

XSL•FO
RenderX

Table . Categories and subcategories of stakeholders' perceptions of both facilitators and barriers to work among cancer survivors in a return to work process.

Category	Subcategory
Collaboration and clear division of responsibilities	• Desire for developed and improved cooperation • Who is responsible for what? • Clear division of responsibilities
Balancing individual adaptations	• Adaptations to the work situation • Flexibility in RTW[a] • A balancing act
Reducing structural barriers through support	• Financial obstacles to RTW • Challenging sick leave bureaucracy
Views and expectations of the individual effect of RTW	• Courage to push and set demands • Inclusion in the workplace
Emotional significance of work	• Desire to work • Existential questions take focus

[a]RTW: return to work.

Collaboration and Clear Division of Responsibilities

The interviews revealed not only a strong desire for more developed and improved collaboration among stakeholders but also a lack of awareness about available support and confusion over roles and responsibilities. Stakeholders emphasized the need for a structured collaboration plan to clarify roles and enhance teamwork. This, according to them, would facilitate collaboration and ensure that each party had a clear understanding of their respective roles and responsibilities.

Desire for Developed and Improved Cooperation

The informants stressed that cooperation between stakeholders sometimes had been lacking or functioned poorly, negatively affecting the RTW process. They described an impermeable silo mentality among stakeholders who were expected to collaborate, causing irritation and frustration over this lack of coordination, emphasizing that it had hindered efficiency in helping individuals return to work.

> *I often get nasty answers and a feeling they think I'm not knowledgeable and that I disrupt contact with healthcare. That can be a barrier to returning to work.* [12, Social Insurance Agency]

Throughout the interviews, a desire to increase and improve cooperation emerged. Informants strongly believed that closer collaboration is crucial for addressing the challenges and would lead to better, more coordinated outcomes. They noted that greater cooperation would have benefited cancer survivors' RTW and resulted in better, faster, and more cost-effective care. Furthermore, informants also argued for a unified body to oversee the overall coordination.

They felt that moving away from siloed work structures toward team-based collaboration would be better for everyone and more cost-effective for society. Teamwork was seen as promoting continuity and reducing vulnerability, since remaining members could ensure stability even if 1 key person was replaced.

> *We need more cooperation in teams. The healthcare system would save a lot of money if we got out of our silos, if we worked in teams, which I've had the benefit of doing at times. Because then you really can help people, compared to getting help from a physical therapist here, then a doctor and then a nurse, an occupational therapist, a psychologist. And then they don't talk to each other.* [6, occupational therapist]

Informants working in inpatient hospital care described well-functioning collaborations and established team models, but in other areas there was a total lack of collaboration between specialties. They emphasized the importance of enhanced collaboration, suggesting specialized outpatient teams with in-depth knowledge of diseases, as this might be difficult for primary care to manage on their own. They also recommended appointing a dedicated coordinator to oversee and support the entire RTW process and stressed the need for clear consensus and direction from higher leadership levels. Rehabilitation coordinators were highlighted as important facilitators of collaboration and serve as a link supporting cancer survivors' RTW.

Who Is Responsible for What?

Among the informants, there was a perceived lack of knowledge about who was responsible for what, which they believed hindered the RTW process. More broadly, they noted an insufficient understanding of the tasks and roles of different professional groups and their potential contributions. This lack of clarity and knowledge was seen as a cause of failed initiatives, thereby negatively affecting the process. Furthermore, interviews revealed a lack of trust in the competence of certain individuals expected to participate in the sick leave process.

> *...something I wonder about is that the person who's supposed to decide on the sickness benefit isn't required to have any knowledge at all of healthcare but is responsible for coordination.* [19, manager]

XSL•FO
RenderX

Informants emphasized frequent mistreatment by the Social Insurance Agency. Some described such negative experiences that they questioned the agency's role and purpose in the sick leave process. They believed that this situation imposed further barriers to the RTW process for cancer survivors.

> *The collaboration between actors is dysfunctional—the Social Insurance Agency ignores us when we contact them; I'm not sure what they're good for.* [10, physician]

On the other hand, it was mentioned on several occasions that Social Insurance Agency employees felt that they were treated poorly, particularly by doctors.

> *Well, it's just that you feel you don't know anything and that you're a bother. Unfortunately, with time I've gotten quite a few sarcastic answers when I've...or supplemented a doctor's certificate that I should have understood.* [12, Social Insurance Agency]

They described experiencing a sense of being a disturbance and sometimes having been given substandard sick leave documentation to manage. When they asked supplementary questions, they felt that their inquiries were considered foolish and that they were expected to know more.

Clear Division of Responsibilities

During the interviews, the informants reported a lack of division of responsibilities and expressed a desire for greater clarity around who was responsible for what. They emphasized that lack of clarity regarding division of responsibilities prolonged the RTW process or, in some cases, prevented it altogether.

> *I said she should do work training, but her employer was on vacation, so I had to put her on full-time sick leave // --- // I had to change her sick leave several times. If the Social Insurance Agency had contacted me instead, it would have been much simpler than having a patient try to explain.* [8, physician]

There was a desire for a holistic approach to RTW that also considered social aspects. Doctors reported having control over medical issues but noted that the social perspective received far less attention due to time constraints. They believed that the process could have been facilitated and improved if a more holistic approach had been applied. Informants repeatedly stated that a specialized unit focusing on RTW for this group would have facilitated the process. The need for such a unit was further emphasized by those who described the situation as complex. They explained that doctors were sometimes expected to issue sickness certificates even when they were no longer involved in the patient's treatment and had limited knowledge of, or contact with, the patient.

> *Then there's another aspect I think is sometimes a bit complicated. It's that a lot of follow-ups occur through me, where they don't have a doctor to contact, but anyway it's the doctor who's supposed to be behind the sick leave, which can sometimes cause confusion.* [2, occupational therapist]

To improve efficiency and clarify responsibilities, informants suggested involving certain functions earlier in the process and assigning them a more defined role as a consistent link throughout the process. They emphasized the need for a dedicated person to follow up with the patient beyond the acute stage, indicating that the rehabilitation coordinator was well suited for this role.

Balancing Individual Adaptations

The stakeholders reported that a flexible RTW approach was required to facilitate cancer survivors' RTW process during and after cancer treatment, where tasks were adapted to cancer survivors' abilities and needs. They said the process can be compared with a balancing act that requires continual adjustment in how it is set up.

Adaptations to the Work Situation

To facilitate a smooth and sustainable RTW process, informants reported tailoring the work situation to individuals' needs. They emphasized adapting tasks and establishing a plan that ensures long-term sustainability for cancer survivors. Gradually increasing workload, based on a plan developed with the cancer survivor, was seen as essential. They also stated that adaptations may be necessary if cancer survivors are unable to handle excessive sensory input or work in large groups.

Informants noted that it is the manager's responsibility to modify the work situation and ensure a workable solution. Specific adaptations could include adjusted working hours or a condensed schedule for additional recovery time. Informants indicated that, although most employers recognized the need and were willing to make individual adjustments, ongoing challenges persisted. The time required to identify alternative solutions for employees varied, and in recent years the process has sometimes been more challenging and restrictive. Some informants perceived a reluctance among employers to adapt to cancer survivors' working situation.

> *Maybe returning to work full-time isn't doable, so instead you get to see if there are alternative solutions. But you're always thinking along with colleagues and maybe others, so that you always have a plan, continuous conversations, follow-ups, so that all parties are agreed on the direction we're going in.* [21, manager]

There were different opinions about how flexible the system is in helping cancer survivors return to work after treatment. Some felt that making individual adjustments had become easier, while others thought that it had become more difficult due to changes in legislation. The bottom line, however, is that everyone felt that being able to make flexible adjustments was important.

Flexibility in RTW

Although work tasks were adapted to cancer survivors' needs, informants noted that plans often required rebalancing as the survivors' requirements changed after returning to work. Flexible tasks include the possibility to take short breaks during the day, while adjustment and shielding were sometimes necessary for those with treatment-related immune weakness,

XSL•FO
RenderX

increasing vulnerability to infection. Consequently, cancer survivors might need to influence aspects of their work situation to ensure their own health and safety.

> *Well, sometimes people's immune system is suppressed due to treatment, or lack of treatment. So, then we've...Well, not discouraged her, but said you can do that from home during this period, that would be good, to avoid possible risks, like.* [21, manager]

Employees may also have the flexibility to be at the workplace at times that suit them, with the option to work remotely and participate in meetings virtually.

A Balancing Act

Regarding the RTW process, the informants emphasized that it is a balancing act that affects how successful RTW and the process will be. They noted that planning is easy, but that checking progress along the way is often neglected. That neglect often undermines a sustainable RTW. Without regular check-ins, the likelihood of a successful transition decreases. It is crucial to navigate the process by finding the right balance between pushing forward and pulling back when needed.

> *In my experience, it's easy to push things and go too fast.* [19, manager]

The informants found it important to be aware of physically and mentally demanding tasks and to monitor cancer survivors' progress, checking how they manage these responsibilities. Furthermore, they emphasized the need to avoid putting excessive pressure on cancer survivors, while still valuing and using their skills and expertise. Finding this balance is essential and plays a significant role in ensuring a sustainable RTW.

Reducing Structural Barriers Through Support

One area the interviewees felt had worsened concerned the structural barriers that could arise in connection with RTW. Among other things, they thought that regulation of working hours for RTW was a problem. They also pointed to the financial situation that could arise when employees wanted to return to work but for various reasons were unable to perform their regular tasks, as this could lead to increased costs. Furthermore, they stressed that lack of qualified access was an obstacle to creating a "smooth" RTW process.

Financial Obstacles to Returning to Work

Informants reported that patients' financial situation could be a barrier to RTW. A key challenge was that employees were often unable to perform their pre-illness tasks. Even when employees could not carry out their duties fully, employers were still required to cover the costs, creating difficult circumstances. This could result in a situation where patients wanted to return to work, but employers could not afford to accommodate them. Conflicts sometimes arose when employees believed that they could work while employers doubted their ability.

Refusals or dismissals in such cases were described as more common among larger employers who, despite greater resources, still struggle to make necessary adjustments. Similarly, physically demanding occupations, such as industrial work, often faced considerable challenges in providing suitable accommodation. Nonetheless, many employers, despite lacking financial support, allowed employees to return even when not fully able to work, demonstrating notable commitment and fostering a more inclusive work environment.

> *I think it's pretty great that so many employers take them back, because they don't gain anything; they're just helping out. People need different degrees of support, but just having a supervisor, a specific person, I think that's a good foundation for things working out.* [18, Employment Service Agency]

One proposal that emerged in the interviews was that employers who accepted employees who were not yet fully able to work should receive financial support. The informants emphasized the importance of individuals feeling needed and having a role, without feeling like a financial burden on the employer.

Challenging the Sick Leave Bureaucracy

There was a broad consensus among informants that simplicity and flexibility in sick leave regulations were health-promoting, although not all agree. While many acknowledged recent simplification efforts by the Social Insurance Agency, others remained critical. They also highlighted the difficulties cancer survivors face when dealing with RTW regulations. One example concerned the requirement to distribute reduced working hours evenly across the week, which they viewed as impractical for cancer survivors able to work only brief periods; for example, 25% of working time equated to less than 2 hours a day. The informants described the regulation as inflexible in relation to fluctuating health and argued that RTW would be facilitated if each cancer survivor could determine their own scheduling. The regulation was considered complicated, and its lack of flexibility could cause cancer survivors to choose full-time sick leave instead of trying to balance work with sick leave.

> *Today it's possible to be on sick leave part-time and work part-time, but then every time the person gets worse, a new application for a change in sick leave is needed and that can...there's so much administration around it, even the person has to keep track, so in the end you don't do it.* [14, Social Insurance Agency]

Informants noted that sick leave was generously granted during the first year, with minimal administrative demands to avoid burdening cancer survivors. Few questions were asked by the Swedish Social Insurance Agency during that period, and the prevailing attitude was that cancer survivors should not be bothered with routine bureaucracy, which could add unnecessary stress during an already challenging time. There were also certain circumstances that allowed cancer survivors to be on sick leave for special reasons. Furthermore, if the treatment is ongoing, this patient group does not need to be assessed for all work in Sweden.

> *As long as cancer treatment is ongoing, the person doesn't have to be assessed in relation to all jobs in Sweden. So that exception we have is great.* [16, Social Insurance Agency]

XSL•FO
RenderX

The advantages and disadvantages of the ease of getting sick leave during the first year were discussed as something that could prolong sick leave. However, they believed that the real problem comes after patients have been on sick leave for 550 days and are fully covered by social insurance. At this point, cancer survivors need to be matched against the entire labor market, which can be a problem for many.

Views and Expectations of the Individual Effect of RTW

In the interviews, stakeholders on the labor market emphasized that, in several respects, individual conditions affect RTW. They said that this was a matter of providing support, having empathy, and calibrating when a push is needed to help the individual summon up the strength or courage to return to work. It is also about helping the individual feel included in the social interaction that a workplace can provide.

Courage to Push and Make Demands

There was a perception that individuals on sick leave sometimes needed encouragement to avoid getting stuck in their situation. If people have been on sick leave for a long time and have completed all treatment phases, they might need a gentle push out of their comfort zone to regain the confidence to return to work. This encouragement was seen as crucial in determining whether the individual would dare to take the step back into working life.

> *And then the healthcare system plays a very important role and then maybe they need to be the ones who push patients a bit "but now you need to start thinking about your job." Instead of prolonging and prolonging and prolonging the sick leave period.* [16, Social Insurance Agency]

The informants reported finding it easy to fall into the role of feeling sorry for the person on sick leave. However, they did not believe that this was beneficial to people on sick leave, as they could easily adopt that role. Therefore, they emphasized the importance of not allowing the person on sick leave to remain in that condition for too long, as it could lead to passivity. It was mentioned that laying out a clear plan for RTW, with realistic requirements, was beneficial. The informants believed that applying pressure was necessary, although it should be well balanced and based on the patient's situation and well-being.

> *I think having support, understanding and a little push from people in a person's life is helpful. But it should take into account the treatment stage and how difficult the treatment is.* [12, Social Insurance Agency]

The informants also emphasized the need to be less afraid of providing that extra push. This approach, they noted, should be carried out with care and consideration for the patient's individual conditions, while still daring to challenge and motivate the patient when appropriate.

Inclusion in the Workplace

The informants discussed the importance of including cancer survivors in the workplace as part of health promotion work. They described various approaches to achieving this. Some informants described a long and balanced process to maintain social contact with the person on sick leave, such as regular monthly check-ins via SMS text messages to later invite them to lunch or breakfast. Over time, they might encourage the individual to visit the workplace and participate in social events, for example, by attending a shared 30-minute coffee break.

> *We met regularly. At first maybe every three months or so // --- // And then it was more like: How are things going? How do you feel? When do we think it's time to start working?* [22, manager]

The informants emphasized the importance of people on sick leave maintaining contact with their work group and participating in social activities. Otherwise, they noted, it could feel like walls were being built, making it difficult to reconnect after a long absence. Managers also described how they would check in with the person on sick leave beforehand to understand their preferences regarding communication about their cancer diagnosis. They had experience not only with coworkers who wanted to talk openly about their diagnosis but also with those who found it too difficult to discuss in social settings. By gathering this information, managers could help prepare other employees for interacting in a way that aligned with the sick person's wishes. They highlighted the need for continuous adaptation, as preferences varied across individuals.

> *I've sometimes just said "but can't you just go back right after treatment and bring some cake and sit in the breakroom for 30 minutes just to get it over with?" so your first day back at work doesn't mean working and taking care of everything. // --- // Most people who keep in touch throughout the whole period find it easier to return.* [7, physician]

The informants also reported that challenging situations could arise, for example, when a replacement had to be brought in for the person on sick leave. This could make the person on sick leave feel threatened or uncomfortable. The informants stressed the great importance of not forgetting the person on sick leave but instead ensuring that they felt included in what was happening at work, even if they were physically unable to be there. They believed that this was a big step toward making the road back to work short when that time came.

Emotional Significance of Work

In several interviews, stakeholders on the labor market described how individuals' experiences and attitudes toward returning to work are, in many respects, based on emotions. This included the feeling of wanting to work and the social interaction that work can provide. Several concerns were also raised, such as the fear of working or not having the strength to do so.

The Desire to Work

There was a general opinion among informants that cancer survivors had a strong desire to work. In many cases, this was described as a deep-seated and significant aspiration. The informants reasoned that work was not only a source of income, but it also met important social and psychological needs. Being able to continue working creates a sense of belonging,

XSL•FO
RenderX

strengthens identity, and promotes an experience of belonging to a group and being part of the healthy world.

> *Most people want to work. I must say that's a really exciting lesson I learned from working with people, that everyone is so eager to get back to work. In my experience.* [2, occupational therapist]

The informants reported that most people who wanted to continue working or return to work after a cancer diagnosis often succeeded, even if the process was challenging. They said that it could be particularly difficult for those who had more physically demanding work compared with those who had lighter physical jobs. Moreover, they indicated that the status of the profession was important for the possibility of returning to work, although this aspect was not clear-cut.

Existential Questions Come Into Focus

The informants discussed existential questions as factors that could both promote and hinder RTW. The period following treatment was described as challenging for many patients with cancer. In addition to the physical challenges that could arise, existential dimensions could influence an individual's ability to return to work. These dimensions included questioning the very purpose of work, feeling that work was meaningless, or that the job lacked purpose when you were facing uncertainty about your survival.

> *Well, if you get a disease, cancer or something else resulting in sick leave, then the person gets caught up in that process, mostly alone, accepts the disease, but is maybe afraid of not surviving. That's a limiting aspect.* [20, manager]

In addition to existential concerns, the informants discussed the fact that cancer survivors might fear being infected by colleagues. During treatment, cancer survivors may have a weakened immune system, making the fear of infection very real, as an infection could jeopardize their ability to continue treatment. To address this, stakeholders reported adjusting work arrangements to minimize contacts with others, including enabling remote work. Such measures reduce commuting, lower infection risk, and allow survivors to manage their workload according to their capacity.

Discussion

Principal Findings

This study underscores that the RTW process for cancer survivors is a complex and multifaceted challenge, requiring coordinated efforts across the health care, insurance, and employment sectors. The interview findings reveal several key factors that act as either facilitators or barriers to successful RTW. Notably, the significance of interdisciplinary collaboration, clearly defined roles and responsibilities, and flexible support structures emerged as critical areas with considerable potential for improvement. However, these areas also pose challenges due to the different perspectives and priorities among stakeholders.

Building on this overall complexity, the findings underscore the need for enhanced collaboration and clearer role definition within the RTW process for cancer survivors, and in the planning of future RTW interventions. Despite a shared consensus among stakeholders to support individuals in their transition back to work, systemic barriers such as siloed organizational structures, ambiguous responsibilities, and insufficient communication were perceived to impede effective coordination. Similar challenges have been noted in other contexts. Svärd et al [38] observed that stakeholders in RTW processes for individuals with common mental disorders often operate under competing goals and ambiguous mandates, leading to fragmented efforts. In this study, stakeholders expressed expectations of other actors while remaining uncertain about their own responsibilities. This finding is noteworthy given Sweden's rehabilitation coordinator role, designed to support individuals on sick leave and facilitate coordination among stakeholders, including health care professionals, employers, and social insurance officers. Strengthening the mandate and visibility of these coordinators may therefore improve coordination outcomes, and comparable roles could be valuable in other national contexts. Désiron et al [39] likewise emphasized that such coordinators can provide tailored support, maintain continuity, and help bridge gaps between stakeholders.

The reported lack of coordination and cooperation between stakeholders may be linked to how rehabilitation coordinators have been implemented in Sweden. Although such functions have been introduced and are present in many settings, previous research has indicated that their role is not yet consistently established or fully integrated into RTW processes [32,33]. Barriers such as unclear mandates, variable recognition among stakeholders, and limited resources may restrict their ability to fulfill their intended coordinating function [32,33]. This may partly explain why participants in this study continued to describe persistent gaps in coordination.

More broadly, previous research has emphasized the importance of facilitators in changing processes [1]. Strengthening collaboration and clarifying the division of responsibilities among stakeholders are essential for ensuring a smoother RTW experience. For instance, Lau et al [36] highlight that siloed health care systems impede information exchange and collaborative evidence generation, ultimately undermining patient outcomes and system efficiency. The lack of integration among health care providers, social insurance agencies, and employers results in duplicated efforts, delayed interventions, and increased frustration among professionals. In our study, participants consistently emphasized the importance of teamwork and interprofessional collaboration. This statement aligns with findings from Désiron et al [39], who advocated for a dedicated RTW coordinator to improve work-oriented rehabilitation interventions. In a previous interview study by Bilodeau et al [37], employer representatives' perspectives on supporting breast cancer survivors in their RTW process were explored. These findings closely align with stakeholders' perceptions in our study, reinforcing the notion that collaboration challenges, unclear responsibilities, and communication barriers are prevalent across contexts. The highlighted issues of stakeholder collaboration reflect our observations regarding fragmented efforts and unclear mandates.

XSL•FO
RenderX

In addition to these coordination challenges, stakeholders perceived that structural barriers, such as financial challenges and sick leave regulations, must be addressed when promoting cancer survivors' RTW. Financial constraints often discouraged employers from accommodating employees who were not fully productive, reflecting the findings of Fitch and Nicoll [47], who identified reduced income as a significant adverse consequence for cancer survivors. Financial difficulties are often associated with increased psychological distress and reduced quality of life [48].

Employers frequently struggled with balancing economic considerations by providing suitable workplace adjustments, resulting in conflicts, redeployment, or even unemployment for cancer survivors. The complexity and inflexibility of sick leave regulations were also identified as critical issues. Cancer survivors faced significant administrative burdens when adjusting their sick leave arrangements, particularly regarding rules that mandated even distribution of working hours across the week. Such rigid regulations often discouraged survivors from attempting gradual RTW, potentially prolonging full-time sick leave unnecessarily. To address these barriers, simplifying sick leave regulations and providing clear, adaptable guidelines are essential. Additionally, introducing financial incentives for employers who facilitate flexible and partial RTW arrangements could encourage greater inclusivity and reduce economic pressures. These measures could significantly enhance the feasibility of accommodating cancer survivors in workplaces, promoting healthier, sustainable RTW.

Our findings underscore the importance of tailoring work conditions to cancer survivors' individual needs during RTW. Key supportive factors were flexible, personalized arrangements; gradual workload increases; remote work options; and adaptable schedules. Limited, nonpressured testing of work capacity was particularly valued for balancing health and rebuilding confidence. Stakeholders across professions emphasized individualized support, reflecting the complexity of recovery. This aligns with López-Faneca et al [35], who highlight the value of personalized RTW programs, and Bilodeau et al [37], who emphasize humanistic management and flexibility. They also stress the importance of addressing unclear responsibilities and expectation gaps, as these may hinder coordination. Together, these findings underscore the need for structured measures such as clear communication, emotional support, respect for privacy, and tailored interventions. Overall, our findings reinforce the need for individualized, flexible, and coordinated RTW approaches to promote recovery, sustainable employment, and workplace inclusion.

Beyond workplace adaptations, stakeholders considered cancer type, health status, treatment duration, and family circumstances as influential for cancer survivors' motivation and ability to return to work. Personal attitudes, expectations, and the emotional meaning of work were also emphasized. A workplace where individuals feel included and not defined by illness was viewed as essential, and encouraging workplace contact and inclusion was seen as an important aspect of stakeholder support, aligning with reviews indicating broad consensus that RTW should be encouraged when health permits [49]. Stakeholders further highlighted health-promoting factors, such as social belonging and adjusted workload, as important for sustainable RTW. This is in line with a previous review evaluating the importance of personal and social factors to sustainable RTW after ill health due to mental disorders or musculoskeletal disorders [34]. Furthermore, stakeholders stressed the need to gently give cancer survivors a push back to work, always with the cancer survivors' well-being in mind. One study showed that strengthening people's self-efficacy regarding RTW is an important factor for successful and more rapid RTW [50]. Earlier research has also shed light on the perceived importance of maintaining contact with work during sickness absence [51]. However, uncertainty about when to initiate communicating with employees and the fear of exacerbating cancer survivors' condition by making contact were described by stakeholders in earlier research and perceived as barriers to RTW [51].

Extending these findings, the results showed that stakeholders clearly perceived that RTW can promote multiple dimensions of well-being for cancer survivors on sick leave. Social benefits include reestablishing connections with colleagues, a sense of belonging, and receiving collective support, while economic benefits involve transitioning from sick leave benefits to earned income. This multifaceted value of RTW is an important finding in this study. However, stakeholders may need to consider that RTW can serve as a coping mechanism for managing existential reflections associated with a potentially life-threatening illness. The transition back to work can help survivors regain a sense of normalcy and control [52], yet it may also mask underlying emotional distress [53]. Research shows that cancer survivors often experience heightened anxiety and depression after treatment ends, partly due to reduced contact with health care providers and lingering fears of recurrence [13]. These psychological challenges can be exacerbated in cases where recovery is delayed or complicated, increasing the risk of emotional setbacks. Therefore, RTW interventions must address both physical and emotional dimensions of recovery [35] and involve stakeholders not only from the health care and the Social Insurance Agency but also from employers, who are generally not involved in developing RTW interventions [54].

Taken together, these findings are in line with previous research on RTW across a range of chronic conditions [7,25,34], which consistently highlights the importance of coordination, communication, and role clarity among stakeholders involved in the RTW process [20,38]. Similar barriers, such as fragmented responsibilities, limited collaboration between organizations, and challenges in navigating complex systems, have been described in studies of other chronic disorders [36,50,54], suggesting that many of the identified themes reflect more general structural and organizational challenges in RTW processes.

At the same time, some aspects appear to be more specific to cancer. These include the unpredictability of the disease trajectory [9,53], the impact of treatment-related side effects such as fatigue and cognitive impairments [13,20,52], and the need for flexible and individually adapted RTW processes over time [10,21]. Such factors may place additional demands on both coordination and workplace adaptations and highlight the importance of addressing cancer-related needs within RTW interventions. Taken together, these findings suggest that while

XSL•FO
RenderX

several barriers and facilitators are shared across diagnostic groups, effective RTW support for cancer survivors also requires attention to condition-specific challenges [22,34].

The findings also align with the model by Feuerstein et al [20], which emphasizes the need to tailor rehabilitation to the individual cognitive and emotional resources of cancer survivors and to the contextual demands they face. Although the analysis was inductive and not theoretically driven, the results underscore the importance of coordinated, individualized support across multiple systems. The complexity of the RTW process—requiring interdisciplinary collaboration, clearly defined roles, and flexible support structures—reflects the view of Feuerstein et al [20] that effective rehabilitation must integrate both personal and structural factors. Framed within this model, the study advances understanding of how rehabilitation practices and policies can better support survivors' transition back to work.

Finally, the findings of this study have also informed the development of a planned intervention. In particular, the identified challenges related to coordination and communication suggest a need to strengthen structured collaboration between stakeholders. The importance of role clarity highlights the need to define responsibilities more explicitly within the intervention. Furthermore, the identified need for individualized and flexible support indicates that the intervention should allow for adaptation to individual circumstances and changing needs over time. Finally, the findings underline the importance of addressing both workplace-related and health care–related aspects within a coordinated framework.

Strengths and Limitations

The study has several strengths, including the methodological approach, which was considered appropriate for understanding and describing perceptions. In addition, a purposive sampling strategy and multiregional representation ensured broad stakeholder perspectives and increased contextual diversity and potential transferability. The sample size was considered sufficient, reflected in the rich interview data. One explanation could be the use of a fictional case during semistructured interviews. This may have helped the participants reflect on realistic scenarios, while the semistructured format allowed for depth in responses. One limitation of the study is that some stakeholder groups were underrepresented, which may have limited the diversity and comprehensiveness of perspectives. The sample comprised fewer participants from the Employment Service Agency compared with other stakeholder groups, which may limit the depth of insights from this sector. However, this may reflect the limited involvement of this stakeholder group in RTW processes for cancer survivors within the Swedish system. Nevertheless, the sampling strategy was designed to maximize variation across key roles rather than to ensure equal group sizes, and we gathered substantial input from representatives in health care, social insurance, and employer organizations. Moreover, stakeholders were asked about cancer survivors as if they were a homogeneous group. This may be a limitation, because although rehabilitation and the conditions for RTW after cancer vary depending on the cancer diagnosis and severity, the tasks to be performed at work also vary.

A further limitation of the study is that the study did not specifically investigate stakeholders' experiences of rehabilitation coordinators or their expectations regarding this function. Given the ongoing implementation of coordination efforts, future research should examine how rehabilitation coordination is perceived and how it can be further developed to support RTW processes.

In addition, cancer survivors were not included as participants. As key actors in RTW processes, their perspectives are essential for a comprehensive understanding. However, the study was designed to focus on stakeholders in working life, and the findings should be interpreted in light of this scope. Previous studies by our research group have explored cancer survivors' perspectives, which complement the present findings.

Implications and Further Research

Building on these findings, a clearer definition of roles and shared responsibilities among working-life stakeholders is essential to effectively support the RTW process among cancer survivors. Flexibility within the RTW process is crucial for enabling individuals to resume work at their own pace, facilitating their transition out of illness-related isolation, and promoting social interaction with colleagues. These are important aspects to consider in future policy development, interventions, and support measures. Additional research is needed to explore cancer survivors' personal RTW experiences, with the goal of obtaining a more comprehensive understanding of the factors that influence the RTW process. To support interpretation and guide future research, Table 3 summarizes the implications of the findings for the Swedish RTW system.

XSL•FO
RenderX

Table . Summary of the implications of the findings for the return to work system.

Findings	Implications
A desire for collaboration and clear division of responsibilities	• Ensure that each stakeholder has a clear understanding of their respective roles and responsibilities. • Ensure clarity regarding the division of responsibilities. • Appoint a dedicated person to oversee and support the entire RTW[a] process.
Balancing individual adaptations	• Gradually increase workload tailored to needs and work conditions. • Flexible RTW plan, developed with the cancer survivor. • Allow, if possible, adaptations to the work situation.
Reducing structural barriers through support	• Stakeholders emphasized the need for a structured collaboration plan to clarify roles and enhance teamwork. • Promote awareness about available support. • Check progress along the way.

[a]RTW: return to work.

Conclusions

This study highlights strategies that facilitate a successful RTW process among cancer survivors from the perspectives of working-life stakeholders. The findings underline the importance of individualized and tailored support, as well as the need for clear policies to guide stakeholders' roles and responsibilities. Clarifying the rehabilitation coordinator's role in improving stakeholder cooperation, and enhancing knowledge of cancer survivors' specific workplace needs, can collectively facilitate a smoother and more sustainable RTW transition.

Abstract

Background: Consumer fitness tracker devices offer scalable opportunities to monitor real-world behavior and support health in cancer survivorship. However, adoption and sustained use outside structured research settings remain incompletely characterized, limiting their integration into survivorship care.

Objective: The primary objectives were to describe the prevalence of fitness tracker ownership and use patterns among cancer survivors and to identify sociodemographic, psychosocial, and usability-related correlates of device ownership and frequent use.

Methods: We conducted a cross-sectional survey of 893 cancer survivors enrolled in the Total Cancer Care protocol at a comprehensive cancer center. Participants completed an adapted online questionnaire assessing fitness tracker ownership, frequency of use, and perceived barriers and facilitators. Multivariable logistic regression models were used to identify sociodemographic, psychosocial, and usability-related correlates of device ownership and frequent use.

Results: More than half of the participants (506/893, 56.7%) reported owning a fitness tracker, and among owners, 82.2% (416/506) reported frequent use (most days or every day), including 71.3% (361/506) who wore the device every day. The most commonly used devices were the Apple iWatch (272/506, 53.8%) and Fitbit (147/506, 29.1%). In multivariable analyses, fitness tracker ownership was independently associated with sex, household income, and cancer site. Male participants had lower odds

XSL•FO
RenderX

of ownership (adjusted odds ratio [aOR] 0.61, 95% CI 0.42-0.87; *P*=.006), while higher household income was associated with greater ownership (US $50,000-$99,999: aOR 1.70, 95% CI 1.13-2.57; *P*=.01; ≥US $100,000: aOR 3.64, 95% CI 2.41-5.50; *P*<.001). Ownership also differed by cancer site. Among owners, frequent use was concurrently and inversely associated with self-reported device discomfort (*P*<.001), low motivation (*P*<.001), information overload (*P*=.04), and limited app integration (*P*=.007).

Conclusions: In this single-center, predominantly White, higher-income sample of cancer survivors, fitness tracker ownership was common and patterned by demographic and socioeconomic characteristics, while sustained engagement among device owners was associated with psychosocial and usability factors. These findings suggest that scalable, fitness tracker–enabled survivorship care will need to address both structural disparities in ownership as well as behavioral readiness and user experience to ensure clinically meaningful implementation.

Introduction

Fitness tracker sensing technologies have become increasingly prominent in oncology research as tools for continuously capturing real-world physiological and behavioral data, including physical activity (PA), heart rate, heart rate variability, sleep, and circadian rest-activity rhythms. These devices offer a potentially scalable approach for monitoring patient recovery, functional status, and emerging health risks in daily life, complementing infrequent clinic-based assessments [1-3]. Their expanding role reflects a broader shift toward digital health measurement in cancer survivorship and the need for objective data streams that can inform timely intervention and long-term self-management.

PA is among the most frequently assessed metrics in fitness tracker–enabled oncology research because of its established relevance to cancer survivorship outcomes. Moreover, exercise is safe before, during, and after treatment and is associated with improved quality of life, reduced fatigue, and better physical function [3,4]. Observational studies consistently link higher postdiagnosis PA with lower risks of cancer-specific and all-cause mortality across multiple cancer types [3,5]. However, many survivors experience declines in PA during treatment that persist into survivorship, and exercise promotion is not routinely embedded in oncology care [6]. Reflecting this gap, Stout et al [7] highlighted the need for patient-centered pathways that support repeated assessment of functional status and timely referral for personalized exercise interventions. In this context, fitness tracker devices may complement clinic-based performance tests by enabling continuous monitoring of functional proxies, such as habitual and ecologically valid measures of PA walking patterns and heart-rate responses to daily ambulation, as well as emerging estimates of cardiorespiratory fitness (eg, maximum volume of oxygen consumed [VO_2 max] derived from walking-based algorithms), thereby supporting scalable identification of functional decline between visits.

Recent reviews indicate substantial growth in the use of fitness trackers across oncology studies. In a synthesis of 199 trials involving more than 18,500 patients, Chow et al [8] reported that the most commonly used devices were ActiGraph (36% of studies), Fitbit (19% of studies), Garmin (7% of studies), and activPAL (6% of studies) [8]. Activity minutes and step counts were the most frequently collected metrics, with adherence rates reported at or above 80%, when available. Complementary work has emphasized the role of fitness trackers in behavioral interventions: a meta-analysis of randomized controlled trials found that programs incorporating pedometers or activity trackers yield significant increases in moderate-to-vigorous PA, total activity, and daily steps, as well as improvements in fatigue, aerobic fitness, and quality of life relative to usual care [9]. A scoping review concluded that wearable fitness trackers are generally acceptable and can facilitate short-term increases in activity in cancer survivors, although long-term adherence and maintenance remain inconsistent [10].

Tracker-derived signals may also provide insight into broader health outcomes beyond PA. For example, rest-activity rhythm parameters obtained from accelerometry have demonstrated moderate-to-strong associations with survival, functional status, and symptom burden [11]. However, the overall literature remains limited by methodological heterogeneity, reliance on small or trial-selected samples, variability in device algorithms, and minimal integration into routine survivorship care [8,10,11]. These limitations underscore the need to understand the real-world feasibility of relying on fitness tracker devices to inform clinical or behavioral decision-making.

A critical barrier to translation is that little is known about real-world patterns of fitness tracker ownership and use among cancer survivors. Most existing oncology studies recruit participants who agree to use devices provided by the research team, leaving unanswered questions on whether survivors in the general population own fitness trackers, use them consistently, or differ from the broader population in meaningful ways. Moreover, digital health interventions risk reinforcing inequities if fitness tracker access and engagement vary by age, race, ethnicity, socioeconomic status, or cancer history. Characterizing these patterns is essential for determining the feasibility, reach, and equity of tracker-enabled survivorship care.

XSL•FO
RenderX

To address these gaps, this study examined fitness tracker ownership and active use among a large sample of cancer survivors. We identified sociodemographic, clinical, and behavioral correlates of ownership and sustained use, providing data needed to inform the design and implementation of equitable, scalable digital health strategies for cancer survivorship.

Methods

Study Design and Setting

This cross-sectional study examined fitness tracker ownership and use among cancer survivors enrolled in the Total Cancer Care (TCC) protocol at the Ohio State University Comprehensive Cancer Center – James Cancer Hospital and Solove Research Institute. The study followed the CONSORT (Consolidated Standards of Reporting Trials) guidelines. Data were collected between December 2023 and December 2024 using a self-administered online survey delivered through REDCap (Research Electronic Data Capture). A trained research assistant was available over email to address participants' questions.

Ethical Considerations

The study was approved by the Ohio State University Institutional Review Board (IRB #2023C0190) with a waiver of signed consent, and standardized protection of participants' rights and interests was ensured. Online consent was obtained through survey completion. The right to discontinue involvement in the survey at any point was guaranteed to participants. Participants were offered entry into a raffle for US $25 Amazon electronic gift cards as compensation for their participation. Data security and participant confidentiality were protected via several measures: data were fully deidentified, secure and password-protected data storage systems were installed, access to identifying information was implemented, and confidentiality protocols were mandated.

Participants and Recruitment

Eligible participants were adults (≥18 years), English speaking, diagnosed with a neoplasm (breast, prostate, lung, colorectal, head and neck, gynecologic, genitourinary, endocrine, hematologic, thoracic, digestive, nervous system, cutaneous, or soft-tissue/bone sites), and with an active email address in the TCC registry. Individuals with cognitive or psychiatric impairments precluding informed participation were excluded.

Recruitment was conducted by querying the TCC database for all eligible patients who had not been recently contacted for other survey requests (ie, ≥3-4 months since the last contact). The sampling frame included 8568 patients with cancer at different sites: breast (n=2137, 24.9%), thyroid (n=1451, 16.9%), head and neck (n=1670, 19.5%), digestive system (n=661, 7.7%), urinary system (n=727, 8.5%), thorax (n=409, 4.8%), hematologic system (n=533, 6.2%), gynecologic system (n=190, 2.2%), and additional sites (cutaneous, nervous system, soft-tissue/bone, and unknown; n=790, 9.2%). Of these, 7700 (89.9%) individuals had an email address registered with the TCC and were contacted via email invitations sent in monthly batches. Participants received an email invitation with a short study description and a link to a landing webpage with a full description.

Of the 7700 (89.9%) individuals contacted, 895 (11.6%) completed the survey, 152 (2.0%) partially completed the survey, and 6653 (86.4%) did not respond. Two completed surveys were excluded due to missing key demographic variables required for analysis, yielding a final analytical sample of 893 (11.6%) participants. The overall survey response rate (completed or partially completed surveys) was 13.6% (n=1047).

Survey Instrument

The survey was part of the Lifestyle Technology in Cancer Study, a broader multimodule questionnaire designed to assess how cancer survivors engage with mobile health (mHealth) technologies across several domains.

For the fitness tracker component, an instrument developed by Holko et al [12] for Federally Qualified Health Center patients was used and adapted with permission. The adaptation retained the original structure (awareness, ownership, reasons for use and nonuse, perceived barriers, and data-sharing preferences), while updating language to reflect survivorship contexts (eg, anchoring items to recovery and health after cancer treatment) and modern device features, such as sleep tracking, workout guidance, and integration with other apps and devices. Additional items were added to capture survivor-specific considerations, including participants' interests in topics, format, and features for future digital lifestyle interventions. Prior engagement with supportive care services, including nutrition and PA counseling, was assessed in alignment with American Cancer Society survivorship recommendations [3].

The broader Lifestyle Technology in Cancer survey also included modules on mHealth app use, health and lifestyle behaviors, and social and structural determinants of health. These modules were collected to support a series of future analyses and manuscripts focused on different aspects of mHealth engagement; however, they fall outside the scope of the study. Here, the fitness-tracker module and its associated outcomes (ownership and use) are reported, consistent with the analytic aims of this study. All items were administered electronically in English via REDCap, with multiple-choice responses and optional free-text fields. The adapted survey was pilot-tested internally for clarity prior to study launch and can be found in Multimedia Appendix 1.

Measures

The survey assessed multiple domains related to fitness tracker ownership, use, and perceptions. Participants were first asked whether they currently owned a fitness tracker and, if so, to indicate the device brand, duration of ownership, and frequency of wear. Follow-up questions explored reasons for using the tracker, including activity monitoring, sleep and heart rate tracking, goal setting, motivation, and accountability, as well as reasons for nonuse, such as discomfort, technical issues, or loss of interest. Non-owners were asked to identify reasons for not owning a tracker (eg, cost, lack of interest, privacy concerns, or feeling self-motivated without a device) and to indicate whether they were interested in obtaining one in the future. Barriers to and facilitators of use were assessed through

XSL•FO
RenderX

multiple-choice items adapted from Holko et al [12], with optional free-text responses, allowing participants to elaborate on personal challenges and motivations related to wearable engagement.

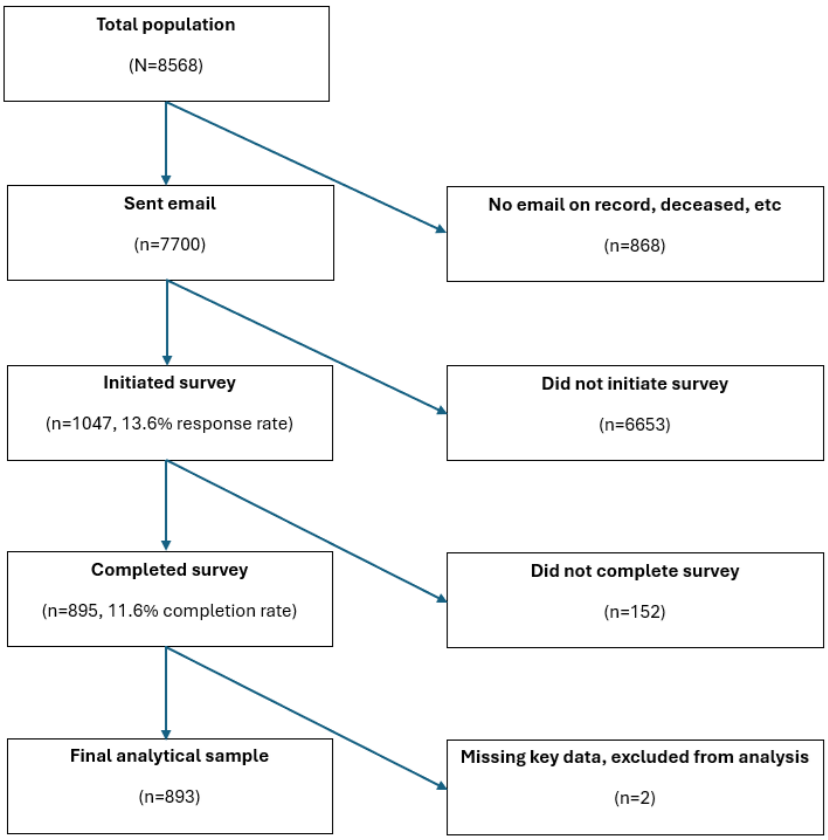
Sociodemographic and social determinants of health variables were assessed using items adapted from the PRAPARE (Protocol for Responding to and Assessing Patient Assets, Risks, and Experiences) survey, a widely used, nationally standardized screening tool for social and structural determinants of health in clinical settings [13]. Psychosocial measures included perceived stress and confidence in one's ability to take good care of one's health. The confidence item was adapted from the Health Information National Trends Survey (HINTS-5), a nationally administered and validated population-based survey [2].

Statistical Analyses

Descriptive statistics, including means (SEs) and percentages, were used to characterize participants and their reported reasons for owning and using a fitness tracker. To explore associations between various factors and fitness tracker ownership, univariate logistic regression was performed to estimate odds ratios (ORs) and 95% CIs for demographic, socioeconomic, psychosocial, and PA-related variables. Similarly, univariate logistic regression was used to assess associations between demographic characteristics and specific challenges that may hinder fitness tracker usage (eg, concerns about accuracy, discomfort, or lack of motivation). These associations were evaluated in relation to frequent use (ie, using a fitness tracker on most days or every day) versus less frequent use (including the remaining categories). This binary threshold was predetermined to differentiate habitual use from sporadic use, as both "most days" and "every day" signify a consistent integration of the device into daily life. Furthermore, this threshold was selected to align methodologically with the common operationalization of adherence in digital health and the wearable literature [14]. To identify independent predictors of fitness tracker ownership and frequent use, multivariable logistic regression models were constructed. Variables with at least marginal statistical significance ($P<.15$) in univariate analyses were initially included. A stepwise backward elimination approach was then applied: variables were removed sequentially, starting with the least significant, until all remaining variables were either (1) statistically significantly associated with the outcome or (2) demonstrated substantive confounding effects (defined as altering the association of another variable in the model with the outcome by ≥15%). The final multivariable models thus included only those factors that were independently associated with fitness tracker ownership or frequent use. Breast cancer was selected as the reference category for the cancer-site variable because it represented the largest single cancer site in the analytic sample (n=278, 31.1%) and provided the most stable and interpretable comparison group; this choice is descriptive only and does not imply a substantive hypothesis about breast cancer survivors as a normative referent. This variable selection strategy was chosen to accommodate the exploratory aims of the study, which sought to identify correlates of fitness tracker ownership and use across a broad set of candidate domains, for which no single established theoretical framework jointly specifies predictors in cancer survivor populations. A purely confirmatory, theory-driven specification was therefore not feasible, and a data-driven screening approach was selected to allow empirical identification of independently associated factors, while controlling for potential confounding. Multicollinearity among candidate predictors was evaluated using variance inflation factors (VIFs) prior to model fitting; all VIFs were below conventional thresholds (<5), indicating no problematic collinearity. To assess model stability, both multivariable models were refit with all candidate predictors entered simultaneously (Tables S1 and S2 in Multimedia Appendix 2) to confirm that the direction and magnitude of the primary associations were consistent across specifications. Given the cross-sectional design, all models estimated associations and could not establish temporal order or causality. Moreover, the two regression models were crafted with distinct analytical objectives. The ownership model explored a wide array of sociodemographic, clinical, and behavioral factors to pinpoint correlates linked to device ownership. In contrast, the frequent-use model was more narrowly focused, concentrating on modifiable usability and psychological barriers reported by device owners.

Notably, PA was excluded as a potential predictor in the frequent-use model due to this model's emphasis on actionable usability and psychological barriers. Complete-case analysis was used for all regression models; participants with missing data on any variable included in a given model were excluded from that analysis. For household income, which had a substantial nonresponse rate (149/893, 16.7%), "no response" was retained as an explicit category in both univariable and multivariable ownership models rather than excluding these participants in order to preserve the sample size and avoid bias from listwise deletion of a nonrandomly missing variable. Missingness on other covariates was minimal and handled via complete-case exclusion. The multivariable model predicting fitness tracker ownership included 893 participants, and the multivariable model predicting frequent use among device owners included 504 participants.

Results



Participant Characteristics

Figure 1 shows the participant selection flowchart based on CONSORT guidelines. A total of 893 cancer survivors were included in the analytic sample (Table 1). The mean age was 61.8 (SE 0.38) years; 68.8% (614/893) identified as female and 93.5% (835/893) as non-Hispanic White. The most common cancer sites were breast (278/893, 31.1%), thyroid (166/893, 18.6%), and oral cavity/pharynx (149/893, 16.7%). The majority of survivors had the *International Classification of Diseases for Oncology* (ICD-O) cancer classification of "malignant" (742/893, 83.1%), and the mean time since diagnosis at the time of survey completion was 10.3 (SE 0.20) years. Approximately one-third of the participants reported annual household incomes exceeding US $100,000 (324/893, 36.3%), and 68.3% (610/893) earned at least a college degree. Regarding psychosocial factors, 20.8% (186/893) participants reported feeling "quite a bit" or "very much" stressed, and 52.3% (467/893) were "very" or

XSL•FO
RenderX

“completely” confident in their ability to take good care of their health.

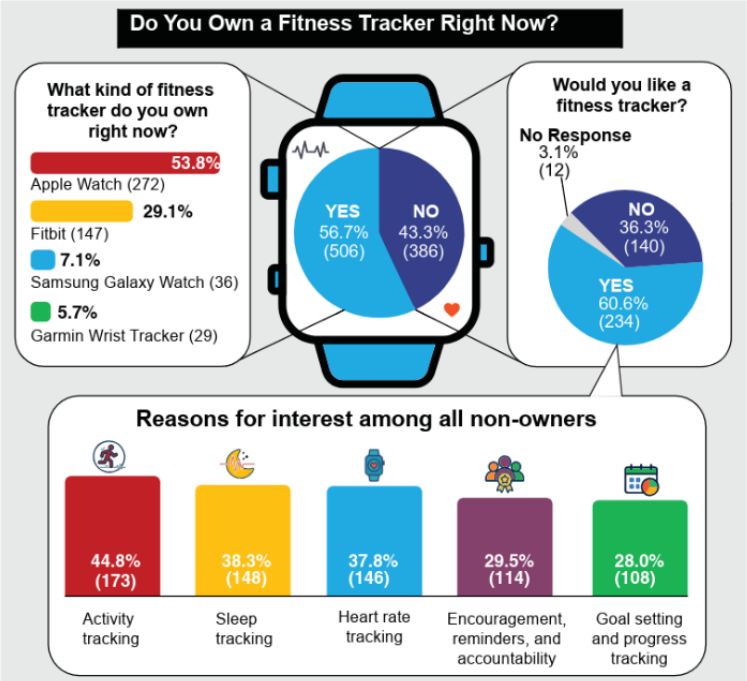
[a]mHealth: mobile health.

[b]Age is presented as a continuous variable with mean (SE). Percentages may not total 100% due to rounding. Small cell sizes (eg, <5) are presented because the data were fully deidentified and not linked to sensitive or identifiable subgroups. Categories with small response counts (eg, <5) should be interpreted with caution.

Fitness Tracker Ownership

More than half of the respondents (506/893, 56.7%) reported currently owning a fitness tracker, while 43.3% (386/893) did not, and 1 (0.1%) individual declined to answer (Figure 2). The most common devices were the Apple iWatch (272/506, 53.8%), Fitbit (147/506, 29.1%), the Samsung Galaxy Watch (36/506, 7.1%), and the Garmin Wrist Tracker (29/506, 5.7%). Among non-owners, 60.6% (234/386) participants expressed interest in obtaining a tracker, with the most common reasons being to monitor activity (173/386, 44.8%), sleep (148/386, 38.3%), and heart rate (146/386, 37.8%), as well as for encouragement, reminders, and accountability (114/386, 29.5%).

The most frequently endorsed facilitators of ownership were activity tracking (403/506, 79.6%), heart rate tracking (228/506, 45.1%), sleep tracking (164/506, 32.4%), and integration with other apps and devices (148/506, 29.2%), followed by goal setting or progress tracking (112/506, 22.1%). Preventive health tracking (38/506, 7.5%) and food/calorie tracking (31/506, 6.1%) were less commonly reported. Barriers to ownership reported among non-owners included cost (165/386, 42.7%) and lack of interest (138/386, 35.8%), which were the most frequently cited reasons for not having a tracker. Other common barriers were believing they did not need a fitness tracker to stay healthy (78/386, 20.2%) and limited technology skills (73/386, 18.9%). Smaller proportions of participants reported comfort issues (34/386, 8.8%), privacy concerns (33/386, 8.5%), and lack of awareness about fitness trackers (31/386, 8.0%).



In univariate analyses (Table 2), several demographic and clinical factors were significantly associated with fitness tracker ownership. A younger age, female sex, a higher household income, higher educational attainment, and the cancer site were each associated with greater odds of ownership in unadjusted models. Specifically, male participants had lower odds of ownership compared to females (OR 0.42, 95% CI 0.31-0.56; *P*<.001), while higher household income was positively associated with ownership (US $50,000-$99,999: OR 1.61, 95% CI 1.08-2.38; *P*=.02; ≥US $100,000: OR 3.85, 95% CI 2.61-5.68; *P*<.001).

In the final adjusted multivariable model, fitness tracker ownership remained independently associated with sex, household income, and cancer site. Male participants had 39% lower odds of ownership compared to females (adjusted odds ratio [aOR] 0.61, 95% CI 0.42-0.87; *P*=.006). Higher household income was strongly associated with ownership, with participants reporting annual household incomes of US $50,000-$99,999 (aOR 1.70, 95% CI 1.13-2.57; *P*=.01) and ≥US $100,000 (aOR 3.64, 95% CI 2.41-5.50; *P*<.001) having greater odds of owning a tracker compared to those earning <US $50,000. Ownership also varied by cancer site, with lower odds observed among participants with thyroid cancer (aOR 0.64, 95% CI 0.41-1.00; *P*=.05), oral cavity/pharyngeal cancer (aOR 0.39, 95% CI 0.25-0.63; *P*<.001), bone marrow cancer (aOR 0.49, 95% CI 0.26-0.90; *P*=.02), and other cancer types (aOR 0.48, 95% CI 0.31-0.73; *P*<.001) relative to the reference group. Age was marginally associated with ownership in the adjusted model (aOR 0.99 per year, 95% CI 0.97-1.00; *P*=.05). Education, race/ethnicity, the BMI, perceived stress, and self-rated health confidence were not independently associated with ownership after adjustment.

The demographic homogeneity of the sample (primarily non-Hispanic White, college-educated individuals with higher household incomes, recruited via email) may limit statistical power to detect associations for certain characteristics, particularly race/ethnicity. Consequently, null findings for sociodemographic variables, such as race/ethnicity and education, should be interpreted in this context rather than as evidence that disparities do not exist. Finally, in a sensitivity analysis in which all candidate predictors were entered simultaneously, the direction, magnitude, and significance of associations were largely consistent with the reduced model (Table S1 in Multimedia Appendix 2).

XSL•FO
RenderX

Figure 2. Fitness tracker ownership, interest, and associations among cancer survivors. Participants were asked about their current ownership of fitness trackers, their interest in using one, and specific features or functionalities they find helpful. Over half reported owning a tracker, with the Apple iWatch being most common. Among those interested in owning one, top motivations included activity tracking and health monitoring. Facilitators of ownership included usability features such as integration with other apps, while common barriers were cost and lack of interest. Participants could select multiple responses, but those who chose “no response” for a section could not select other options. The "%" column refers to the percentage of participants who selected each option. Participants could select multiple responses.

Facilitators of Ownership

	%	n=506
Activity Tracking	79.6%	403
Heart Rate Tracking	45.1%	228
Sleep Tracking	32.4%	164

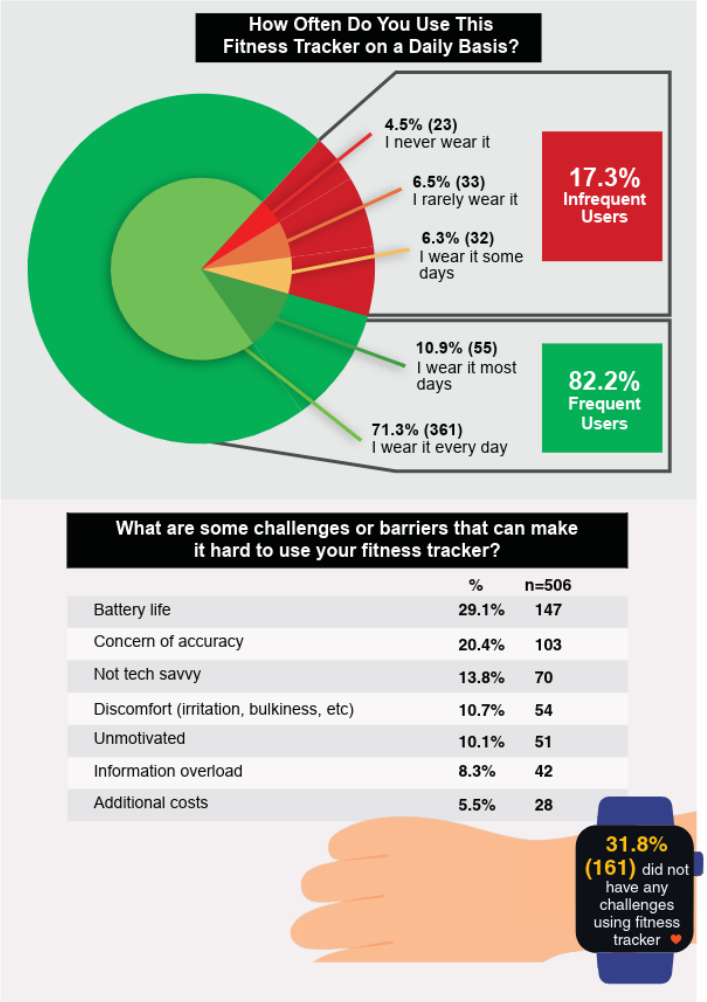
Use Patterns and Perceived Barriers Among Fitness Tracker Owners

Among participants who owned a fitness tracker, most reported daily use: 71.3% (361/506) wore their device every day, and an additional 10.9% (55/506) wore it most days, while 6.3% (32/506) wore it some days, 6.5% (33/506) rarely used it, 4.5% (23/506) never used it, and 0.4% (2/506) declined to answer the question (Figure 3). For analytic purposes, “never,” “rarely,” and “some days” were grouped as infrequent use (88/506, 17.3%), and “most days” and “every day” were categorized as frequent use (416/506, 82.2%). This binary variable served as the outcome for the logistic regression analyses presented in Table 3.



Among current users, the most commonly reported challenges to regular use were battery life (147/506, 29.1%) and concerns about accuracy (103/506, 20.4%). Other barriers included not feeling tech savvy (70/506, 13.8%); discomfort, such as irritation or bulkiness (54/506, 10.7%); low motivation (51/506, 10.1%); information overload (42/506, 8.3%); and additional costs (28/506, 5.5%). Notably, nearly one-third of the owners (161/506, 31.8%) reported having no challenges using their device.

In multivariable models (Table 3), several barriers were significantly associated with lower odds of being a frequent tracker user. In the multivariable model, participants who reported device discomfort or irritation were 75% less likely to use their trackers frequently (aOR 0.25, 95% CI 0.13-0.48; *P*<.001). Those citing information overload were 55% less likely to use their trackers frequently (aOR 0.45, 95% CI 0.21-0.97; *P*=.04). Similarly, participants reporting low motivation were 76% less likely to use their trackers frequently (aOR 0.24, 95% CI 0.12-0.46; *P*<.001). Reports of device malfunction and lack of integration with other apps or devices were each associated with 75% lower odds of frequent use (aOR 0.25, 95% CI 0.10-0.62; *P*=.003; aOR 0.25, 95% CI 0.09-0.69; *P*=.007, respectively). Accuracy concerns, privacy issues, and battery life were not significantly associated with the frequency of use. It is important to note, however, that some barrier items (particularly low motivation and information overload) are conceptually proximate to the outcome of infrequent use and may partially reflect participants’ descriptions of their current behavior rather than independent antecedent factors. Device-level barriers, such as discomfort, malfunction, and limited app integration, are more clearly separable from use frequency, but the cross-sectional design precludes establishing temporal order for any of these associations. Finally, in a sensitivity analysis in which all candidate predictors were entered simultaneously, the direction and magnitude of the primary associations were consistent with the reduced model (Table S2 in Multimedia Appendix 2). Two variables near the conventional significance threshold exhibited minor shifts: concern about accuracy moved from nonsignificant to significant, and information overload moved from significant to nonsignificant. These fluctuations are consistent with the modest size of the infrequent-use group (n=88, 17.3%) that do not alter the substantive conclusions. A sensitivity analysis restricting the outcome to daily use produced largely consistent findings (Table S3 in Multimedia Appendix 2).

Overall, although most participants used their fitness trackers regularly, less frequent use was concurrently associated with self-reported device usability and motivational factors rather than demographic characteristics or privacy concerns. As these factors were measured at the same time as the outcome, they should be interpreted as correlates rather than established antecedent barriers.

XSL•FO
RenderX

Figure 3. Frequency of fitness tracker use and barriers to use among cancer survivors. Participants were asked how often they used their fitness tracker and whether they experienced any challenges with use. Most participants reported wearing their tracker daily, while others indicated less frequent use. Of the five response categories, three reflected infrequent use, while two represented frequent use. Among the identified barriers, the most common were battery life, accuracy concerns, and discomfort. Participants could select more than one challenge. Barriers were only reported if participants either selected specific issues or indicated "I did not have any challenges." Those who chose not to answer or skipped the question were excluded from the barrier summary. The "%" column refers to the percentage of participants who selected each option. Participants could select multiple responses. Those who chose "no response" for a section were not allowed to select additional options. Note: 0.5% of responses are missing due to nonresponse.

[e]Variables not retained are indicated by an em dash (—). All included variables were mutually adjusted.

[f]Statistical significance at $P<.05$ (two sided).

Discussion

Principal Findings

This study included one of the most comprehensive examinations to date of real-world fitness tracker ownership and engagement among cancer survivors. More than half of the respondents reported owning a tracker, yet frequent use (defined as wearing the device most days or every day) was less universal, highlighting important distinctions between device adoption and sustained engagement. Patterns of ownership were associated primarily with demographic and socioeconomic characteristics within this cohort, while continued use among device owners appeared more strongly related to psychosocial and usability-related factors. These prevalence estimates should be interpreted in light of the cohort's characteristics: participants were recruited from a single institution, required an active email address to be contacted, and were predominantly non-Hispanic White, with a college education and a higher household income. Concurrent self-reports of device discomfort, information overload, and technical issues were associated with less consistent engagement in cross-sectional analysis.

Although the sample was relatively homogeneous in terms of race and ethnicity, which may limit the identification of certain access and equity-related barriers, the observed differences in ownership by sex, income, and cancer site highlight significant disparities in access, even within this group. Although this study was underpowered and not ideally suited to detect such patterns, they were still discernible within our limited sample. These patterns are becoming increasingly relevant as oncology moves toward digitally supported survivorship care, where fitness trackers offer a potential data source for monitoring PA, symptoms, and functional recovery.

Comparison With Prior Research

In this study, approximately 57% of cancer survivors reported owning a fitness tracker, a prevalence higher than that reported in several prior population-based studies. This difference likely reflects, in part, the cohort's recruitment approach and

XSL•FO
RenderX

demographic composition rather than a uniform increase in adoption among cancer survivors generally. Despite this caveat, Zhou et al [15], using Health Information National Trends Survey – Surveillance, Epidemiology, and End Results (HINTS-SEER) data, documented increasing adoption of wearables among US cancer survivors over time, with ownership rising from approximately 21% in 2019 to 31% in 2022. Prior work has also documented lower wearable adoption among older cancer survivors. For example, Faro et al [16], in a study with a mean participant age of 74 years, found that only 31.8% of survivors owned a wearable device and that increasing age is inversely associated with ownership.

In addition to overall prevalence, we observed differences in fitness tracker ownership by sex, household income, and cancer site that are largely consistent with the established literature. Higher ownership among female participants corresponds with previous population-based research indicating a greater adoption of self-monitoring technologies by women. Similarly, higher ownership is also observed among individuals with higher incomes [17]. In this cohort, cancer-specific ownership patterns were also identified; however, such patterns have been less frequently explored in previous survivorship research, and the findings of this study should be viewed as preliminary observations to be tested in studies with detailed treatment and clinical data.

Population-based analyses of mHealth tracking have identified lower engagement among older cancer survivors. In a large HINTS-SEER analysis, Hong [18] reported that mHealth and behavior tracking is independently associated with younger age, although this outcome combines app- and wearable-based tracking rather than wearable ownership alone. In this study, age was significantly associated with fitness tracker ownership in unadjusted analyses and was marginally associated in adjusted models, suggesting that the age gradient in this cohort is partially but not fully explained by correlated sociodemographic factors. Differences in cohort composition, outcome definitions, and baseline levels of technology engagement may also contribute to variation across studies. Importantly, these findings should not be interpreted as evidence that age-related disparities have resolved, particularly in geriatric oncology populations, where continued evaluation remains warranted.

Prior oncology research has primarily evaluated the feasibility of fitness trackers under supervised conditions. In chemotherapy populations, Nilanon et al [19] demonstrated that continuous monitoring is feasible, with adherence above 68% and lower activity predicting unplanned clinical encounters. Ng et al [20] similarly reported very high adherence (94%-96%) and high perceived usefulness among inpatient and outpatient rehabilitation patients provided with trackers. These intervention-based findings confirm feasibility when devices are supported within structured settings, but reveal little about voluntary, sustained use. This study extended prior research by examining behavioral, motivational, and usability factors linked to real-world fitness tracker engagement.

Interpretation of Key Findings

The observed associations between fitness tracker ownership and demographic and socioeconomic characteristics suggest that access to these technologies remains patterned by structural factors within cancer survivor populations. In this study, ownership was associated with household income, sex, and cancer site, indicating that socioeconomic resources and survivorship context may play a central role in shaping initial adoption. The income gradient is consistent with broader patterns of unequal access to consumer digital technologies documented in population-based studies [17]. Consumer-grade fitness trackers and smartwatches typically range from US $100 to US $400, a cost that may present a meaningful barrier for lower-income individuals, particularly given the financial burden associated with cancer treatment. Notably, cost was the most frequently endorsed barrier among non-owners in this study (42.7%), further supporting the interpretation that financial accessibility contributes to the observed income gradient.

Lower odds of fitness tracker ownership among male participants is consistent with sex-based differences in health self-monitoring behaviors observed in general population studies [17]. Prior research has documented that women are more likely than men to engage in preventive health behavior, patterns attributed, in part, to gender socialization around health vigilance and self-care [21].

Differences in fitness tracker ownership by cancer site have not been widely examined in prior survivorship research, and the cross-sectional design and absence of clinical covariates (treatment status, disease stage, recurrence, symptom burden, and functional limitations) preclude evaluation of the mechanisms underlying these patterns. The interpretations offered below are therefore hypothesis generating rather than explanatory. Breast cancer survivors, who served as the reference group, demonstrated the highest ownership prevalence, which may reflect both the demographic composition of this group (predominantly female, higher income) and the well-established culture of survivorship engagement, peer support, and wellness-oriented self-management in breast cancer communities. The lower ownership observed among survivors of oral cavity/pharynx cancers (aOR 0.39), bone marrow malignancies (aOR 0.49), and other sites may reflect differences in the treatment burden, physical sequelae that limit device wear (eg, peripheral neuropathy, dermatologic toxicity), or lower exposure to fitness-oriented survivorship messaging.

In contrast to ownership, frequent use among device owners was more closely associated with experiential and motivational factors within this cohort. Device discomfort, technical malfunctions, limited app integration, and information overload emerged as the most strongly associated barriers with lower frequent use. However, these associations warrant different levels of interpretive confidence. Device-level factors, such as discomfort, malfunction, and limited integration, are conceptually distinct from use frequency and are therefore more defensible as independent correlates. In contrast, self-reported motivational and cognitive burden items (low motivation, information overload) overlap conceptually with the outcome itself: reporting that one is “unmotivated” to use a tracker is difficult to disentangle from the behavior of not using it. These items may therefore function, in part, as retrospective explanations for disengagement. This distinction does not invalidate the observed associations but does constrain their

XSL•FO
RenderX

interpretation; none should be treated as established causal barriers, given the cross-sectional design. With this caveat, our findings align with prior digital oncology research emphasizing simplicity, interoperability, and actionable feedback as key correlates of sustained engagement [10,11].

Fitness trackers play a key role in PA monitoring, a central behavioral target in survivorship. PA is safe and beneficial before, during, and after treatment, improving fatigue, functional capacity, and quality of life and reducing mortality risk [6,7,22]. In a systematic review, Singh et al [9] found moderate-to-large improvements in PA and related outcomes from wearable-supported interventions. Similarly, oncology rehabilitation frameworks emphasize early identification of functional decline and referral to exercise oncology services [7]. Together, these bodies of work highlight why understanding real-world fitness tracker engagement is clinically significant.

Implications for Digital Health and Survivorship Care

Although this study did not evaluate implementation strategies, clinical integration models, or interventions targeting usability, the observed patterns of fitness tracker ownership and use may inform future research and program development. As survivorship care increasingly incorporates remote monitoring, the relatively high prevalence of fitness tracker ownership in this cohort (506/893, 56.7%) and frequent use among owners (416/506, 82.2%) suggest that for digitally engaged subgroups, wearables could meaningfully extend assessment beyond the clinic. These rates should not, however, be taken as population-level estimates of what scalable tracker-enabled care can rely on. Wearables may support the identification of emerging functional vulnerability by enabling longitudinal monitoring of mobility-related activity patterns, including sustained reductions in daily step counts and overall activity levels, which have been associated with postoperative recovery trajectories, readmissions, and frailty-related outcomes in cancer and older adult populations [23-25]. In parallel, wearable-derived measures of PA, sedentary behavior, heart rate, and sleep have been proposed as scalable digital indicators of cardiovascular and cardiometabolic risk in cancer survivorship, complementing clinic-based evaluations rather than replacing them [26].

The significant associations between sociodemographic factors and device ownership indicate that equitable access may be the first and most critical step in facilitating fitness tracker adoption. The strong income gradient observed in this study, combined with cost being the most frequently endorsed barrier among non-owners, suggests that financial accessibility remains a meaningful obstacle for lower-income participants. Strategies to address this barrier may include device subsidy or loaner programs, integration of fitness tracker provision into survivorship care plans, or partnerships with device manufacturers to reduce cost. Similarly, the lower ownership observed among male participants and among survivors of certain cancer types suggests that outreach and engagement strategies may need to be tailored to reach populations that are less likely to adopt these technologies independently.

However, inconsistent engagement among device owners highlights that access alone may not be sufficient to support sustained use. Future studies should evaluate implementation approaches that directly address behavioral and usability barriers, including device comfort, cognitive burden, and platform interoperability. Evidence from patients receiving care at federally qualified health centers indicates that baseline wearable ownership is low (21%), despite substantial interest among those without a device (58%), highlighting that effective implementation may require education, onboarding, and user support to address commonly reported usability and knowledge barriers beyond device provision alone, even when economic barriers are addressed [12]. It is important to note, however, that the ownership prevalence in this study cohort was significantly higher, at 56.7%, and the cohort itself showed limited sociodemographic diversity. This suggests that further research involving more diverse study populations is necessary to determine if the sociodemographic patterns observed within this study generalize to populations with greater racial, ethnic, and socioeconomic diversity.

Finally, because most owners in this cohort were already using consumer devices, such as the Apple iWatch and Fitbit, future digital lifestyle interventions may benefit from supporting multidevice integration and bring-your-own-device approaches, allowing cancer survivors to continue using familiar technologies and reducing friction to participation. Evaluating these strategies in more diverse populations and health care settings will be essential to determine how tracker-enabled survivorship approaches can be implemented effectively and equitably.

Strengths and Limitations

This study has several limitations. The cross-sectional design precludes causal inference, and fitness tracker ownership and use were self-reported rather than objectively verified, which may introduce recall or social desirability bias. Second, the dataset lacked clinical characteristics, such as treatment status and recurrence history, which may limit interpretation. In addition, in the use-frequency analysis (Table 3), both the barrier items and the outcome were ascertained simultaneously through the same self-report instrument. Although device-level barriers (eg, discomfort, malfunction) are conceptually separable from use frequency, motivational and cognitive burden items (eg, low motivation, information overload) are difficult to distinguish from the outcome they are intended to predict, raising the possibility of criterion contamination. Future longitudinal designs that assess barriers at baseline and track use patterns prospectively would help clarify whether these factors precede, accompany, or result from changes in engagement.

The sample primarily consisted of non-Hispanic White individuals with a college educated and higher household incomes, which limits the generalizability to more diverse survivor populations. Although several sociodemographic correlates of ownership were detected, including sex, income, and cancer site, the limited racial and ethnic diversity of the sample constrains the ability to identify disparities along these dimensions, and the observed associations may not generalize to populations with greater sociodemographic variability. We were also unable to evaluate device-level characteristics, such as accuracy, brand-specific differences, or wear time

XSL•FO
RenderX

verification, which constrain the interpretation of how technical performance may influence engagement. In particular, several of the barriers identified in the frequent-use model, such as battery life, device malfunction, and limited app or device integration, are plausibly device or brand specific and may vary by manufacturer, device generation, or operating-system ecosystem; because brand-level subgroup analyses were not powered in the sample, these barriers should be interpreted as aggregate user experiences rather than properties of fitness trackers as a class. Finally, although the survey captured additional digital health constructs, the analysis focuses specifically on fitness tracker behaviors to maintain conceptual and analytic clarity.

Despite these limitations, this study has important strengths. The sample included survivors across a broad range of cancer types, and the survey simultaneously assessed demographic, psychosocial, and experiential correlates of fitness tracker use, domains that are not often examined together. By characterizing real-world engagement with consumer-owned devices rather than study-provided fitness trackers, this work provides insight into naturalistic patterns of adoption and sustained use. These findings help fill a critical gap in the literature, which has largely been divided between population-level estimates of device ownership and feasibility studies conducted under structured clinical or research conditions. By integrating both perspectives, this study advances understanding of how survivors adopt and maintain fitness tracker use in everyday contexts, providing a behavioral foundation for developing scalable, equitable digital health interventions to support long-term self-management.

Conclusion

In summary, we conducted one of the largest studies of real-world fitness tracker engagement among cancer survivors and found that within this single-center, demographically homogeneous cohort, although ownership was common, initial ownership was primarily correlated with sociodemographic factors, while sustained use within this sample varied widely and was concurrently associated with self-reported psychosocial and usability factors, which should be interpreted as correlates rather than established antecedent barriers. Because the sample likely reflects a digitally engaged subgroup, these patterns should be interpreted as upper-bound estimates rather than broadly representative figures. These findings highlight the importance of integrating behavioral support, human-centered design, and seamless system-level interoperability into digital survivorship programs. Future research should examine longitudinal associations between fitness tracker–derived activity and clinical outcomes, test interventions targeting motivational and emotional barriers, and develop implementation models that facilitate integration of fitness tracker data into oncology workflows. By strengthening both access and sustained engagement, fitness trackers may help support scalable, personalized approaches to survivorship care.

Acknowledgments

This study was supported by discretionary research funds provided to RMB through the Ohio State University Comprehensive Cancer Center. We also thank the participants who shared their time and insights. The authors wish to acknowledge the late Dr Brian Focht for his invaluable guidance, mentorship, and support throughout the study. This work was made possible, in part, through the use of his laboratory facilities at the Ohio State University. His dedication to the field and to his students continues to inspire this work. The authors thank the Total Cancer Care program staff for facilitating participant recruitment, and Drs Michelle Holko and Tamara Litwin for permission to adapt and reuse their survey instrument originally developed for *npj Digital Medicine*. The authors are grateful to the Lifestyles Lab team members for their contributions to data management and administrative coordination.

Abstract

Background: Thyroid cancer is often labeled a “good cancer” due to high survival rates. However, many patients diagnosed with differentiated thyroid cancer (DTC) treated with radioactive iodine (RAI) experience short- and long-term symptoms as a result of treatment. These include salivary dysfunction, dry mouth, dry eyes, and nausea. Despite these challenges, patients report limited knowledge and unmet informational needs regarding RAI symptoms and symptom management. Evidence-based, patient-centered education to support symptom management during DTC survivorship is needed. Our team developed Radioactive Iodine Support (RAI Support), a prototype of a 4-week web-based intervention for RAI symptom management among survivors of DTC.

Objective: This study aimed to evaluate the usability of the RAI Support intervention among survivors of DTC who completed RAI treatment and assess preliminary effect sizes of change in RAI symptom burden, self-efficacy for managing chronic symptoms, informational needs, global physical and mental health, and health-related quality of life (HRQOL).

Methods: We conducted a longitudinal usability testing study with 8 participants over a 4-week period. At baseline (T1), participants completed an online survey and a 90-minute virtual usability testing session. During usability testing sessions, study staff used a think-aloud protocol to elicit feedback on the content, language, and visual appeal of the prototype across 5 tasks. Participants also completed the System Usability Scale (SUS). Participants were encouraged to continue using the intervention over the 4-week period, during which use data were recorded. A follow-up after assessment (T2) was completed at the end of the 4-week period of home use. Survey outcomes included RAI symptom burden, self-efficacy for managing chronic symptoms, informational needs, global physical and mental health, and HRQOL.

Results: Among the 8 survivors of DTC who had undergone RAI treatment (age: mean 45, SD 8.2 years), the mean SUS score was 88.1 (SD 8.7), indicating above-average usability. All participants effectively completed each task, with ease of use ranging from 100% to 87.5% and error rates ranging from 0% to 25%. Preliminary *r* effect size signals of change were found for improved self-efficacy, global mental health, and HRQOL (*r* values ranged from 0.31 to 0.45).

Conclusions: Survivors of DTC reported above-average usability of the RAI Support prototype and completed each task successfully. Variability in error rates and ease of use suggests that refinements are needed to further optimize usability and

XSL•FO
RenderX

patient engagement. RAI Support also shows preliminary promise in improving self-efficacy for symptom management, global mental health, and HRQOL among survivors of DTC. Findings support future pilot testing.

(JMIR Cancer 2026;12:e84151) doi:10.2196/84151

internet-based intervention; iodine radioisotopes; self-efficacy; survivorship; symptom burden; thyroid neoplasms; user-centered design

Introduction

Thyroid cancer is frequently referred to as a "good cancer" due to its excellent 5-year survival rates and favorable prognosis [1-5]. However, this label often minimizes the lived experiences that many patients undergo. Radioactive iodine (RAI) treatment is not routinely indicated for all patients with thyroid cancer. Those who do receive RAI typically have undergone total or near-total thyroidectomy, after which postoperative risk stratification incorporating histopathology, staging, and imaging determines whether RAI is indicated for remnant ablation, adjuvant therapy, or treatment of known residual or recurrent disease [6]. Because RAI is used selectively based on these characteristics, those who do receive it often represent a subgroup with higher-risk cancer who correspondingly experience a longer course of surveillance and symptom management [6,7]. These patients report significant and persistent side effects such as salivary gland dysfunction, dry mouth, eye irritation, and nasal discomfort [1,8,9]. These symptoms can negatively impact quality of life, especially in the absence of coordinated, ongoing support [10,11]. Survivors of thyroid cancer also report lower health-related quality of life (HRQOL) than other groups of survivors of cancer [11,12], perhaps due, in part, to symptom burden [11]. Following RAI treatment, care coordination for symptom burden is often inconsistent across health care settings and typically involves multiple subspecialists, including endocrinologists, nuclear medicine physicians, oral health specialists, and otolaryngologists, which may contribute to fragmented follow-up care [10-13].

As cancer survivorship care remains fragmented and increasingly extends beyond traditional clinical settings, scalable strategies are needed to support patient engagement and symptom management throughout the continuum of care [14]. Digital health interventions have demonstrated potential for addressing gaps in survivorship care after primary treatment, particularly by enhancing access to timely support and empowering patients to manage chronic symptoms [15,16]. Despite the complexities of thyroid cancer survivorship care, we are unaware of any dedicated digital health tools to support symptom self-management after RAI treatment, presenting a critical gap in the continuum of care for this population.

We developed Radioactive Iodine Support (RAI Support) as a web-based intervention to fill this unmet need by providing tailored guidance and symptom support to survivors of thyroid cancer following RAI treatment. A number of systematic reviews have highlighted the facilitators and barriers to behavioral intervention adherence due to digital technology–related factors, including website usability ratings, ease of use, plain language, and connectivity [15-17]. One systematic review identified that low ease of use and connectivity issues were associated with 8% to 14% of intervention nonadherence [17]. The literature also highlights that the successful implementation of sustainable digital tools depends heavily on their usability, accessibility, and alignment with patient needs [18,19]. Yet, as with all digital interventions, optimal usability is a necessary component of sustained user engagement, which in turn relates to the efficacy of the digital tool. Human factors, such as interface design, ease of navigation, and relevance of content, play central roles in determining whether users adopt, engage with, and benefit from such tools [16]. Without attention to these factors, even well-designed interventions may fail to translate into real-world impact. Therefore, we conducted a usability and proof-of-concept study to (1) optimize the usability of the web-based intervention and (2) provide an initial exploration of whether RAI Support improves clinically significant end points, with the aim of addressing the complex needs of survivors of thyroid cancer in preparation for future pilot testing.

Methods

Study Design

From September to November 2024, we conducted usability testing in a single-arm longitudinal proof-of-concept study at an academic medical center in the mid-Atlantic United States. A sample size of 8 participants was selected for the usability evaluation, consistent with the study's objective of identifying usability issues [20] with RAI Support and obtaining user feedback to inform intervention optimization rather than testing intervention efficacy.

Recruitment and Setting

Adult patients were identified from medical record review and through a thyroid cancer nonprofit organization's publicly available Facebook (Meta Platforms Inc) page, on which the study was advertised. The 2 sources for recruitment were intended to understand the spectrum of experiences of survivors of differentiated thyroid cancer (DTC), RAI symptom burden profiles, and website feedback from individuals across the United States who were treated across a variety of hospital settings.

Eligible patients met the following inclusion criteria: (1) age of ≥18 years; (2) able to provide informed consent in English; (3) diagnosed with DTC (papillary or follicular carcinoma) in the past 3 years; (4) received RAI treatment within the past 3 years; (5) access to a computer, tablet, or smartphone with internet connectivity; and (6) completion of the Radioiodine-6 screener [21] with a total score of ≥7.6 or a score of ≥3 on at least 1 out

XSL•FO
RenderX

of the 3 RAI symptom subitems (mouth, eyes, or nasal). Exclusion criteria included non–English-speaking patients and individuals with cognitive, psychiatric, or hearing impairments that could limit their ability to consent or participate in the study.

Following institutional review board approval (#00005285), potential participants were contacted through introductory emails or mailed study flyers, followed by a Health Insurance Portability and Accountability Act (HIPAA)–compliant videoconference with research staff to assess eligibility through the completion of a screening questionnaire. Informed consent was obtained through a 15-minute telephone call or a HIPAA-compliant videoconference. Participants reviewed and signed the informed consent form electronically. A total of 8 patients diagnosed with DTC and treated with RAI within the past 3 years were enrolled.

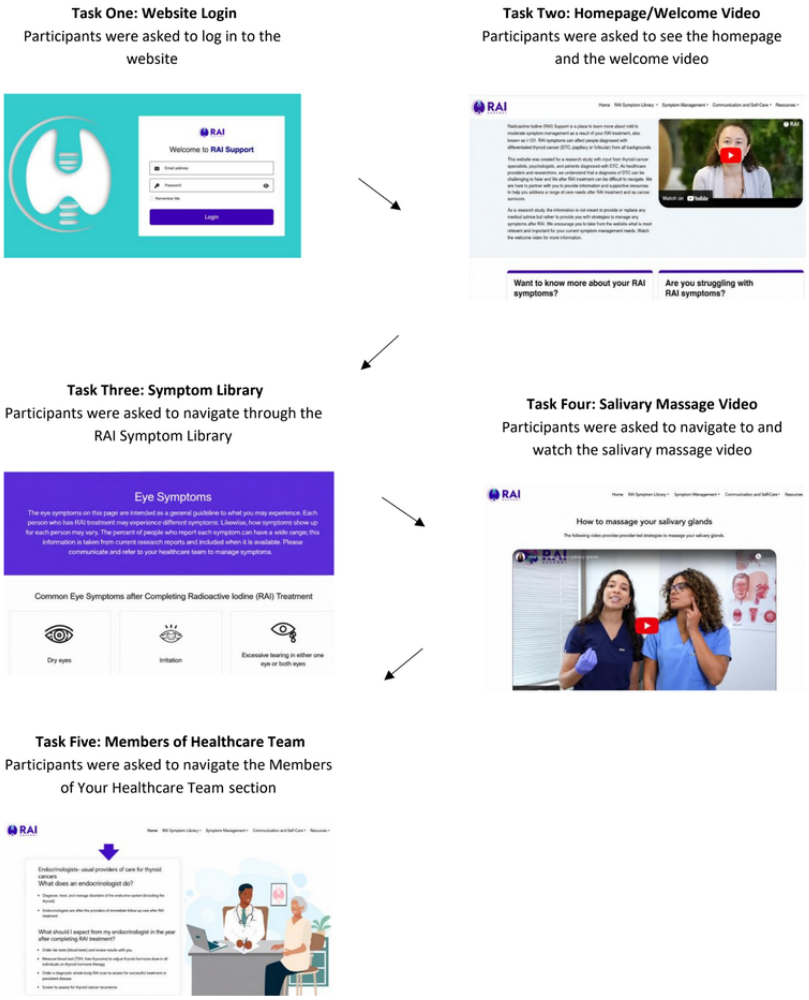
Imposter Participants

Our Facebook recruitment approach also led to 29 "imposter participants," defined as individuals who provide false identities and information for the purpose of participating in research studies [22-24]. Imposter participants were identified by a combination of the following indicators: nonworking telephone numbers or telephone numbers for businesses, refusal to turn on their cameras (a requirement for usability participation), use of similar (yet unusual) email domains, and inconsistent internet connectivity.

To increase rigor and guard against imposter participants, study staff modified the screening procedure to include open-ended questions about the name of the hospital or clinic setting in which participants received treatment. We then ended Facebook recruitment to reduce the likelihood of additional imposter participants. Of note, imposter participants were not included in the final data analysis.

Data Collection

Participants completed baseline and postintervention surveys via REDCap (Vanderbilt University) [25] (for details, refer to the Measures section).



Study staff trained in qualitative research methods developed the semistructured usability testing interview guides (including author AC, a female psychologist, author KM, a female human factors scientist, and a nonauthor, female research and human factors scientist). Interviews lasted approximately 90 minutes.

Study staff (authors) trained in qualitative research conducted the interviews: AMJ (a female research assistant), JP (a male research assistant), and RM (a male research assistant). A second member of the research team (JAL, a female research assistant, and JP), trained in qualitative data research, took detailed notes during the interviews to track usability task outcomes.

Study staff used a think-aloud method to prompt participants to provide feedback as they navigated key website elements, including the log-in process, home page, welcome video, symptoms page, salivary symptom management page, and resource page. Feedback focused on content clarity, visual appeal, and ease of navigation (Figure 1). All recorded usability testing interviews were transcribed verbatim and deidentified prior to data analysis. At the end of the usability testing interviews, participants completed a System Usability Scale (SUS) questionnaire [26] via REDCap. Participants were then asked to continue using RAI Support for 4 weeks. At the conclusion of the 4 weeks, they completed a follow-up questionnaire.

XSL•FO
RenderX

Figure 1. Screenshots of web-based Radioactive Iodine Support (RAI Support) prototype.

Intervention

RAI Support has been previously described [9]. RAI Support is a theoretically driven web-based intervention to support self-management of RAI symptoms among survivors of DTC. RAI Support is informed by social cognitive theory [27] and was developed following person-based design principles, with survivors of DTC and health care providers (endocrinologists, endocrine surgeons, nuclear medicine providers, registered oncology dietitians, social workers, and psycho-oncologists) as integral members of the intervention development process [28]. The web-based intervention is asynchronous and consists of content related to education on RAI symptoms; brief provider-led videos on symptom management strategies for mild to moderate symptoms; communication and self-care, including mindfulness exercises; and DTC survivorship resources. Website programming was produced by DreamSoft4u, Pvt. Ltd [29].

Measures

Usability Evaluation Outcome Measures: SUS

The SUS is a 10-item questionnaire that assesses patients' perceived usability of a system [26]. Items are rated on a 5-point Likert scale (1="Strongly disagree" to 5="Strongly agree"), with composite scores ranging from 0 to 100. A SUS score >68 represents above-average usability [26].

Effectiveness is defined as the success rate or the degree to which a participant can successfully achieve their goal in using the system. For the present study, effectiveness is assessed dichotomously (yes or no) to indicate the ability to complete a task.

Ease of use is the degree to which a participant can complete a task on their very first attempt without training. For the present study, ease of use is assessed dichotomously (yes or no) and refers to the ability to complete a task the first time.

Error rate is the degree to which the interaction between the participant and the system is smooth and/or the type of mistakes a participant makes while completing each task. For the present study, error rate is assessed on a 4-point Likert scale (1="cosmetic or visual error," 2="minor error or user recovers quickly," 3="major error or user recovers with difficulty," and 4="catastrophic error or system crashes"), with higher scores indicating greater severity of error.

Intervention Outcome Measures

Salivary, Lacrimal, and Nasal Measure

The salivary, lacrimal, and nasal (SALANS) [8] measure consists of 33-items and assesses SALANS symptoms among

XSL•FO
RenderX

patients with DTC after RAI treatment on a 5-point Likert scale (0="Not at all" to 4="Very much"). The scale has 6 subscales (sialadenitis, taste, xerostomia, dry eyes, epiphora, and nasal). Higher scores indicate greater symptom burden. The internal consistency α coefficient for the current sample is 0.98.

Functional Assessment of Cancer Therapy-General-7 Item

The Functional Assessment of Cancer Therapy-General-7 Item (FACT-G7) [30] is a 7-item questionnaire that assesses physical, emotional, and functional well-being of adult oncology patients. Each item is rated on a 5-point Likert scale (0="Not at all" to 4="Very much"). Scores range from 0 to 28, with higher total scores indicating greater HRQOL. The α coefficient for the current sample is 0.88.

Patient-Reported Outcomes Measurement Information System Scale

The Patient-Reported Outcomes Measurement Information System (PROMIS) Scale version 1.2 Global Health is a 4-item assessment of physical and mental health measured on a 5-point Likert scale [31]. Raw summed scores range from 4 to 20 and are converted to T-scores, with a mean of 50 and an SD of 10. A higher T-score indicates greater physical and mental health. The α coefficient for the current sample is 0.92.

PROMIS Self-Efficacy for Managing Chronic Conditions–Managing Symptoms

The PROMIS Self-efficacy for Managing Chronic Conditions–Managing Symptoms is a 28-item questionnaire that evaluates physical, mental, and social health in individuals with chronic conditions, with the T-score (mean 50, SD 10) representing the final score [32]. A higher score indicates higher self-efficacy. The α coefficient for the current sample is 0.96.

Informational Needs Questionnaire for DTC

The Informational Needs Questionnaire for DTC (INQ-DTC) contains 33 items and assesses informational needs of patients after RAI treatment [33]. Items are measured on a 5-point Likert scale (1="Not at all" to 5="Very"). Higher total scores indicate greater informational needs. The α coefficient for the current sample is 0.93.

Exit Questionnaire

Participants completed an exit questionnaire to assess their perceptions of the helpfulness of components of the RAI Support intervention, likelihood of recommending the program to survivors of DTC, satisfaction with intervention length, and overall satisfaction with the program. Responses were assessed using 10-point Likert scales for the majority of items.

Intervention Back-End Use Data

Intervention back-end use data were captured through the RAI Support back-end system. Metrics captured included frequency of log-ins and number of website pages visited. Use data were exported in aggregate form for analysis to complement self-report measures of intervention engagement.

Data Analysis

A mixed methods approach was used, incorporating quantitative data from questionnaires, usability logs, and the web-based intervention back-end system, as well as qualitative data from usability interviews for analysis. Descriptive statistics were used to summarize the demographic and clinical characteristics and web-based intervention use of participants. Signals of change in outcomes of interest were evaluated using within-group effect sizes calculated with the Rosenthal effect size formula ($r=Z/\sqrt{N}$), where Z is the standardized Wilcoxon signed-rank test statistic and N is the number of paired observations [34,35]. Cohen guidelines for r effect sizes were used and defined as "small" for $r=0.1$; "medium" for $r=0.3$; "large" for $r=0.5$ [35]. Signed effect sizes were reported to indicate the direction of change, with directionality defined based on follow-up minus baseline. Positive values indicate increases from baseline, whereas negative values indicate decreases.

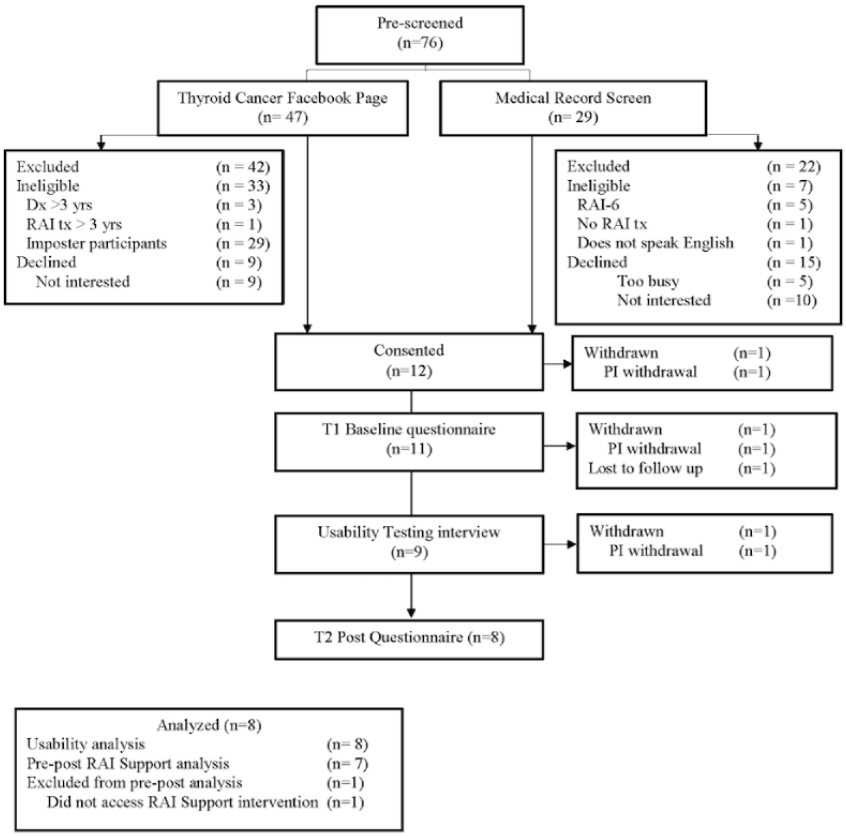
Content analysis was used to analyze the usability testing interviews [36,37]. To gain an initial understanding of the content, 3 authors (AC, AMJ, and JAL) independently reviewed the interview transcripts and met biweekly to identify and refine preliminary codes and examine data discrepancies until team resolution. Coding was conducted using ATLAS.ti Scientific Software Development GmbH (version 8.15.3; Lumivero LLC). Three authors (AC, AMJ, and JAL) collaboratively developed a codebook, consolidating initial codes into broader categories through iterative discussion. These categories were further synthesized into major themes and subthemes to capture key patterns in participant feedback regarding the context underlying usability issues and potential methods for optimization. Thematic saturation [38] was operationally defined as the point at which review of interviews did not identify new themes or subthemes relevant to usability. Using this approach, no new themes or subthemes emerged from the final interview data, indicating thematic saturation within the scope of the usability evaluation.

Ethical Considerations

Ethics approval was obtained in accordance with the principles of the Declaration of Helsinki. The protocol was reviewed and approved by the Georgetown University Institutional Review Board (#00005285). All participants provided signed informed consent. Study data were deidentified prior to data analysis. Participants were compensated with a US $50 gift card for study participation.

Results

Recruitment



A total of 76 individuals were assessed for eligibility (Figure 2). A total of 47 (61.8%) individuals contacted study staff in response to Thyroid Cancer Survivors' Association Inc (ThyCa) Facebook advertisements, and 29 (38.2%) individuals were screened for eligibility from medical records. In total, 24 participants declined study participation: 19 were not interested and 5 were too busy. Overall, 64 individuals were excluded, including 24 who declined and 40 who were ineligible for the following reasons: 3 were diagnosed with DTC >3 years ago, 1 received RAI >3 years ago, 1 did not receive RAI, 1 was not an English speaker, 29 were imposter participants, and 5 did

XSL•FO
RenderX

not meet screening criteria. Among those who were eligible, 12 participants consented to the study.

Of the total sample of consented participants (n=12), 1 was lost to follow-up and 3 withdrew, leaving a final sample of 8 consented participants who completed baseline, usability testing, and postassessment procedures. In the final study sample (N=8), the average age of participants was 45 (SD 8.2; range 35-61) years. In terms of clinical characteristics, the average times since diagnosis and RAI treatment were 1.2 (SD 1.1) and 0.6 (SD 0.4) years, respectively. Most participants were diagnosed with papillary thyroid cancer (7/8, 87.5%), and most received an RAI dose of 100 to 150 mCi (n=6, 75%). See Table 1 for demographics and clinical characteristics.

Usability Evaluation

Eight participants completed usability testing sessions. The mean SUS score was 88.1 (SD 8.7), indicating above-average usability. All participants effectively completed each task. Ease of use, as measured by completion of a task on the first attempt, ranged from 100% to 87.5%, and error rates ranged from 0% to 25%. Participants rated the clarity of the welcome page (mean 4.3, SD 0.8) and the welcome video (mean 5.0, SD 0; task 1), indicating that the page was perceived as clear and the video as very clear. Mobile device screen sharing blocked the visuals needed to complete tasks 3 (RAI symptom library) and 4 (health care provider–led salivary gland massage video) for 1 participant. When the screen sharing issue was resolved with prompting from study staff, ease of use for this participant increased to 100% for task 5. Refer to Table 2 for an overview of the usability outcome metrics, including error rates by task.

Table 2. Usability evaluation outcomes (N=8).

Tasks	Participants
Task 1: website log in	
Effectiveness	8 (100)
Ease of use	8 (100)
Error: none	8 (100)

User Testing Feedback

Participants reported that they found the website content “informative,” “helpful,” and that they would recommend the website to someone else experiencing RAI symptoms. User testing feedback provided insight into barriers to user engagement, contextual information about the root causes of barriers to user engagement with the prototype, and areas for improvement. Overall, participants highlighted navigation across website pages as a primary area for improvement. Participants noted challenges in locating specific content and suggested adding hyperlinks to facilitate navigation. Participants also reported being timed out of the website and suggested increasing the session idle time. Example suggestions for website improvement and refinement are illustrated in Table 3.

XSL•FO
RenderX

Table 3. User testing feedback.

Domains	Exemplar quotes	Refinements
Navigation (all elements related to moving between website pages and additional functions to enhance user engagement with the website)		
Hyperlinks	• "There should be like more of a connection between and leading you where to go. Or if you want to learn more about this, 'Go here.' I wanted to be guided to something more, instead of having to go look for it." [PID[a] 16] • "I think, clicking to the solution. A direct click might have been beneficial." [PID 58]	Incorporation of hyperlinks to facilitate user navigation within the system
Session time-out	• "Let's see. I have to sign back in...Now, that might be something want to look into." [PID 59] • "Oops got logged out...Look at it logged out again." [PID 16]	Increase in the session idle time
Design (reference to the visual appeal, length, formatting, or other design elements of the web-based platform, regardless of task or section of website)	• "I think the fonts size has to be a little bit more uniform." [PID 49] • "Making it a less medicalized and more down to earth like you're talking more to an actual human being instead of somebody specializes in it [thyroid cancer]." [PID 52] • "It's just three paragraphs. When you use bullets where it's quick that makes for a better, cleaner, read." [PID 59]	Inclusion of bullet points to ease readability and understanding of complex information
Features: welcome page or video (area for refinement to acclimate the user to key features of the intervention)	• "I didn't know if the [welcome] video was going to lead into more interactive things or showing what maybe clicking around or how to use the site." [PID 58] • "I don't know if you want to include the navigation here as an additional video." [PID 65]	Refinement of the welcome video to include website navigation instructions
Features: interactive (areas for refinement to reduce the static nature of the intervention)	• "Graphic visuals, pop ups or things that move across the screen. Just so, it's not like quite as static and just information sitting there. Make a little more flash to it, or activity." [PID 16] • "This is not static content that you're presenting... And when I hover on top of this card, perhaps you can then pop that information out, or pop it as a mobile dialogue, or expand on the key concept, on this one box." [PID 65]	Incorporation of interactive features to enhance user engagement

[a]PID: participant ID.

Exit Questionnaire and Intervention Back-End Use Outcomes

Participant scores on the exit questionnaire (n=7) indicate moderate to high ratings of helpfulness for the website videos: managing dry mouth (mean 7.14, SD 2.11), changes in taste (mean 6.5, SD 2.65), and relaxation and mindfulness (mean 6.83, SD 1.94). Back-end use data indicate that, on average, 6 (85.7%) of the 7 website users engaged with 3 out of the 4 content sections during the 4-week home intervention period. Refer to Multimedia Appendices 1 and 2 for the participant exit questionnaire and back-end metrics.

Preliminary Intervention Outcomes

Preliminary effect size signals of change were calculated for participants who completed baseline and postassessment measures (n=7). The distributions of scores on outcomes of interest are presented in Table 4. Overall, preliminary effect size signals of change were found in self-efficacy (r=0.32), global mental health (r=0.31), and HRQOL (r=0.45), with positive effect sizes indicating increases from baseline. A small negative effect size was observed for RAI informational needs (r=−0.15), indicating a favorable decrease in informational needs from baseline. RAI symptom burden and psychosocial informational needs remained relatively stable throughout the study, and global physical health decreased across study time points.

Table 4. Signals of change from baseline to postintervention assessment with RAI Support (N=7).

Measures	Baseline assessment	Postintervention assessment	Changes in mean from baseline	*r* effect sizes[a]
RAI[b] symptom burden[c], mean (SD; range)	62.3 (38.7; 35-148)	63.0 (36.6; 38-144)	+0.7	+0.03
Self-efficacy, mean (SD; range)	40.6 (5.8; 31.4-50.3)	44.2 (12.2; 30.6-69.5)	+3.6	+0.32
Informational needs , mean (SD; range)				
RAI	28.0 (2.2; 24-30)	25.7 (5.8; 14-30)	−2.3	−0.15
Psychosocial	19.4 (5.7; 10-25)	19.1 (5.2; 10-25)	−0.3	0
Global mental health, mean T-score (SE; range)	40.5 (3.45; 26.1-56.7)	42.5 (3.68; 21.3-48.8)	+1.9	+0.31
Global physical health, mean T-score (SE; range)	43.9 (4.11; 19.7-50.7)	42.7 (3.94; 19.7-50.7)	−1.2	−0.55
HRQOL, mean (SD; range)	15.0 (7.3; 0-22)	15.9 (7.5; 1-23)	+0.9	+0.45

[a]Cohen *r* effect size: 0.1="small," 0.3="medium," and 0.5="large."

[b]RAI: radioactive iodine.

[c]RAI symptom burden is measured by the salivary, lacrimal, and nasal (SALANS) measure.

Discussion

Principal Results

Findings from this study add to the literature by showing high usability and preliminary proof-of-concept data for a website designed to support symptom management following RAI treatment among patients with DTC. In addition, this is among the first studies to evaluate the usability of a web-based intervention for symptom management in an understudied population of survivors of DTC. Overall, participants found the RAI Support intervention to be informative and the health care provider–led videos to be helpful. Participant feedback identified user-centered areas to enhance the intervention's ease of use, including navigation across webpages and interactive features to foster user engagement. Future adequately powered studies should further examine temporal patterns and predictors of intervention engagement, including whether sustained or repeated use varies by baseline RAI symptom burden, clinical characteristics, or recruitment source, to better understand for whom and under what circumstances the RAI Support intervention is most engaging. These focal points are consistent with broader gaps identified in the implementation literature on digital health interventions in thyroid cancer care. A recent scoping review of digital health interventions in thyroid cancer care synthesized intervention characteristics, effectiveness, and uptake, as well as reported barriers and facilitators, and identified few interventions focused on symptom self-management following primary treatment [39], highlighting the limited availability of digital approaches addressing this need. Within this context, among participants with complete pre-post RAI intervention data, we found evidence of small to medium clinically meaningful changes in self-efficacy for managing chronic symptoms, RAI informational needs, global mental health, and HRQOL. These findings support the potential of digital interventions such as RAI Support as a valuable and feasible approach to address symptom management needs, with further research and refinement likely to enhance their utility.

Results did not support RAI Support's preliminary effect size signals of change on RAI symptom burden, informational needs for personal growth, and global physical health. One explanation for these findings is that the RAI Support intervention is intended to provide noncurative symptom management strategies, which may not eliminate the persistent nature of the frequency and severity of RAI symptoms [40-42]. Additionally, these data did not capture information on common medical comorbidities among survivors of DTC such as myocardial infarction, osteoporosis, hyperthyroidism, and hypothyroidism [10,11], which may explain the pre-post differences in PROMIS Global Physical Health scale scores in the sample. Future studies with larger samples that capture common medical comorbidities are warranted to further evaluate these outcomes. Another explanation for these findings is that the static informational content of the website may not fully address the range of patient needs. Future research could explore more integrative and interactive features, such as direct messaging with health care professionals or cancer-specific conversational agents to provide tailored guidance and deeper patient connection [43,44]. Recent interventions using a range of web-based elements yielded a reduction in chemotherapy-related side effects and improved effectiveness in self-care behaviors in patients with cancer [43,44]. These findings also contribute to a broader shift toward risk-adapted, digitally enabled thyroid cancer care. Advances in molecular testing and AI-assisted cytopathology are refining the diagnostic evaluation of indeterminate nodules, while biomarker approaches are being examined to refine selection for RAI [45-47]. Together, these changes further underscore the potential value of scalable digital survivorship interventions, such as RAI Support, for addressing persistent symptoms and supporting patients throughout posttreatment care.

Limitations

There are several limitations of this study. Despite recruitment efforts through a publicly available thyroid cancer nonprofit Facebook page, most participants were recruited based on purposeful sampling from electronic medical record review. This led to participants in the study being relatively similar, with the majority being female, well educated, and from higher-income backgrounds (>US $200,000 per year). Although DTC does predominantly affect female individuals, having the preponderance of study participants come from such analogous backgrounds limits the generalizability of the study to larger and more diverse DTC populations. Usability and acceptability need to be confirmed in patients with broader socioeconomic, educational, and digital literacy backgrounds before implementation.

The small sample size of the study was appropriate to address the aims of the usability evaluation and ORBIT (Obesity-Related Behavioral Intervention Trials) model proof-of-concept testing, which focused on identifying preliminary effect size signals of change [20,48]. However, this limited sample size and the absence of a comparison condition further limit the generalizability of the findings and do not allow analyses of statistical differences or preliminary intervention effects. The study also covered a short time frame for participants, with user engagement and clinical outcomes tracked only over a 4-week period. This limited interval of analysis prevents a full understanding of the long-term benefits of the intervention for patients after RAI treatment.

An additional limitation is that the study encountered 29 imposter participants. Although those individuals were excluded, this recruitment issue is relevant to feasibility, recruitment, and generalizability of remote usability testing procedures and should be interpreted with caution [20,48]. The potential influence of outlier scores is another limiting factor, such as for PROMIS Global Physical Health, particularly given the small sample size. Future pilot feasibility trials should incorporate larger participant samples from different geographic areas, participants with varying intervals since RAI treatment, and a control condition to allow more rigorous evaluation of the RAI Support intervention.

Conclusions

This study demonstrated a positive usability testing evaluation of the web-based RAI Support prototype for RAI symptom management among survivors of DTC, a population that has received limited survivorship-focused attention. The study also identified preliminary effect size signals of change in self-efficacy in survivors of DTC, global mental health, and HRQOL. Ongoing research has incorporated the patient-recommended refinements and will examine the feasibility and acceptability of the RAI Support intervention through a pilot randomized controlled trial.

Acknowledgments

The authors thank Gary Bloom, Jana Schwartz, Kelsie Hitesman, Rachel Wong, Cynthia McDonald, Amanda Rhodes, Elyse Jackson, Tatiana Ferraro, Lauren Bello, and Joseph Voight for their contributions to the intervention content development. The authors also thank Robin A Littlejohn, for their contribution to the development of the semistructured moderator guide. The authors declare the use of generative AI (GenAI) in the research and writing process. According to the Generative AI Delegation Taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading, editing, and reformatting. The GenAI tool used was ChatGPT (GPT-5.6 Sol; OpenAI).The authors used ChatGPT 5.6 Sol to provide a higher-resolution version of Figure 1. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

This project was funded by the National Cancer Institute (K99CA277588). AMJ received research funding support for trainees provided by the Lombardi Comprehensive Cancer Center CCSG (P30CA051008). This work was supported in part through funding provided by the Lombardi Comprehensive Cancer Center (LCCC) Cancer Research Training Education Coordination (CRTEC) Office, awarded to JAL. This project has been supported with services from Federal funds (UL1TR000101 previously UL1RR031975) from the National Center for Advancing Translational Sciences (NCATS), National Institutes of Health, through the Clinical and Translational Science Awards Program (CTSA), a trademark of the US Department of Health and Human Services (DHHS), part of the Roadmap Initiative, “Re-Engineering the Clinical Research Enterprise.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to ethical considerations related to the protection of participant confidentiality, given the small sample size in this study, and in accordance with the guidance of the Health Insurance Portability and Accountability Act (HIPAA) and the consent process but are available from the corresponding author on reasonable request.

Conflicts of Interest

Abstract

Background: Emerging evidence indicates that inflammation plays a crucial role in cancer prognosis. Inflammatory response biomarkers are recognized as promising prognostic factors for mortality in patients with cancer.

Objective: This study aims to evaluate the prognostic significance of the systemic inflammatory response index (SIRI), systemic immune-inflammation index (SII), platelet-to-lymphocyte ratio (PLR), neutrophil-to-lymphocyte ratio (NLR), inflammatory prognostic index (IPI), and C-reactive protein-albumin-lymphocyte (CALLY) index.

Methods: Weighted Cox regression analyses, restricted cubic spline models, Kaplan-Meier survival curves, and receiver operating characteristic analyses were performed to assess the predictive value of the 6 inflammatory markers for mortality. Subgroup analyses and sensitivity analyses were conducted to examine associations within specific subpopulations.

Results: Cox regression models demonstrated that SIRI, NLR, IPI, and CALLY were significant predictors of all-cause mortality (tertile 3 vs tertile 1; hazard ratio [HR]: SIRI: 1.72, 95% CI 1.29 - 2.27; NLR: 1.33, 95% CI 1.02 - 1.74; IPI: 1.48, 95% CI 1.14 - 1.92; CALLY: 0.66, 95% CI 0.51 - 0.85). IPI (HR 1.91, 95% CI 1.11 - 3.27) and CALLY (HR 0.53, 95% CI 0.31 - 0.90) were significantly associated with cancer-specific mortality, whereas only SIRI was able to predict cardiovascular mortality (*P* value for trend=.04). Dose-response relationships were observed between the 6 inflammatory markers and mortality outcomes. Kaplan-Meier survival curves further illustrated significant differences between tertile groups (log-rank test, *P*<.001). The 6 inflammatory indices exhibited moderate predictive ability for all-cause mortality. IPI yielded the highest area under the curve (AUC) for cancer-specific mortality (AUC=0.6338), and SIRI was the most efficient predictor of cardiovascular mortality (AUC=0.687). No significant interactions were observed between the 6 inflammatory markers and most subgroup variables.

Conclusions: SIRI, NLR, IPI, and CALLY represent convenient and cost-effective prognostic tools for predicting mortality in patients with cancer. In contrast, SII and PLR may not be reliable prognostic biomarkers.

KEYWORDS

inflammatory markers; all-cause mortality; cancer mortality; cardiovascular mortality; prognosis

Introduction

Cancer remains a major societal, public health, and economic burden, ranking as the third leading cause of death worldwide [1-3]. Although advances in diagnosis and treatment have substantially reduced cancer-related mortality rates, the number of cancer survivors is projected to exceed 26 million by 2040 [4,5]. Nevertheless, cancer treatments—particularly anticancer agents—may induce cardiotoxicity and elevate the risk of cardiovascular disease (CVD) [6]. Moreover, cancer and CVD may share common pathophysiological pathways, given the overlapping risk factors, inflammatory processes, metabolic dysregulation, and neurohormonal activation associated with both conditions [7,8]. Consequently, there is an urgent clinical need for early detection and routine screening of all-cause, cancer-specific, and cardiovascular mortality among patients with cancer, using simple, cost-effective, and readily accessible tools.

XSL•FO
RenderX

Accumulating evidence has established inflammation as a common pathogenic driver of various diseases. Inflammation is a hallmark of tumorigenesis and plays a critical role in cancer initiation, progression, and metastasis [9-11]. Similarly, CVD is recognized as a chronic inflammatory condition, with inflammation being central to the onset and progression of atherosclerosis [11-13]. Inflammatory status can be assessed using various immune cell parameters and biochemical markers. Furthermore, systemic inflammatory responses contribute to decreased serum albumin levels. Wu et al [14] demonstrated that albumin levels were associated with cause-specific mortality in older adults [14]. In recent years, novel composite inflammatory markers—including the systemic inflammatory response index (SIRI), systemic immune-inflammation index (SII), platelet-to-lymphocyte ratio (PLR), neutrophil-to-lymphocyte ratio (NLR), inflammatory prognostic index (IPI), and C-reactive protein-albumin-lymphocyte (CALLY) index—which integrate complete blood count (CBC) with albumin and C-reactive protein (CRP)—have emerged as promising prognostic indicators for predicting disease outcomes [15-19].

The primary objective of this study was to evaluate the predictive value of SIRI, SII, PLR, NLR, IPI, and CALLY for all-cause, cancer-specific, and cardiovascular mortality in patients with cancer, and to further explore the potential use of these markers in the early identification of mortality risk.

Methods

Study Population and Exclusion Criteria

Data for this study were obtained from the National Health and Nutrition Examination Survey (NHANES) [20], a program designed to generate vital and health statistics for the US population. Given that CRP data were available only for 5 consecutive survey cycles (2001 - 2002, 2003 - 2004, 2005 - 2006, 2007 - 2008, and 2009 - 2010), we initially collected data from 52,195 participants across these cycles. Participants were excluded if they met any of the following criteria: (1) missing blood test results for albumin, CBC, or CRP; (2) absence of a cancer diagnosis or missing information on cancer history; (3) missing data on relevant covariates; or (4) pregnancy.

Evaluation of 6 Inflammatory Markers

For all participants, CBC was performed on blood specimens using a Beckman Coulter MAXM instrument at the Mobile Examination Centers. CRP levels were quantified using latex-enhanced nephelometry, and albumin concentrations were measured using the DcX800 method.

The inflammatory markers were calculated using the following formulas:

SIRI=neutrophil count × monocyte countlymphocyte count

SII=neutrophil count × platelet countlymphocyte count

PLR=platelet countlymphocyte count

NLR=neutrophil countlymphocyte count

IPI=CRP × NLRalbumin

CALLY=albumin × lymphocyte countCRP × 10

Outcome and Follow-Up

Cancer diagnosis was based on self-reported medical history. Participants were identified as having cancer if they responded affirmatively to the question: "Have you ever been told by a doctor or other health professional that you had cancer or a malignancy of any kind?" Mortality status for the NHANES follow-up population was obtained from the publicly available mortality files [21]. The primary outcome was all-cause mortality, while secondary outcomes included cancer-specific and cardiovascular mortality, coded according to the *International Classification of Diseases, 10th Revision* (*ICD-10*). Follow-up time was calculated in person-months from the date of the interview, with the observation period ending on December 31, 2019.

Assessment of Covariates

Demographic characteristics included gender, age, race, educational level, marital status, smoking status, alcohol consumption, and the poverty-to-income ratio. Race was categorized as non-Hispanic White, non-Hispanic Black, other Hispanic, Mexican American, or other races. Educational level was classified as: less than 9th grade, 9th to 11th grade (including 12th grade with no diploma), high school graduate or General Educational Development diploma, some college or associate degree, and college graduate or above. Marital status included the following categories: married, widowed, divorced, separated, never married, and living with a partner. Participants who consumed at least 12 drinks of any type of alcoholic beverage within 1 year were defined as drinkers. Those who reported smoking at least 100 cigarettes during their lifetime were categorized as smokers. Medical history—including hypertension, diabetes, hyperlipidemia, myocardial infarction (MI), congestive heart failure (CHF), coronary heart disease (CHD), and stroke—was based on prior medical records provided by health care professionals or physicians.

Statistical Analysis

The distribution of continuous variables was assessed using the Shapiro-Wilk test. Given the nonnormal distribution of the variables, they were summarized as medians with IQRs. Categorical data were expressed as frequencies and percentages. Differences among groups stratified by the 6 inflammatory markers were evaluated using the Kruskal-Wallis test or Fisher exact test, as appropriate.

To evaluate the prognostic value of the 6 inflammatory markers for mortality, weighted Cox regression analyses were performed to estimate hazard ratios (HRs) with 95% CIs. Three adjustment models were constructed: model I was unadjusted; model II was adjusted for gender, age, race, educational level, marital status, and poverty-to-income ratio; and model III was additionally adjusted for smoking, alcohol consumption, hypertension, diabetes, hyperlipidemia, CHF, CHD, MI, and stroke, in addition to the covariates included in model II. Restricted cubic spline (RCS) models were further used to explore potential dose-response relationships between the inflammatory markers and mortality outcomes, with adjustment for demographic characteristics, smoking, alcohol consumption,

XSL•FO
RenderX

and disease history. Kaplan-Meier survival curves with log-rank tests were used to estimate survival distributions across tertiles of the inflammatory markers. Receiver operating characteristic curves were generated to assess the sensitivity and specificity of the 6 inflammatory markers, and the area under the curve (AUC) was calculated to evaluate their predictive performance for all-cause, cancer-specific, and cardiovascular mortality. Subgroup analyses were conducted concurrently to elucidate potential interactions between the 6 inflammatory markers and covariates. To assess the robustness of the results, a sensitivity analysis was performed excluding patients with asthma and arthritis.

All statistical analyses were performed using R software (version 4.3.0; R Core Team 2023), and a *P* value of less than .05 was deemed statistically significant.

Ethical Considerations

The protocol for NHANES was approved by the National Center for Health Statistics Ethics Review Board (protocols: 98‐12 and 2005‐06 [22]) in accordance with the Declaration of Helsinki. All participants signed written informed consent.

Results

Baseline Characteristics

A total of 946 participants were enrolled in this study (Figure S1 in Multimedia Appendix 1). Based on all-cause mortality status, participants were classified into survival and nonsurvival groups. Table 1 summarizes the weighted baseline characteristics comparing the 2 groups. The survival group had a higher proportion of women, was younger, and exhibited higher educational levels, higher income, and more favorable marital status compared with the nonsurvival group. The nonsurvival group reported a higher prevalence of hypertension, diabetes, CHF, CHD, MI, stroke, and weak or failing kidneys. Furthermore, the values of SIRI, SII, PLR, NLR, and IPI were higher in the nonsurvival group than in the survival group, whereas the CALLY index was lower in the nonsurvival group (Table 1; Figure S2 in Multimedia Appendix 1).

Associations of 6 Inflammatory Markers With Study Outcomes

In Cox regression models, the levels of the 6 inflammatory markers were stratified by tertiles to evaluate their associations with all-cause, cancer-specific, and cardiovascular mortality (Table 2 and Tables S1 and S2 in Multimedia Appendix 1). A 1-SD increase in SIRI was associated with an increased risk of all-cause, cancer-specific, and cardiovascular mortality (all *P*<.001). Similar associations were observed for SII, NLR, and IPI, with elevations in these markers corresponding to higher mortality risks for all 3 outcomes. Associations of PLR and CALLY with all-cause and cardiovascular mortality were observed only in unadjusted or partially adjusted models, with no significant associations with cancer-specific mortality.

[a]Model I was not adjusted for any covariates.

[b]HR: hazard ratio.

[c]Model II was adjusted for gender, age, race, educational level, marital status, and poverty-to-income ratio.

[d]Model III was adjusted for gender, age, race, educational level, marital status, poverty-to-income ratio, smoking, drinking, hypertension, diabetes, hyperlipidemia, congestive heart failure, coronary heart disease, myocardial infarction, and stroke.

[e]SIRI: systemic inflammation response index.

[f]Not applicable.

[g]SII: systemic immune-inflammation index.

[h]PLR: platelet-to-lymphocyte ratio.

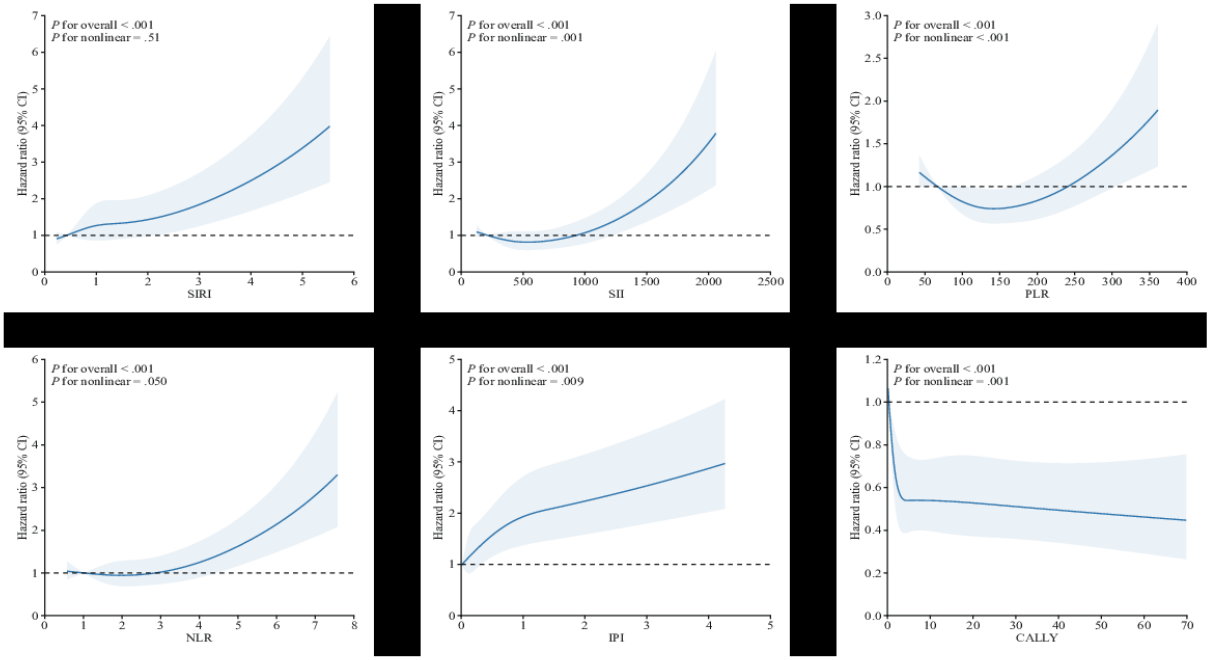
[i]NLR: neutrophil-to-lymphocyte ratio.

[j]IPI: inflammatory prognosis index.

[k]CALLY: C-reactive protein-albumin-lymphocyte index.

With regard to the primary outcome of all-cause mortality, the higher SIRI tertile was associated with an increased risk (tertile 3 vs tertile 1; hazard ratio [HR]: model I: 2.67, 95% CI 2.09 - 3.41; model II: 1.74, 95% CI 1.35 - 2.25; model III: 1.72, 95% CI 1.29 - 2.27). The HRs for NLR and IPI in the second and third tertiles were significantly higher than those in the first (reference) tertile, with *P* value for trend less than .05. CALLY was the only protective factor, with HR values progressively decreasing from tertile 2 to tertile 3 compared with tertile 1 (*P* value for trend<.001).

Regarding cancer-specific mortality, IPI and CALLY appeared to be the most sensitive indicators. A higher IPI level was associated with an increased risk of cancer-specific mortality (tertile 3 vs tertile 1; HR: model I: 2.74, 95% CI 1.74 - 4.33; model II: 2.55, 95% CI 1.59 - 4.09; model III: 1.91, 95% CI 1.11 - 3.27). In contrast, a higher CALLY level was associated with a decreased risk of cancer-specific mortality (tertile 3 vs tertile 1; HR, 95% CI: model I: 0.38, 0.24 - 0.60; model II: 0.41, 0.25 - 0.65; model III: 0.53, 0.31 - 0.90). The other 4 markers were not significantly associated with cancer-specific mortality.



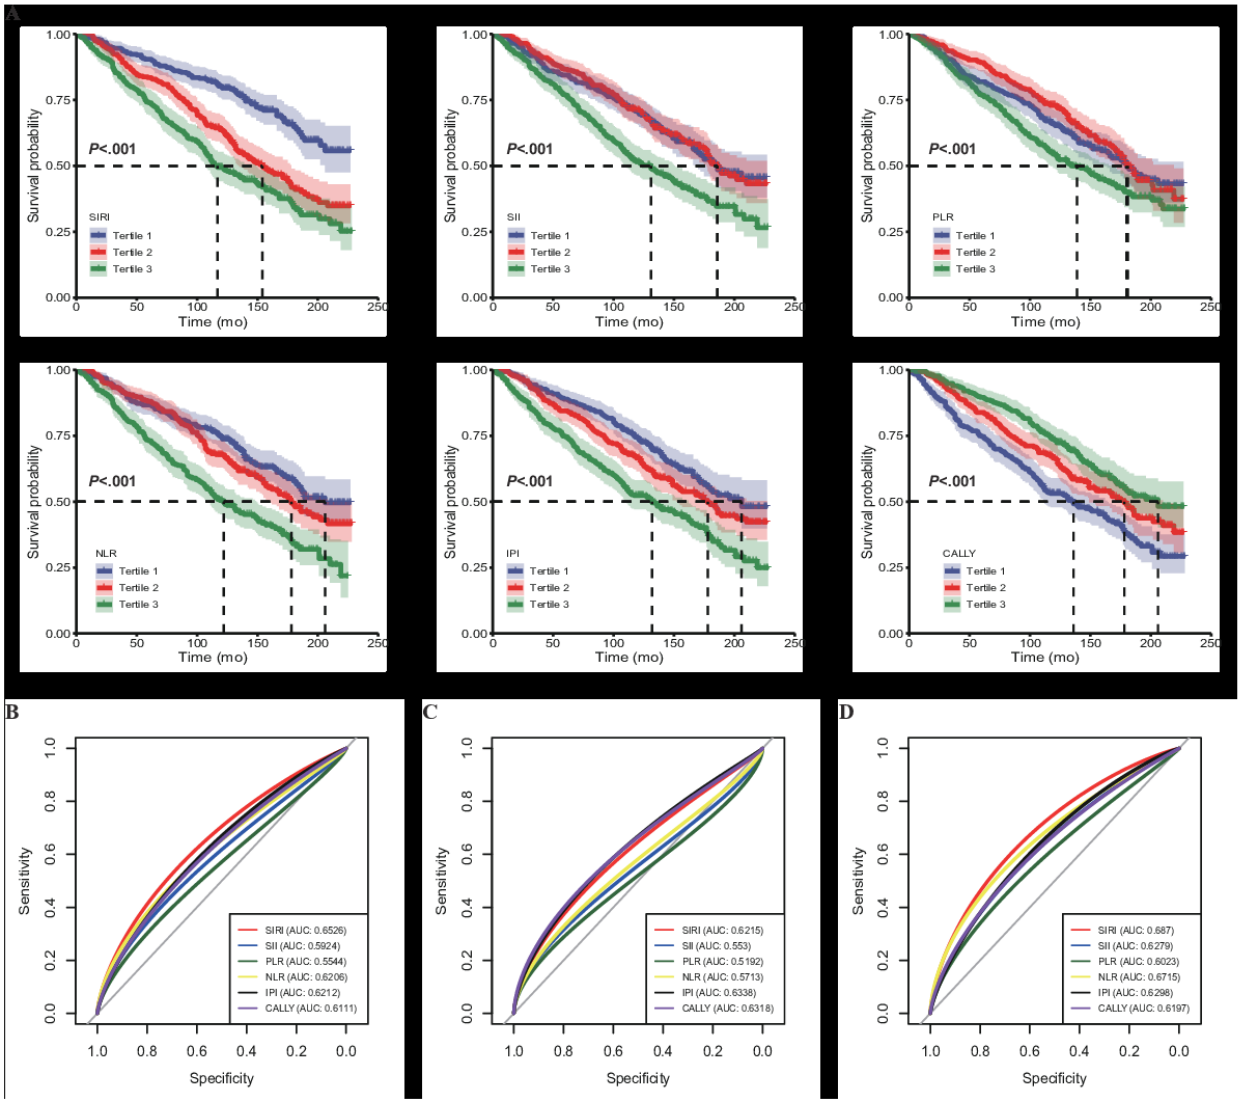
As shown in Table S2 in Multimedia Appendix 1, SIRI may be considered a predictor of cardiovascular mortality. Compared with tertile 1, the HR for tertile 3 was 3.50 (95% CI 1.51 - 3.66) in model I, 1.86 (1.06 - 3.27) in model II, and 1.83 (0.99 - 3.39) in model III, with *P* value for trend of less than .001, .02, and .04, respectively. The other markers were not significantly associated with cardiovascular mortality.

Dose-Response Relationship of 6 Inflammatory Markers With Study Outcomes

Multivariable-adjusted RCS analyses revealed significant dose-response relationships between the 6 inflammatory markers and all-cause mortality (Figure 1). SIRI (*P* value for nonlinear=.51) and NLR (*P* value for nonlinear=.05) presented linear correlations, while SII (*P* value for nonlinear=.001), PLR (*P* value for nonlinear<.001), IPI (*P* value for nonlinear=.009), and CALLY (*P* value for nonlinear=.001) exhibited nonlinear associations.

XSL•FO
RenderX

Figure 1. The restricted cubic spline (RCS) curve of the association between SIRI, SII, PLR, NLR, IPI, CALLY, and all-cause mortality. RCS regressions were adjusted for gender, age, race, educational level, marital status, PIR, smoking, drinking, hypertension, diabetes, hyperlipidemia, congestive heart failure, coronary heart disease, myocardial infarction, and stroke. CALLY: C-reactive protein-albumin-lymphocyte index; IPI: inflammatory prognosis index; NLR: neutrophil-to-lymphocyte ratio; PIR: poverty-to-income ratio; PLR: platelet-to-lymphocyte ratio; SII: systemic immune-inflammation index; SIRI: systemic inflammation response index.



As shown in Figure S3 in Multimedia Appendix 1, SII (*P* value for nonlinear<.001), PLR (*P* value for nonlinear<.001), NLR (*P* value for nonlinear<.001), IPI (*P* value for nonlinear<.001), and CALLY (*P* value for nonlinear=.008) exhibited nonlinear dose-response relationships with cancer-specific mortality, whereas SIRI did not (*P* value for nonlinear=.16). Regarding cardiovascular mortality, SII (*P* value for nonlinear=.005) and CALLY (*P* value for nonlinear=.02) demonstrated nonlinear dose-response relationships, whereas SIRI, NLR, and IPI did not.

Six Inflammatory Markers as Predictors of the Clinical End Points

Survival curves for all-cause mortality stratified by tertiles of SIRI, SII, PLR, NLR, IPI, and CALLY are presented in Figure 2A (log-rank test; *P*<.001). Higher levels of SIRI, SII, PLR, NLR, and IPI were associated with worse survival probability, whereas CALLY exhibited the opposite trend.

XSL•FO
RenderX

Figure 2. (A) Kaplan-Meier survival curve for all-cause mortality. In the Kaplan-Meier curves, the population is stratified into tertile groups, and statistical analysis is conducted using the log-rank test. (B) Receiver operating characteristic (ROC) curve analysis of SIRI, SII, PLR, NLR, IPI, CALLY, and all-cause mortality. (C) ROC curve analysis of SIRI, SII, PLR, NLR, IPI, CALLY, and cancer mortality. (D) ROC curve analysis of SIRI, SII, PLR, NLR, IPI, CALLY, and cardiovascular mortality. AUC: area under the curve; CALLY: C-reactive protein-albumin-lymphocyte index; IPI: inflammatory prognosis index; NLR: neutrophil-to-lymphocyte ratio; PLR: platelet-to-lymphocyte ratio; SII: systemic immune-inflammation index; SIRI: systemic inflammation response index.

Notably, the survival trends for cancer-specific and cardiovascular mortality across the 6 inflammatory markers were similar to those observed for all-cause mortality. However, no significant difference in survival probability was observed among PLR tertile groups (Figure S4 in Multimedia Appendix 1).

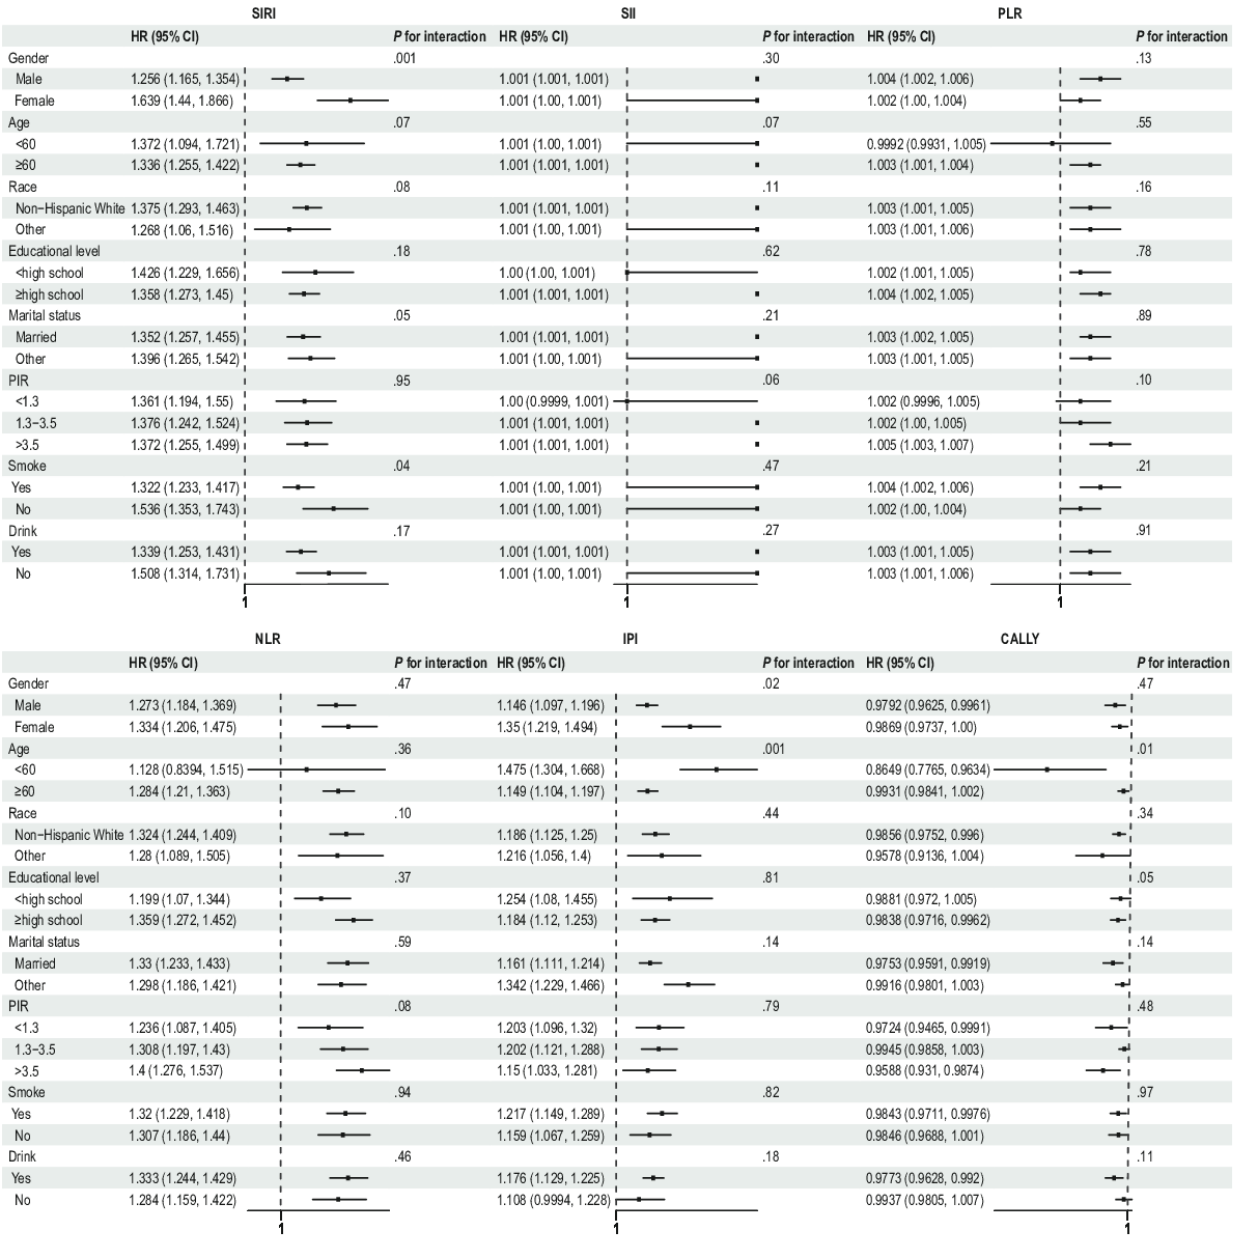


Figure 2B-D presents the predictive performance of the 6 inflammatory indices for all-cause, cancer-specific, and cardiovascular mortality. For all-cause mortality, the following AUC values were observed: SIRI: 0.6526, SII: 0.5924, PLR: 0.5544, NLR: 0.6206, IPI: 0.6212, and CALLY: 0.6111. Additionally, IPI yielded the highest AUC for cancer-specific mortality, while SIRI was the most efficient predictor of cardiovascular mortality.

Subgroup Analysis

No significant interactions were observed between SII, PLR, or NLR and all-cause mortality (all $P>.05$). However, gender, age, and smoking were found to potentially interact with SIRI, IPI, and CALLY (Figure 3). Regarding cancer-specific mortality, race, educational level, and marital status exhibited prominent interactions with SIRI, PLR, and IPI (Figure S5 in Multimedia Appendix 1). Furthermore, higher SIRI, SII, and NLR levels were more strongly associated with a higher prevalence of cardiovascular mortality in the married subgroup, whereas a higher cardiovascular mortality risk associated with IPI was observed in the other group (Figure S6 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 3. Subgroup analysis for the association between SIRI, SII, PLR, NLR, IPI, CALLY, and all-cause mortality. CALLY: C-reactive protein-albumin-lymphocyte index; HR: hazard ratio; IPI: inflammatory prognosis index; NLR: neutrophil-to-lymphocyte ratio; PIR: poverty-to-income ratio; PLR: platelet-to-lymphocyte ratio; SII: systemic immune-inflammation index; SIRI: systemic inflammation response index.

Sensitivity Analysis

After excluding patients with asthma, the risk of all-cause mortality showed a progressively increasing trend across tertiles of SIRI, NLR, and IPI, whereas CALLY showed a progressively decreasing trend (*P* value for trend<.01; Table S3 in Multimedia Appendix 1). After excluding patients with arthritis, the risk of all-cause mortality showed a progressively increasing trend across tertiles of SIRI and IPI, whereas CALLY showed a progressively decreasing trend (*P* value for trend<.05; Table S4 in Multimedia Appendix 1).

Discussion

To investigate the predictive role of inflammatory biomarkers in patients with cancer, we conducted a cross-sectional study involving 946 participants from the NHANES database. Our findings indicate that SIRI, SII, PLR, NLR, IPI, and CALLY were, to some extent, associated with mortality outcomes in patients with cancer, even after adjustment for selected confounders. Dose-response relationships were observed between most of these inflammatory indicators and mortality outcomes, with the exception of PLR in relation to cardiovascular mortality. Based on receiver operating characteristic curve analyses, the 6 inflammatory biomarkers demonstrated moderate predictive value for all-cause, cancer-specific, and cardiovascular mortality in patients with cancer. Furthermore, subgroup and sensitivity analyses validated the robustness of our models.

It is now well established that inflammation may contribute to the initiation and maintenance of unregulated cellular

XSL•FO
RenderX

proliferation, which can lead to tumor formation and growth [9]. Accumulating evidence supports the role of both local immune responses and systemic inflammation in tumor progression and patient survival [23,24]. Systemic inflammatory markers have been linked to increased cancer risk and mortality in numerous studies [25].

SIRI and SII are commonly used to assess the balance between inflammatory response and immune status. Previous studies have found that elevated levels of these markers are associated with poor prognosis in various cancers, including colorectal cancer [26,27], pancreatic cancer [28], breast cancer [29], chordoma [30], and lung cancer [27]. Our study demonstrated that SIRI and SII were elevated in patients who died of cancer, with SIRI showing strong prognostic value across all 3 mortality outcomes. However, the predictive power of SII was less robust in our analysis.

NLR and PLR are major leukocyte-based scores [25] and have been shown to be superior to traditional indicators in renal cell carcinoma [31], multiple sclerosis [32], and acute pancreatitis [33]. In predicting mortality in patients with cancer, NLR may be considered a significant predictor to some extent. Unfortunately, PLR did not demonstrate strong predictive capability in our study.

IPI and CALLY are novel composite indicators that evaluate prognosis through a comprehensive analysis of inflammatory levels, nutritional status, and immune function [17,18]. In our study, IPI was identified as a risk factor for mortality, whereas CALLY was negatively associated with mortality. These findings are consistent with previous cancer-related studies [17,18,34,35]. Both markers are highly promising indicators for predicting prognosis in patients with cancer and warrant further exploration and promotion in future clinical practice.

Collectively, these 6 inflammatory biomarkers—SIRI, SII, PLR, NLR, IPI, and CALLY—represent a simple and economical tool for evaluating systemic inflammation and predicting mortality across multiple cancer types. There is a genuine possibility that these biomarkers may have clinical use in the future. They may enable early stratification of patients for treatment and could potentially be used in clinical settings to determine the optimal timing for treatment modification.

Several limitations of this study should be acknowledged. First, as a single-center, retrospective study, selection bias was inevitable. Therefore, large-scale, multi-institutional, prospective studies are warranted to validate the effectiveness of the examined inflammatory biomarkers. Second, owing to data collection constraints, participants from other survey cycles were not included. In addition, several participants were excluded for failing to meet the inclusion criteria, which may have biased the results. Third, information on cancer history and other diseases was self-reported by participants, rendering it susceptible to recall bias and potential inaccuracies. Moreover, the inability to obtain detailed information on cancer type, stage, or treatment precluded stratified analyses by these variables. This limitation restricts our understanding of the predictive value of inflammatory markers across different malignant tumor types or disease severities. Fourth, this study could not accurately capture the long-term dynamic variations in CBC, CRP, and albumin. Inflammatory markers can vary considerably over time due to infections, treatments, or disease progression. Consequently, future longitudinal studies with repeated biomarker assessments are needed to confirm our findings. Finally, the set of covariates included in this study was incomplete, and some unmeasured confounding factors were not addressed. Specifically, data on the use of anti-inflammatory medications—which are known to lower inflammatory marker levels—were not available. The absence of this information likely introduces nondifferential misclassification of exposure, potentially leading to an underestimation of the true association. Future prospective studies are needed to adjust for these potential confounders.

In conclusion, our preliminary findings indicate that SIRI, NLR, IPI, and CALLY are economical, convenient, and readily available predictors of all-cause, cancer-specific, and cardiovascular mortality in patients with cancer. However, insufficient evidence was found to support the use of SII and PLR as reliable prognostic biomarkers. These inflammatory biomarkers appear to be potential supplementary tools for predicting mortality in patients with cancer. Future prospective trials with long-term follow-up are required to accurately determine the optimal timing and cutoff values that may be applied in clinical practice.

Abstract

Background: Immune checkpoint inhibitors (ICIs) have revolutionized cancer treatment, but their safety profile in patients with thymic epithelial tumors (TETs) remains poorly characterized due to the rarity of these malignancies.

Objective: This study aims to comprehensively analyze immune-related adverse events (irAEs) profiles in patients with TETs using real-world pharmacovigilance data.

Methods: We conducted a retrospective analysis of the US Food and Drug Administration Adverse Event Reporting System database from the first quarter of 2016 through the fourth quarter of 2024. Cases of TETs with ICI-related adverse events were identified and deduplicated following Food and Drug Administration recommendations. Disproportionality analysis was performed by calculating odds ratios, using the entire US Food and Drug Administration Adverse Event Reporting System database as the reference cohort. Signals were defined as significant with at least 3 cases and a lower 95% CI exceeded 1. Time-to-onset analysis and Weibull Shape Parameter testing were used to characterize the temporal pattern of irAEs. Clinical characteristics between fatal and nonfatal cases and cardiotoxicity specifics were analyzed descriptively.

Results: Among 152 eligible TET cases with irAEs, males slightly predominated (80/152, 52.6%), with a median age of 58.5 years. Reports originated predominantly from the United States (51/152, 33.6%) and Japan (16/152, 10.5%). PD-1 inhibitors were implicated in 66.4% (101/152) of cases. Disproportionality analysis identified 14 significant irAE signals across 11 System Organ Classes. Myositis (reporting odds ratio [ROR] 113.15, 95% CI 26.65 - 480.34), myocarditis (ROR 10.96, 95% CI 5.70 - 21.07), myasthenia gravis (ROR 3.86, 95% CI 1.86 - 7.85), and febrile neutropenia (ROR 18.33, 95% CI 4.57 - 73.55) demonstrated the strongest associations. The median time to irAEs onset was 21.0 days, with 73.2% (41/56) occurring within 2 months of treatment initiation. Fatal outcomes were reported in 23.7% (36/152) of cases and were significantly associated with gender distribution (P=.04) and different treatment strategies (P=.01). The utilization of PD-1 inhibitors was higher in the fatal group (29/36, 80.06%) than in the nonfatal group (72/116, 62.1%). Myocarditis was the most frequent cardiotoxicity, accounting for 51.3% (20/39) of cardiac events.

Conclusions: This large-scale pharmacovigilance study delineates a distinct and severe irAEs profile for ICIs in patients with TETs, characterized by robust disproportionality signals for myositis, cardiotoxicity, and myasthenia gravis. As a hypothesis-generating analysis, these findings underscore the need for vigilant monitoring and early detection strategies to mitigate irAE risks, particularly in high-risk subgroups such as patients with thymoma. The results provide clinically relevant evidence to guide risk-benefit evaluation and inform tailored surveillance protocols during ICI therapy in this population.

Introduction

Thymic epithelial tumors (TETs), originated from thymic epithelial cells, are categorized as thymomas, thymic carcinomas, and thymic neuroendocrine tumors according to the World Health Organization [1]. TETs encompass a group of rare malignancies but constitute a significant proportion of anterior mediastinal tumors [2]. For early-stage TETs, curative surgical resection is the standard treatment strategy, yielding promising outcomes for a subset of patients. For those with advanced TETs, platinum-based chemotherapy has been considered as the first-line treatment [2,3]. However, there is no standard therapy for patients who experience disease progression after the first-line treatment of platinum-based regimens. Antiangiogenic drugs, mammalian target of rapamycin inhibitors, or other chemotherapy may be the potential option, although their effectiveness in this context remains uncertain [4,5].

Immunotherapy has gained great promise in the treatment landscape of various cancers, which sparked a significant shift in the paradigm of treating oncological malignancies [6,7]. The efficacy of immune checkpoint inhibitors (ICIs) was considered with a close relationship to the expression of programmed death-ligand 1 (PD-L1) [8,9]. Notably, TETs have been reported to exhibit high PD-L1 expression, with positivity rates ranging from 23% to 92% [10]. Encouraging clinical benefits have been observed with ICIs such as pembrolizumab, nivolumab, avelumab, and atezolizumab in patients with advanced thymic carcinoma or thymoma [11-14]. A phase II clinical trial demonstrated that the objective response rate (ORR) of pembrolizumab in 41 patients with thymic carcinoma was 23%, with a median progression-free survival (PFS) of 4.2 months and a median duration of response of approximately 3 years [11,12]. In the PRIMER study, the median PFS for nivolumab was 3.8 months, and the 12-month overall survival rate was 60.0% in a cohort of 15 patients with unresectable or recurrent thymic carcinoma [13]. In a study of 7 patients with thymoma treated with avelumab, an ORR of 57% was reported [14]. Despite these advancements, the unique immunologic environment of the thymus, which plays an essential role in T-cell maturation, raises concerns regarding immune-related adverse events (irAEs) [15].

Although the spectrum of irAEs associated with ICIs has been reported in various malignancies, the safety profile in TETs remains poorly defined [16]. This represents a critical knowledge gap, as the thymus is a primary lymphoid organ central to immune tolerance. The administration of ICIs in this immunologically unique context may disrupt central tolerance mechanisms, potentially leading to a distinct and more severe irAEs profile. Evidence from small-scale studies had shown a high frequency of severe toxicities in patients with TETs receiving ICI therapy [17,18]. Therefore, a TET-specific pharmacovigilance analysis is essential to systematically delineate these unique safety signals and inform clinical management. The US Food and Drug Administration Adverse Event Reporting System (FAERS) database provides real-world data on a global scale, while disproportionality analysis offers a validated method for detecting drug-event associations, especially for rare cancers such as TETs, where clinical trial data are limited. This approach effectively addresses evidence gaps by identifying clinically relevant toxicity signals and generating actionable hypotheses for risk management.

To gain a deeper understanding of the adverse events (AEs) associated with the therapy of ICIs in patients with TETs in clinical practice, we conducted a systematic analysis using the FAERS database to statistically evaluate irAEs in this patient population. This research endeavor aims to provide valuable insights into optimizing immunotherapy strategies for TETs while mitigating potential adverse effects.

Methods

Study Design and Data Source

This study was designed as a disproportionality analysis of individual case safety reports extracted from the FAERS database [19], covering the period from the first quarter of 2016 through the fourth quarter of 2024. The study was conducted and reported in accordance with the REporting of A Disproportionality analysis for drUg Safety signal detection using individual case safety reports (READUS) guidelines for studies using spontaneous reporting systems [20,21]. The primary analysis used disproportionality methods to detect significant associations between ICIs and irAEs in patients with TETs. Sensitivity analyses included stratification by ICI subclass and TETs histologic subtype. Additional methodological components comprised case-by-case clinical review of cardiotoxicity reports and contextualization of findings within the existing scientific literature. All AEs are coded using the preferred term (PT) according to the international MedDRA (Medical Dictionary for Regulatory Activities) (version 26.1). Detailed descriptions of the FAERS database and MedDRA structure are provided in Multimedia Appendix 1.

Identification of ICIs Reports With Adverse Events

Our comprehensive analysis was conducted in 4 steps to identify AEs linked to ICIs in the patients diagnosed with TETs. Initially, we performed a deduplication process according to the Food and Drug Administration's (FDA's) recommendations in the FAERS database. For reports sharing the same Case Identifier (CASEID), the latest FDA Date (FDA_DT) is selected, which contained the most comprehensive information. If the CASEID and FDA_DT are the same, we retained the higher Primary Identifier (PRIMARYID). In addition, an extra deduplication step was performed by excluding cases that had identical gender, age, reporting country, event date, AEs, and prescribed drugs. Second, we extracted data for patients diagnosed with TETs in the INDI files. Our focus was on ICIs reported in the DRUG files, including programmed death-1 (PD-1) inhibitors (nivolumab, pembrolizumab, sintilimab, penpulimab, tislelizumab, toripalimab, camrelizumab, and cemiplimab), PD-L1 inhibitors (atezolizumab, avelumab, and durvalumab), and cytotoxic T-lymphocyte–associated antigen 4 inhibitors (ipilimumab and tremelimumab). Reported drug names were mapped to their corresponding active pharmaceutical ingredient names using the FDA's National Drug Code directory and manual verification. For ICIs, both generic names and common brand names were unified under their respective active

XSL•FO
RenderX

pharmaceutical ingredient terms. Age, gender, and country fields were normalized to FAERS conventions. Only reports in which ICIs were classified as the primary suspect were included, as the AEs in these cases were deemed most likely to be associated with the ICIs compared with other medications. Third, we extracted all reports containing AEs from the REAC files. Finally, we identified ICIs reports diagnosed with TETs with AEs by intersecting the PRIMARYID.

Signal Mining

A disproportionality analysis is frequently conducted in pharmacovigilance research to identify safety signals and develop hypotheses concerning potential causal links between drugs and AEs. The reporting odds ratio (ROR) is used to compare the odds of reporting a specific event related to a particular drug against all other events while considering the reporting odds for other drugs within the FAERS database. The ROR was selected as the primary metric for this analysis due to its computational simplicity, transparency, and widespread adoption in the pharmacovigilance literature for initial signal detection. In this study, the ROR was used to identify signals of AEs in reports associated with ICIs in the patients experiencing TETs. By using AE reports from the complete FAERS database as a reference, we conducted a disproportionality analysis to evaluate the potential association between AEs and ICIs through the calculation of the ROR. The ROR and the 95% CI were calculated using the following formula:

$$ROR=a/cb/d$$

$$95\%CI=eln\ ROR\pm1.961a+1b+1c+1d$$

a: Number of reports with both the target ICIs and the target events; b: number of reports with the target ICIs but without the target events; c: number of reports with the target events but without the target ICIs; and d: number of reports with neither the target ICIs nor the target events.

Following established pharmacovigilance practice aimed at balancing sensitivity and specificity, we defined a significant signal as one with at least 3 case reports and a lower limit of the 95% CI for the ROR exceeding 1.

Data Analysis

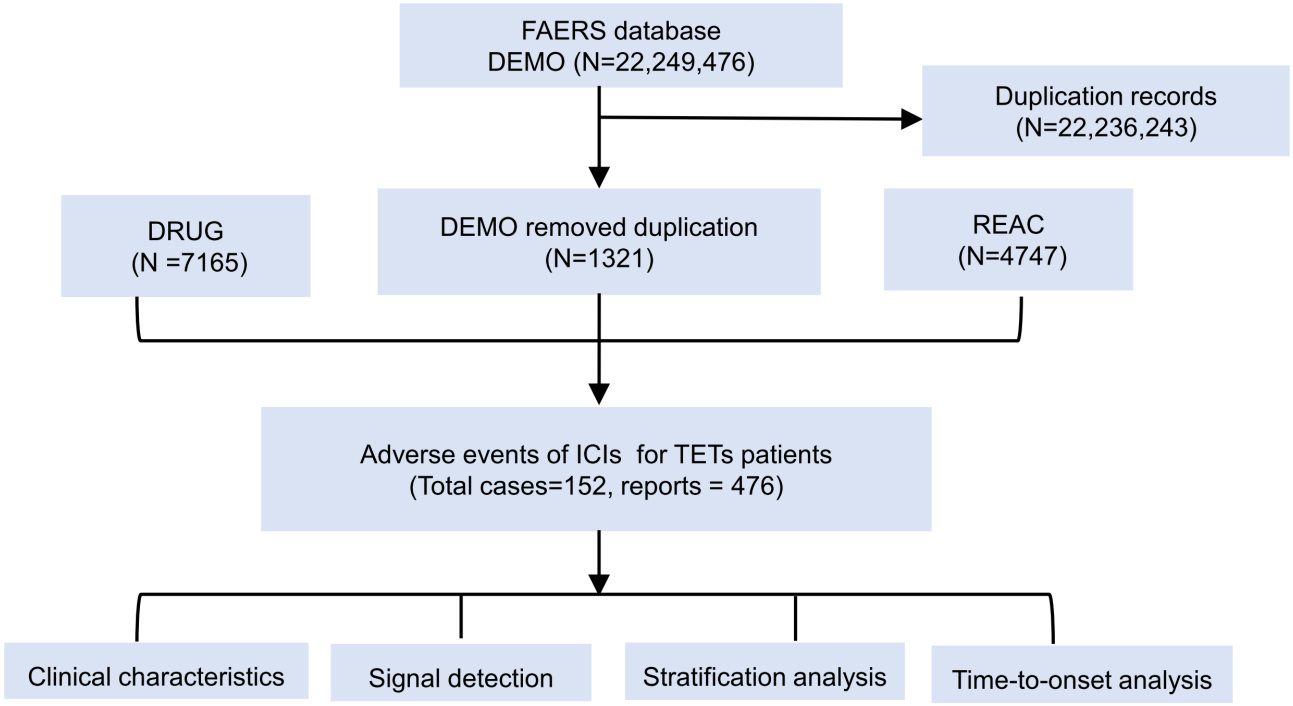
A descriptive analysis of the clinical characteristics of reports with ICI-related AEs was conducted after screening. The outcome of death reported was included in the fatal group, while others were identified in the nonfatal group. The analysis of time to onset used cases that had a completed START_DT (the date when therapy commenced) recorded in the THER files along with EVENT_DT (the date on which AEs occurred) documented in the DEMO files. To appropriately account for right truncation in estimating the time to onset of AEs from spontaneous reporting databases, we defined an analysis period of 365 days following the commencement of drug administration. The statistical analysis of time to onset was performed with the Weibull Shape Parameter (WSP) test, which assesses the likelihood of changes in AE occurrence over time [22-24]. Specifically, when the shape parameter β is less than 1 and its 95% CI is also less than 1, this indicates a decreasing hazard of AEs over time. Conversely, if β is approximately equal to 1 with a 95% CI that includes 1, this suggests that the hazard remains constant. Furthermore, when β exceeds 1 along with a 95% CI greater than 1, this signifies an escalating hazard over time. Cumulative distribution curves were performed to illustrate the event-to-onset data for ICI-related AEs in different groups.

Statistical Analysis

Descriptive statistics were applied to summarize the demographic and administrative features of cases involving ICI-related AEs. Categorical variables are presented as frequencies and percentages, compared using chi-square or Fisher exact test. The human anatomy heatmap was conducted with the MOAHIT web tool [25]. Statistical analysis was conducted using R software (version 4.3.0; R Foundation for Statistical Computing) in this study. In this study, statistical significance was determined at the $P<.05$ level.

Ethical Considerations

This research uses the publicly available and anonymized FAERS database. As this database contains no personally identifiable information and the study does not involve experiments on human participants, it qualifies for exemption from institutional review board assessment and approval.



Results

ICI-Related AEs in the Patients With TETs in the FAERS, 2016 Q1 to 2024 Q4

We first investigated the amount of irAEs among patients diagnosed with TETs in the FAERS database. The comprehensive data processing procedure of this study is shown in Figure 1. From the first quarter of 2016 to the fourth quarter of 2024, the FAERS database cataloged a total of 22,249,476 AE reports. The number of ICI-related reports has experienced an increase since 2016 and the proportion of irAEs also varied among different ICI treatment strategies (Figure S1 in Multimedia Appendix 2).

XSL•FO
RenderX

Figure 1. Flowchart showing the analysis process of the study. A detailed description of the selection process of adverse events for ICIs in the FAERS. FAERS: US Food and Drug Administration Adverse Event Reporting System; ICIs: Immune checkpoint inhibitors; TETs: thymic epithelial tumors.

After excluding duplicate cases, 152 cases with TETs who experienced irAEs were identified. The clinical characteristics of patients are summarized in Table 1. Among the total study population with TETs, males accounted for 52.6% (80/152) of cases experiencing irAEs, compared with 40.8% (62/152) in females. Our results indicated that patients aged 18-64 years demonstrated a higher prevalence, accounting for 47.4% (72/152), with the median age of 58.5 years. The majority of cases were sourced from the United States (51/152, 33.6%), followed by Japan (16/152, 10.5%), France (14/152, 9.2%), and China (14/152, 9.2%), with the remaining reports (51/152, 37.5%) coming from 22 other countries. About 77.6% (118/152) of the cases were submitted by health care professionals, while 22.4% (34/152) were reported by consumers (Table 1). We found that 66.4% (101/152) of patients were associated with PD-1 inhibitor treatment strategies, 25.7% (38/152) with PD-L1 inhibitors, and 7.9% (12/152) in the group of the combination therapy of PD-1 inhibitors plus cytotoxic T-lymphocyte–associated antigen 4 inhibitors. Notably, a total of 85.5% (130/152) cases with irAEs were reported in patients receiving ICIs therapy, while 14.5% (22/152) were related to the use of immunotherapy in combination with chemotherapy or targeted agents.

Descriptive Analysis of Cases With ICI-Related AEs

We analyzed the categories and number of irAEs reported in patients with TETs treated with ICIs, and a total of 476 AEs were reported in 152 cases of TETs. To further investigate these irAEs, the disproportionality analysis was conducted using the full FAERS database as a reference by calculating ROR of PTs with at least 3 reported cases and the lower limit of the 95% CI for the ROR more than 1. About 14 specific PTs were considered as valid and strongly associated with ICI therapies, covering 11 System Organ Classes. Respiratory, thoracic, and mediastinal disorders were present in 9.03% (43/476) of reports, while cardiac disorders and musculoskeletal and connective tissue disorders were present in 8.19% (39/476) and 7.77% (37/476) of reports, respectively (Table S1 in Multimedia Appendix 2). In addition, myositis (24/476, 5.04%), myocarditis (20/476, 4.20%), myasthenia gravis (11/476, 2.31%), febrile neutropenia (9/476, 1.89%), and pneumonitis were among the top 20 of ICI-related AEs (Table 2). The frequent irAEs of TETs comprised myositis (n=24; ROR 113.15, 95% CI 26.65 - 480.34), myocarditis (n=20; ROR 10.96, 95% CI 5.70 - 21.07), myasthenia gravis (n=11; ROR 3.86, 95% CI 1.86 - 7.85), and febrile neutropenia (n=9; ROR 18.33, 95% CI 4.57 - 73.55) (Figure 2A). Among the ICI treatment strategies, anti-PD-1 accounts for the highest proportion at 66.4% (101/152), while anti-PD-L1 and combination therapies account for 25.7% (39/152) and 7.9% (12/152), respectively (Table S2 in Multimedia Appendix 2). The analysis revealed that different irAEs were associated with different ICIs treatment strategies (Figure 2B). The most common AEs of anti-PD-1 agents included myositis (n=18; ROR 56.68, 95% CI 19.08 - 168.42), myocarditis (n=17; ROR 6.37, 95% CI 6.37 - 25.38), and myasthenia gravis (n=9; ROR 4.23, 95% CI 1.97 - 9.09). The most common AEs of anti-PD-L1 agents included febrile neutropenia (n=9; ROR 15.09, 95% CI 6.99 - 32.57), rash maculopapular (n=4; ROR 29.12, 95% CI 8.38 - 101.24), and pneumonitis (n=3; ROR 10.79, 95% CI 3.05 - 38.18). The ICI-related AEs occurrence sites and the number of cases in patients with TETs are shown in the anatomical diagram of Figure 2C.

Figure 2. Descriptive analysis of reports with immune-related adverse events (irAEs). (A) A forest plot shows the ROR of the top 20 irAEs. (B) The heatmap shows the ROR for top 20 irAEs (with cases no less than 3) in the US Food and Drug Administration Adverse Event Reporting System database under different immune checkpoint inhibitor treatment strategies (including overall situation, anti-PD-1, and anti-PD-L1). Red indicates ROR values greater than 1, green indicates ROR values less than 1, and gray indicates ROR values that could not be calculated. A significant association signal was labeled in dark red when the lower limit of the 95% CI for the ROR was greater than 1 and the number of cases was at least 3. (C) The anatomical diagram of irAEs occurrence site and the number of cases in patients with thymic epithelial tumors. The darker the color, the more cases with irAEs form this site. NA: not available; PD-1: programmed death-1; PD-L1: programmed death-ligand 1; PT: preferred term; ROR: reporting odds ratio.

Time-to-Onset Analysis

Among the 152 ICI-related cases, 57 patients contained time-to-onset data. The cumulative distribution curves for the onset time of irAEs in different subgroups are present in Figure S2 in Multimedia Appendix 2. The median onset time of irAEs was significantly shorter in patients treated with ICIs plus chemotherapy than in those treated with ICIs alone (9.5 days vs 27.0 days; *P*=.005). No significant difference was present in the subgroup of age, gender, or the specific ICI treatment regimens on the onset time of irAEs in patients with TETs. We found that more than 70% of irAEs occurred within the first 2 months of initiating ICI therapies, with a median onset time of 21.0 days. Results of the WSP test for irAEs are summarized in Table S3 in Multimedia Appendix 2. The distribution of irAEs over the course of ICI treatment is shown in Figure 3. In the WSP test for irAEs, the upper limit of 95% CI of the shape parameter of other drugs was less than 1, indicating an early failure-type profile. Analyses of the time-to-onset profiles of irAEs indicated that early failure–type profiles were found in all populations with ICIs (Figure 3A) or subgroup of anti-PD-1 (Figure 3B) or anti-PD-L1 therapy (Figure 3C). The combination therapy group (anti-PD-1 plus anti-CTLA-4) exhibited a random failure pattern (Figure 3D).

Figure 3. Density plot of the onset time of cases with immune checkpoint inhibitor–related adverse events in different populations with thymic epithelial tumor. (A) Density plot of all populations. (B) Density plot of patients with anti-PD-1 treatments. (**C**) Density plot of patients with anti-PD-L1 treatments. (D) Density plot of patients with anti-PD-1 plus anti-CTLA4 treatments. CTLA4: cytotoxic T-lymphocyte–associated antigen 4; PD-1: programmed death-1; PD-L1: programmed death-ligand 1.

Comparison Between the Fatal and Nonfatal Groups

In cases of thymoma or thymic carcinoma with irAEs, about 23.7% (36/152) of patients experienced fatal outcomes. Although the presence of irAEs may not directly lead to death, analyzing the differences between the fatal and nonfatal groups remained crucial, as it may provide clues to reduce mortality rates. The gender distribution differed significantly between the fatal and nonfatal groups (P=.04). The proportion of female patients was higher in the fatal group (20/36, 55.6%) than in the nonfatal group (42/116, 36.2%). A significant difference was found in the application of ICIs treatment strategies between the fatal and nonfatal groups (P=.01). In total, 80.6% (29/36) of cases were treated with PD-1 inhibitors in the fatal group, while 62.1% (72/116) in the nonfatal group.

Cardiotoxicities Associated With ICIs in Patients With Thymomas and Thymic Carcinomas

A total of 29 patients experienced cardiac toxicities among the 152 cases of TETs with irAEs. More than 1 type of ICI-related cardiotoxicities was found in 7 patients. Among 39 cardiotoxicity-related AEs, myocarditis was the most frequent (20/39, 51.3%), followed by cardiac failure (3/39, 7.9%). ICI treatments showed a significant association with myocarditis (ROR 10.96, 95% CI 5.70-21.07), but no significant association was observed with cardiac failure (ROR 1.82, 95% CI 0.52-6.30). Among the 20 patients diagnosed with TETs who experienced immune-related myocarditis, 11 were female, representing a significant proportion of this subgroup. The median age of these patients was 58 years, and 95.0% (19/20) of patients received PD-1 inhibitor treatment. ICI-related myocarditis was more predominantly observed in patients with thymoma, accounting for 75% (15/20) of cases, and occurs in 25% (5/20) of those with thymic carcinoma (Table S4 in Multimedia Appendix 2). Among the 20 immune-related myocarditis cases, only 6 reports contained time-to-onset data, with the median time of 7 days.

Discussion

Principal Findings

This large-scale pharmacovigilance study, using the FAERS database from 2016 to 2024, systematically characterizes the safety profile of ICIs in the patients with TETs. Among 152 identified cases, we observed a distinct and severe spectrum of irAEs. Disproportionality analysis revealed strong signals for myositis (ROR 113.15, 95% CI 26.65 - 480.34), myocarditis (ROR 10.96, 95% CI 5.70 - 21.07), febrile neutropenia (ROR 18.33, 95% CI 4.57 - 73.55), and myasthenia gravis (ROR 3.86, 95% CI 1.86 - 7.85). The irAEs profile differed between ICI subclasses, with PD-1 inhibitors predominantly associated with myotoxic and cardiac events, while PD-L1 inhibitors showed stronger signals for febrile neutropenia and rash. Notably, 23.7% (36/152) of reported cases had fatal outcomes, and the median time to irAEs onset was 21 days, with more than 70% of events occurring within the first 2 months of therapy, significantly earlier when ICIs were combined with chemotherapy. These findings underscore a unique and concerning toxicity pattern for ICIs in TETs, dominated by early, severe neuromuscular, cardiac, and hematological complications. The findings will provide crucial insights for the clinical management of ICI therapy in patients with TETs, guiding safer and more effective treatment strategies.

Comparison With Prior Work

ICIs are now widely used in the treatment of various tumors [6,7]. In long-term follow-up of 40 patients with thymic carcinoma treated with pembrolizumab, an ORR of 22.5%, a median duration of response of 35.9 months, and a 5-year survival rate of 18% were observed [12]. In an open-label phase II trial, pembrolizumab showed encouraging antitumor activity in patients with advanced TETs, with the median PFS of 6 months [26]. Several clinical trials indicated that patients with TETs experienced varying degrees of clinical efficacy from the treatment with PD-1 and PD-L1 inhibitors [11,13,14]. As we all know, tumors escape the surveillance and elimination of the host immune system by activating immune checkpoints, which in turn suppress the cytotoxic killing effect of T cells. By blocking the interaction between immune checkpoints and their ligands, immune checkpoint drugs relieve the inhibition imposed on immune cells, thereby reactivating them to fight against cancer. However, the use of ICIs can also adversely affect normal cells, leading to the disruption of self-tolerance, inducing the development of autoimmune diseases in the body. In a systematic study of toxicities associated with cancer immunotherapy, about 81.15% (6959/8576) of patients had at least 1 toxicity event of varying degrees, and 29.27% (2510/8576) of cases had at least 1 toxicity event at grades 3 - 4 [27]. Hematologic toxicities, the most common types of grades 3 - 4 toxicities, were present in 9.41% (807/8576) of cases, followed by gastrointestinal toxicity in 5.34% (458/8576) of patients. For toxicities at any grade, patients experiencing respiratory toxicity were at a higher rate of treatment discontinuation than those with gastrointestinal toxicity or hematologic toxicity. However, compared with other cancers, there were certain differences in the terms of irAEs in patients with TETs. Although a meta-analysis reported that ICIs may bring clinical advantages for patients with thymomas, the advantages are limited by the excessively high risk of toxicity [28]. Grades 3 - 5 irAEs were reported in 26.4% for patients with TETs, with proportions of 17.1% for thymic carcinoma and 58.3% for thymoma [28]. The most common grade of ≥3 irAEs in TETs included myocarditis, hepatitis, myositis, and myasthenia gravis [12,26,28]. Consistent with reported studies, within our analysis of 476 AEs reports associated with ICIs, myositis and myocarditis were the common AEs, identified in 5.04% (24/476) and 4.20% (20/476) of the cases, respectively. Interestingly, there are differences between thymoma and thymic carcinoma in terms of irAEs in patients with TETs treated with ICIs [29]. Patients with thymoma tend to have a higher incidence of irAEs than those with thymic carcinoma [30]. In patients treated with ICIs, grade 3 or 4 irAEs were reported in 15.4% (4/26) of thymic carcinoma cases compared with 71.4% (5/7) of thymoma cases [26]. They suggested that ICIs should be avoided in patients with thymomas and should be considered with careful monitoring in those with thymic carcinoma. Patients with thymoma who receive ICIs are at considerable risk of experiencing severe immune-mediated toxicity, often presenting

XSL•FO
RenderX

with multiple irAEs simultaneously, which is not frequently seen in patients with other cancers receiving ICIs [31].

However, there are several researchers who have been dedicated to unraveling the mechanisms behind the distinct irAEs observed in TETs following the treatment of ICIs. The thymus, a crucial immune organ, is integral to the development and maturation of T cells. It is fundamental in maintaining immune tolerance by generating self-tolerant T cells through positive and negative selection processes [32]. In the context of tumorigenesis, the expression of autoimmune regulator and major histocompatibility complex in thymic epithelial cells declines, resulting in structural alterations within the thymus and impairing immune tolerance mechanisms [33]. This disruption can lead to an increase in immature CD8+ T cells and a decrease in CD4+ T cells and regulatory T cells, consequently promoting the development of autoimmune diseases [34,35]. TETs can promote the release of autoreactive T cells, disturbing peripheral homeostasis and predisposing patients to autoimmunity or causing autoimmune diseases. Some cytokines and chemokines produced by tumor cells induce cross-reactions between tumor antigens and tissue-specific antigens, promoting autoantibody production [29,36]. Furthermore, the administration of ICIs impacts central immune tolerance and disrupts the homeostasis of the peripheral T-cell receptor repertoire, leading to the activation of autoreactive T cells. This disruption can trigger autoimmune diseases in susceptible individuals [37].

ICI-induced myocarditis is a rare immune-related AE in various cancers, occurring in approximately 1% of patients undergoing treatment. However, it is noteworthy for its exceptionally high fatality rate, ranging between 30% and 50% [38-40]. There is limited knowledge on risk factors for ICI myocarditis, with only the combination therapy involving ICIs identified as a reliable risk factor of this condition [41,42]. In addition, the frequency of ICI myotoxicity has been reported 10 - to 30-fold higher in patients with TETs than in those with other cancers [43]. The seriousness of several life-threatening ICI-related myotoxicity was demonstrated in young patients with thymoma, who experienced a fatal triad of fulminant myocarditis, myositis, and a myasthenia gravis–like syndrome, emerging within a few days following a single dose of ICI treatment [44]. In line with our findings, the median time to onset of myocarditis was 7 days after the administration of immunotherapy. ICI-related myocarditis in patients with TETs tends to occur earlier and more severely after the initiation of ICI treatment than other cancers, resulting in life-threatening arrhythmias. Our findings revealed that the ICI-related myocarditis in patients with TETs was observed more in females and those with the treatment of anti-PD-1 inhibitors or the presence of thymomas. Emerging evidence indicated that autoreactive T cells recognizing the cardiac antigen α-actinin played a crucial role in the development of ICI-related myocarditis, unveiling the key mechanisms behind ICI-related myocarditis [45]. Increased frequencies and spatial colocalization of cytotoxic T lymphocytes, conventional dendritic cells, and inflammatory fibroblasts have been shown in ICI-related myocarditis heart tissue. In addition, the presence of heart-expanded T-cell receptors in a cycling blood CD8+ T-cell population may indicate whether a patient's myocarditis could potentially lead to death [46]. For patients with TETs who experienced myocarditis, research indicated that thymus-related dysfunction was linked to the incidence and severity of ICI-induced myotoxicities, including myocarditis and myositis, and identifying TETs and assessing acetylcholine receptor through radiobiological workup may help predict and stratify the risk of severe ICI myotoxicities in patients with cancer undergoing ICI treatment [43].

Strengths and Limitations

We conducted a relatively large-scale, disease-specific pharmacovigilance analysis of irAEs in patients with TETs in the real-world setting. This study addressed a significant knowledge gap in the field, as TETs originate from the central immune organ, thereby establishing a distinctive and high-risk immunological context for ICIs toxicity that is often obscured in broader, pan-cancer analyses. The findings provide essential evidence to inform clinical guidelines for ICIs use in TETs, representing a significant contribution to a niche yet high-stakes area of oncology. By systematically delineating the unique toxicity profile, our work has the potential to impact both clinical decision-making and design of future studies in TETs.

There were several limitations in this research. First, the data were sourced from a spontaneously reported database, which is subject to known biases such as underreporting, duplicate reports, and confounding factors, potentially affecting data quality and completeness [47]. Moreover, reports in the FAERS database predominantly originate from North America and Europe, resulting in a relatively low representation of Asian populations. Second, the use of ROR, although valuable for signal detection, may inflate associations for established class-specific AEs, such as myocarditis, myositis, and pneumonitis in the context of ICIs, due to heightened clinical awareness and targeted reporting. Consequently, ROR-based signals for known irAEs should be interpreted cautiously, as they largely reflect anticipated class effects rather than novel risks. Furthermore, the signal strength reflects relative risk and does not allow for the quantification of absolute risk. Third, the comparative analysis between anti-PD-1 and anti-PD-L1 agents should be interpreted with caution. While the differential toxicity signals provide hypothesis-generating insights, the clinical application of PD-L1 inhibitors in TETs remains limited. Consequently, the smaller sample size for PD-L1 cases in this study may reduce the statistical robustness of direct comparisons and limit the generalizability of subclass-specific findings. Finally, it is of critical clinical importance to understand the factors that determine who may develop irAEs. Due to the limited number of cases with time-to-onset data, the study could not conduct univariate or multivariate regression analyses for irAEs, which represents an important gap for clinical risk stratification. In addition, these findings are hypothesis-generating and require validation through well-designed epidemiological studies to clarify incidence rates, underlying mechanisms, and real-world clinical relevance of the identified signals.

Clinical Implications and Future Directions

The findings from this pharmacovigilance analysis carry significant clinical implications for the management of patients

XSL•FO
RenderX

with TETs receiving ICI therapy. The robust and early-onset signals for severe toxicities, particularly myositis and myocarditis, necessitate a paradigm shift in monitoring protocols. We recommend implementing proactive, protocol-driven monitoring within the first 2 months of treatment initiation for this high-risk population. Furthermore, the high fatality rate associated with cardiotoxicity, especially in specific subgroups, underscores the critical need for multidisciplinary management involving cardio-oncology specialists.

Future research should be directed toward translating these hypothesis-generating signals into actionable clinical knowledge. First, prospective cohort studies are needed to establish accurate incidence rates and validate risk stratification models incorporating clinical and molecular biomarkers. Second, mechanistic investigations should explore the unique immunobiology of TETs that predisposes patients to these severe toxicities. Third, there is an urgent need to develop TETs-specific clinical guidelines for irAE prevention, monitoring, and management, which should include standardized baseline assessment protocols and treatment algorithms tailored to this population's distinct risk profile.

Conclusions

This large-scale pharmacovigilance analysis, using real-world data from the FAERS database, delineates irAEs profile associated with ICIs therapy in patients with TETs. The study identified strong disproportionate reporting signals for myositis, myocarditis, myasthenia gravis, and febrile neutropenia, with more than 70% of irAEs occurring within the first 2 months of treatment initiation, with a median onset time of 21.0 days. As a hypothesis-generating investigation, these findings emphasize the need for vigilant early monitoring and support tailored surveillance strategies in clinical practice, particularly in patients with thymoma. Further research is warranted to elucidate underlying mechanisms, identify predictive biomarkers, and develop risk mitigation approaches to optimize the safety and efficacy of immunotherapy in this population.

Acknowledgments

The authors express their sincere gratitude to all colleagues and participants involved in this research, whose expertise and collaborative spirit were essential to its success.No artificial intelligence was used in this work.

Funding

This work was supported by the Guangdong Province General Universities Young Innovative Talents Program (2024KQNCX071) and the Guangzhou Municipal Science and Technology Bureau Basic Research Program (2023A03J0300). The funding source had no role in design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Abstract

Background: Hemophagocytic lymphohistiocytosis (HLH) is a life-threatening hyperinflammatory syndrome that requires rapid diagnosis and intervention. However, identifying these patients is difficult because the HLH-2004 diagnostic criteria are complex and not always captured systematically in electronic health records (EHRs). Furthermore, it is unclear how clinicians use these criteria to diagnose HLH and make treatment decisions. There is a critical need for validated computable phenotypes to accurately identify patients and study treatment-related outcomes in HLH.

Objective: The aim of this study is to compare different approaches to using the EHR to build computable phenotypes of patients with HLH and to evaluate characteristics and outcomes of patients meeting the HLH-2004 diagnostic criteria who received HLH-directed therapies compared to those who did not.

Methods: Three approaches to computable phenotype development in the EHR were taken by identifying patients (1) with an HLH-specific *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*) code, (2) with an HLH-specific treatment plan, and (3) meeting the HLH-2004 clinical criteria for diagnosis of HLH. Among patients who met the HLH-2004 criteria, we evaluated the characteristics and outcomes of patients who received HLH-directed therapies compared to those who did not. HLH treatment was defined as either any chemotherapy or HLH-specific therapy (dexamethasone, methylprednisolone, anakinra, ruxolitinib, cyclosporine, etoposide, or emapalumab).

Results: We identified 388 patients with possible HLH across the three cohorts. An HLH *ICD-10* diagnosis (n=220) and meeting 5 or more clinical criteria (n=245) were much more common than a HLH treatment plan (n=42). Among the patients meeting HLH-2004 clinical criteria, 193 (79%) received HLH-directed therapy. There was no difference in any specific HLH criteria between those who did and did not receive HLH-directed therapy. In-hospital mortality was very high among both groups and was 15% among those who received HLH-directed therapy and 13.5% among those who did not receive HLH-directed therapy. Among 1325 patients with an elevated ferritin and fever, only 252 (19%) met >5 clinical criteria.

Conclusions: Constructing HLH cohorts from EHR data is challenging, with diagnosis codes, treatment plans, and clinical criteria each capturing distinct but overlapping populations.

HLH; electronic health record; pediatrics; computable phenotype; oncology; hemophagocytic lymphohistiocytosis

Introduction

Hemophagocytic lymphohistiocytosis (HLH) is a rare but often life-threatening syndrome represented by excessive inflammation resulting in organ dysfunction and potentially death [1]. Early recognition and treatment of HLH are critical to patient outcomes. Traditionally, HLH has been classified as primary, where there is a documented or presumed genetic etiology [2,3], or secondary, where excessive inflammation can be attributed to a trigger such as infection, malignancy, or a rheumatological condition in the absence of a genetic etiology [4]. Although there are an increasing number of genes identified responsible for primary HLH [5], there are patients with presumed primary HLH without a known mutation. Further, patients with both primary and secondary HLH may require HLH-directed therapy. Consequently, diagnostic criteria have

XSL•FO
RenderX

been developed for HLH (Multimedia Appendix 1), which often guide decision-making about treatment initiation. Criteria were initially proposed in 2004 [2,3] and recently updated in 2024 [3].

In general, diagnosis of HLH can be made based upon molecular or functional cellular findings consistent with HLH in combination with meeting at least 5 clinical criteria (Textbox 1). While these criteria have been widely used for diagnosis and treatment decision-making, there have been questions raised about the specificity of these criteria, particularly as they relate to secondary HLH [4]. HLH frequently presents with nonspecific clinical features that overlap with severe infection, sepsis, malignancy, and other inflammatory syndromes, leading to substantial diagnostic uncertainty in real-world clinical practice. Most studies of HLH have focused on small cohorts of participants who have received a clinical diagnosis of HLH. To evaluate the utility of HLH criteria, it may be informative to determine the association of each individual HLH criterion against an overall clinical HLH diagnosis, whether HLH-specific treatments received or an HLH outcome such as mortality.

XSL•FO
RenderX

Textbox 1. HLH-2004 and HLH-2024 diagnostic criteria.

HLH-2004 [3]

Criterion 1 or 2 is fulfilled.

1. A molecular diagnosis consistent with hemophagocytic lymphohistiocytosis (HLH)
2. Diagnostic criteria for HLH fulfilled (5 of the 8 criteria below):

- Fever
- Splenomegaly
- Cytopenias (affecting ≥2 of 3 lineages in the peripheral blood)
  - Hemoglobin <90 g/L (hemoglobin <100 g/L in infants <4 wk)
  - Platelets $<100\times10^9$/L
  - Neutrophils $<1.0\times10^9$/L
- Hypertriglyceridemia and/or hypofibrinogenemia
  - Fasting triglycerides ≥3.0 mmol/L (ie, ≥265 mg/dL)
  - Fibrinogen ≤1.5 g/L
- Hemophagocytosis in bone marrow or spleen or lymph nodes. No evidence of malignancy.
- Low or no natural killer cell activity (according to local laboratory reference)
- Ferritin ≥500 µg/L
- CD25 (ie, soluble IL-2 receptor) ≥2400 U/mL

HLH-2024 [2]

Criterion 1, 2, or 3 below is fulfilled.

1. Functional cellular findings consistent with familial HLH (FHL) in a patient with signs/symptoms suggestive of HLH
2. A molecular diagnosis consistent with FHL in a patient with signs/symptoms suggestive of HLH
3. Clinical diagnostic criteria for FHL with at least 5 of the 7 criteria below fulfilled:

- Fever ≥38.5°C
- Splenomegaly (≥2 cm below the costal margin)
- Cytopenias (affecting ≥2 of 3 lineages in the peripheral blood)
  - Hemoglobin <90 g/L (hemoglobin <100 g/L in infants <4 wk)
  - Platelets $<100\times10^9$/L
  - Neutrophils $<1.0\times10^9$/L
- Hypertriglyceridemia and/or hypofibrinogenemia
  - Fasting triglycerides ≥3.0 mmol/L
  - Fibrinogen ≤1.5 g/L
- Hemophagocytosis
- Ferritin ≥500 µg/L
- sCD25 (ie, soluble IL-2 receptor) ≥2400 U/mL

Most studies of patients with HLH use small, highly curated datasets. Such studies are therefore limited in their ability to evaluate how well diagnostic criteria perform in broader, unselected clinical populations. Few studies have leveraged electronic health record (EHR) data, which may represent broader populations and contain a wider range of clinical information. Leveraging EHR data to facilitate clinical research of HLH requires the construction of an accurate patient cohort. Given that EHR data are not entered with the goal of facilitating future downstream research, manually entered data such as diagnosis codes can often be incorrect or missing. Computable phenotypes are machine-evaluable definitions for a given

XSL•FO
RenderX

condition developed using EHR data. Multisource computable phenotypes incorporating laboratory results, medications, procedures, and clinical events may improve case ascertainment and reduce bias compared with diagnosis codes alone [6]. To our knowledge, no attempt has been made to use diverse EHR data to develop a machine-evaluable approach to HLH identification [7-9]. It is unknown how alternative EHR-based definitions perform for a clinically heterogeneous and dynamically evolving syndrome such as HLH.

The primary objective of this study was to compare various approaches to using EHR data to build a computable phenotype of patients with HLH—specifically, we compared three approaches: (1) HLH-specific diagnosis code usage, (2) HLH-specific treatment plan application, and (3) HLH clinical criteria, among all patients at a pediatric hospital. Our hypothesis was that the use of diagnosis codes and treatment plans would undercapture patients and the use of clinical criteria would overcapture patients. Among patients who met at least five HLH clinical criteria, the secondary objective was to explore characteristics and outcomes among those who received HLH-directed therapy versus those who did not.

Methods

Ethical Considerations

This observational study was approved by the Research Ethics Board at The Hospital for Sick Children (SickKids). The requirement for informed consent and assent were waived given the retrospective nature of the study. In keeping with our Research Ethics Board approval, no potentially identifying information of any participant is disclosed in this report. All data are presented as aggregates.

Data Source

The data source was the SickKids Enterprise-wide Data in Azure Repository (SEDAR) [10]. SEDAR is a curated and validated version of the Epic Clarity database that lives in Microsoft Azure. To create SEDAR, we transformed Clarity first into a Filtered Schema that retains only valid SickKids patients, then into a curated schema where the data are structured into clinically relevant units such as patients, encounters, laboratory tests, and medication administrations. During SEDAR creation, all data were validated via random sampling. This project focused on the following SEDAR tables: patient, diagnoses, cancer treatment plans, hospital encounter, nonhospital encounter, medication administration, prescriptions, laboratory tests, pathology results, flowsheets, and notes.

Operationalizing HLH Criteria

We used the HLH-2004 criteria (as opposed to the HLH-2024 criteria) as these would have been the criteria in place for most of the patient cohort. The time window to evaluate clinical criteria was centered on an episode, which was usually an inpatient admission spanning admission to discharge. A criterion was considered met if it occurred at any point during the episode. Five of the criteria were based on the laboratory results table (ferritin, cytopenia, hypertriglyceridemia or hypofibrinogenemia, sCD25, and low natural killer cell activity) and were considered met if the patient ever had a value above or below the criteria, as appropriate. Fever was defined as an oral temperature of at least 38.3°C once or 38.0°C to 38.2°C for at least one hour [11]. If a laboratory test was not performed or a criterion was not met, the criteria was categorized as not abnormal.

Two of the criteria required searching of text. Hemophagocytosis was identified by searching for “h(a)emophagocytosis” or “h(a)emophagocytic” in all pathology results. These reports were manually reviewed to identify true hemophagocytosis. Splenomegaly was identified by searching all notes for any of the following terms “splenomegaly,” “big spleen,” “organomegaly,” and “enlarged spleen.” Negative terms were excluded using the following terms within 3 words previous to the splenomegaly term: “no,” “none,” “absence,” “without,” and “negative.” The number of mentions were too high to manually review each note. Thus, a random sample of 20 notes underwent chart review to validate the approach. We found that 19/20 were correct. One of 20 was incorrect. We considered this satisfactory to proceed.

Eligibility Criteria

We established three cohorts of HLH “diagnosis” based upon encounters that occurred between June 2, 2018, and May 31, 2025. First, patients with a coded diagnosis of HLH were those with an *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*) code of D76.1 (hemophagocytic lymphohistiocytosis) or D76.2 (hemophagocytic syndrome, infection-associated). Second, cancer treatment plans are electronic care plans that are a component of Epic’s Beacon oncology module. All chemotherapy at our institution must be ordered within a treatment plan; however, treatment plan use is restricted to use by oncologists. To that end, an oncologist would therefore order a drug such as emapalumab within a treatment plan, while a rheumatologist using the same drug would not. We manually identified either treatment plan or protocol display names that included “HLH” or “h(a)emophagocytosis.” Use of a treatment plan was defined as having an HLH-specific treatment plan applied in Epic.

The third approach consisted of identifying the number of HLH-2004 clinical criteria within an encounter. The HLH-specific encounter was the encounter with the maximum number of criteria. If there was more than one encounter with this number of criteria, the first encounter was selected. For establishment of HLH based on clinical criteria, we identified encounters with at least 5 criteria within that encounter regardless of encounter length.

Given that there is no gold-standard adjudicated HLH cohort, determining which computable phenotype for cohort creation was most accurate was not possible with this data set.

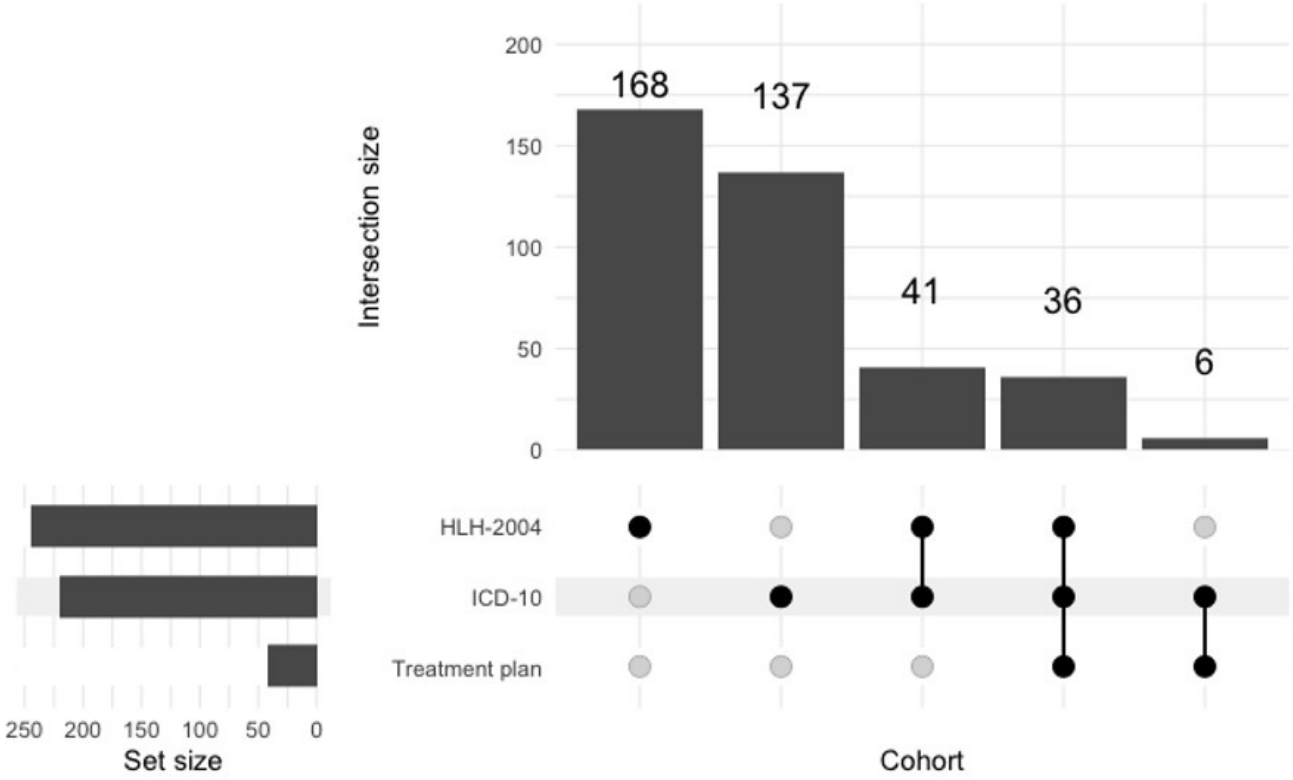
Procedure

We were interested in two measures of whether patients received HLH treatment; these might be administered within or outside of an HLH treatment plan. First, we considered any chemotherapy. Second, we considered HLH-directed therapy, which we defined as receipt of any dosage of dexamethasone, methylprednisolone, anakinra, ruxolitinib, cyclosporine, etoposide, or emapalumab [12-16].

XSL•FO
RenderX

We compared demographic features, HLH-related variables, and clinical outcomes among those with at least 5 HLH clinical criteria for those who received HLH-directed therapy (yes vs no) during the encounter where the criteria were met. The goal of this analysis was description and hypothesis generation given the possibility of confounding by indication for treatment. Demographic features were sex and age group (0-<1, 1 - 4, 5 - 14, and ≥15 years). HLH-related variables were whether there was an *ICD-10* HLH diagnosis associated with that encounter, timing of *ICD-10* HLH diagnosis relative to the encounter, and specific clinical criteria met. Clinical outcomes were services involved, length of stay, intensive care unit admission, in-hospital mortality, 30-day mortality, and whether the patient underwent stem cell transplantation following the encounter. To calculate 30-day mortality, we identified all patients with a date of death within 30 days of the visit where they met the HLH-2004 criteria. We also evaluated the 5 most common admission diagnoses among the cohort with at least 5 clinical criteria. Primary admission diagnosis was derived from the admitting diagnosis field in our EHR.

As an exploratory objective, we hypothesized that high ferritin and fever are common conditions in pediatric patients. Thus, we identified all encounters that met the HLH-2004 ferritin and fever criteria. Any encounter where the patient met both criteria at any point during the encounter were counted. We then described the distribution of the other HLH-2004 criteria in this cohort and stratified encounters by whether there were at least 5 clinical criteria present during an HLH-specific encounter.



Analysis

To compare patients who received HLH-directed therapy (yes versus no) among patients who met at least 5 clinical criteria, we used the Wilcoxon rank-sum test for continuous variables and χ^2 or Fisher exact test for categorical variables. Absolute risk differences in in-hospital mortality, 30-day mortality, and median length of stay were calculated with 95% confidence intervals. Analyses were performed with R (version 4.2.2; R Foundation for Statistical Computing).

Results

Figure 1 shows the intersection of the 388 patients identified as having HLH using our three approaches to HLH-cohort creation using three different computable phenotypes (diagnosis code, treatment plan, or HLH criteria). All patients with an HLH-specific treatment plan also had either an *ICD-10* HLH diagnosis or met clinical HLH criteria. Only 36 patients were identified by all three methods as having HLH. Table 1 shows the number of patients with an HLH *ICD-10* diagnosis code, an HLH treatment plan, or who met at least 5 HLH clinical criteria. An HLH *ICD-10* diagnosis (n=220 patients) and meeting 5 or more clinical criteria (n=245) were much more common than an HLH treatment plan (n=42 patients). Among the 220 patients with an HLH *ICD-10* code, only 35 patients received chemotherapy during the HLH-specific encounter. However, 85 patients received HLH-directed therapy during the HLH-specific encounter. Conversely, among the 245 patients who met at least 5 clinical criteria, 78 patients received chemotherapy and 193 patients received HLH-directed therapy during the HLH-specific encounter.

Figure 1. Intersection of HLH cohorts derived using three different approaches to cohort creation (N=388 patients). HLH: hemophagocytic lymphohistiocytosis; *ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

XSL•FO
RenderX

Table . Number of patients with possible hemophagocytic lymphohistiocytosis (HLH) by different approaches.

	HLH *ICD-10*[a] diagnosis code	HLH treatment plan	Five or more HLH criteria
Total number of patients	220	42	245
Number of patients with chemotherapy during HLH-specific encounter[b]	35	37	78
Number of patients with chemotherapy during any encounter	73	38	99
Number of patients with chemotherapy or HLH-directed therapy[c] during HLH-specific encounter	85	41	198
Number of patients with chemotherapy or HLH-directed therapy during any encounter	143	42	213
Number of patients with HLH-directed therapy during HLH-specific encounter	85	41	193
Number of patients with HLH-directed therapy during any encounter	142	42	212

[a]*ICD-10*: *International Statistical Classification of Diseases, Tenth Revision.*

[b]HLH-specific encounter is associated with first HLH diagnosis, first HLH treatment plan, or first encounter with the maximum number of criteria met.

[c]HLH-directed therapy includes dexamethasone, methylprednisolone, anakinra, ruxolitinib, cyclosporine, etoposide, and emapalumab.

Table 2 shows the demographic features of unique patients who met 5 or more HLH criteria stratified by receipt of HLH-directed therapy versus not. The median age of the cohort was 7.7 years (IQR 1.4 - 13.9). Of the 193 patients who received HLH-directed therapies, 67.9% (n=131) only received steroids and 29% (n=56) received steroids in combination with an additional HLH-directed therapy. Those with sepsis were less likely to receive HLH-directed therapy (13.5% vs 4.7%; *P*=.05). Those patients receiving HLH-directed therapy were more likely to have an *ICD-10* HLH diagnosis code during that encounter (*P*=.001). Notably, there was no difference in any specific HLH criteria between those who did and did not receive HLH-directed therapy although high ferritin was almost universal in both groups. The absolute difference in in-hospital mortality and 30-day mortality rates between the groups was 1.5% (95% CI –1.1 to 1.1) and 1.2% (95% CI –1.2 to 1.1), respectively. The absolute difference in median length of stay between the two groups was 12.6 days (95% CI 4.1 to 22.4).

[a]Five most common admitting diagnoses for patients with at least 5/8 HLH criteria (n=245).

[b]*ICD-10*: *International Statistical Classification of Diseases, Tenth Revision*.

[c]Number of encounters where measured for HLH-directed therapy (yes versus no): sCD25: 135 versus 36; natural killer cell activity: 53 versus 7.

Table 3 shows that among the 1325 encounters (where individual patients can have more than one encounter) with high ferritin and fever, cytopenia, hypertriglyceridemia or hypofibrinogenemia, and splenomegaly were very common. Of the 1325 encounters, 19% (n=252) had >5 HLH criteria. Even among those with less than 5 clinical criteria, cytopenia was present in 44% (n=475) of encounters while hypertriglyceridemia or hypofibrinogenemia and splenomegaly were present in 24% (n=255) and 27% (n=290) of encounters, respectively.

Table . Distribution of criteria among encounters with high ferritin and fever[a].

	All encounters (N=1325 encounters), n (%)	5 or more criteria (n=252 encounters), n (%)	<5 criteria (n=1073 encounters), n (%)
Cytopenia of at least 2 lineages	706 (53)	231 (92)	475 (44)
Hypertriglyceridemia or hypofibrinogenemia	485 (37)	230 (91)	255 (24)
Splenomegaly	519 (39)	229 (91)	290 (27)
sCD25[b]	159 (12)	114 (45)	45 (4)
Hemophagocytosis	27 (2)	27 (11)	0 (0)
Low natural killer cell activity[b]	12 (1)	11 (4)	1 (0.1)

[a]The table represents all encounters where ferritin and fever met the threshold for HLH diagnosis without considering if the patient was diagnosed with HLH by any approach. There may be multiple episodes per patient.

[b]Number of encounters where measured for ≥5 versus <5 criteria were as follows: sCD25: 172 (68%) versus 165 (15%); natural killer cell activity: 55 (22%) versus 24 (2%).

Multimedia Appendix 1 shows the distribution of clinical criteria among those with an HLH *ICD-10* code and among those with at least 5 clinical criteria. Some patients with their first HLH *ICD-10* diagnosis code had no clinical criteria.

Discussion

In this study, we compared three approaches to constructing an EHR-derived cohort of pediatric patients with HLH: (1) *ICD-10* diagnosis codes, (2) HLH-specific treatment plans, and (3) fulfillment of HLH-2004 clinical criteria. Our findings demonstrate substantial variation in the populations identified by each approach, with diagnosis codes and clinical criteria identifying a far greater number of encounters than HLH-specific treatment plans. We also identified that among patients meeting at least five HLH-2004 clinical criteria, a large proportion received HLH-directed therapy, and that among a cohort of patients with fever and an elevated ferritin, a substantial portion have other findings of HLH such as cytopenia, hypertriglyceridemia or hypofibrinogenemia or splenomegaly.

Comparing our three approaches to EHR-based cohort construction yields numerous interesting insights. First, we observed that HLH *ICD-10* codes were relatively common in our dataset. A large proportion of patients with an HLH *ICD-10* code did not receive HLH-directed therapy, suggesting that coded diagnoses may be used for suspected but unconfirmed HLH. Conversely, while HLH treatment plans were highly specific, they were rarely used. This is likely because many pediatric patients with HLH do not require chemotherapy and receive HLH-directed medications that are ordered outside of a chemotherapy plan. Thus, the use of treatment plans, which are likely the most accurate way to identify HLH-directed medications, likely underestimates the true HLH population. Clinical criteria, while nonspecific, identified the broadest cohort, consistent with the recognition that HLH represents a clinical syndrome overlapping with other hyperinflammatory states. The exclusive use of these criteria can also be problematic in an EHR cohort, where certain laboratory tests may be done at a referring institution such as for a patient with HLH being referred for a hematopoietic stem cell transplant. This is supported by the fact that we had some patients who met zero HLH clinical criteria but had an HLH *ICD-10* code applied. Future research leveraging EHR data to assemble an HLH cohort needs to consider the advantages and disadvantages of different techniques for cohort assembly to select the best approach for a given project. For example, a researcher interested in understanding the diagnostic odyssey of patients with HLH prior to treatment to improve time to diagnosis might use diagnostic criteria as this would more broadly capture patients compared to using a more narrow approach like diagnostic codes. Future work should also explore the usage of a

XSL•FO
RenderX

combination of approaches such as having both HLH-criteria met and an HLH diagnosis code and using additional filters in the treatment approach such as dosages or duration for medications that might be used for indications other than HLH management such as dexamethasone. It will also be important to validate these approaches at other institutions to understand generalizability.

Using our newly developed EHR-based cohort of children with HLH, we were able to generate new insights into the management and outcomes of patients with HLH. Of the 245 patients who met the HLH-2004 criteria for HLH, 27% (n=52) received no HLH-directed therapy. No differences were identified in the occurrence of HLH-specific criteria such as ferritin or fever between the two cohorts. From this work, it remains unclear as to what drove the difference in clinical decision-making to start HLH-directed therapy for patients meeting 5 criteria. We did identify that patients who did not receive HLH-directed therapy were more likely to have sepsis than those who did [17]. This is not surprising given that we know that sepsis and HLH have an overlapping presentation. Patients who received HLH-directed therapy also had a significantly longer length of stay (33.4 vs 20.8 d). It is important to note that regardless of whether or not a patient who met 5 criteria received therapy, their 30-day mortality risk was approximately 1 in 6. This is similar to other contemporary studies of patients treated for HLH, where mortality rates have ranged from 23% to 55% [14,18-20]. Given the high mortality rate in those who did not receive therapy, it raises the question of whether or not we are failing to treat a subset of patients with HLH with appropriate HLH-directed therapies.

We also evaluated the distribution of HLH criteria within an EHR-derived cohort of patients with high ferritin and fever. An elevated ferritin and fever are often used as the entrance criteria into a "rule-out" HLH algorithm at many institutions that results in the ordering of additional HLH-specific labs or consultation of an HLH-specific team such as hematology/oncology and/or rheumatology [16,21]. In this cohort that mirrors a potential cohort of patients where an HLH work-up and diagnosis may be considered, we identified that a significant proportion of patients will meet additional HLH criteria. However, only 20% (n=252) of the patients in this cohort met >5 HLH criteria, suggesting that if fever and ferritin are used as entrance criteria into an HLH algorithm, 5 patients would need to be evaluated to identify 1 patient meeting the HLH clinical criteria.

The strengths of this study are access to all data in a curated and validated EHR data set, which allows for the inclusion of patients without an HLH diagnosis. Unlike prior studies restricted to curated clinical cohorts, our approach provides insight into the challenges of applying HLH diagnostic frameworks in real-world, unselected populations. However, limitations of this study include that it was done at a single pediatric institution, so results may not generalize to other institutions. Specifically, in the Canadian context, we may underutilize ICD codes compared to American peers given different implications on billing and remuneration [22]. Second, we were limited in validating the performance of our cohorts against a gold-standard cohort, as no such curated dataset exists that includes both primary and secondary patients with HLH. Third, EHR-derived data are prone to misclassification. Diagnosis codes may not reflect confirmed diagnoses, laboratory results may be incomplete (as SickKids is a large referral center so some labs may have been done at a referring institution and may not have been included in our dataset), and text-mining strategies (eg, for splenomegaly) have imperfect specificity. Fourth, we centered our analysis on the HLH-2004 criteria given these were the criteria being used by clinicians during our study period. The HLH-2024 criteria have since been published, which differ slightly from the HLH-2004 criteria by removal of the natural killer cell activity criterion. Given that only 5% (n=60) of patients had natural killer cell activity testing performed in our cohort, removal of this criteria is unlikely to impact results. Finally, treatment receipt was defined by medication administration records, which may not fully capture the intent of medication prescribing, and this analysis may be confounded by medication indication.

Constructing HLH cohorts from EHR data is challenging, with diagnosis codes, treatment plans, and clinical criteria each capturing distinct but overlapping populations. While clinical criteria identify the broadest group, they lack specificity, underscoring the limitations of applying rigid diagnostic frameworks to real-world EHR data. Developing accurate, machine-evaluable HLH phenotypes will be critical to advancing both clinical care and research in this rare but important condition.

Abstract

Background: With the rapid development of medical technology and the emphasis on early lung cancer screening, the detection rate of multiple primary lung cancer (MPLC) has increased in recent years. However, the prognostic determinants and clinical characteristics of patients with MPLC remain poorly characterized.

Objective: This study aimed to develop and validate a nomogram for predicting overall survival (OS) in patients with MPLC using data from the Surveillance, Epidemiology, and End Results database.

Methods: This study was reported in accordance with the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines. A cohort of 4177 patients with MPLC (2007 - 2015) was obtained from the Surveillance, Epidemiology, and End Results database. The patients were randomly divided into training (n=2923) and validation (n=1254) cohorts at a 7:3 ratio. Backward stepwise Cox regression identified 11 independent risk factors, which were integrated into a nomogram predicting 3-, 5-, and 8-year OS rates.

Results: The nomogram demonstrated superior discriminative ability compared to the American Joint Committee on Cancer staging system, with higher area under the receiver operating characteristic curve values for 3-, 5-, and 8-year OS predictions in both cohorts (training cohort: 0.743, 0.751, and 0.759, respectively; validation cohort: 0.737, 0.734, and 0.695, respectively). Calibration curves and decision curve analysis confirmed its clinical utility.

Conclusions: This study establishes a validated nomogram incorporating clinical and socioeconomic variables to optimize prognostic assessment and personalized treatment planning for patients with MPLC.

KEYWORDS

multiple primary lung cancer; Surveillance, Epidemiology, and End Results database; SEER database; nomogram; survival prediction; overall survival

Introduction

Lung cancer remains a leading cause of cancer-related mortality worldwide [1,2]. Multiple primary lung cancer (MPLC), defined as the presence of 2 or more distinct primary lung tumors either synchronously or metachronously, accounts for 3.5% to 15% of newly diagnosed cases [3-6]. With advancements in imaging and an emphasis on early lung cancer screening, the incidence rate of MPLC is increasing worldwide.

MPLC can be classified into metachronous MPLC and synchronous MPLC according to the time of lesion occurrence [7-9]. While advancements in imaging modalities have improved MPLC detection, differentiating it from intrapulmonary metastasis remains clinically challenging, particularly in histologically similar lesions [5-7,10]. Notably, patients with MPLC exhibit significantly better survival outcomes than those with intrapulmonary metastasis, with reported 5-year postresection survival rates ranging from 77.3% to 87% [6,11-17]. Moreover, the prognosis of surgically treated MPLC has been reported to be comparable to that of stage-matched solitary lung cancer [18,19]. Therefore, accurate diagnosis and prognostic assessment of MPLC are of substantial clinical importance.

XSL•FO
RenderX

The TNM staging system plays an important role in treatment selection and prognostic evaluation for patients with lung cancer. However, substantial survival heterogeneity still exists among patients with similar histological subtypes and TNM stages, particularly in MPLC [20]. In MPLC, each lesion is evaluated separately for the tumor, node, and metastasis categories according to current staging recommendations [21]. Furthermore, staging strategies differ among various forms of multifocal lung cancer and among MPLC cases with different radiological manifestations [21]. Thus, patients with MPLC may be inadvertently upstaged to T3 and/or T4 or even M1a, leading to erroneous staging, inaccurate prognosis, and improper treatment [20,22].

Several prognostic nomograms for MPLC have been developed using Surveillance, Epidemiology, and End Results (SEER)–based cohorts [15,23]. However, most existing models primarily focus on clinicopathological variables and provide limited evaluation of socioeconomic factors or the distinct prognostic contributions of the first primary lung cancer (FPLC) and second primary lung cancer (SPLC). In addition, few studies have established long-term survival prediction models for patients with MPLC, and the prognostic applicability of the conventional TNM and American Joint Committee on Cancer (AJCC) staging systems in this population remains limited.

Therefore, this study aimed to identify independent prognostic factors associated with overall survival (OS) in patients with MPLC using the SEER database and develop and validate a prognostic nomogram for predicting 3-, 5-, and 8-year OS. Furthermore, the predictive performance of the nomogram was compared with that of the AJCC staging system to evaluate its potential clinical utility in individualized prognostic assessment and risk stratification for patients with MPLC.

Methods

Ethical Considerations

This study analyzed publicly available, deidentified data from the SEER database. The use of this dataset is exempt from institutional review board approval, and the requirement for informed consent was waived for this analysis. The study was conducted in accordance with the Declaration of Helsinki and its subsequent amendments. This study was reported in accordance with the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines.

Patient Selection and Data Processing

From 465,552 lung cancer cases in the SEER database (2007 - 2015), a total of 8354 (1.8%) tumor records corresponding to 4177 unique patients were identified as meeting the 2013 American College of Chest Physicians criteria for MPLC. These 4177 patients were included in the final analysis. Exclusion criteria encompassed age below 18 years, diagnosis via autopsy or death certificate, and incomplete variables. Patients with MPLC were identified using *International Classification of Diseases for Oncology, Third Edition*, site codes for lung and bronchus tumors (C33.9 and C34.0-C34.9). The SEER sequence number variable was used to distinguish FPLC from SPLC, with sequence numbers 01 and 02 representing the first and second primary lung tumors, respectively. Patients with sequence numbers of 03 or higher were excluded. Synchronous MPLC and metachronous MPLC were defined according to a diagnostic interval of 6 months or less and more than 6 months, respectively. To minimize potential misclassification of intrapulmonary metastasis, cases with identical histological subtypes were conservatively excluded if tumors were located within the same lobe, accompanied by N1 or N2 disease, or associated with distant metastasis (M1). Eligible patients were randomized into training (70%) and validation (30%) cohorts. The following variables were evaluated: age, sex, AJCC stage, FPLC and SPLC histology, SPLC tumor size, FPLC and SPLC surgery status, average household income, marital status, race, survival status, and survival time. Age (<65 vs ≥65 years), SPLC tumor size (≤3, 3 - 5, and >5 cm), and household income (<US $50,000, US $50,000 - 80,000, and >US $80,000) were categorized according to the SEER database records for model construction. All TNM stages were uniformly converted to the Eighth Edition of the *AJCC Cancer Staging Manual* using the standard mapping algorithm provided by the SEER database.

Construction and Validation of the Nomogram

To improve the prediction power of the nomogram, 4177 patients were randomly assigned to the training cohort (n=2923) and the validation cohort (n=1254) at a ratio of 7:3. The prognostic nomogram in this study was developed using the Cox proportional hazards regression model, a conventional statistical method. No machine learning, artificial intelligence, or deep learning algorithms were used for model construction, data analysis, or outcome prediction. Multivariate Cox proportional hazards regression analysis was performed to identify variables that affect OS in the training cohort. Using these predictors of OS, we constructed a nomogram for predicting 3-, 5-, and 8-year survival rates in patients with MPLC.

We subsequently evaluated the discrimination ability of the nomogram by calculating the index of concordance (C-index) and the area under the receiver operating characteristic curve (AUC). The calibration curves show the associations between the predicted and actual probabilities. Both discrimination and calibration were evaluated via bootstrapping with 1000 resamples. The net reclassification improvement (NRI) and integrated discrimination improvement (IDI) were used to compare the accuracy of the nomogram with that of the traditional AJCC staging model. Decision curve analysis (DCA) was used to assess the actual clinical benefits. Finally, AUC values and Kaplan-Meier survival curves were used to compare the nomogram with AJCC staging alone.

Statistical Analysis

The primary end point was OS, defined as the time from diagnosis of the FPLC to death from any cause or last follow-up. All the statistical analyses were performed via SPSS (version 27.0; IBM Corp) and R (version 4.0.3; R Foundation for Statistical Computing). The statistical tests were 2 sided, and a *P* value of less than .05 was considered to indicate statistical significance.

Results

Baseline Characteristics of the Study Participants

We evaluated a total of 4177 patients with MPLC who were randomly divided into a training cohort (n=2923, 70%) and a validation cohort (n=1254, 30%). The selection process of patients with MPLC is shown in Figure 1. The baseline characteristics of the patients in the training and validation cohorts are presented in Multimedia Appendix 1. In the training cohort, most patients (2277/2923, 77.9%) were aged 65 years or older, and 54% (1578/2923) were female. AJCC stage 1 was the most common stage (1459/2923, 49.9%), followed by stage 3 (775/2923, 26.5%). Adenocarcinoma was the predominant histological subtype in both FPLC (1696/2923, 58%) and SPLC (1681/2923, 57.5%). In addition, 61.4% (1796/2923) of patients presented with bilateral lesions. The surgical resection rate was lower for SPLC (1566/2923, 53.6%) than for FPLC (2147/2923, 73.5%). Detailed demographic and clinicopathological characteristics are summarized in Multimedia Appendix 1. During the follow-up period, a total of 2354 deaths were observed, with a maximum follow-up duration of 119 months. For the entire cohort of 4177 patients, the median OS was 68 (95% CI 66 - 71) months. The estimated 3-, 5-, and 8-year OS rates were 70.8% (95% CI 69.4% - 72.2%), 55.3% (95% CI 53.7% - 56.9%), and 32.6% (95% CI 30.8% - 34.4%), respectively.

Univariate and Multivariate Analyses of OS in the Training Cohort

Through univariate and multivariate Cox proportional hazards regression, we identified 11 independent risk factors in the training cohort as follows: age, sex, AJCC stage, histology of FPLC and SPLC, tumor size of SPLC, surgery of both FPLC and SPLC, average household income, marital status, and race, as shown in Table 1.

Construction and Validation of the Nomogram

A nomogram was constructed for prediction based on the 11 independent risk factors, which were statistically significant prognostic factors in the Cox proportional hazards model. The nomogram revealed that the AJCC stage had the greatest contribution to survival outcomes, followed by histology, tumor size, and SPLC surgery. We obtained a total score by adding the total points for the score assigned to each variable. The total score corresponded to the prediction of 3-, 5-, and 8-year OS for each patient with MPLC. The higher the score, the worse the survival prognosis. The nomogram is shown in Figure 2.

XSL•FO
RenderX

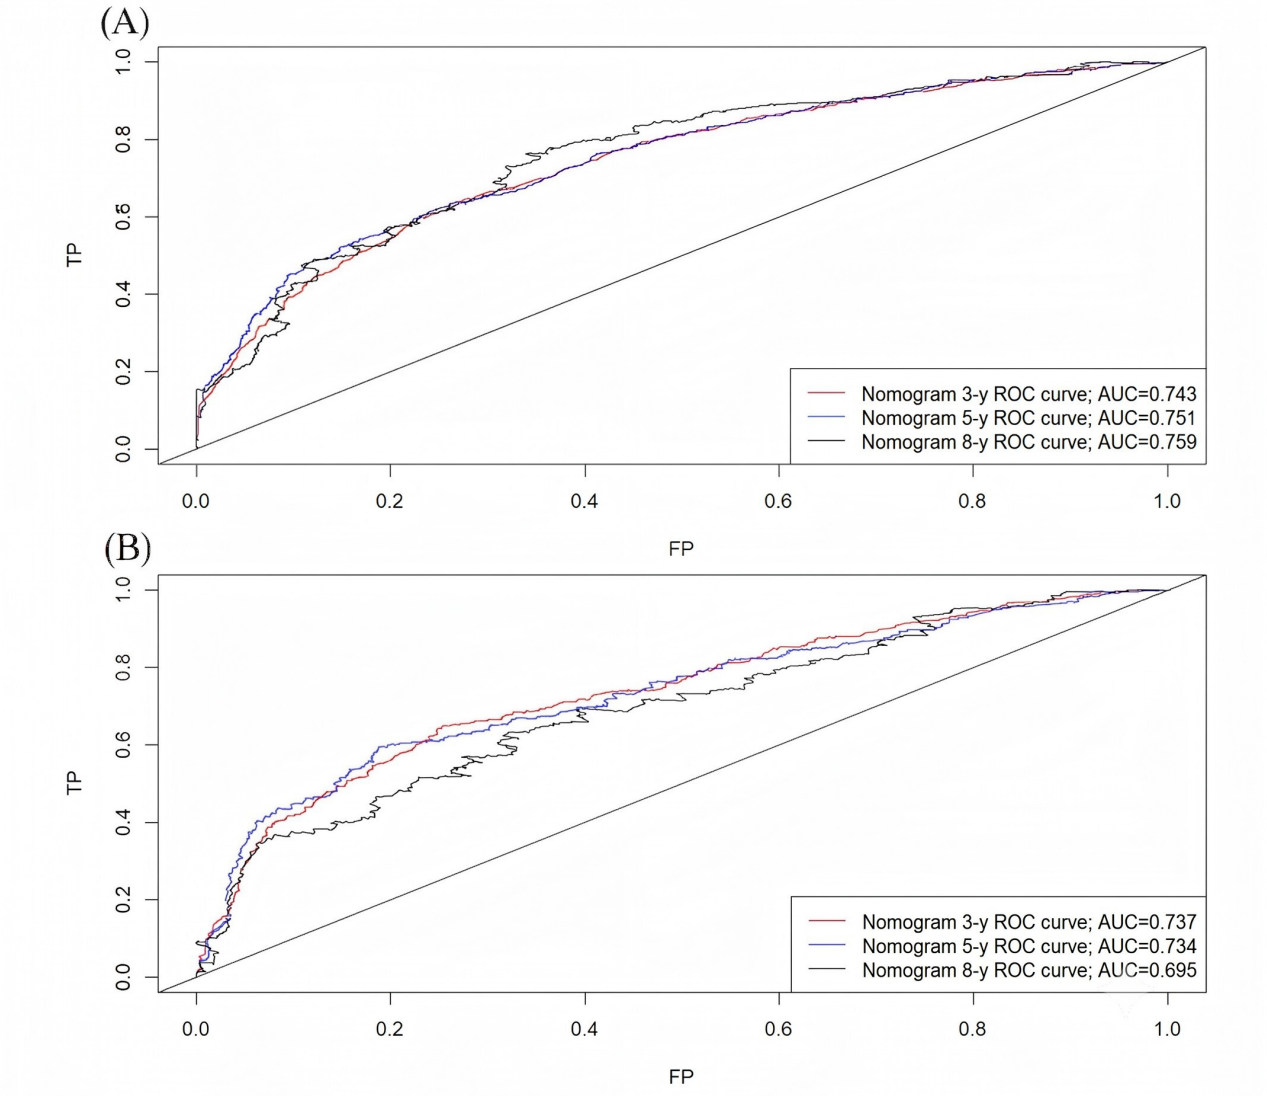

Figure 2. Nomogram predicting 3-, 5-, and 8-year overall survival of patients with multiple primary lung cancer. The factors of age, sex, American Joint Committee on Cancer (AJCC) stage, histology of first primary lung cancer (FPLC; His1) and second primary lung cancer (SPLC; His2), tumor size of SPLC (Size2), surgery for both FPLC (Surg1) and SPLC (Surg2), average household income, marital status, and race were included in the model. SCLC: small-cell lung cancer.

The C-index of the nomogram in the training cohort was 0.702, whereas it was 0.699 in the validation cohort. The AUCs used to predict 3-, 5-, and 8-year OS in the training cohort were 0.743, 0.751, and 0.759, respectively (Figure 3A). In the validation cohort, these values were 0.737, 0.734, and 0.695, respectively (Figure 3B). Furthermore, the calibration curves of the nomogram demonstrated a favorable fit for the 3-, 5-, and 8-year OS probabilities in both the training (Figure 4A-C) and validation (Figure 4D-F) cohorts. There was good consistency between the predicted values and the actual observed values. These findings demonstrated the high accuracy and discriminatory capacity of the nomogram.

RenderX

Figure 3. Receiver operating characteristic (ROC) curves of the nomogram for 3-, 5-, and 8-year overall survival prediction: (A) training cohort and (B) validation cohort. AUC: area under the ROC curve; FP: false positive; TP: true positive.

XSL•FO
RenderX

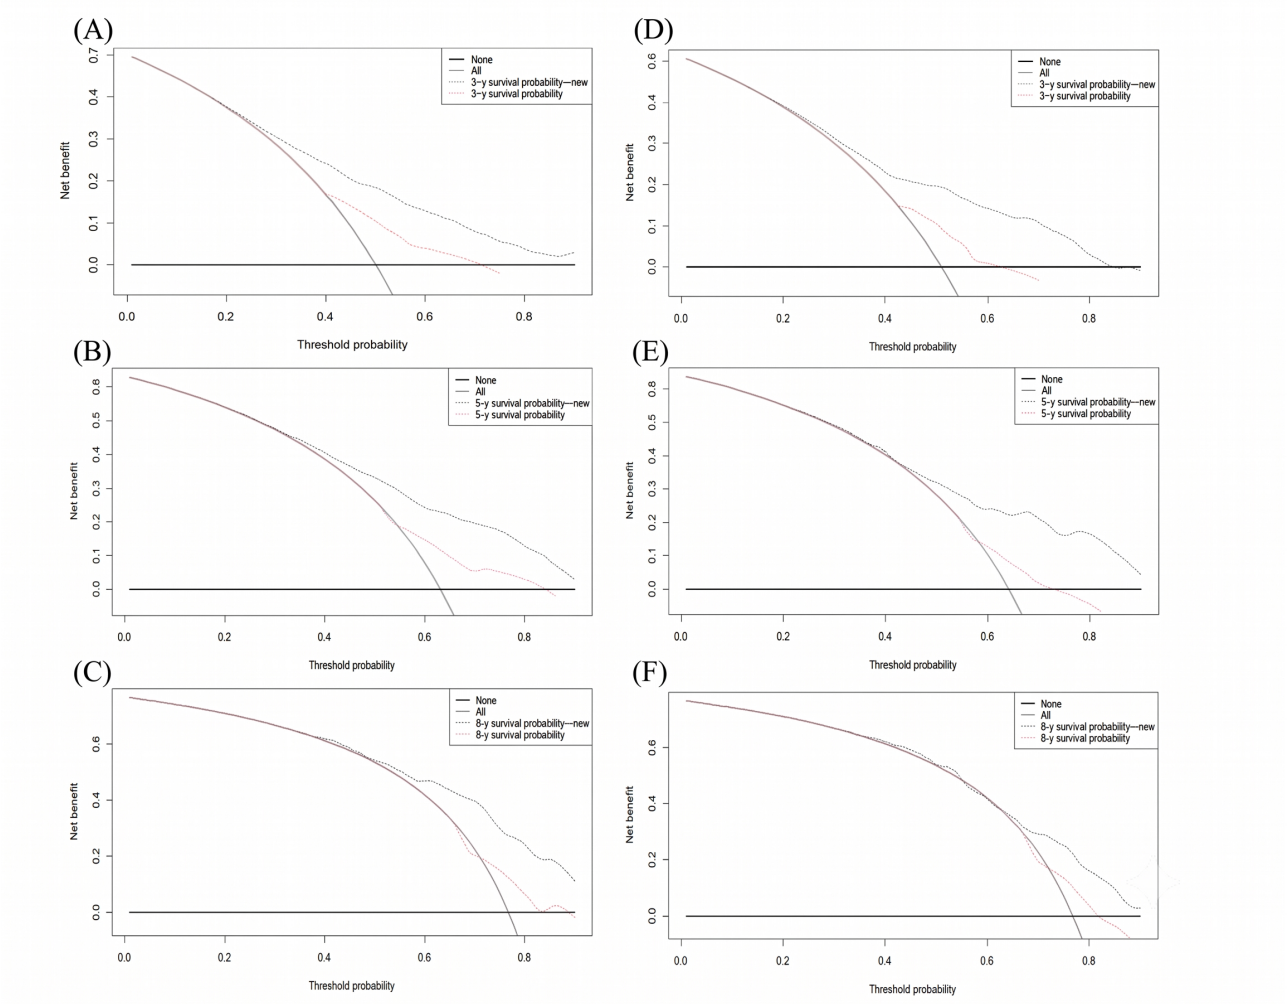

Figure 4. The calibration curves for predicting patient overall survival at 3, 5, and 8 years in the training cohort (A-C) and validation cohort (D-F).

In addition, the NRI values at 3, 5, and 8 years in the training cohort were 0.590 (95% CI 0.505 - 0.664), 0.576 (95% CI 0.522 - 0.688), and 0.577 (95% CI 0.467 - 0.762), respectively. The IDI values for 3-, 5-, and 8-year survival were 0.097, 0.091, and 0.070, respectively, in the training cohort and 0.102, 0.090, and 0.066, respectively, in the validation cohort. All the IDI values were greater than 0 (P<.001), indicating a significantly improved prediction performance of the nomogram compared with the AJCC stage model. In both the training cohort and the validation cohort, DCA strongly improved the prediction of 3-, 5-, and 8-year OS (Figure 5).

Comparison of the Predictive Accuracy Between the Novel Risk Stratification Model and the Conventional Prognostic Model

Using AUC values, we compared the accuracy between the nomogram and traditional AJCC staging system. The AUC values of the nomogram and the traditional prediction model were 0.743 vs 0.622, 0.751 vs 0.612, and 0.759 vs 0.583, respectively, in the training cohort (Figure 6A-C) and 0.737 vs 0.60, 0.734 vs 0.572, and 0.695 vs 0.569, respectively, in the validation cohort (Figure 6D-F). We observed that the nomogram had higher AUC values than the AJCC staging model regardless of the prediction of 3-, 5-, and 8-year OS in both the training and validation cohorts.

Discussion

Principal Findings

In recent years, the survival prognosis of patients with MPLC has garnered significant research interest. Current evidence indicates that patients with MPLC exhibit substantially improved OS compared to those with intrapulmonary metastasis [5,24,25]. Notably, female patients demonstrate a markedly elevated MPLC incidence (54.2%-73.2%) relative to SPLC (27.9%) or intrapulmonary metastasis (31.6%) [5,20,24], a finding corroborated by our study. However, studies on the prognosis of MPLC are mostly based on small sample sizes, and some important factors affecting the prognosis of patients with tumors are ignored [4-6,12].

In this retrospective study, we developed a Cox proportional hazards regression model and prognostic nomogram for patients with MPLC. Our analysis identified 4 key independent risk factors: AJCC stage, histological subtype of SPLC, secondary tumor size, and surgical management of SPLC. Additionally, female sex, higher socioeconomic status, and race emerged as favorable prognostic indicators. On the basis of these factors, a nomogram predicting the probability of survival calibrated well and was a good measure of discrimination.

Compared with previously published SEER-based prognostic nomograms for MPLC, our model incorporated both clinicopathological and socioeconomic variables and separately evaluated the histological characteristics of FPLC and SPLC. In addition, this nomogram provided simultaneous prediction of 3-, 5-, and 8-year OS and demonstrated improved predictive performance compared with the conventional AJCC staging system. These findings suggest that the model may offer additional value for individualized prognostic assessment in patients with MPLC.

While the AJCC staging system partially predicts lung cancer outcomes, its prognostic utility in MPLC requires refinement. A prior study by Tanvetyanon et al [15] highlighted sex, younger age, smaller tumor size, absence of nodal involvement, and bilateral presentation as significant prognosticators in MPLC. Our findings align with these observations and further establish AJCC stage as the most influential prognostic determinant [26]. Notably, Yu et al [18] identified tumor size as the sole prognostic factor in node-negative patients with MPLC, whereas subsequent studies [15,27-29] confirmed that survival outcomes in early-stage MPLC (T1-T2) parallel those of solitary lung nodules, significantly surpassing stage 3 and 4 non–small-cell lung cancer outcomes based on the Eighth Edition of the *AJCC Cancer Staging Manual*.

Histological characteristics, particularly those of SPLC, significantly impacted survival outcomes. Adenocarcinoma histology was independently correlated with improved prognosis, consistent with prior reports [15,30]. However,

XSL•FO
RenderX

neither the aforementioned study by Tanvetyanon et al [15] nor a study by Song et al [23] determined that the histology from FPLC or SPLC had a greater impact on the prognosis of MPLC. We conducted an independent analysis of the histology of 2 primary lung cancers in MPLC. The nomogram revealed that the contribution of histological variables to SPLC was significantly greater than that to FPLC. The survival prognosis of patients with MPLC was related mainly to the histological type of SPLC.

In clinical evaluation, distinguishing between synchronous and metachronous MPLC is of great significance. Although the SEER database does not provide variables that can be used to clearly define the sequence of onset, the proportion of bilateral lesions in the training cohort of this study was as high as 61.4% (1796/2923), suggesting that this patient population was predominantly characterized by synchronous or near-synchronous onset. Regarding pathological consistency, the model in this study included the histological types of FPLC and SPLC as 2 independent variables in the analysis rather than simply combining them into a binary "pathologically consistent/inconsistent" indicator. This design allows the line plot to more fully reflect the prognostic value of the corresponding histological types of the 2 tumors, particularly highlighting the importance of the histological subtype of SPLC for prognosis without being confounded by whether the histologies of the 2 primary cancers were consistent. In the future, it will be necessary to further validate the results of this study in different subgroups based on more detailed information regarding the sequence of onset.

Surgical intervention for SPLC conferred superior prognostic benefits compared to FPLC management. Cox regression analysis revealed substantially worse outcomes in nonsurgical cohorts, potentially attributable to misdiagnosis as metastatic or recurrent disease leading to therapeutic delays. Current consensus emphasizes surgical resection as the main approach to MPLC management [3], supported by evidence of enhanced long-term survival vs stage 4 non–small-cell lung cancer or metastatic disease [30,31]. The research by Stella et al [31] further advocates for aggressive surgical approaches for eligible patients with adequate cardiopulmonary reserve in MPLC or multiple lesions. Moreover, the differences in imaging assessment, inconsistencies in pathological diagnostic criteria, interobserver variability, variability in tissue sampling methods, lack of standardized definitions for distinguishing MPLC from intrapulmonary metastasis, and differences in diagnostic workup across institutions or time periods could bias the diagnosis of MPLC considering that current guidelines focus mainly on the recurrence of intrapulmonary metastasis rather than the development of MPLC. Establishing a risk profile for the survival prognosis of patients with MPLC would be beneficial.

In our study, being older; male; from a low-income background; divorced, separated, or single; or White were poor prognostic factors for MPLC. MPLC is common in patients aged 65 years and older, and the prognosis of patients with MPLC becomes worse with age, similar to most malignant tumors. Although there were more female patients than male patients in this study, the risk of death in female patients is lower than in male patients, which is due to the emotional and psychological stress and hormone levels of female patients. In terms of economic value, low-income individuals do not pay attention to the disease and cannot afford medical expenses, which is an important reason for the high risk of death of patients with MPLC among low-income individuals. Married patients may have better survival outcomes than other patients. However, with respect to the impact of race on the prognosis of MPLC, because the information was collected from the SEER database, White patients comprised most of the data, and more real-world data are needed to support the conclusion that White individuals have a high incidence of MPLC.

According to the results of this study, the nomogram demonstrated good distinguishing ability and high accuracy, with training and validation cohort C-indexes of 0.702 and 0.699, respectively. Time-dependent AUC values exceeded 0.70 for 3-, 5-, and 8-year survival predictions. The calibration curve was close to the reference line and fell along the diagonal line of 45 degrees, which shows that the nomogram was in good agreement with the actual results and that the degree of fit was high. The NRI and IDI values were greater than 0, indicating that the nomogram had improved prediction performance over traditional AJCC staging. The DCA curve demonstrated that the nomogram yielded a high net benefit compared to alternative strategies in both the training and validation cohorts, indicating that it meets the practical needs of clinical decision-making and can be widely used in clinical analysis. This nomogram provides continuous estimates of survival probability rather than assigning patients into predefined risk categories. Preserving continuous probability estimation avoids the loss of prognostic information associated with arbitrary cutoff selection and enables more individualized risk assessment. The continuous scores generated by the model may assist clinicians in personalized follow-up surveillance, prognostic evaluation, and clinical risk stratification for patients with MPLC. For example, patients with progressively increasing model-derived risk scores may benefit from more intensive follow-up monitoring, thereby avoiding the limitations of the traditional "one-size-fits-all" approach inherent in coarse risk stratification systems. Therefore, we frame this nomogram as a clinical decision support tool for individualized prognostic assessment and risk stratification rather than as a stand-alone prognostic classifier.

Limitations

This study has certain limitations, and caution should be exercised when interpreting and applying its findings. First, as this was a retrospective analysis based on the SEER database, some clinical information was incomplete, which may introduce selection bias; key prognostic factors such as smoking, alcohol consumption, family history of cancer, genotyping, detailed imaging characteristics, and laboratory test results were missing, making it impossible to adjust for these as confounding factors in the analysis. Second, due to limitations in the database itself, treatment details were limited. Data on specific regimens for radiotherapy, chemotherapy, targeted therapy, and immunotherapy were lacking, making it difficult to accurately assess the impact of different treatments on patient prognosis. Third, this study included only cases of dual primary lung cancer and did not include cases with 3 or more primary tumors; therefore, the conclusions cannot be extrapolated to a broader

XSL•FO
RenderX

population of patients with MPLC. Fourth, the constructed nomogram has not yet undergone external validation in independent cohorts from other medical institutions; its generalizability across different populations and clinical settings requires further verification. Fifth, this study used OS as the primary end point rather than tumor-specific survival; non–cancer-related deaths may introduce confounding factors into the survival analysis results. Additionally, the model's C-index was approximately 0.70, indicating moderate but clinically meaningful discriminatory ability rather than perfect prediction accuracy. Therefore, this nomogram should be considered a clinical decision support tool for individualized prognostic assessment and risk stratification rather than an independent prognostic classifier. In summary, the model may assist clinicians in developing individualized follow-up and treatment strategies, but it should not be used alone for final clinical decision-making.

Conclusions

In summary, we constructed a nomogram for patients with MPLC using the SEER database that has good ability to predict the individual survival of patients with MPLC more efficiently, accurately, and easily. This information can help clinicians evaluate the prognosis of patients better than before and provide individualized treatment.

Abstract

Background: Renal cell carcinoma (RCC) is a common, often lethal kidney cancer that originates in the renal cortex. Its incidence is rising, and major factors include smoking, obesity, and hypertension, though its etiology is uncertain. While surgery is effective for localized RCC, treatments for metastatic RCC have advanced significantly due to better diagnostic, prognostic, and predictive tools. Despite this progress, challenges remain, including long-term drug resistance and the complexity of RCC as a diverse group of diseases rather than a single entity.

Objective: The aim of this bibliometric review was a comprehensive analysis of the topics and trends in RCC research, offering a foundation for future investigations.

Methods: We used R "Bibliometrix" to conduct a bibliographic search in Scopus and PubMed covering publications from 1975 to 2023 to statistically assess the distribution of publications associated with RCC by year, journal, and country. Topic modeling of RCC research was conducted using latent Dirichlet allocation, a Bayesian network-based probabilistic algorithm that identifies unobserved thematic clusters in a collection of text documents. Trends in the retrieved themes were then characterized by using regression slopes over time, across countries, and in different journals. These trends were visualized as a heatmap, which was then used for hierarchical clustering to group similar topics based on their correlation strengths.

Results: A total of 35,228 documents from 3070 sources were found, with a steady yearly growth of 9.86% and 118 participating countries. Thirty topics with the best coherence score were found in 8 crucial domains: treatment and therapies, biomolecular and genetic characteristics, disease characteristics and progression, diagnosis and evaluation, metastasis and dissemination, epidemiology and risk factors, related conditions, and pathological features. The pertinent clustergrams that resulted from the heatmaps mirrored the latent Dirichlet allocation's algorithm identification of major RCC research subjects.

Conclusions: Over 50 years, RCC research's focus has shifted from diagnosis and assessment to a more thorough understanding of disease characteristics and progression. Because many patients are diagnosed with abdominal imaging studies, an emerging topic in RCC is diagnostic imaging and radiological evolution. The advances in omics technologies and the function of microRNA signature in the progression, diagnosis, therapy targeting, and prognosis of RCC have garnered a lot of attention. The discovery of the genetic background has enhanced our understanding of the growth of RCC. Drug resistance, local RCC ablation, and postoperative surveillance of RCC recurrence following nephrectomy are key future research avenues. The next generation of drug-targeted therapy and immunotherapy will make it possible to successfully treat metastatic RCC following nephrectomy. Neglected topics include the association between ferroptosis and RCC, the long-term assessment of novel treatments, and the application of artificial intelligence on RCC. Our bibliographic review delivered pertinent data for clinical decision-making and the planning of future RCC research.

Introduction

Renal cell carcinoma (RCC) is the term coined to describe the malignant transformation of proximal renal tubular epithelium within the renal cortex [1]. RCC accounts for approximately 90% of all renal malignancies [2] and for approximately 2% of all cancer diagnoses and cancer deaths worldwide [3]. With a 2:1 ratio of new diagnoses, men are more likely than women to be affected by RCC, whose incidence rises significantly with age. RCC is a serious health problem since it is often a lethal kidney cancer with an increasing incidence worldwide. Its relevance is also tied to challenges in early diagnosis and the development of aggressive subtypes like those involving tumor thrombus. RCC's etiology is uncertain. The 3 main risk factors for RCC include being overweight, having hypertension, and smoking cigarettes [3]. Medical disorders such as chronic kidney disease, hemodialysis, kidney transplantation, polycystic kidney disease, and renal stones are additional risk factors for RCC. Numerous dietary, occupational, environmental, and lifestyle factors have also been linked to the development of RCC [4]. Even though the majority of RCCs are sporadic, 3% - 5% of all RCC diagnoses occur in patients younger than 46 years, which suggests an underlying RCC form that is inherited [5].

In terms of treatment, surgery is a successful strategy for managing localized RCC, but conventional chemotherapy is ineffective for treating metastatic RCC. Thankfully, during the past 10 years, amazing progress has been made in treating metastatic RCC, resulting in a significant drop in the cancer's death rates despite a continuous rise in the number of individuals receiving a diagnosis. The main factor for the improvement in RCC survival over the past few decades has been the wide diagnostic, prognostic, and predictive methodologies that are currently available [6,7]. Despite these advancements, long-term RCC drug resistance is still a problem [8]. While accelerating RCC cures is critically needed, research on RCC faces various obstacles. Prior to the discovery of the *VHL* gene, kidney cancer was regarded as a single disease [9]. In fact, kidney cancer is a multitude of diverse diseases, each with its own genetic makeup [10]. This has delayed the search for a cure by impeding reproducibility across studies and appropriate interpretation of the research [11].

RCC offers an intricate and challenging research landscape that hinders scientific progress. The goal of this study was to conduct a comprehensive and up-to-date summary of the topic structure, novel research avenues, study trends, and knowledge gaps in RCC research. Conventional bibliometric methods, scientific mappings, and network visualization studies fall short in offering this kind of text analysis [12], since they frequently necessitate manual categorization or extensive, subjective human intervention [13-16]. Instead, we sought a corpus of text-based data for research trends and topics by using a topic algorithm model called latent Dirichlet allocation (LDA) [17]. We intended for RCC research documents "to tell the story themselves" and for topics to emerge on their own, without human intervention, and only based on their statistical characteristics.

Methods

Search Strategy and Data Collection

This study was based on data obtained from PubMed [18] and Scopus [19] as of April 6, 2023. We chose Scopus over other databases because of its superior coverage in the health sciences field, accurate indexing, and "federated search interface" (ie, functionality), which enables us to query the content found across its sources using a common or standardized search form. The authoritative and comprehensive PubMed is the top choice for searching medical and health sciences literature. Medical Subject Headings (MeSH) terms were used for the PubMed search to improve comprehensiveness. Raw data were stored in *TXT* and *CSV* files, respectively. The R "Bibliometrix" tool of the R Statistical software [20] was used to clean data and integrate the 2 databases' unique publications into a combined dataset (with and without assigned DOI) [18,19,21-23]. At this point, duplicate documents with an assigned DOI (1809 in total) were eliminated. The inclusion criteria for the outcome were all the research documents, written in English in peer-reviewed journals, that were published between 1974 (the earliest article we found) and 2023, and that dealt with RCC. Books, book chapters, gray literature, and reports were not included to avoid noise. The search strings, which used a Boolean computation, are indicated in Table 1. Only those articles with the term "renal cell carcinoma" in their title or abstract were selected. The leader and the other authors reviewed the complete list of all possible acceptable publications. Their reliability and value to the field were based on criteria like the journal's impact factor, author affiliations, and citation count.

Bibliometrix Analysis

Our bibliometric review procedure adhered to best practice guidance published elsewhere [24] (Checklist 1). A preliminary descriptive analysis of the retrieved information was carried out using the R package bibliometrix [22]. This open-source application analyzes publication and citation metrics using mathematical and statistical methods to obtain a broad picture of the scientific output that was within the purview of the study. The questions answered were as follows: (Q1) What are the primary research topics in RCC? (Q2) How have RCC research questions changed over time? (Q3) How are these research topics distributed across countries and scientific journals? Three levels of analysis—countries, sources, and authors—were included at this stage to answer the above questions.

The annual growth rate of publications was calculated using the Bibliometrix package in R, which computes the compound annual growth rate (CAGR) using the following equation:

$$(1) CAGR=(Vf/Vi)1n-1,$$

where V_f is the number of publications in the final year of the study period, V_i is the number of publications in the initial year of the study period, and n is the number of years between the initial and final year.

Latent Dirichlet Allocation

The unsupervised machine learning algorithm LDA [17] was applied to identify topics. Considered an extension of the probabilistic latent semantic analysis, it has its roots in Bayesian models [17,25]. Topics in LDA are thought of as multinomial distributions of vocabulary terms, in which each word has a given probability of occurring in a topic. This leads to the prominence of words that are more frequently used in a topic, creating clusters that reflect specific underlying themes. LDA does not require prior knowledge of the topics or the way they are presented in the texts. Rather, topics merely flow from the statistical properties of the data and the model’s underlying assumptions. For thematic analysis, it was decided to use abstracts rather than entire texts because topics are more coherent and ranked higher in large document collections. Inaccurate or noisy terms have less impact on topic word distribution [26].

The LDA model was validated using the Cv metric, which is grounded in the distributional hypothesis stating that words with similar meanings tend to coexist in similar contexts [27]. In other words, Cv rates the semantic similarity of words within a topic (ie, topic interpretability). The Cv score was calculated by looking at word co-occurrence statistics in a reference corpus and their conformity to human-like semantic interpretation. The package textmineR was used for such analysis, which made it easier to determine the ideal number of topics (k) for the study. Because higher scores indicate better interpretability, a model with the highest coherence score among those in the study rank (from k=4 to 50) was selected to reach a balance between granularity and thematic clarity.

Identifying Research Topics

The procedure for identifying topics through LDA was divided into 3 stages: (1) preprocessing, (2) construction of the LDA model, and (3) assigning labels to topics. LDAShiny [28], an open-source R package that uses Bayesian inference for LDA and machine learning algorithms to improve the analytical process, was selected for the first 2 stages.

Preprocessing

Converting all documents into a standardized format for ease of handling was the objective of the stage known as “Text refining” [29]. Initially, textual data consisted solely of character sets. To enhance topic coherence, each abstract underwent tokenization using bigrams, which are consecutive unigram combinations. This process involves converting text to lowercase and removing punctuation marks, dashes, brackets, numbers, spaces, and “stop words.” The list of stop words was extracted from standard libraries such as Natural Language ToolKit and Snowball and was modified to include unrelated terms unique to the medical and technical domains.

The preprocessed data result in the creation of a document-term matrix in which each document is represented as a vector containing an unordered collection of words. If the corpus contains a total of V words, each document becomes a V-dimensional vector, with the value of each element representing the frequency of the corresponding word in the document.

XSL•FO
RenderX

Construction of the LDA Model

LDA assumes that topics are shared by all documents in the collection, while subject proportions vary stochastically between documents, as they are randomly extracted from a Dirichlet distribution [30]. Establishing the expected number of topics was done a priori, making it a nontrivial task to choose the right number of topics (*k*) for a given collection of items. Since the optimal number of topics was unknown beforehand, we generated different models ranging from 4 to 40 topics. We ran 1000 iterations for Gibbs sampling [31] and utilized the default values of the LDAShiny package for Dirichlet parameters α and β. We used Cv as the topic coherence measure of the topics generated by LDA models [32].

Assigning Labels to Topics

The LDA model generates topics without semantic labels. Given that algorithmic analyses are not always able to fully capture the implicit meanings of human language, manual labeling is widely recognized as a normal practice in topic modeling [32]. The manual topic labeling involved a diverse team of 7 experts, including the authors and independent scholars with backgrounds in oncology research and bibliometric analysis. Team members were provided with 2 sources of information: the lists of most frequently occurring words (presumably) provided by the model and a sample of 3 document titles with their corresponding summaries classified by the algorithm. They were asked to independently validate and summarize the identified topics and investigate existing literature to identify research trends, gaps, and influential works. Discrepancies between team members were resolved through remote communications to minimize bias, improve rigor, and ensure the theme structures and semantic interpretation were aligned with the research objective. Reference [32] provides a guide to the procedures used to ensure the trustworthiness of the labels issued, with the difference that we used up to 16 annotators rating candidate labels.

By providing the most relevant and thematically aligned examples within each topic, these articles guaranteed readability and clarity. The 2 articles chosen allowed for a concise and efficient summary of each topic's key ideas without overwhelming the analysis and the reader. This approach strikes a balance between realistic representation and practical interpretability. These articles were then condensed into succinct summaries that encapsulated the essence of each topic. This manual approach not only provided a gold-standard reference [32] but also ensured interpretability and utility in the context of the study.

Quantitative Indices

For each topic, additional characteristics were revealed, especially at the journal and country levels, through statistical description based on the probability distributions of document-topic and topic-word acquired through LDA. To make results and findings more evident, we used certain quantitative indices suggested by Xiong and colleagues [33], which were obtained by adding document-topic and topic-word distributions. The indexes were described as follows.

The distribution of topics over time was obtained by the following equation:

$$(2)\theta ky=\sum m\in y\theta mk/ny,$$

where *m j* represents articles published each year, θ_{mk} is the proportion of the *k*th topic in each item, and n^y is the total number of articles published in the year.

Topic distribution across journals was defined as the ratio of the *k*th topic in the journal *j*: θkj as indicated in the following equation:

$$(3)\theta kj=\sum m\in j\theta mk/nj,$$

where *m j* represents the articles in a particular journal, θ_{mk} is the proportion of the *k*th topic on each item, and n^j is the total number of articles published in the journal *j*.

Topic distribution across countries was defined as the ratio of the *k*th topic in the country *c*, as in the following equation:

$$(4)\theta kc=\sum m\in c\theta mk/nc,$$

where *m c* represents the articles in a particular country, θ_{mk} is the proportion of the *k*th topic on each item, and n^c is the total number of articles published in the country *c*.

Statistics

With the purpose of facilitating the characterization of the topics in terms of their tendency, topic datasets were also submitted to simple regression slopes where the year, country, and journal were the dependent variables, while the proportion of the topics in the corresponding year, country, and journal was the response variable [34]. From the regression slopes, we determined the directionality of these trends and set a significance threshold of $P<.01$ (Eq2). Topics that showed statistically significant positive slopes were identified as having upward trends, while those with statistically significant negative slopes were in decline. Tendencies were finally visualized using the *ggcorrplot* library of R to represent correlation strengths as a heatmap matrix. The color-mapped matrix was subjected to advanced hierarchical clustering analysis in order to investigate and compile correlation datasets, given its visual form like a tree-shaped dendrogram. The *Agnes* function with *Ward's* method showed the agglomerative hierarchical clustering of variables. Each leaf of the dendrogram corresponded to one observation (variable), and the fusion height showed the dissimilarity between 2 observations on the vertical axis. A cut height for cluster identification was calculated using the Average Silhouette method [35].

Results

Overview of the Dataset

The consolidated dataset was obtained by combining the results and removing duplicates, totaling 39,856 articles (Figure 1). After the relevant Excel file was created, 4628 articles lacking titles, abstracts, or affiliations were removed. Within this extensive dataset, 35,228 documents were assembled, demonstrating an annual growth rate of 9.86%. The extensive summary of the key descriptive characteristics pertaining to RCC from 1974 to 2023 can be found in Table 2. A substantial

XSL•FO
RenderX

number of information sources, 3070 in total, were revealed by the data. Given that the document's average age was 11.6 years (the time since the publication of the examined articles), it is likely that much of the research was carried out some time ago. On average, however, each document received 32.35 citations, demonstrating their influence and recognition in the field (Table 2).

With respect to the yearly output of documents on RCC, Figure 2 provides an overview of increased production from 1974 (24 articles) to 2023 (2401 articles). Throughout the 1980s and 1990s, the document production grew modestly. However, the 2000s saw a significant increase in production, reaching a peak in 2017 (1832 articles) and indicating a solid trend in recent

XSL•FO
RenderX

years. Table 3 lists the top 30 scientific journals, while a global map (Figure 3) shows the 118 countries that were involved in RCC research. With 10,308 publications, the United States clearly was the top contributor.

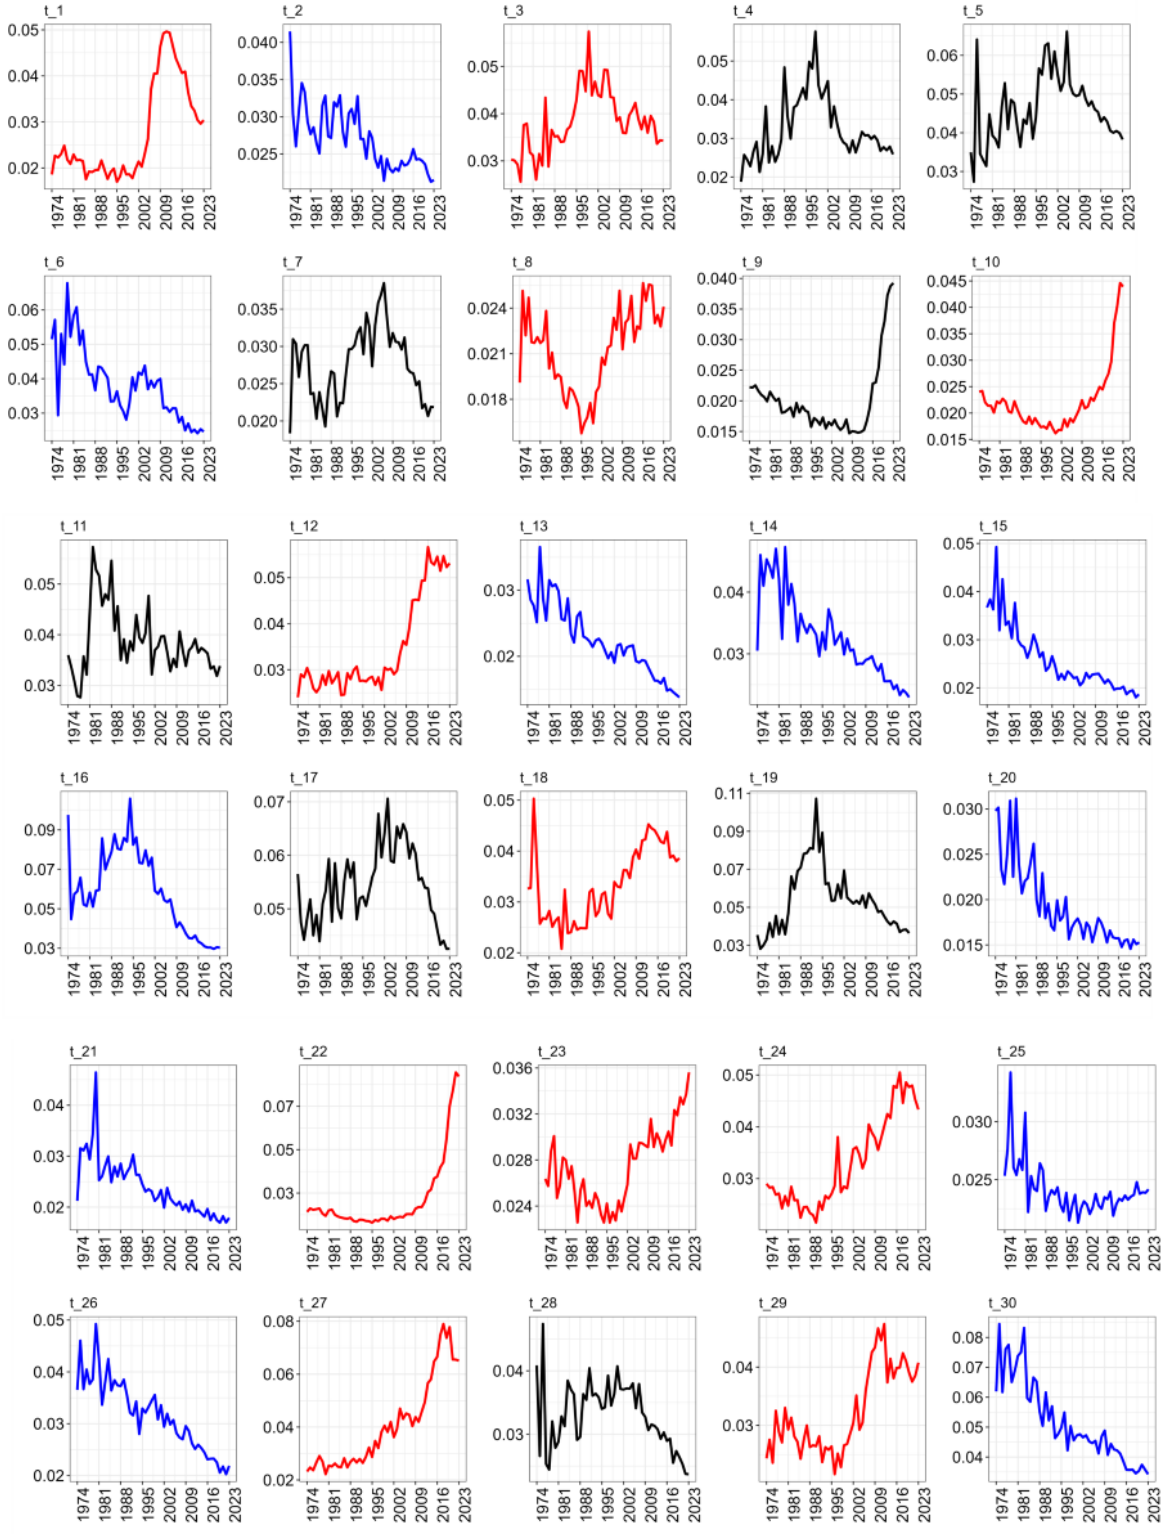
Figure 4. Evaluation of coherence scores for topic models in oncology across different numbers of topics (*k*). Coherence: measures the semantic quality of topics. Higher values indicate stronger word relationships. Topic models: identify thematic patterns in texts; in oncology, they reveal key research areas; *k* represents the number of topics in the model. Helps determine the optimal value for thematic analysis.

The 30 identified topics were in 8 crucial domains of RCC research:



- Treatment and Therapies: This category focused on different approaches to treating RCC, including targeted inhibitors (t_1), local ablation effects (t_8), immunotherapy responses (t_9), and advanced management of metastatic disease (t_29).
- Biomolecular and Genetic Characteristics: Here, the emphasis was on understanding the molecular and genetic makeup of RCC, covering topics like protein expression in tissues and tumors (t_3, t_22, and t_27) and genetic mutations and chromosomal alterations (t_4).
- Disease Characteristics and Progression: This category delved into the histological features and subtypes of RCC (t_5), as well as the dynamics of tumor activity and immune responses (t_16), and survival rates and disease progression (t_12 and t_24) and pathological features (t_28).
- Diagnosis and Evaluation: Topics in this category included diagnostic imaging and radiological evaluation (t_2 and t_11) for RCC detection and the characterization of tumors (t_26 and t_30) for accurate diagnosis.
- Metastasis and Dissemination: Here, the focus was on understanding how RCC spreads, including its involvement with lymph nodes (t_13), lesions in other organs (t_14), and the recurrence of the disease post nephrectomy (t_17).
- Epidemiology and Risk Factors: This category examined the risk prediction models and clinical assessment tools (t_10) used to evaluate RCC risk, as well as the epidemiological factors associated with the disease (t_18).
- Related Conditions: Topics here explored conditions related to RCC, such as urological cancers (t_20), chronic kidney disease, and transplant issues (t_21).
- Pathological Features: Finally, this category encompassed various pathological features of RCC, including surgical approaches and complications (t_6), hypoxia factors and related proteins (t_7), syndromes and clinical manifestations (t_15), toxicity and adverse events in treatments (t_19), molecular advances and therapeutics (t_23), and comparisons with nonrenal cancers (t_25).

Topic Trends

The topic distribution by document θm was added to compute the average probability θky of all the articles published in a particular year to identify the trends (Figure 5). We found that the probabilities of some topics steadily increased over time (red). Black indicates topics with no discernible trend, whereas blue denotes topics with a decreasing behavior.

XSL•FO
RenderX

Figure 5. Trends of research topics in renal cell carcinoma between 1973 and 2023: increasing (red), decreasing (blue), and stable (black) topic dynamics over time.

Heatmaps

Although the discovery of 30 unique themes with high coherence scores, a granular and nuanced analysis of the research landscape, was made possible by the LDA method, there was a need for validating the theme output by a form of visual data analytics. Heatmaps helped examine and understand how thematic patterns were related to variables like publication year, country, and journal. Red highlighting indicates the strongest associations among variables, reflecting higher correlation levels.

Figure 6A illustrates correlations between specific topics and years. Red highlighting indicates the strongest associations among variables, reflecting higher correlation levels. For example, within Cluster 4, Topic 16 (t_16) “Tumor Activity and Immune Responses” is primarily associated with the years

XSL•FO
RenderX

1993, 1985, 1988, 1990, 1992, 1991, 1989, 1995, 1994, 1996, and 1999. Topic 17 (t_17) "Nephrectomy and Recurrence" exhibits stronger correlations with the years 1993, 1990, 1992, 1991, 1989, 1995, and 1994. In Cluster 3, Topic 22 (t_22) "Gene Expression and Prognosis" significantly correlates with the years 2020, 2021, 2022, and 2023, while Topic 27 (t_27), also addressing "Gene Regulation and microRNA Expression," shows significant associations with the years 2017, 2018, 2019, and 2020. Finally, in group 3, Topic Thirty30 (t_30) "Clinical Presentation and Diagnosis of Rare Cases" is linked with the years 1982, 1983, 1981, 1978, 1977, and 1975.

Figure 6. Heatmaps to correlate topics with year (A), country (B), and source (C).

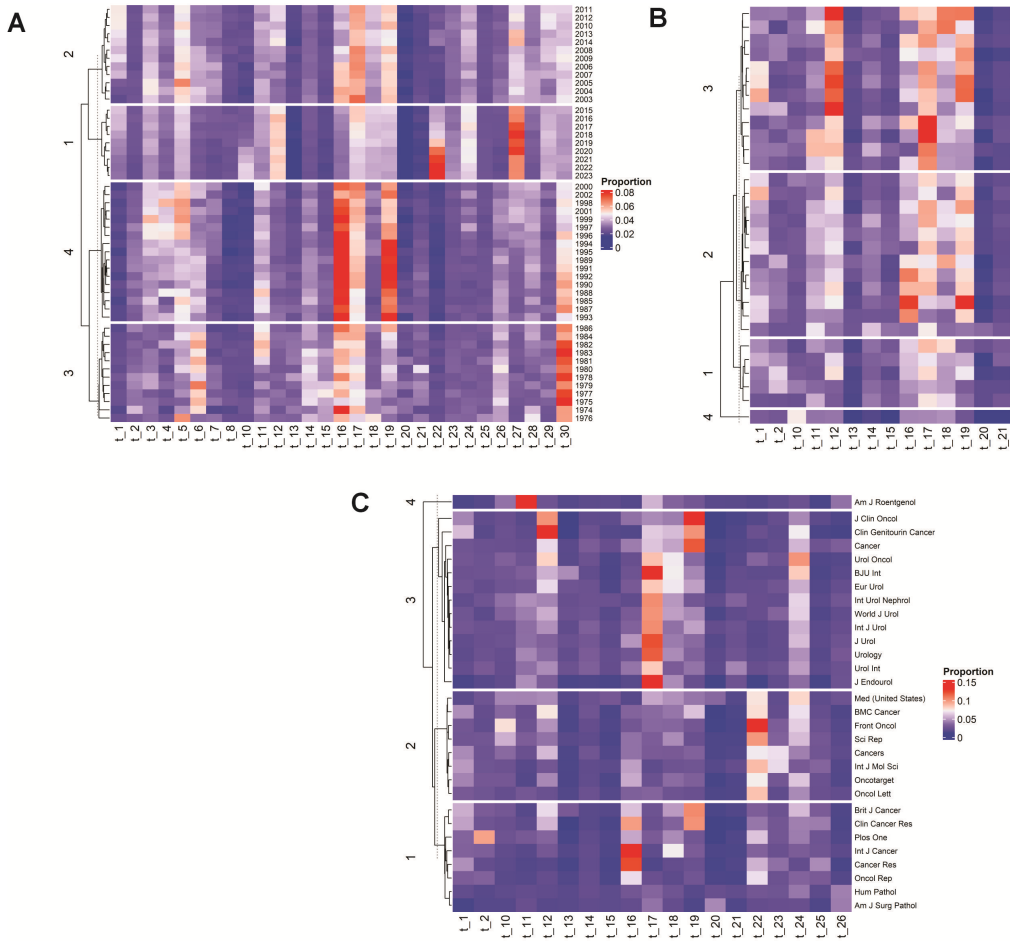


Figure 6B presents the interactions between countries and topics across different groups. In group 1, Topic 27 (t_27), "Gene Regulation and microRNA Expression," is predominantly correlated with Taiwan. Group 2's topics, "Tumor Activity and Immune Responses" and "Toxicity and Adverse Events in Treatments," are closely associated with the Netherlands. For group 3, "Survival and Disease Progression" shows significant correlations with the Czech Republic, Denmark, Belgium, France, and Italy, and "Nephrectomy and Recurrence" is notably linked with Israel and South Korea. Lastly, in group 4, "Gene Expression and Prognosis" and "Gene Regulation and microRNA Expression" are primarily connected with China.

Figure 6C outlines the dominant publication patterns for specific topics within various journals. In group 1, "Tumor Activity and Immune Responses" is predominantly linked with the *International Journal of Cancer* and *Cancer Research*. Group 2's topic, "Gene Expression and Prognosis," has a significant association with *Frontiers in Oncology*. In group 3, "Survival and Disease Progression" relates to *Clinical Genitourinary Cancer*, and "Nephrectomy and Recurrence" is associated with *BJU International*, *Journal of Endourology*, and *Urology*. Lastly, in group 4, "Diagnostic Imaging and Radiological Evaluation" is prominently linked to the *American Journal of Roentgenology*. LDA algorithm's identification of the key RCC research themes was mirrored in the relevant clustergrams that emerged from the hierarchical cluster analysis of the heatmaps.

Discussion

Principal Findings

By displaying each topic as a group of related words, LDA was able to identify latent (hidden) topics within a corpus of documents and demonstrate how each document may be represented as a combination of these topics. According to this method, RCC research has evolved over the past 50 years from concentrating on surgery to comprehending its genetic underpinnings and the impact of new treatments like immune checkpoint inhibitors and targeted therapies, which have improved the prognosis of metastatic RCC.

The disease characterization, progression, and pathological features have dominated the RCC research landscape for the past 50 years (t_16 and t_19) [10]. Kidney cancer was regarded

XSL•FO
RenderX

as a single disease until the *VHL* gene was discovered [9]. Since then, scientists have realized that kidney cancer is a multitude of diverse diseases, each with its own genetic makeup. Although the characterization of genetic mutations and chromosomal alterations linked to the growth of RCC [36,37] has recently improved our knowledge of this kidney cancer (t_22), RCC research does emphasize the necessity of assessment of treatment effects' safety and efficacy, as well as surveillance of RCC recurrence following nephrectomy. Therefore, a better understanding of resistance mechanisms, molecular prognosis (t_22), and immunological responses (t_16) is essential.

The advances in omics technologies over the last 10 years constitute a promising area of personalized RCC cure [1,38,39]. In addition, the microRNA signature in RCC and its function in progression, diagnosis, therapy targeting, and prognosis of RCC (t_27) have also received particular attention [40,41]. Recent RCC research also moves toward earlier cancer detection through broad imaging and radiological evolution (t-11). RCC has a difficult pathological classification, since the histological analysis reveals three most recurrent sporadic types: clear-cell RCC (70% - 75%), papillary RCC (10% - 15%), and chromophobe RCC (5%) [42]. It is predicated on morphologies, architecture, underlying genetic abnormalities, and tumoral protein expression [43,44]. Pathologists can detect these malignancies more accurately and provide better treatment plans and patient outcomes if they are aware of the significance of these markers (t_12 and t_19).

A major cause for worry is the postoperative surveillance of RCC recurrence following nephrectomy (t_17) [45]. Research on local RCC ablation and assessment of treatment effects on safety and efficacy is still ongoing (t_12, t_16, and t_19). The discovery of tailored medication like tyrosine kinase inhibitors (also called TKIs), such as Sunitinib and Sorafenib, has been beneficial in treating metastatic RCC [46,47]. Another well-established component of RCC treatment is checkpoint inhibitor immunotherapy [48], which shows its superior therapeutic efficacy when combined with TKIs [49]. The next generation of TKIs and immunotherapy (t_16) [50] is being developed to overcome some unfavorable outcomes with kinase inhibitors [51,52] and immunotherapy (t_19) [53], as well as the emergence of drug resistance [54]. Only a small number of themes still earn little attention. The topics "Serum Levels and Patient Control" (t_2), "Hypoxia Factors and Related Proteins" (t_7), and "Risk Prediction Models and Clinical Assessment" (t_18) are overlooked and should require additional attention.

In line with the LDA analysis and our own scientific expectations and goals, it was also feasible to identify untapped topics that have not yet been covered by scholarly literature. Intriguing lines of inquiry are the prognostic value of vascular endothelial growth factor [55], endostatin [56], C-reactive protein [57], the hypoxia-induced pathway [58], and ferroptosis [59]. The involvement of chronic inflammation [60] and gut and urinary microbiota in immune modulation of metastatic RCC [61] remains poorly investigated. Clinical judgments and patient stratification in RCC may be enhanced by the creation of new predictive models [62] based on, for instance, genetic biomarkers [63]. The application of artificial intelligence is another potential topic that could help physicians in identifying RCC subtypes by analyzing computed tomography scans, as well as in deconstructing complex epidemiological and environmental factors that influence RCC occurrence, like hypoxia [64].

In contrast to traditional bibliometric analysis, the LDA approach effectively extracted potential themes and inferred implicit information from a large collection of documents. The LDA approach and other topic modeling methods like co-citation and keyword co-occurrence cannot be compared with the same conceptual granularity or depth. LDA goes beyond who cites whom (ie, intellectual connection and research lineage) and uncovers the underlying conceptual themes that bind the literature, which may not be immediately apparent from citation patterns alone. Unlike a list of keywords, which reveals basic relationships, LDA organizes these co-occurring words into meaningful higher-order themes, offering a more detailed knowledge of topic relationships and structure. For this reason, the LDA analysis was not affected by the potential simplicity of the keywords chosen in the study.

The subjectivity involved in manually labeling LDA topics, the possibility of missing publications by using only 2 databases, the linguistic bias introduced by excluding articles written in languages other than English, the constraints of the "bag-of-words" model which disregards grammar and context, and the effects of excluding literature like book chapters are some limitations of the study. Despite the constraints, LDA can disclose "unknown unknowns" by revealing unarticulated or unacknowledged themes. It can also give an overview of the research landscape to identify new topics and interdisciplinary connections, as well as demonstrate how old themes are resurfacing in new ones. As a result, LDA remains the most often used natural language model [13,14,65].

Conclusions

This review offered a thorough summary of how research on RCC has changed over the previous 50 years. LDA helped identify important emerging trends in treatment development to address drug resistance and undesirable side effects, surgical techniques, and immunotherapy advancements, among other topics pertinent to clinical practice and medical research. In summary, this study presents a methodological synthesis of the development of RCC research and delivers pertinent data for clinical decision-making, early identification, and the planning of new biomedical research.

Abstract

Background: Bone metastasis is a prevalent complication of malignant tumors, often resulting in restricted mobility, severe pain, and diminished quality of life.

Objective: This study aimed to assess the analgesic effect and safety of a co-ablation system that combines elements of hyperthermic ablation and cryoablation in patients with bone metastases.

Methods: This retrospective study included patients with histologically confirmed painful bone metastases treated with the co-ablation system between January and October 2024. Pain intensity was assessed using the numerical rating scale (NRS), and functional status was evaluated using the Karnofsky Performance Status score at baseline and during a 12-week follow-up. Technical success, adverse events, analgesic use, and pain response (defined as a ≥2-point reduction in NRS) were analyzed.

Results: Nine patients were included. Technical success was achieved in all procedures, with no procedure-related adverse events observed. Median NRS scores decreased progressively from 5 (IQR 4-6) at baseline to 2 (IQR 1-3) at 12 weeks. By the fourth week, 8 (88.9%) patients achieved a clinically meaningful pain reduction. Karnofsky Performance Status scores showed gradual improvement during follow-up. No patients required escalation of analgesic therapy, and some experienced dose reductions.

Conclusions: The co-ablation system appeared to be feasible and was associated with short-term pain reduction in patients with bone metastases, with no ablation-related adverse events observed.

Introduction

Bone metastasis is a prevalent complication of malignant tumors, often resulting in restricted mobility, severe pain, and diminished quality of life [1]. Pain represents the most frequent symptom of bone metastasis [2]. Inadequate pain management is particularly prevalent among patients with bone metastases; approximately 80% of cancer-related pain originates from bone metastases, and as many as 25% of patients report insufficient symptom control [3]. In addition, chronic pain can cause depression and anxiety [4,5]. Currently, numerous treatment options exist for managing pain associated with bone metastases, including systemic therapies (chemotherapy, hormonal therapy, radiopharmaceuticals, and bisphosphonates), various analgesics, local interventions (radiotherapy, laser-induced interstitial thermotherapy, and ablation therapy), and surgical approaches [6-8].

Currently, the most prevalent form of local ablation used in analgesic treatment includes techniques such as radiofrequency ablation, cryoablation, and microwave ablation. These methods have been extensively validated for their safety and analgesic effect [9,10]. However, each modality has inherent limitations. Hyperthermic ablation techniques (radiofrequency ablation and microwave ablation) may be constrained by heat-sink effects

XSL•FO
RenderX

and carry a risk of thermal injury to adjacent structures [11,12], whereas cryoablation, although allowing improved visualization of the ice ball, does not permit needle tract ablation.

Chinese scientists have developed a co-ablation system that combines elements of hyperthermic ablation and cryoablation, using liquid nitrogen and alcohol as thermal media. The system is capable of achieving temperatures as low as −196 °C in freezing mode and up to approximately 80 °C in heating mode. The system operates by sequential application of freezing and heating, delivering extreme temperature changes to the target tissue. This design is intended to provide controlled thermal injury through alternating cold and heat exposure. Previous studies have demonstrated its effectiveness in cancer treatment [13,14].

However, there is currently limited literature documenting the use of a co-ablation system for the analgesic treatment of bone metastases. To address this knowledge gap, we conducted a retrospective exploratory study to assess the effectiveness and safety of the co-ablation system in managing pain associated with bone metastases.

Methods

Ethical Considerations

This was a retrospective study approved by the ethics committee of Henan Cancer Hospital (2025-KY-0026). Informed consent was waived by the ethics committee. All patients signed the procedural informed consent form and the general informed consent for anonymous use of their information in research before receiving treatment. During statistical analysis, all patient information was anonymized. Therefore, this study does not involve informed consent, privacy, or compensation.

Participants

From January to October 2024, we retrospectively analyzed patients with histologically confirmed bone metastases treated with the co-ablation system.

The exclusion criteria included the following: (1) survival time less than 3 months, (2) lack of a definitive pathological diagnosis, (3) the ablation site was not a bone metastasis, (4) absence of pain before ablation, and (5) loss to follow-up.

Procedure

According to the tumor size, appropriate co-ablation needles (RBL20, RCS17, and RAL26; Hygea Medical Technology Co) were selected preoperatively, and their functionality was verified using normal saline. Patients were positioned in a supine, prone, or lateral position on the computed tomography (CT) examination bed (GE Large Aperture CT; GE Healthcare Bio-Sciences Corp). A conventional CT scan was initially performed to identify the optimal puncture pathway, which was then marked and subsequently sterilized. Under local anesthesia, the bone metastatic lesion was gradually punctured, and the correct positioning was confirmed before connecting the co-ablation system (Hygea Medical Technology Co) for ablation treatment. Relevant parameters, including freezing time and rewarming time, were adjusted according to the extent of the tumor. Immediate postablation CT imaging was performed to evaluate technical adequacy. The assessment included confirmation of complete coverage of the target lesion by the ablation zone; appropriate extension beyond the lesion margins when feasible; and the absence of procedure-related adverse events (AEs), such as hemorrhage, pathological fracture, or injury to adjacent critical structures.

Data Collection and Follow-Up

Patient pain was assessed using a numerical rating scale (NRS) [15], and the Karnofsky Performance Status (KPS) score was used to evaluate patients' physical condition. NRS scores were recorded before the procedure and at 1 day, 1 week, 4 weeks, 8 weeks, and 12 weeks after the procedure. Pain assessment primarily targeted pain related to the treated bone metastatic lesion. Patients were instructed to focus on pain originating from the target lesion identified for the co-ablation system. KPS scores were recorded before the procedure and 1, 4, 8, and 12 weeks after the procedure. For patients outside the hospital, follow-up assessments were conducted via telephone interviews.

Age, gender, primary tumor type, location and number of bone metastases, administration of bone-modifying agents, use of analgesic drugs, dose adjustments, procedure-related AEs, and other concomitant treatments were reviewed through the electronic medical record system. All procedure-related AEs were recorded and classified according to the Society of Interventional Radiology AE classification system [16]. AEs were graded as mild, moderate, severe, life-threatening, or fatal based on clinical severity, imaging findings, and the requirement for medical intervention or prolonged hospitalization. Technical success and pain response were assessed for each procedure.

Technical success was defined as successful placement of the needle into the target lesion and completion of the planned protocol without technical failure or premature termination. Clinical success was predefined as a clinically meaningful pain reduction, defined as a decrease of ≥2 points in the NRS score compared with baseline [17]. Patients meeting this criterion at a given follow-up time point were classified as responders, and the corresponding proportion was reported as the responder rate.

Statistical Analysis

Statistical analyses were performed using GraphPad Prism software (version 9.5; GraphPad Software). Continuous and ordinal variables were presented as median and IQR. Changes in NRS and KPS scores across multiple time points were analyzed using the Friedman test. When the Friedman test indicated a statistically significant difference, post hoc comparisons between baseline and follow-up time points were performed using Dunn multiple comparisons test with adjustment for multiple testing. All tests were 2-sided, and an adjusted $P<.05$ was considered statistically significant.

Results

Participant Characteristics

From January 2024 to October 2024, a total of 16 patients with bone metastases were treated with the co-ablation system, among whom 2 died within 3 months after treatment, 4 had primary

XSL•FO
RenderX

lesions, and 1 was excluded due to loss of follow-up data. Finally, 9 patients were included in the analysis (Figure 1), including 6 male patients and 3 female patients, with a median age of 60 (IQR 55-69) years. Primary malignancies included hepatocellular carcinoma (n=4, 44%), lung adenocarcinoma (n=4, 44%), and colon adenocarcinoma (n=1, 11%). All patients had a single bone metastasis lesion. Metastatic involvement was primarily located in the femur (n=3, 33%), ilium (n=4, 44%), and ribs (n=2, 22%). Treatment regimens varied among patients: 1 (11%) patient received denosumab injections, 5 (56%) patients were treated with zoledronic acid, and 3 (33%) patients received ibandronate. All patients continued to undergo systemic antitumor therapy (Table 1).

Figure 1. Flow diagram of patient enrollment and study inclusion. A total of 16 patients with bone metastases underwent treatment using the co-ablation system. Of these, 2 patients died within 3 months after ablation, 4 patients received ablation for primary lesions, and 1 patient had incomplete clinical data. The remaining 9 patients met the inclusion criteria and were included in the final analysis.

Pain Intensity Outcomes

Pain intensity assessed using the NRS showed a significant change over time (P<.001). An overall comparison using the Friedman test demonstrated a statistically significant difference in NRS scores across all assessed time points (baseline, 1 day, 1 week, 4 weeks, 8 weeks, and 12 weeks after treatment; P<.001).

Median NRS scores decreased from 5 (IQR 4-6) at baseline to 4 (IQR 3-5) at 1 day and 3 (IQR 2-4) at 1 week after treatment. Further reductions were observed at 4 weeks (median 2, IQR 2-3) and 8 weeks (median 2, IQR 1-2), with improvement maintained at 12 weeks (median 2, IQR 1-3; Table 2).

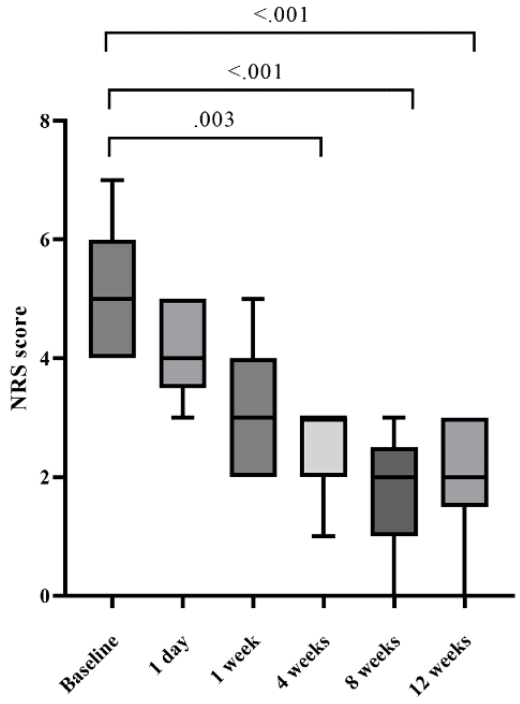

Table 2. Changes in the numerical rating scale and Karnofsky Performance Status scores over time.

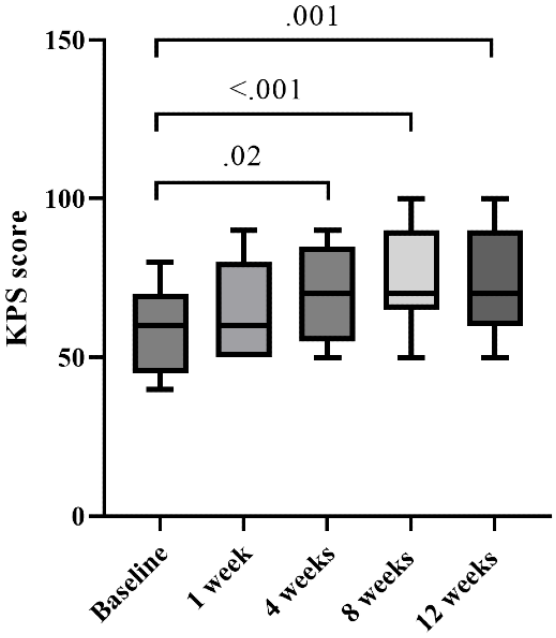
Time point	Numerical rating scale, median (IQR)	Karnofsky Performance Status, median (IQR)
Baseline	5 (4-6)	60 (50-70)
1 day after treatment	4 (4-5)	—[a]
1 week after treatment	3 (2-4)	60 (50-80)
4 weeks after treatment	3 (2-3)	70 (60-80)
8 weeks after treatment	2 (1-2)	70 (70-90)
12 weeks after treatment	2 (2-3)	70 (60-90)

[a]Not available.

Compared with baseline, NRS scores were significantly lower at 1 week (adjusted P=.003), 8 weeks (adjusted P<.001), and 12 weeks (adjusted P<.001; Figure 2). By week 4, among the 9 patients, a clinically meaningful pain reduction (≥2-point decrease in NRS) was observed in 8.

Figure 2. Changes in pain intensity (numerical rating scale [NRS] scores) over time after the procedure. Box-and-whisker plots show NRS scores at baseline and at 1 day, 1 week, 4 weeks, 8 weeks, and 12 weeks after treatment. Data are presented as median, IQR (box), and range (whiskers). Overall differences across time points were assessed using the Friedman test. Post hoc comparisons between baseline and follow-up time points were performed using the Dunn multiple comparisons test with adjustment for multiple testing. Adjusted P values for statistically significant comparisons are shown.

Functional Status Outcomes



Functional performance, as measured by the KPS score, improved over the course of follow-up. A significant difference in KPS scores was observed across baseline and subsequent assessment time points (P<.001).

At baseline, patients demonstrated limited functional status, with a median KPS score of 60 (IQR 50-70). An increase in KPS was observed at 1 week after treatment (median 60, IQR 50-80); however, this early change was not statistically significant (adjusted P=.54). In contrast, KPS scores showed significant improvement at later follow-up visits, reaching a median of 70 (IQR 60-80) at 4 weeks and 70 (IQR 70-90) at 8 weeks, with these improvements maintained through 12 weeks (median 70, IQR 60-90; Table 2).

XSL•FO
RenderX

Compared with baseline, KPS scores were significantly higher at 4 weeks (adjusted *P*=.02), 8 weeks (adjusted *P*<.001), and 12 weeks (adjusted *P*=.001; Figure 3).

Figure 3. Changes in functional status (Karnofsky Performance Status [KPS] scores) during follow-up. Box-and-whisker plots illustrate KPS scores at baseline and at 1, 4, 8, and 12 weeks after co-ablation. Values are expressed as median, IQR (box), and range (whiskers). Longitudinal changes were analyzed using the Friedman test, followed by the Dunn post hoc test with correction for multiple comparisons. Adjusted *P* values for significant differences compared with baseline are indicated.

AEs and Analgesic Dosage

All patients underwent successful treatment with the co-ablation system, achieving a technical success rate of 100% without any procedure-related AEs. At the 12-week follow-up, no patients switched analgesic agents, 3 patients experienced a 25% reduction in their analgesic dosage, 1 patient experienced a 50% reduction, and no patients required an increase in medication dosage.

Discussion

In this retrospective single-arm exploratory study, the use of the co-ablation system was feasible and well tolerated in patients with bone metastases, with no procedure-related AEs observed. A reduction in pain intensity was noted over the follow-up period, with NRS scores showing a statistically significant overall decrease and most patients achieving a clinically meaningful pain reduction by week 4. Improvements in functional status, as reflected by KPS scores, were observed at later follow-up time points; however, these findings should be interpreted cautiously given the small sample size and study design. No patients required escalation of analgesic therapy during follow-up, and some were able to reduce their baseline analgesic doses. Collectively, these preliminary findings support the technical feasibility and short-term safety of the co-ablation system for palliative pain management in bone metastases.

Several studies have reported favorable pain control outcomes following ablation for bone metastases. Ma et al [18] evaluated microwave ablation, radiofrequency ablation, and cryoablation in patients with bone metastases from non-small cell lung cancer and observed a substantial reduction in pain scores at 4 weeks after treatment. Consistent with these findings, our study demonstrated a marked decrease in NRS scores over time, with median pain scores declining from baseline to 4 weeks after the procedure and most patients achieving a clinically meaningful pain reduction. Although an early reduction in pain was observed as soon as 1 day after treatment in our cohort, this change did not reach statistical significance, which may be related to the small sample size. In contrast, Yang et al [19] reported significant pain relief within 1 day following cryoablation; however, pain was assessed using a visual analog scale rather than NRS, which may limit direct comparability. Additionally, Tomasian et al [20] reported sustained pain relief at 3 months after ablation for painful vertebral metastases, a finding that aligns with the maintained reduction in NRS scores observed through 12 weeks in our study. Taken together, these observations suggest that the co-ablation system may offer pain control outcomes comparable to established ablation modalities, although direct comparisons should be interpreted cautiously.

High-intensity focused ultrasound is a noninvasive image-guided ablation technique that has demonstrated a favorable safety profile and promising analgesic effects in patients with painful bone metastases [21]. Previous prospective studies have shown that magnetic resonance–guided high-intensity focused ultrasound (MR-HIFU) can achieve rapid and clinically meaningful pain reduction without treatment-related AEs [22,23]. Bongiovanni et al [22] reported complete or partial pain responses in all treated patients at 30 days, whereas Napoli et al [23] observed significant improvements in pain severity and interference, with additional evidence of local tumor response in some cases. Although MR-HIFU differs from the co-ablation system evaluated in this study in terms of

XSL•FO
RenderX

invasiveness and ablation mechanism, both approaches support the role of targeted local ablation in pain palliation. In our cohort, short-term pain relief without ablation-related AEs was observed, which is consistent with the analgesic and safety trends reported for MR-HIFU.

Previous studies have shown that multimodality approaches combining local ablation with radiotherapy, vertebroplasty, or iodine-125 seed implantation can improve pain control in patients with bone metastases [24-26]. These findings suggest that co-ablation could potentially be incorporated into multimodal palliative strategies in future practice and investigation. In our study, we also observed that the dosage of analgesic drugs was significantly reduced in some patients following the procedure. This finding is consistent with previous reports indicating a reduction in analgesic requirements after cryoablation [19,20,24,27].

Following treatment with the co-ablation system, patients demonstrated a gradual improvement in functional status, as reflected by increasing KPS scores over the follow-up period. Although no statistically significant improvement was observed at 1 week after treatment, KPS scores improved significantly from 4 weeks onward and remained stable through 12 weeks. These findings are in line with the MOTION (Multicenter Study of Cryoablation for Palliation of Painful Bone Metastases) study, which reported that cryoablation provided rapid pain relief while functional status was maintained and quality of life improved during follow-up [28].

This study is limited by its small sample size and retrospective, single-arm design; these factors reduce statistical power, limit generalizability, and preclude adjustment for pain-related confounders. Patient heterogeneity in primary tumors and metastatic sites, as well as the absence of a comparative control group, prevents assessment of relative efficacy vs established ablation modalities. The 12-week follow-up period was sufficient for short-term pain assessment but inadequate for evaluating the durability of response, pain recurrence, or delayed AEs. Pain from untreated disease sites may have influenced NRS and KPS scores, and the use of KPS without patient-reported outcome measures provides limited insight into overall quality of life.

In this small retrospective exploratory study, the co-ablation system was technically feasible and well tolerated in patients with painful bone metastases. Pain reduction was observed during short-term follow-up, and functional performance was maintained or gradually improved, with no procedure-related AEs recorded. These preliminary findings support further evaluation of the co-ablation system in larger, prospective controlled studies.

Funding

This research was funded by the National Key Research and Development Program of China (grants 2023YFC2414006 and 2023YFC2414002; June 2023-June 2026), the Henan Province Outstanding Foreign Expert Workstation Project (grant GZS2022020; January 2023-December 2025), the Foreign Expert Project of the Ministry of Science and Technology of China (grant G2023026016L; January 2023-December 2024), the Medical Education Research Project of Henan Province (grant Wjlx2021334; January 2022-December 2024), and the General Project of the Natural Science Foundation of Henan Province (grant 212300410403; January 2023-December 2024).

Abstract

Background: Lung cancer remains a major contributor to cancer mortality in sub-Saharan Africa (SSA), where late diagnosis, driven by low awareness, sociocultural barriers, and health system constraints, limits effective treatment. Despite the growing burden, evidence on patients' quality of life (QoL) and symptom experience in SSA is limited.

Objective: This study aimed to describe the common symptoms and QoL of patients with lung cancer treated at 2 hospitals in SSA, and to investigate the association of demographics, clinical characteristics, and symptom burden with QoL.

Methods: This was a cross-sectional study that consecutively recruited patients with lung cancer from 2 teaching hospitals in SSA: Bugando Medical Centre (BMC) in Tanzania and the University of the Witwatersrand Centre of Respiratory Excellence (WITS-CORE) in South Africa. Data collected included demographics, clinical information, and performance status using the Eastern Cooperative Oncological Group Performance Scale (ECOG-PS). Health-related QoL was assessed using the 30-item European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC QLQ-C30). The study followed all ethical procedures, and data were analyzed using both descriptive and inferential statistics in Stata 18. A *P* value of <.05 was considered statistically significant.

Results: A total of 174 patients with lung cancer were enrolled across the 2 sites. The score on the EORTC QLQ-C30 global health status/QoL subscale was low, with a median of 41.67 (IQR 33.33-41.67), and it varied by site. Patients from WITS-CORE demonstrated higher social functioning scores, while those from BMC reported greater financial difficulties. A low global health status/QoL score was independently associated with the BMC site (adjusted odds ratio [aOR] 3.5, 95% CI 1.3-9.3) and poor performance status (ECOG-PS 3-4; aOR 3.4, 95% CI 1.2-6.6). Furthermore, symptoms such as nausea and vomiting, pain, dyspnea, insomnia, appetite loss, diarrhea, and financial struggles were all associated with a low global health status/QoL score.

XSL•FO
RenderX

Conclusions: QoL among patients with lung cancer in SSA is poor. Low QoL is strongly associated with the Multinational Lung Cancer Control Program study site, poor performance status, and a range of symptoms and financial difficulties. Addressing these factors may help to improve patient outcomes and well-being in SSA.

KEYWORDS

cancer; lung; quality of life; QoL; symptoms

Introduction

GLOBOCAN estimates indicated that more than 19 million new cancer cases occurred worldwide in 2022, with lung cancer accounting for 12.4%, making it the most diagnosed cancer [1]. Although the incidence of lung cancer in Africa is lower than in high-income countries, it remains among the top 5 cancers in both sexes, and it is the fourth leading cause of cancer-related mortality, with southern Africa bearing the highest burden on the continent [1]. In sub-Saharan Africa (SSA), most patients present at advanced stages, partly due to limited community awareness, alongside the influence of sociocultural factors, health system constraints, and gaps in health care provider knowledge [2-5]. These challenges contribute to delayed diagnosis, limited treatment options, and consequently high mortality rates [6].

Lung cancer is associated with a substantial symptom burden, including fatigue, dyspnea, cough, pain, appetite loss, and hemoptysis. However, in SSA, late presentation often results in more severe complications, such as brain metastases, pleural effusion, spinal cord compression, and superior vena cava obstruction syndrome [7,8]. As a result, treatment is frequently limited to palliative approaches, including chemotherapy and radiotherapy, aimed primarily at improving quality of life (QoL).

QoL is a critical outcome in cancer care, particularly for patients with advanced disease [9-11]. Lung cancer significantly compromises physical, emotional, social, and spiritual well-being, with strong evidence linking QoL to symptom burden, clinical characteristics, and sociodemographic factors [12,13]. Importantly, better QoL is associated with improved health outcomes and survival [9,14]. Interventions such as chemotherapy, targeted therapy, immunotherapy, radiotherapy, and palliative care have demonstrated benefits in symptom control, functional status, and overall well-being [10,15]. However, most evidence on symptom burden and QoL originates from high-income settings, with limited data from SSA.

This study aimed to describe the common symptoms and QoL of patients with lung cancer receiving care at 2 tertiary institutions in SSA: the University of the Witwatersrand (WITS) Centre for Respiratory Excellence (CORE) in South Africa and Bugando Medical Centre (BMC) in Tanzania. The study also examined the association between sociodemographic and clinical characteristics, symptom burden, and QoL. We hypothesized that patients with lung cancer in SSA would experience a high symptom burden and poor QoL, with significant associations between these outcomes and patient-related factors.

Methods

Ethical Considerations

This study was conducted in accordance with the ethical principles outlined in the Declaration of Helsinki, including respect for individuals, their right to make informed decisions, and the protection of their health and rights. Ethics approval was obtained from the Human Research Ethics Committee (Medical), WITS (M180436). In Tanzania, the ethics approval was obtained from the Joint Catholic University of Health and Allied Sciences and BMC Research Ethics and Review Committee (CREC/278/2018) and the National Institute for Medical Research (MR/53/100/598). Informed consent was obtained from all participants before participating in this study. Participants' privacy and confidentiality were strictly maintained throughout the study by anonymizing data and securely handling all research information.

Setting

The study was conducted at 2 teaching hospitals participating in the Multinational Lung Cancer Control Program (MLCCP) in 2 SSA countries: Tanzania and South Africa. WITS-CORE is a specialized respiratory unit providing comprehensive lung cancer services to patients in Johannesburg, South Africa. It is based at Helen Joseph Hospital, a teaching hospital affiliated with the WITS. BMC is a consultant-teaching and referral hospital for the Lake and Western zone of the United Republic of Tanzania affiliated with the Catholic University of Health and Allied Sciences in Mwanza, Tanzania. The hospital's Oncology department is the only cancer center in the Lake and Western zone of United Republic of Tanzania that provides comprehensive cancer care with outreach services to urban and rural areas.

Design and Participants

This cross-sectional study consecutively recruited patients with lung cancer from 2 teaching hospitals in SSA. The inclusion criteria were patients aged 18 years or older, a confirmed primary lung cancer diagnosis, and being physically and mentally able to participate in the study. A similar protocol was applied across the study sites; once the diagnosis was confirmed and before treatment began, patients were invited to participate in the study. Those who consented were enrolled, and sociodemographic and clinical information were collected. Thereafter, the questionnaire was administered in English (WITS-CORE) or Swahili (BMC) and, where needed, translated into the vernacular. Data collection was conducted for 1 year, from August 2020 to August 2021.

XSL•FO
RenderX

Study Measures

Trained nurses and interviewers conducted interviews following the standardized protocol to obtain demographic information (age, gender, marital status, education level, employment status, smoking, and mining history) and clinical information (histology, clinical staging, Eastern Cooperative Oncological Group Performance Scale [ECOG-PS], weight loss, active or current tuberculosis, and other comorbidities). The ECOG-PS was used to determine the performance status of patients [16].

QoL, functional status, symptom burden, and financial impact were assessed using the 30-item European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC QLQ-C30) [17]. The EORTC QLQ-C30 is composed of 3 multi-item or single-item subscales: the global health status/QoL scale, 5 functional scales (physical, role, social, emotional, and cognitive functioning), 8 symptom scales (fatigue, pain, nausea and vomiting, dyspnea, insomnia, appetite loss, constipation, and diarrhea), and a financial impact scale. Each item has four possible response alternatives: (1) “not at all,” (2) “a little,” (3) “quite a bit,” and (4) “very much.” The responses to the scale items refer to “last week,” with the exception of the patient’s physical performance scale, where the timeframe is the present. The scores of each scale were calculated in accordance with the EORTC QLQ-C 30 scoring manual [11]. The sum of items in each category was added, and the total was divided by the number of questions in the category. A linear transformation was then undertaken to convert the score to a percentage scale. All the scales and single-item measures range from 0 to 100. Higher scores on the functional and QoL scales translated to better health-related QoL, whereas higher scores on the symptom scales translated to a higher level of symptoms or problems.

Data Analysis

Study data were collected and managed using REDCap tools hosted at WITS. Patients’ demographics, clinical characteristics, and health-related QoL information were extracted from the REDCap database and exported to Stata (version 18; StataCorp) for statistical analysis [18,19]. Categorical variables were presented as frequency tables, and continuous variables were presented as descriptive measures, expressed as medians and interquartile ranges (IQRs). The nonparametric Wilcoxon rank-sum test was used to compare the QoL scores between study sites. Univariate and multivariate binary logistic regression analysis were performed to evaluate the association between QoL and sociodemographic factors, clinical characteristics, and symptom burden. Consistent with previous studies, QoL was dichotomized using the median (50th percentile) as the cut-off point: a score greater than or equal to 50 was defined as “above-average QoL,” while a score less than 50 was defined as “below-average QoL” [20]. Odds ratios (ORs) were used to test the association between variables, and 95% CI that did not span unity were considered as thresholds of statistical significance. Adjusted ORs (aORs) were used in multivariate analysis.

Results

Sociodemographic Characteristics

A total of 174 patients with lung cancer consented and were enrolled across the 2 sites: 35 (20.1%) at BMC, and 139 (79.9%) at WITS-CORE. Table 1 shows the sociodemographic characteristics of the participants. Most patients were male (n=115, 66.1%), unemployed or retired (n=135, 80%), with a mean age of 61.6 (SD 11.6) years. There were significant differences in the demographic characteristics between the patients at the 2 MLCCP sites. More WITS-CORE patients were male (97/139, 69.8%) than those at BMC (18/35, 51.4%; P=.04). More than two-thirds of the patients with lung cancer at WITS-CORE (98/139, 70.5%) had a high school or higher level of education compared with participants at BMC (8/35, 22.9%; P<.001). A significant proportion of WITS-CORE patients (108/139, 77.7%) were current or ex-smokers compared with patients at BMC (8/35, 22.9%; P<.001).

Clinical Characteristics

Most patients (157/174, 90.2%) were diagnosed with non–small cell lung cancer (NSCLC). Most presented with late-stage (III-IV) diseases, including 96.7% (148/153) of the patients with NSCLC and 85.7% (18/21) of those with small cell lung cancer. Only 4% (5/126) of the WITS-CORE patients with NSCLC presented with early stage (I-II) disease (Table 2). Most patients at BMC (30/35, 85.7%) presented with weight loss compared with patients at WITS-CORE (94/139, 67.6%; *P*=.04). Similarly, a significant proportion of BMC patients had current tuberculosis (12/35, 34.3%) compared with those at WITS-CORE (5/139, 3.6%; *P*<.001). A higher proportion of WITS-CORE patients presented with one or more comorbidities (81/139, 58.3%) compared with patients at BMC (14/35, 40%; *P*<.001).

QoL, Functional Status, and Symptom Burden

Overall, the EORTC QLQ-C30 global health status/QoL subscale score was low (Table 3); the median score was 41.7 (IQR 33.33-41.67). WITS-CORE patients had higher QoL (*P*=.004) and social functioning scores (*P*<.001) compared with patients at BMC. Financial difficulty was significantly higher among BMC patients compared with WITS-CORE (*P*<.001). Overall, the highest symptom scores reported were pain (66.67, IQR 33.33-66.67) and fatigue (55.56, IQR 44.44-55.56). Pain and insomnia scores were significantly higher among patients at BMC, with median scores of 83.33 (IQR 50.00-83.33; *P*<.001) and 66.67 (IQR 33.33-66.67; *P*<.001), respectively, compared with patients at WITS-CORE.

[c]Significant at *P*<.003 (Bonferroni corrected).

[d]Despite identical medians and IQRs in both groups for constipation and diarrhea, the statistical test revealed a significant difference (*P*<.001) due to the presence of small but systematic differences in the distribution of values that are not captured by median or IQR.

Associations Between Sociodemographics, Clinical Characteristics, and QoL

The results of the multiple logistic regression analysis using the dependent variable (QoL) as a binary outcome based on the 50th percentile or median (median QoL score <50 and median QoL score ≥50) are shown in Table 4. A significantly higher proportion of patients with lung cancer at BMC had below-average QoL compared with patients at WITS-CORE (aOR 3.5, 95% CI 1.3-9.3). Poor ECOG-PS score (3-4) was associated with poorer QoL score (aOR 3.4, 95% CI 1.2-6.6).

Association Between Symptom Burden and QoL

Symptom scores were significantly higher among patients with below-average QoL (<50) for fatigue, pain, dyspnea, insomnia, and appetite loss when compared with above-average QoL (≥50; Table 5). Higher symptom scores were associated with poor QoL.

XSL•FO
RenderX

Table 5. Associations between symptom burden and quality of life (QoL) of patients with lung cancer at 2 teaching hospitals across sub-Saharan Africa.

	Below-average QoL (<50; n=97), median (IQR)	Above-average QoL (≥50; n=77), median (IQR)	*P* value
Fatigue	66.67 (44.44-66.67)	44.44 (33.33-44.44)	<.001
Nausea and vomiting	0.00 (0.00-0.00)	0.00 (0.00-0.00)	.01[a]
Pain	66.67 (50.00-100.00)	50.00 (33.33-50.00)	<.001
Dyspnea	66.67 (33.33-66.67)	33.33 (0.00-33.33)	.004
Insomnia	66.67 (33.33-66.67)	33.33 (0.00-33.33)	<.001
Appetite loss	33.33 (0.00-66.67)	33.33 (0.00-33.33)	.001[a]
Constipation	0.00 (0.00-0.00)	0.00 (0.00-0.00)	.17
Diarrhea	0.00 (0.00-0.00)	0.00 (0.00-0.00)	.05
Financial difficulties	66.67 (33.33-66.67)	66.67 (33.33-66.67)	.01[a]

[a]Despite identical medians and IQRs in both groups (for nausea and vomiting, appetite loss, and financial difficulties), the statistical test revealed a significant difference ($P<.005$) due to the presence of small but systematic differences in the distribution of values—particularly in the frequency or magnitude of nonzero observations—that are not captured by median or IQR.

Discussion

Principal Findings

This study provides important insights into the QoL, symptom burden, and associated factors among patients with lung cancer across 2 sites in SSA. Overall, the findings demonstrated that QoL among participants was markedly low (median 41.67, IQR 33.33-41.67), substantially below the EORTC reference population, and varied between BMC and WITS-CORE [21]. Consistent with existing literature, a higher symptom burden, particularly pain, fatigue, dyspnea, insomnia, and appetite loss, was strongly associated with poorer QoL. Significant intersite differences were also observed in sociodemographic characteristics, clinical profiles, functional status, symptom experience, and financial challenges.

Regarding QoL domains, physical and role functioning were notably impaired, reflecting patients' reduced capacity to perform daily activities, maintain independence, and fulfill social and family responsibilities. These findings are consistent with prior studies indicating that disease progression significantly compromises functional status. As lung cancer advances, patients often require assistance with basic activities, such as mobility, personal hygiene, and household responsibilities, which in turn affects their social roles and overall well-being [22]. Interestingly, cognitive functioning in this study appeared relatively preserved despite the high symptom burden. This aligns with some previous studies suggesting that cognitive domains may remain intact compared with physical and emotional domains [11,23-26]. However, this finding contrasts with evidence indicating that symptoms such as insomnia can negatively affect cognitive performance, while better cognitive functioning may help patients cope more effectively with stress and symptom distress [27]. This discrepancy highlights the need for more nuanced and longitudinal assessments of cognitive outcomes in this population.

The comparison between the 2 sites revealed both similarities and differences. Participants at both BMC and WITS-CORE were predominantly male, unemployed, and commonly presented without active tuberculosis, with many diagnosed at earlier stages (stage I-II). However, WITS-CORE participants generally had higher levels of education, were more likely to be smokers, and had a higher prevalence of comorbidities. These differences may reflect broader contextual factors, such as urban-rural disparities, health care accessibility, and diagnostic capacity. For example, the urban setting of WITS-CORE may facilitate earlier detection and access to specialized services, including advanced imaging and oncology expertise. In contrast, BMC serves a larger rural population, where geographical barriers, limited resources, and delayed health-seeking behaviors may influence disease presentation and outcomes. Previous studies have highlighted distance to health care facilities as a major barrier to timely cancer diagnosis and care in SSA [28].

Among sociodemographic factors, education level emerged as a significant determinant of QoL, while other variables, such as age, sex, and economic status, showed inconsistent associations, reflecting mixed findings in the literature [11,21,29,30]. Higher education may enhance health literacy, enabling patients to better understand their condition, seek timely care, adhere to treatment, and engage in self-management [31]. The lower education levels observed among BMC participants, who largely came from rural communities, underscore the need for targeted health education interventions delivered in local languages to improve awareness, early detection, and ultimately QoL outcomes.

Symptom burden in this study was substantial, particularly among patients with advanced disease, and aligned with global evidence identifying fatigue, pain, dyspnea, insomnia, and appetite loss as the most prevalent and distressing symptoms in lung cancer [7,11,22,32,33]. Notably, pain and insomnia were more severe among patients at BMC, possibly reflecting disparities in access to pain management and supportive care services. In many settings in SSA, effective pain control remains a challenge due to regulatory restrictions on opioid availability, limited health care provider training, and financial constraints faced by patients [34]. Addressing these barriers through policy reforms, task sharing in opioid prescribing, and capacity building

XSL•FO
RenderX

among health care providers is essential. Given the strong association between symptom burden and poor QoL observed in this study, integrating palliative care into routine cancer services is critical to ensure effective symptom management and improve patient outcomes [35-37].

Financial hardship was widely reported, particularly among BMC participants, and is consistent with the high unemployment rate observed in the study population. Although financial difficulties were not statistically associated with QoL in this analysis, extensive evidence indicates that economic burden significantly affects access to care, treatment adherence, and overall well-being [21,25,34,38,39]. Financial challenges may include direct health care costs as well as indirect costs, such as transportation, nutrition, and loss of income. Differences in social protection systems, such as disability grants available in South Africa, may partly explain variations between sites. Expanding financial support mechanisms for patients with life-limiting illnesses across SSA could play a crucial role in improving QoL.

Limitations

This study has several limitations. The relatively small sample size at BMC may limit generalizability and statistical power. Although a standardized tool (EORTC QLQ-C30) was used, differences in interview languages across sites may have influenced data consistency. Variability in diagnostic and staging capabilities between facilities may also affect the accuracy of clinical classification. Additionally, some relevant factors such as cough, treatment-related effects, nutritional status, use of alternative therapies, and polypharmacy were not assessed but may influence QoL. The cross-sectional design further limits the ability to establish causal relationships or assess changes over time. Future prospective or longitudinal studies are therefore recommended to better understand causal pathways and temporal dynamics of QoL and symptom burden. Despite these limitations, this study represents one of the first multicountry analyses of QoL and symptom burden among patients with lung cancer in SSA. The findings underscore the urgent need for integrated, patient-centered cancer care that prioritizes symptom management, strengthens health system capacity, addresses socioeconomic barriers, and incorporates palliative care as a core component of oncology services.

Conclusions

In consistency with previous studies, this study revealed disparities in QoL and symptom burden among patients with lung cancer in SSA. Overall, patients experienced low QoL, functional impairment, and financial impact, with prevalent symptoms such as pain, fatigue, dyspnea, insomnia, and appetite loss. Variations in education levels, health care access, and site-specific factors further underscored inequalities in cancer care across the region. These findings highlight the pressing need for context-sensitive interventions that strengthen palliative care services, enhance cancer health literacy through community-based education, and expand social and financial support for patients. Collectively, the study offers valuable regional evidence to guide policies and practices aimed at improving the QoL and clinical outcomes of patients with lung cancer in SSA.

Acknowledgments

The authors acknowledge the support received from the clinical teams at Bugando Medical Centre (Tanzania) and University of the Witwatersrand Centre for Palliative Care (South Africa), as well as patients and caregivers who participated in the study. ChatGPT (GPT-4; OpenAI) was used solely to support English language editing of the manuscript to enhance clarity and readability.

Funding

The research was supported through grants from the Bristol Myers Squibb Foundation. The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

The datasets used and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

MR and KM contributed to the conception and design of the study, acquisition, analysis, and interpretation of data and drafted and revised the manuscript. AG, NM, CB, and HOD contributed to the acquisition of funding, design of the study, overall supervision of the project, interpretation of data, and review of the manuscript. ARS, PM, and OA contributed to data management, analysis, interpretation of the data, and revision of the manuscript. RM, MT, DO-F, NM, and HOD contributed to the analysis, interpretation of data, and revision of the manuscript. Abstract

Background: Accelerating the transition to value-based health care (VBHC) is essential to ensure sustainable care delivery. VBHC maximizes patient value by optimizing outcomes, controlling costs, and leveraging data to improve quality and patient-doctor communication. Integrating real-world data in health care is important to achieve informed decisions, especially in palliative care, where choices are complex.

Objective: This study described the development and pilot-testing of an information tool that incorporates real-world outcome data for women with metastatic breast cancer who are initiating CDK4/6 inhibitor treatment. Real-world insights are needed to better inform these patients, in particular because real-world outcomes are known to differ from trial results because of larger heterogeneity in patient characteristics, and differences in frequency of check-ups and handling side effects.

Methods: We developed an information tool together with patient representatives and clinicians using a participatory development approach that consisted of five key steps: (1) establishment of a multidisciplinary steering group (n=10 steering group members), (2) mapping of the patient journey and patients' needs through focus groups (n=9) and semistructured interviews (n=8), (3) extraction of real-world outcome data from electronic health records systems of 229 patients, (4) prototyping of the tool (n=10), and (5) pilot evaluation with the targeted patient population using semistructured interviews (n=38). We used qualitative analysis methods to analyze the focus group and interview data.

Results: We developed a tool consisting of (1) a communication aid for use during doctor-patient consultations (ie, KIJKgesprek [Stichting Kijksluiter]) and (2) a 2-component companion app with informational videos for use at home, both incorporating real-world outcome data (ie, KIJKbericht and KIJKsluiter [Stichting Kijksluiter]). Participants valued the tool for its clarity and structured design, reporting that the outcome data reinforced their experiences and facilitated the setting of realistic expectations. However, some participants described the outcome data as overwhelming, underscoring the importance of careful framing and delivery. Preferences regarding the type, level of detail, and timing of information presentation varied among participants, highlighting the necessity of individualizing information tools to meet diverse informational needs.

Conclusions: Most patients valued the inclusion of real-world outcome data in the information tool, although many found it challenging to process. Preferences for the type and presentation of information varied widely among individuals. Information tools incorporating outcome data have the potential to enhance patient understanding and support informed decision-making about care that they value most. However, these tools must be designed to allow for customization, ensuring they address individual informational needs and preferences effectively.

KEYWORDS

information tool; real world outcome data; CDK4/6 inhibitor; advanced breast cancer; value-based health care

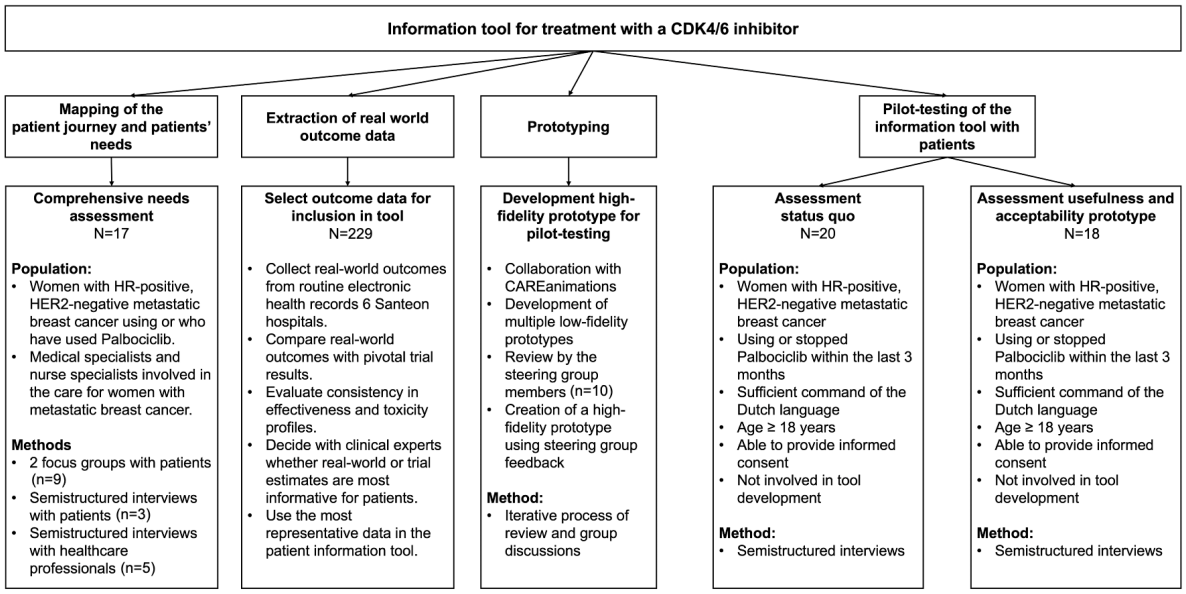
Introduction

Given recent health care challenges, accelerating the transition towards value-based health care (VBHC) has become urgent [1]. VBHC aims to maximize value for patients by optimizing patient-relevant care outcomes, while preferably lowering or maintaining the same costs. Outcome data play a major role in doing so. On a group level, outcome data are increasingly used for quality improvement through benchmarking, that is, comparisons over time, between treatments, and across institutions. On an individual patient level, outcome data should be considered an essential component of patient information and communication. However, such use of outcome data is still not standard in everyday clinical practice [2-5]. In particular, real-world outcome data, collected in daily clinical practice, can be used to support shared decision-making (SDM). These data help patients weigh the pros and cons of treatment options available to them, in line with their own values and expectations. This likely increases patients' satisfaction and treatment compliance [5,6].

SDM is widely recognized for supporting preference-sensitive decisions, particularly when multiple treatment options offer similar benefits or when opting out of treatment is viable, but outcomes remain uncertain [7]. In palliative care, patients have complex needs [8]; however, their desired involvement in decision-making is often not achieved, and their information needs, including their need for prognostic information, are not met [9-11]. They are often not informed about expected survival benefit or the option to refrain from treatment, while the survival benefit is often small and uncertain. Simultaneously, the burden of treatment is likely high in terms of side effects and frequent check-ups [12]. Furthermore, drug performance in clinical trials often differs significantly from results observed in real-world settings [2,13-15], which likely complicates decision-making and raises questions about the applicability of trial findings to broader real-world populations whose characteristics may differ from those of trial participants.

We aimed to deliver a proof-of-concept of including real-world outcome data in patient information and communication. Therefore, we conducted a case study in women with hormone receptor–positive (HR_{pos}), human epidermal growth factor receptor 2–negative ($HER2_{neg}$) metastatic breast cancer (BC). This type accounts for 65% of all BC cases worldwide [16], of which 3% - 12% are projected to have metastatic disease [17] with a 5-year survival rate of approximately 37% [16]. From this target group, we included women eligible to receive the CDK4/6 inhibitor palbociclib combined with endocrine therapy. This targeted therapy aims for disease control by slowing tumor growth, prolonging patients' progression-free survival (PFS). In clinical practice, CDK4/6 inhibitors are most often offered in second- or later-line, following progression on previous endocrine therapy. By targeting cell cycle regulation, CDK4/6 inhibitors reverse or delay resistance to endocrine treatment, and delay the need for more burdensome chemotherapy. Clinical trials have reported promising results (eg, improved time until disease progression with 4 - 10 months [18,19]); however, there are also data that outcomes differ in real-world settings. For example, how modifications are handled in case of neutropenia [20,21]. Based on these considerations, we prioritized the use of real-world data in this research.

In this study, we aimed to (1) systematically develop a patient information tool incorporating real-world outcome data to support patients in making informed decisions about treatment initiation and managing their care throughout the treatment process, and (2) evaluate the tool in a pilot study with the target population. We used a participatory development approach [22] to center this study on patients and health care professionals (HCPs), deepening our understanding of their needs and care experiences and enhancing the usefulness of our patient information tool for supporting SDM. In line with the VBHC emphasis on collaboration across patients, clinicians, organizations, and other stakeholders, participatory design brings these groups together in co-design. This helps surface challenges earlier and leads to more effective and user-friendly solutions.



Methods

Overview

We used qualitative methods to develop the CDK4/6 inhibitor real-world patient information tool. The development process consisted of five steps: (1) establishment of a multidisciplinary steering group, (2) mapping of the patient journey and patients' needs through focus groups and semistructured interviews, (3) extraction of real-world outcome data from electronic health records systems, (4) prototyping of the tool, and (5) pilot evaluation with the targeted patient population using semistructured interviews (Figure 1).

Ethical Considerations

The study protocol was approved by the Medical Research Ethics Committees United (Nieuwegein, the Netherlands; reference SDB2021-010). Ethics and research governance approval were obtained from the local medical ethics committees of the participating hospitals. Participating patients provided written informed consent.

Establishment of a Multidisciplinary Steering Group

The development of the information tool was initiated by Santeon, a Dutch hospital group in which 7 top clinical hospitals openly collaborate to improve medical care [21]. The project initiators (postdoctoral researcher MQNH, program manager CFvUK, and hospital pharmacist EMWvdG) established a multidisciplinary steering group for the development of the tool.

Mapping of the Patient Journey and Patients' Needs

The patient journey mapping (ie, inventory of patients' experiences from diagnosis until disease progression) served as the starting point in the development of the information tool. The goal was to obtain insight into patients' experiences from diverse patients to help identify information and support needs that needed to be addressed in the patient information tool. We collaborated with the Patient Journey Lab, a company specialized in patient journey mapping, to develop the patient journey. First, to roughly outline the patient journey, 2 focus groups were conducted by MQNH and an independent research consultant (experienced in conducting focus groups) with 5 and 4 patients, respectively, that lasted about an hour. They focused on the following topics: (1) information provision, (2) decision-making to start the CDK4/6 inhibitor, (3) unmet information needs, and (4) perspectives on the use of real-world outcome data. Second, to verify and fill out the patient journey in greater detail, semistructured interviews, with an expected duration of 30 minutes, were conducted by MQNH with 3 patients and the 2 oncologists and 3 nurse specialists who participated in the steering group. All recordings were transcribed and summarized by MQNH. Manual summative content analysis [23] was used to infer meaning from recurring keywords and messages. Based on the topic list, keywords were selected to highlight in the text to count their frequencies before defining and contextualizing them in our final summary.

Extraction of Real-World Outcome Data

To inform new patients about the treatment, the information tool includes outcome data of 229 patients treated between 2016 and 2020 in 6 Santeon hospitals (St Antonius Hospital Utrecht/Nieuwegein, Martini Hospital Groningen, Canisius-Wilhelmina Hospital Nijmegen, Catharina Hospital Eindhoven, OLVG Amsterdam, and Maasstad Hospital Rotterdam). More detailed information on the real-world cohort and the data collection has been reported previously and is available elsewhere [24,25]. Briefly, the data collected included PFS, the reason for ending treatment, the severity, frequency, and timing of all side effects and toxicities (with a special focus on neutropenia), and the timing and frequency of all treatment modification strategies. They were derived from routinely collected electronic health records, with 1 hospital excluded due to incomplete documentation of palbociclib use. To ensure the robustness of the real-world data to be included in the tool, we compared in this dataset outcomes in a cohort of 229 patients with HR_{pos}, $HER2_{neg}$ metastatic BC treated with palbociclib plus fulvestrant in second- or later-line therapy to those reported in the pivotal *PALOMA-3* trial that formed the basis for regulatory approval of palbociclib in this setting. On the basis of the comparison, the expert work group concluded that given the greater clinical heterogeneity and the mismatch in toxicity profiles compared with trial participants, real-world outcome estimates were more representative for informing patients and were therefore used in the information tool. [24,25]

Prototyping

In consultation with the steering group and based on the patient journey mapping, it was decided to develop a digital information tool to allow future efforts to link the tool to patients' electronic health records. Such a linkage provides two main benefits: (1) it gives patients access to all medical information in one place,

XSL•FO
RenderX

and (2) it allows the tool to display up-to-date real-world outcome data based on automatic updates retrieved from personal data stored in electronic health record systems. To examine how the tool could best be integrated in the digital landscape of the Santeon hospitals, the Patient Journey Lab inventoried the software potential per hospital, including available health applications. As CAREanimations offers accessible information suitable for most people, including those with low (health) literacy, tailored to each step in the patient journey, it was selected as the development and implementation partner [26]. In collaboration with CAREanimations, the initiators developed several low-fidelity prototypes, which were reviewed by the steering group to arrive at a high-fidelity prototype for pilot-testing.

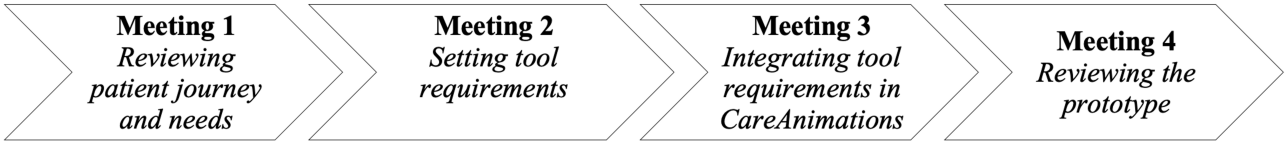
Pilot-Testing of the Information Tool Among the Targeted Population

We carried out a pilot evaluation in 2 steps. First, before implementing the information tool, we assessed the status quo, that is, patients' experiences with treatment and their met and unmet information and support needs. We did this to validate the findings of our previous unmet need assessment. Second, we assessed patients' views on the usefulness and acceptability of the high-fidelity prototype of the information tool and inventoried suggestions for improvement.

In the first step, we conducted in-depth semistructured interviews with women with $HR_{pos}HER2_{neg}$ metastatic BC who (1) were using or had stopped using the CDK4/6 inhibitor Palbociclib within the last 3 months, (2) had sufficient command of the Dutch language, (3) were 18 years or older, (4) did not have (severe) cognitive impairment that would preclude them from providing informed consent, and (5) had not been involved in the development process. We obtained insights into patients' (1) experiences with information provision about their diagnosis, prognosis, and treatment with CDK4/6 inhibitor; (2) experiences with treatment (eg, side effects and impact on daily functioning); (3) experiences with treatment decision-making; and (4) preferences regarding receipt of outcome data. In addition, we obtained information about sociodemographic characteristics (age and educational level) and medical history (date of primary BC diagnosis, treatment history; refer to Multimedia Appendix 1 for the full interview guide). We recruited participants from 5 Santeon hospitals (ie, St Antonius Hospital [Utrecht/Nieuwegein], Martini Hospital [Groningen], Canisius-Wilhelmina Hospital [Nijmegen], Catharina Hospital [Eindhoven], and Maasstad Hospital [Rotterdam]). Patients were invited to participate by their oncologist or nurse specialist. The interviews were conducted by EGE (researcher with interviewing experience).

In the second step, we evaluated the prototype of the information tool through individual semistructured interviews with a new cohort of women not previously involved in the development or pilot-testing, meeting the same inclusion criteria as described in step 1. Participants were recruited at the same 5 Santeon hospitals and via the Dutch Breast Cancer Society. Recruitment through the Dutch Breast Cancer Society broadened the target population, as participants were also treated at other hospitals, which accelerated the recruitment process. Two weeks before the interview, participants were provided with access to all the animation videos contained in the information tool and the graphical information intended for use during the consultation with their oncologist. They were asked to view all the materials and take notes of any suggestions for possible improvements. After they reviewed the information, a telephone interview was conducted by MQNH or EGE. The interview guide to assess patients' experiences with treatment and their met and unmet information and support needs was used and extended to also obtain insight into patients' views on the completeness and clarity of the CDK4/6 inhibitor information tool and to collect suggestions for improvement (refer to Multimedia Appendix 1 for the full interview guide).

All interviews (in the first and second steps) were audio-recorded with the participant's permission and transcribed. The transcripts were analyzed using a combined technique of deductive and inductive thematic analysis [27,28]. For the deductive approach, we constructed an analytic framework based on predefined themes in the interview guide. In addition, we conducted open coding (inductive) on the transcripts to allow the inclusion of other relevant themes. We generated categories and abstractions through detailed review, quantifying keywords and phrases, and comparing findings. As educational level was considered to be an important predictor of patients' comprehension of and satisfaction with the information tool, we explored differences in participants' responses based on their educational background. All transcripts were coded by 2 researchers (MQNH and EGE) independently. Discrepancies were resolved through consensus. Qualitative data analyses were performed using Atlas.ti (version 9; Lumivero) software. Quotes are provided to illustrate our findings.



Results

Establishment of a Multidisciplinary Steering Group

The steering group consisted of patient representatives or advocates from the Dutch Breast Cancer Society (n=3), oncologists (n=2), specialist nurses (n=3), an information architect (n=1), and a health information consultant (n=1; for more details, refer to Multimedia Appendix 2). The steering group convened for 4 cocreation sessions. Figure 2 provides an overview of the focus of each session. The steering group was involved throughout the development process.

XSL•FO
RenderX

Figure 2. Focus of the cocreative steering group sessions.

Mapping the Patient Journey and Patients' Needs

The findings from interviews and focus groups with patients (n=12) and clinicians (n=5) were used to map the patient journey of women undergoing treatment with a CDK4/6 inhibitor, from the start of treatment to its discontinuation (Table 1). A detailed overview of the patient journey is provided in Figure 3. Findings from the interviews with clinicians about the requirements for the information tool were in line with the findings from the patient interviews. All participants valued real-world outcome data in addition to clinical trial results, preferably displayed in a leaflet or app (connected to the electronic medical record). Information needed to be tailored to each step of the patient journey. Repetition and gradually offering more information were believed to be key. Even though dealing with a wide range and likely negative outcomes may be complex, participants wished insight into the timing, frequency, and severity of side effects, as well as the timing and reasons for ending treatment, so they could compare their outcomes to those of peers. Most patients wished to be better informed about possible medication alterations. Information on what type of treatment CDK4/6 inhibitor is, as well as what to do when experiencing side effects, was also valued. A summary of the key findings from the focus groups and interviews conducted to map the patient journey can be found in Table 2.

Table . Summary of findings per theme and subtheme of the focus groups and interviews conducted to map the patient journey.

Theme and subtheme	Description
Information resources	
Health care professionals	Patients were informed about CDK4/6 inhibitor by their medical oncologist. After the initial consultation with their medical oncologist, some, but not all, patients received more detailed information from a nurse specialist or oncology nurse. Patients who did not have a dedicated nurse specialist or oncology nurse experienced a lack of guidance or support.
Websites and information leaflets	Some patients were referred to websites or information leaflets or were given an information leaflet at the hospital pharmacy. Patients liked receiving these additional information resources as the information received from health care providers was a lot to take in all at once, and these additional resources could serve as a reference for later.
Medication leaflet	All patients received the medication leaflet, which they handled differently. Some patients read it partly or in its entirety (multiple times) before starting with the treatment. Others consulted the medication leaflet upon experiencing complaints to avoid forgetting information, getting (unnecessarily) worried, or imagining symptoms that were not there. Some patients consulted peers on the internet.
Experiences with information provision about treatment	
Knowledge gap	To many patients it was not clear what type of treatment CDK4/6 inhibitor is: it was often mistaken for chemo- or immunotherapy. Patients used the internet to search for more detailed information on side effects and how to deal with them.
Variation in information provision and unmet information needs	Participants had mixed experiences with information provision about medication alterations (eg, lowering of the dosage or extension of the time interval between treatments). Some participants were informed about possible medication alterations before treatment started, some when it became relevant during treatment, whilst others were not consulted when an alteration was needed. Most patients wished to be more informed about their options.
Outcome data	
Preferences for receiving outcome data	Patients indicated they would value receiving real-world outcome data in addition to clinical trial results. Real-world outcome data, tailored to their medication combination, could help them compare their outcomes to those of peers, even though dealing with a wide range, and likely negative, outcomes may be complex.
Role in decision-making	
Oncologists	Upon diagnosis, the oncologist often immediately decided to start treatment with CDK4/6 inhibitor, as they believed it to be the best treatment option.
Patients	Some patients liked the oncologist to take the lead as they felt there was a need to act swiftly after their diagnosis and trusted their oncologist. Some patients were more involved in decision making, by proposing treatment with CDK4/6 inhibitor themselves, or by discussing alternatives (eg, chemotherapy) with their oncologist. Overall, conservative treatment was not considered an option by patients.
Requirements for the information tool	
Important content	A description of the type of treatment and what to do when experiencing side effects.
Preferences for incorporating outcome data in the information tool	Also, real-world outcome data related to the timing, frequency, and severity of side effects and medication alterations was deemed important to disclose in the tool, as well as the timing and reasons for ending treatment.
Type of tool and specifications	Patients liked to receive real-life outcome data in a leaflet, handed out by the nurse specialist or oncology nurse, but an app (connected to the electronic medical record) was also mentioned. In terms of information presentation, it was deemed important that the information in the tool was tailored to each step of the patient journey, and that repetition and gradually offering more detailed information is key.

XSL•FO
RenderX

Extraction and Assessment of Real-World Outcome Data

Real-world outcome data were extracted from a cohort of patients treated with palbociclib in combination with fulvestrant in routine clinical practice. In this cohort, the median PFS was 11.6 (95% CI 10.2-13.9) months, which was longer than the 9.5 (95% CI 9.2-11.0) months reported for the PALOMA-3 trial population (more detailed information is available in the study by Hackert et al [24]). This difference may partly reflect differences in outcome assessment between clinical trials and routine clinical practice. When the real-world cohort was stratified according to PALOMA-3 eligibility criteria, differences in outcomes were observed. Patients who would have met the PALOMA-3 eligibility criteria had a median PFS of 14.1 (95% CI 11.5-17.0) months, whereas patients who would not have met these criteria had a median PFS of 10.2 (95% CI 8.8-12.3) months.

The occurrence of hematological toxicities and nonhematological side effects associated with palbociclib was generally similar in real-world settings compared with the clinical trial data. However, patients in routine clinical practice reported certain side effects more frequently, particularly fatigue and decreased appetite. In clinical practice, 54% (124/229) of patients experienced at least 1 cycle delay, 39% (89/229) had at least 1 dose reduction, and 26% (59/229) had at least 1 dose interruption, compared with 36% (124/345), 34% (117/345), and 54% (186/345), respectively, in the PALOMA-3 trial. Detailed findings on patient-reported experiences are described in the study by Vaisson et al [22].

Choices in Data Presentation in the Information Tool

To support the development of the information tool, the extracted real-world outcomes were summarized using lay terminology and reviewed together with the steering group. Based on the extracted outcome data, decisions were made in collaboration with the steering group regarding which outcomes to include in the tool and how these should be presented to patients. Particular attention was given to ensuring that the translation of clinical outcomes into patient-friendly information accurately reflected the limitations of real-world data, such as potential selection bias, missing or incomplete data, and variability in outcome measurement and reporting. For example, rather than presenting outcome distributions based solely on real-world data, outcomes from clinical trial data and real-world data were compared, and presentation choices were made based on this comparison. This approach aimed to provide balanced and transparent information for patients using the information tool.

Prototyping

Based on the requirements set by the steering group (using the results from the patient journey mapping and the patient and clinician needs assessment), prototypes for the information tool were developed. Figures 4 and 5 provide a summary of the patient journey, including components of the information tool, to support information provision and treatment decision-making at each phase of the patient journey. The information tool consists of three main components: (1) KIJKgesprek (Stichting Kijksluiter), (2) KIJKsluiter (Stichting Kijksluiter), and (3) KIJKbericht. The 3 components are described in Figure 6. The steering group reviewed the prototypes, and in an iterative process, the prototypes were refined to a version ready for pilot-testing—the high-fidelity prototype.

Pilot-Testing of the Information Tool Among the Targeted Population

Step 1: Status Quo Prior to Implementing the Information Tool

Overview

To obtain insight into patients' experiences with information provision, treatment decision-making, and the treatment burden before the CDK4/6 inhibitor information tool became available, we conducted 20 interviews. Table 3 provides an overview of the participants' characteristics. We identified 5 key themes and summarized the findings per theme.

XSL•FO
RenderX

Table . Sociodemographic characteristics of women interviewed during pilot-testing of the information tool.

Characteristics[a]	Step 1: before implementation (n=20), n (%)	Step 2: prototype testing (n=18), n (%)
Marital status		
Married or in a relationship	9 (47)	12 (80)
Single	4 (21)	2 (13)
Widowed	6 (32)	1 (7)
Missing	1	5
Education		
Lower	7 (41)	3 (20)

CDK4/6 inhibitor as:		
First-line	9 (56)	8 (57)
Second- or later-line	7 (44)	6 (43)
Missing	4	6

[a]In a small number of interviews, certain sociodemographic questions were not asked or probed further because the conversation centered on highly emotional and sensitive topics, and the interviewer prioritized participant comfort and rapport.

Patients' Treatment Knowledge

Most patients could not describe what kind of treatment a CDK4/6 inhibitor is. Many patients mistook the CDK4/6 inhibitor for chemotherapy:

> [I understood that the drug is a kind of chemotherapy that fights cancer cells. ID03]

Patients did seem to understand that a CDK 4‐6 inhibitor helps to slow or stop the growth of cancer cells. Side effects that most patients knew of before the start of treatment were alopecia, gastrointestinal complaints, fatigue, and hematological changes (eg, neutropenia). Many patients linked blood check-ups to assess how well they were tolerating the treatment and whether they could start a new treatment cycle. There seemed to be variation in information provision; some patients were informed about treatment modification strategies (such as stopping for an additional week before starting the next treatment cycle or lowering the dosage), while others were not.

Information Resources Use

Study participants discussed various information resources they consulted, including HCPs, written materials, medication leaflets, and the internet. Patients consulted medication leaflets before or during treatment, finding them helpful but overwhelming due to the extensive list of potential side effects. Many patients preferred information about side effects in smaller doses, and timing of information was also deemed important (eg, getting information when it became relevant for them instead of hearing everything in advance). Some patients sought additional information online, while others avoided it due to concerns about accuracy and biased narratives (eg, overrepresentation of "horror stories"). Although most participants were satisfied with the information they received from HCPs, some felt it was insufficient, particularly regarding the management of side effects. Also, participants felt that the amount of time available to consult with their oncologist was too limited. Overall, participants appreciated that they could contact HCPs for further clarification outside of their scheduled consultations if the need should arise.

XSL•FO
RenderX

Patients' Preferences Regarding Outcome Data

Many participants were receptive to receiving information about potential side effects, with preferences varying in terms of detail. Some preferred information limited to the most common side effects based on real-world data, without probabilities, while others wanted a comprehensive overview including probabilities. Many trusted their oncologist to provide relevant information as needed, expressing no strong desire to receive all information upfront or to use a tool containing such data. For some, not knowing everything served as a coping mechanism to maintain hope and reduce anxiety about factors beyond their control (eg, response to treatment). Despite this, a few participants acknowledged an internal struggle, balancing the desire to understand what could lie ahead with the comfort of remaining uninformed. Additionally, many patients expressed reluctance to receive outcome data related to prognosis, feeling such statistics might not apply to them (eg, "I do not like statistics or prognoses at all, because I always fall outside their scope" [ID01] or "You have to wait and see how things are going to turn out in your situation" [ID02]) and could be too confronting or overly influential on their life choices (eg, "I do not want to think I only have a year left" [ID03]). Some preferred outcome data to be available only upon request or in urgent situations, such as disease progression requiring decision-making. This ambivalence highlights the complex and individualized nature of patients' preferences for receiving prognostic information.

Experienced Treatment Burden

All patients experienced treatment side effects, with about a quarter encountering cycle delay, dose reductions, or interruptions due to, for example, severe side effects. Participants used several coping strategies. Many spoke of acceptance being important to cope with their situation, and acknowledging the futility of questioning what could have been:

> [You can start wondering, could I have prevented this metastatic disease? Could it have been different? But I know from experience that those kinds of questions don't get answered anyway, and that's no use to you. So, you have to make do with what you have at that moment. ID04]

Some found comfort in hoping to defy the odds:

> [They clinicians did say right away, we cannot cure you, but we can make the quality of your life better and prolong your life. But they also said that bit prolonging life. So, I've had the hope that maybe I would be cured after all... ID05]

Denial and trivialization of their symptoms and situation were also common coping mechanisms. Despite many patients rating their quality of life high, many simultaneously acknowledged significant negative impacts on their daily lives due to the disease and/or treatment side effects, and ways they needed to adapt.

Treatment Decision-Making

Patients expressed that they felt a sense of urgency to start treatment with a CDK4/6 inhibitor, as it is perceived to be the best available option at this stage of their disease:

> [I had already taken letrozole for four years and it wasn't working anymore … so you have to switch to something else. For me it feels like I don't really have a choice … they know which option is best for me. ID02]

A few preferred a CDK4/6 inhibitor due to its perceived lower burden compared with other treatments, such as chemotherapy. Many patients indicated their only other option would be chemotherapy and expressed reluctance to start this, given its potential side effects and impact on their quality of life:

> [For me the choice was chemotherapy and its side effects, or this treatment and its side effects. So, I didn't really focus on what the side effects of this treatment were, because compared with chemotherapy it's obviously much less severe. ID18]

Given that chemotherapy was the alternative, being eligible for treatment with a CDK4/6 inhibitor was seen as positive news. While some patients felt involved in the decision-making process, most patients indicated that their oncologist took the lead in prescribing treatment, often without discussing alternatives. Trust in oncologists played a significant role in patients' acceptance of treatment decisions. However, some oncologists did offer patients the opportunity to decide or take time to consider their options. Patients commonly cited the desire to extend life, slow cancer cell growth, reduce symptoms, and improve quality of life as motivation for starting CDK4/6 inhibitor treatment.

Step 2: Prototype Testing

Overview

A total of 18 patients pilot-tested the information tool (Table 3). Their experiences with treatment, information provision, knowledge about treatment, and coping strategies aligned with the findings from the women who did not have access to the tool (step 1). Therefore, we only summarize the prototype testing participants' views and recommendations for each component of the information tool below.

Views on the Visualized Key Information for Use During the Clinical Encounter (KIJKgesprek)

Participants generally thought that the so-called KIJKgesprek used during a consultation (a visualization using animated pictograms to help patients understand and remember essential medical information from the consultation, eg, medication intake, common side effects, and contraindications) was well-structured and comprehensive in covering key points. However, opinions varied regarding its added value. While some women believed it could enhance doctor-patient communication by aiding information processing, others doubted its added benefit or expressed concerns about it being potentially distracting to patients (eg, it can be too much to have to look at a screen as well as process what the HCP is saying):

> [I didn't feel it added much value for me, although it might be useful for the oncologist to support the explanation …. Personally, I didn't really think it would have added anything to the conversation with my oncologist. Everything was already clear to me.

XSL•FO
RenderX

> What did stand out to me, though, was that I hadn't really received the warnings mentioned, such as avoiding St John's wort, grapefruit, alcohol, and being aware of possible liver problems. That might have been a useful addition. ID12]

One participant acknowledged the KIJKgesprek's potential utility as a guide for HCPs to ensure comprehensive information delivery.

Views on the Animated Information Videos

Most participants found the videos informative, and the language use was deemed clear and accessible:

> [I found it information tool very helpful. I think it can really be a valuable addition when you start with it treatment … although also midway through treatment. I found it clear. ID4]

Participants indicated that it would have been of added value to them if they had had access to this tool at the time they started with treatment. While participants believed all relevant topics were covered in the videos, opinions varied about the level of detail. More highly educated participants desired more information and a greater level of detail. The tips for coping with side effects provided in the videos were highly valued by all. Some provided suggestions for more tips that could be added. The videos' length was deemed appropriate, and participants appreciated the ability to revisit specific topics. Participants saw the tool as a valuable reference, especially for processing information after receiving difficult news. However, a few preferred to avoid excessive information unless necessary, citing concerns about losing hope.

Views on the Incorporation of Outcome Data in the Information Tool

Visualization of real-world outcome data in the information tool introduced a novel aspect, but opinions among participants varied. Overall, participants thought that the visualization of the outcome estimates was clear. Some expressed an internal conflict, acknowledging the importance of knowing realistic probabilities of experiencing outcomes while also feeling overwhelmed or wanting to avoid such information:

> [It outcome data is reality, of course. It's just that sometimes it depends, it's good to know, but at times you also don't want to know. Right? ID07]

Many participants believed it was useful to provide patients with realistic outcome data, particularly regarding PFS and side effects. Some participants indicated that they had explicitly requested information about prognosis from their oncologists, and not all had received numerical information. However, many expressed concerns that providing patients with outcome data could diminish hope or discourage treatment initiation (in line with the findings described in the Step 1: Status Quo Prior to Implementing the Information Tool section). Some worried particularly about visualizing the average time the medication is effective in preventing disease progression without adequately acknowledging the variability in treatment response:

> [If I had seen before starting with treatment that on average women only had four months before the disease got worse, I might not have started. For me, that hasn't been the case. I'm lucky to be able to do well on this CDK4/6 inhibitor for years now. … It would be good to explicitly state that the four months is an average, but there are exceptions. ID08]

Opinions also diverged on whether to provide outcome data about side effects, with some finding it overwhelming and others valuing the insights and validation of their own experiences:

> [Seeing that others other women using a CDK4/6 inhibitor also experience the same complaints is reassuring, it's not just me. ID09]

Linking Baseline Patient Experiences to Prototype Evaluation

Overall, step 1 showed substantial gaps in patients' understanding of CDK4/6 inhibitor therapy, wide variation in information needs and preferences, and challenges in coping with treatment burden and decision-making. These findings underscore the need for structured, accessible, and patient-tailored support materials that incorporate realistic expectations of treatment and side effects. Step 2 demonstrated that the prototype information tool addressed many of these needs. Even though preferences for receiving outcome data varied between patients, many participants did find this information useful. Together, these insights support the incorporation of real-world outcome estimates into the tool.

Discussion

We present the development and pilot testing of a novel online patient information tool for women with $HR_{pos}HER2_{neg}$ metastatic BC undergoing treatment with a CDK4/6 inhibitor. Designed based on patient and HCP needs assessments and input from a multidisciplinary steering group of experts, the tool delivers numerical data on outcomes such as PFS, side effects, and treatment modifications in an accessible format. It also features visualizations to support doctor-patient communication during consultations and includes an app with animation videos and push notifications for home use. By facilitating discussions about treatment outcomes, the tool can help patients form realistic expectations about the benefits and risks of their treatment. This, in turn, is aimed at supporting better-informed SDM and fostering more meaningful patient engagement in their care. Despite its benefits in informing patients and supporting treatment decisions, the use of real-world outcome data in clinical practice is still novel and may be challenging for patients to understand and apply. As its integration becomes more common, it is important to keep in mind that patients may need time to adapt.

Many participants in our pilot test demonstrated significant knowledge gaps regarding CDK4/6 inhibitors. Although participants generally understood that these compounds slow cancer cell growth, awareness of treatment modification strategies and potential side effects was limited. These findings highlight the critical role of patient information tools, like the tool we developed, in promoting consistent and clear communication. Many patients reported that symptom burden significantly impacts their quality of life, underscoring the need

XSL•FO
RenderX

for resources with information about strategies to address this challenge [29-31].

Furthermore, challenges in communicating about palliative care often stem from HCPs' desire to offer hope, which can result in incomplete discussions about treatment options and expected outcomes [32]. The visualizations for use during the consultation incorporated in our tool are designed to support clinicians in delivering complex information more effectively to patients. This approach could be particularly helpful in ensuring patients are better informed, fostering engagement, and setting realistic expectations about their treatment journey. Tailored explanations of treatment mechanisms and side effects, whether detailed or concise, based on individual preferences, can help address misconceptions, reduce concerns, and provide a balanced sense of hope that aligns with patients' needs and preferences.

Preferences for outcome data among participants in the pilot test were highly individualized. While some patients valued receiving numerical outcome data about side effects and PFS, others preferred to avoid such information to preserve hope or reduce anxiety. Many participants in our pilot test expressed a preference for outcome data to be offered only on request or in specific scenarios, such as if there is disease progression, emphasizing the importance of tailoring and sensitivity in presenting this type of data. These findings align with research showing that patients often prefer to be asked whether they want to receive outcome data, rather than having it provided automatically, and that these preferences may change over time, necessitating periodic reassessment [11]. In this evaluation study, all participants were exposed to the full set of outcome information. However, this does not reflect the intended use of the tool in practice, where information would be shown only at clinically relevant time points. Our findings also support adding advanced notifications (eg, pop-ups), alerting patients that outcome estimates are available. This allows patients to decide whether they wish to view the information, thereby supporting autonomy in how and when they receive potentially sensitive data. Finally, while the tool acknowledges that outcomes are highly individual, we were unable to personalize estimates due to limited available data. Future development could further explore personalized presentations of expected benefits and risks as more real-world data become available.

Participants in the pilot test expressed concerns about the potential for numerical outcome data to diminish hope, particularly when averages were presented without sufficient context regarding variability and uncertainty about outcomes for individual patients. While many patients reviewed the visualizations of outcomes as useful for understanding PFS and side effects, others felt overwhelmed or worried that such information might have deterred them from initiating treatment. This aligns with findings from a recent multicenter survey, which reported that a subset of patients with advanced cancer actively prefers not to receive prognostic information to preserve hope and reduce anxiety [33]. Communicating variability in outcomes using outcome ranges instead of only point estimates and explicitly framing numerical data as averages is especially important in palliative care, where maintaining hope is a central aspect of patient engagement. Balancing honesty about prognosis with empathy is critical for fostering trust and minimizing distress [11]. Striking this balance is essential to align treatment decisions with patients' values and priorities. There is a need for future research on how negative emotions in SDM may be minimized [34,35].

Some study limitations need to be considered when interpreting the results of this study. Women reviewed all the components of the tool at once, instead of getting the push notifications in line with the phase of treatment they were in, as intended. Consequently, the tool was less attuned to meet women's diverse informational needs. The benefits of gradual information display and repetition were lost, which may have caused women to feel overwhelmed by (outcome) information. Moreover, the prototype testing phase included more highly educated patients, which may have influenced study outcomes. It requires further testing to determine whether the tools meet the needs of patients with low numeracy and health literacy. Also, the findings of our pilot testing do not provide insight into how the tool will fit into the clinical workflow and potential barriers to implementation. Identifying any potential barriers to clinical use, as well as identifying criteria for when to use and when not to use, is particularly important for the tool component intended for use during consultations (ie, Kijkgesprek). An important strength of this study is the use of real-world outcome data in a patient information tool, specifically to get more realistic data regarding the patient's experience with side effects and their clinical management. The breadth of patient experiences with treatment side effects captured in the real-world information is more likely to reflect the experiences of patients than information obtained from the highly selected populations in clinical trials. An important strength of the tool design process is the participatory development approach we used, involving both patients and HCPs to ensure the resulting information tool matched their needs and preferences. Finally, given the complexity of communicating and understanding outcome data, great effort has been put into presenting the information in an accessible manner to ensure that patients with low (health) literacy can also understand the information.

In conclusion, we used the context of treatment with a CDK4/6 inhibitor in combination with endocrine therapy for $HR_{pos}HER2_{neg}$ metastatic BC as a case study to assess the value and usability of real-world outcome data in informing patients about their treatment and outcomes. Women in the pilot test rated our tool highly, appreciating its clear and structured information. However, preferences for how to receive (different types of) outcome data varied. To accommodate patients' varied preferences for outcome data, we recommend that tool developers provide options for patients to choose whether they want to see additional information (eg, survival probabilities) and in how much detail. For instance, using pop-up warnings or expandable text would be beneficial. Moreover, we highly encourage future studies to evaluate the usage of our tool in clinical practice. In our study, we identified the facilitators and barriers that need to be addressed to enable the successful (nationwide) implementation of our information tool. Finally, our study can serve as a template for others who want to develop patient information tools incorporating real-world data. As most patients are open to receiving outcome data, concerted efforts should be made to set up the infrastructure to collect the

XSL•FO
RenderX

necessary data and facilitate its effective use in patient information tools.

Acknowledgments

We sincerely thank the patients who participated in this study and the health care professionals for their invaluable assistance in recruiting participants. We also extend our gratitude to the Dutch Breast Cancer Society for their valued partnership and support in facilitating participant recruitment for this project.

Funding

This work was supported by Pfizer (grant 62785943) and ZonMw as part of the "Experiment Uitkomstindicatoren Santeon."

Conflicts of Interest

AFdJ declares a potential conflict of interest in relation to the tool evaluated in this study: she is chair of the foundation that created the tool's functionality. The remaining authors declare no conflicts of interest.

Abstract

Background: Wearable devices are becoming more ubiquitous and are capable of capturing health-relevant information that patients may be interested in sharing with their providers. However, limited research has been conducted on oncology provider perspectives on how these data could be used to inform cancer care.

Objective: The goal of this study was to understand oncology clinicians' preferences about which data would be most clinically valuable and in what clinical scenarios, the benefits and barriers to integrating wearable device data into cancer care, and perspectives on how wearable device data could impact decision-making using 3 clinical vignettes.

Methods: A total of 13 oncology care clinicians completed an online questionnaire to assess the perceived value of different types of wearable device data in different clinical scenarios and participated in semistructured interviews to gather preferences around integrating these data into clinical workflows. During the interviews, providers were also presented with 3 clinical vignettes and asked for clinical recommendations both before and after seeing the patient's wearable device data. Descriptive statistics were calculated to summarize quantitative data from questionnaires and structured interview questions, and interviews were transcribed and coded using an iterative thematic analysis approach.

Results: Survey responses indicated that providers were most interested in tracking vital sign metrics, followed by data related to falls and functioning, and then by data on sleep and activity. Clinicians thought that wearable device data might be especially useful for remotely monitoring patients at high-risk moments in their care trajectory, such as after an acute hospitalization or after starting a new outpatient treatment. Four main themes were discussed by providers in the interviews: (1) corroborating reports, (2) identifying new issues, (3) coordinating care, and (4) patient-provider communication. Although there were no statistically significant differences in clinical recommendations before and after viewing wearable device data for any vignette (all $P>.25$), all clinicians reported that the wearable device data impacted their decision-making confidence, and most rated the wearable device data as helpful.

Conclusions: Oncology providers highlighted the potential clinical value of vital sign and physical functioning data from wearable devices, particularly when outpatients might be at risk for readmissions or other acute deteriorations between clinic visits. Providers noted that the objective data captured by consumer wearable devices can be helpful complements to patient and caregiver subjective reports and that this information could improve patient-provider communication and care coordination. During the interviews, most providers found wearable device data to be helpful when making decisions. While there are challenges to address on how to integrate this information into the clinical workflow and communicate alerts with patients, there is cautious enthusiasm among clinicians about how these data could inform and improve cancer care.

KEYWORDS

wearable devices; oncology providers; cancer; symptom management; doctor-patient communication; remote monitoring

Introduction

Background

Data from wearable devices can capture objective patterns of physical activity and physiology that may be useful for remotely monitoring patients during chemotherapy and other outpatient cancer treatments [1]. Work by our team and others suggests that it is feasible to collect wearable device data from patients during cancer treatment [2-4], that patients are willing to share these data with clinicians [5], and that these data are correlated

XSL•FO
RenderX

with clinical outcomes among patients with cancer [6,7]. As these devices become more ubiquitous and powerful, research is needed to understand how best to integrate these devices and data into clinical cancer care.

In previous work, noncancer physicians reported that wearable device data may improve patient-provider communication by efficiently providing objective information about patient health, informing decision-making by monitoring response to treatment and symptom progression outside of the clinic, and helping patients feel like more active participants in their care [8,9]. Physicians also noted potential barriers to the clinical implementation of wearable device monitoring, including concerns about the digital health literacy of older patients, the potential cost of devices widening digital divides, device data increasing anxiety for some patients, and increased strain on clinical workloads [10].

In the area of oncology care, several recent studies have assessed the preferences and perspectives of patients with cancer on wearable health monitors [11,12]. Barriers noted by patients with cancer included fears that wearable devices may serve as a constant reminder of their illness and concerns that technology may replace human interactions if, for example, patients grow to rely on devices to communicate their health status to clinicians and refrain from reaching out directly. Patients also reported benefits, noting that wearable devices can be motivating, can provide new insights into their health and illness, and that they viewed the wearable device as a part of their treatment relationship and wanted their cancer treatment teams to have access to their wearable device data.

Objective

To date, limited work has focused on cancer care clinicians' perspectives on how wearable device data could inform cancer care. The goal of this questionnaire and interview study was to understand oncology clinicians' preferences about which data would be most clinically valuable and in what clinical scenarios, the benefits and barriers to integrating wearable device data into cancer care, and perspectives on how wearable device data could impact decision-making using 3 clinical vignettes.

Methods

Recruitment

Oncology care clinicians (N=13) were recruited through purposive sampling to capture different health professionals involved in providing cancer care. Providers were eligible if they were (1) working as clinical providers caring for patients receiving cancer treatment, (2) aged over 18 years, and (3) fluent in English.

Study Design

Participants first completed an online questionnaire to collect demographic and clinical background information, assess which sensor information they would be interested in receiving and in what scenarios, and explore potential resources that might be helpful to them in integrating wearable device data into their clinics (Multimedia Appendix 1). Semistructured interview guides were developed by the research team with a focus on preferences and needs around how technology could support care management and fit into clinical workflows (Multimedia Appendix 2).

Based on a similar study in pediatric surgery [13], participants were also presented with 3 clinical vignettes using wearable data collected as part of the remote oncology symptom assessment research protocol that followed patients receiving cytotoxic chemotherapy for solid tumors [4]. Patient participants in this study wore a Fitbit Inspire device for 90 days, and the data of 3 participants who had experienced complications during the study were presented at the end of semistructured interviews to determine whether the availability of wearable device data impacted clinician decision-making. The three vignettes presented were as follows: (1) a male patient with stage IV pancreatic cancer, aged 75 years, who received chemotherapy 2 days prior and reported worsening abdominal pain, nausea, vomiting, anorexia, and weakness over the past few days; (2) a male patient with stage IV pancreatic cancer, aged 58 years, who had last received chemotherapy 10 days prior and who reported dizziness as well as intermittent fever and chills with some abdominal pain over the past 4 to 5 days; and (3) a female patient with stage IV breast cancer, aged 56 years, whose treatment plan changed from chemotherapy to targeted therapy 2 weeks prior, following an unplanned hospitalization for cellulitis, and who now reported worsening fatigue, nausea, and decreased appetite.

The 3 clinical vignettes were presented to each clinician participant in 2 formats: without and with wearable data. First, the scenario was presented without wearable data, and participants were asked to triage the patient and determine the urgency of follow-up care. Clinicians were then asked to rate their likelihood of recommending that the patient present to the emergency department (ED) immediately using a 10-point Likert scale, with 0 representing "not at all likely" and 10 representing "very likely."

The scenario was then augmented with wearable data. Participants were shown visualizations of wearable device data (including heart rate, gait speed, and step count data collected around the time of the phone call or visit) and were asked to rate the likelihood of recommending ED presentation using the same 10-point Likert scale. They were also asked if the wearable data increased their confidence in their recommendation and to rate how helpful the wearable device data was to their understanding of the situation on a 10-point Likert scale with 0 representing "not at all helpful" and 10 representing "extremely helpful."

Interviews lasted between 20 and 40 minutes and were conducted remotely over Zoom (Zoom Communications Inc) by members of the research team (LC and CB). Interviews were digitally recorded, transcribed, deidentified, and entered into Dovetail (Dovetail Research Pty Ltd), a qualitative analysis software. Study team members conducted interviews until thematic saturation was achieved.

Analysis

Interview transcripts were analyzed using an iterative thematic analysis approach [14]. A coding team, comprised of 4 authors,

XSL•FO
RenderX

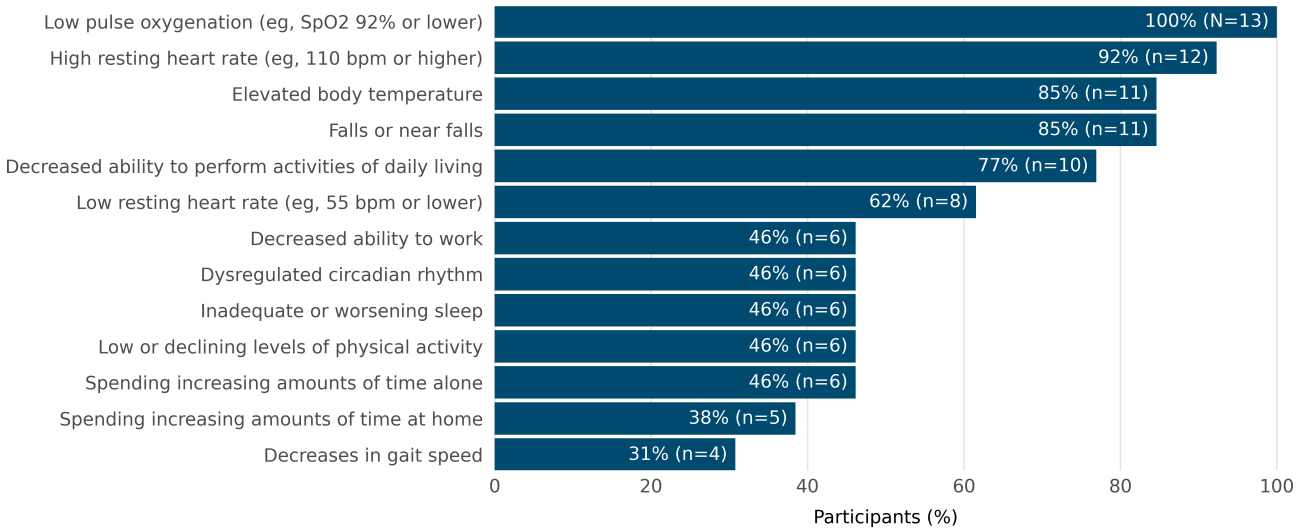
read all the transcripts and developed preliminary codes. A few selected transcripts were coded by 2 research team members to ensure consistency in coding and to group codes into larger thematic classifications. One team member coded all the transcripts. Participant quotes were lightly edited for clarity.

Descriptive statistics, including frequencies, medians, and IQR, were calculated to summarize quantitative data from questionnaires and structured interview questions. Due to the small size of our sample, nonparametric Wilcoxon signed-rank tests were performed to compare clinicians' recommendations for ED presentation without wearable device data to their recommendations after viewing wearable device data for each vignette. An α level of .05 was used as a cutoff for statistical significance. Analyses were performed in Python version 3.10 (Python Software Foundation).

Ethical Considerations

This study was conducted at a National Cancer Institute–Designated Comprehensive Cancer Center. The institutional review board of the University of Pittsburgh approved all study activities (STUDY23120104). Informed consent was obtained from all individual participants included in the study. Participant data were identified only by anonymized study ID numbers and stored in secure locations. Data collection was conducted between March 2024 and June 2024. Participants received US $100 in compensation for their participation.

Results



Participant Characteristics

Participants included physicians (n=4), physician assistants (n=5), nurses (n=3), and a certified registered nurse practitioner (n=1) who had a mean age of 42 (SD 12.60; range 25 - 61) years, were primarily White (12/13, 92%), and had been treating patients with cancer for an average of 9.7 (SD 6.42) years with a range from 5 months to 22 years.

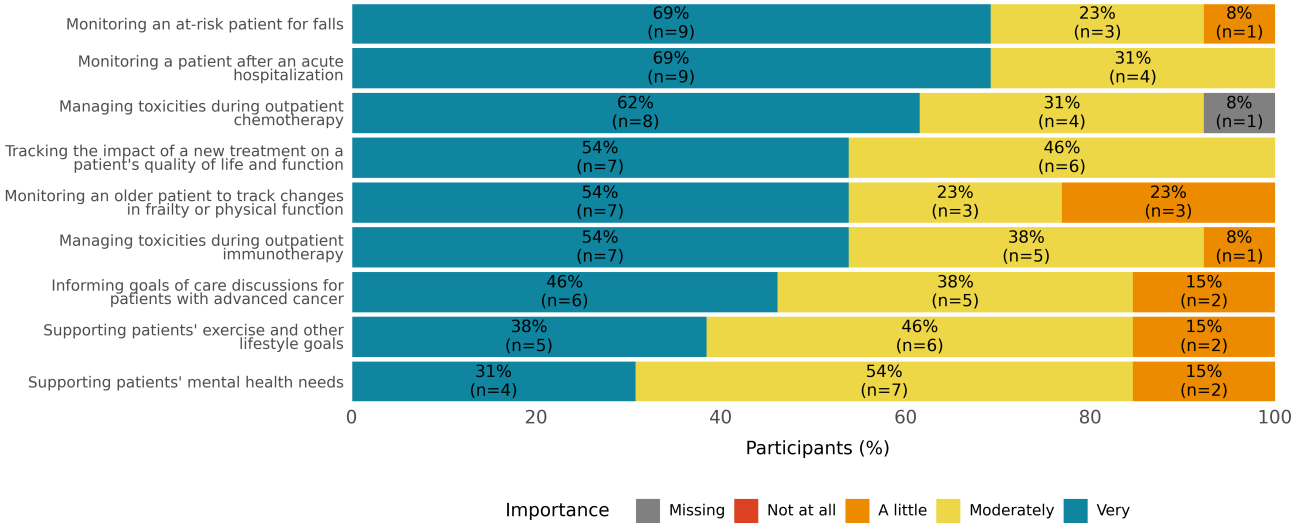
Survey

The majority of providers (11/13, 85%) indicated that they wanted to know if their patients experienced low pulse oxygenation, high resting heart rate, elevated body temperature, and falls or near falls (Figure 1). All providers considered wearable device data to be moderately to very important when monitoring a patient after an acute hospitalization, managing toxicities during outpatient chemotherapy, and tracking the impact of a new treatment on a patient's quality of life and function (Figure 2). When asked what would allow them to integrate wearable device data into their care, all providers responded that information about how to monitor and interpret wearable device data; having an additional member to monitor, respond to, and notify the team as appropriate; and integration of the wearable device data into the medical record system would be moderately to very helpful (Figure 3).

Figure 1. Number of participants who indicated they would want to know the following information about their patients.

XSL•FO
RenderX

Figure 2. Potential clinical scenarios in which wearable devices might be valuable.



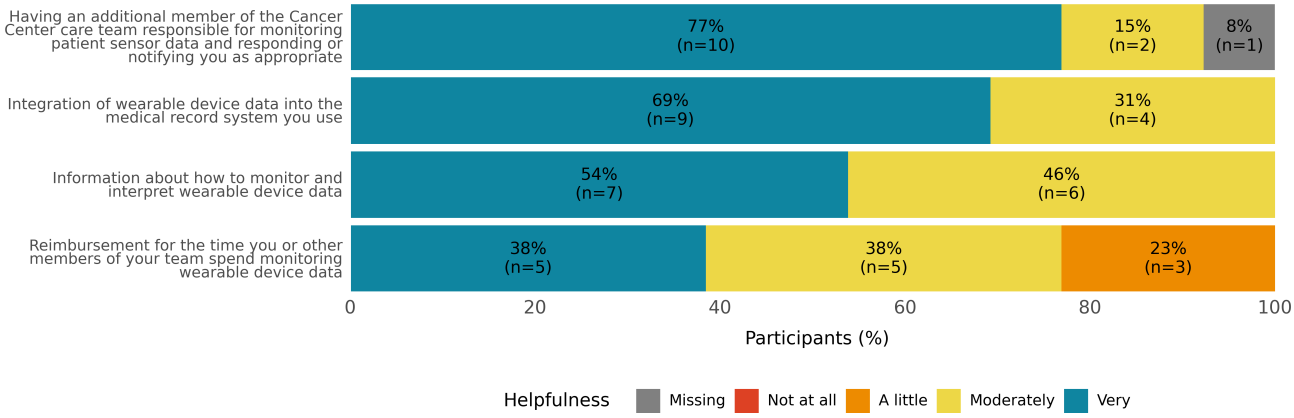


Figure 3. Perceived helpfulness of various supports for integrating wearable device data in the clinic.

Themes

During the semistructured interviews, four primary themes related to the benefits and barriers of integrating wearable device data into care were discussed: (1) corroborating reports, (2) identifying new issues, (3) coordinating care, and (4) patient-provider communication.

Theme 1: Corroborating Reports

Providers discussed how objective wearable device data could provide oncology clinics with a better understanding of patients' concerns and symptoms between clinic visits.

> *It would be nice if somebody's calling me with questions, and I can just pull it up and see what's really going on...It's easier for people to kind of not understand the full grasp of things when they're just talking. When you could just actually see the graph, it would probably be nice. But, also, I think it's important for the providers to see it, because whenever they come in and they're being seen by the providers, it would be good for them to be able to quantify what's going on between visits.* [P014, RN]

In particular, several providers mentioned that wearable device data could be used to help resolve conflicting reports they receive from patients and their support persons.

> *Especially if maybe I was getting one story from the patient and a different story from their caregiver, or I was surprised by what I was hearing.* [P007, MD]

> *Sometimes I feel like patients don't want to be dose reduced and they'll lie. And then I try to usually get the family to rat them out like, "Okay, so are they really grocery shopping and cutting the lawn?" They're like, "No, they're sitting on the couch all day."* [P003, MD]

Theme 2: Identifying New Issues

Some providers discussed the benefits of having wearable device data for identifying new issues that patients may not be reporting. One provider gave an example of a common scenario in which symptoms are typically experienced early in the chemotherapy cycle, but patients do not have another office visit for several weeks. This can lead to symptoms not being detected by the clinic or reported by the patient.

> *But I feel like that would be really helpful, because when we see the patients for chemotherapy, we're generally seeing them at the beginning of a cycle, right? And I feel like we have these people who rally and come in the office and look great because it's been 3 weeks or 4 weeks, or something since their last chemo, and sometimes the data that we would have to kind of say, "Hey, you know, we might have*

XSL•FO
RenderX

> *to dose reduce you, because this whole first 10 day span, here was what was happening from the data that we got back, even if you're not telling us that." So, I feel like that would be a valuable tool.* [P016, PA]

Theme 3: Coordinating Care

Oncology patients often have a number of doctors with whom they must coordinate their care. A few providers additionally discussed how integrated wearable device data could improve patient care coordination across various clinicians and specialties.

> *[T]here's a lot of collaboration between teams. And I think, sometimes the timing of different therapies, and how people are responding, can kind of be indicative. So potentially in multi-disciplinary collaboration between, like, "Hey is a patient, you know, how do we know that they're recovered from their chemo to get surgery? How do we know that they're recovered from their surgery to get chemo? How do we know that they're not having these toxicities from radiation that would make us prevent them from going on?" So, I think there'd be a role to kind of integrate it from a medical oncology perspective, but also kind of have interplay between the groups, to kind of look at what the best avenue of approach of treatment might be. And that's kind of outside of just, individual patient and clinician reporting, and that kind of thing. Just getting other teams involved, utilizing the data.* [P016, PA]

Theme 4: Patient-Provider Communication

Finally, when discussing whether patients should be notified about significant changes in their wearable device data, most providers thought it would be beneficial for promoting patient advocacy.

> *Yeah, I think their kind of awareness can only help the situation, even if it's having a family member call in and say, "Yeah, we did notice this, this pulse ox was really low," or "Yeah, she is having more trouble." Even if they make the contact and it's not necessarily just automatic from the data. If the patients alerted too, I think advocacy for themselves would be helpful.* [P008, PA]

> *Yes, so if they...became febrile or, their pulse ox was low, I would want them to be alerted. That way they could either call us if we weren't getting back to them, or assess how they're feeling. If your temp's 100.0 but you feel okay, that's not necessarily something we need to do anything about. But [it] would allow them, I think, to say, "Hey, this was my temp, but I felt fine," or the opposite. And I think that would be helpful to correlate those two things together.* [P015, PA]

However, several providers raised concerns about how these notifications would be triggered and suggested that careful wording should be used to prevent increasing patient anxiety.

> *That's a little bit harder, because I think it's like, what does that mean? Right? What if it's natural variation for them. I don't want to alarm them. I don't want them to think that there's something critically wrong with them, if they otherwise feel fine, right. If your heart rate bounced up a little bit, but then it comes back down again. They probably already know if they're not sleeping well, right. They probably already know if they feel bad. If it's something that's like a critical alert, then yes. Right. But that's also a little bit nuanced. What's critical? You have to set a value? But I don't know that they need feedback on every little variation.* [P005, MD]

> *I feel like, in a sense, that could be good. But then, in another sense, it could just stress the patient out further if it's a weekend, and somebody's not getting back to them ASAP that might send them into a spiral.* [P004, RN]

Vignettes

Results related to the wearable device data vignettes are presented in Table 1. Across all 3 vignettes, the median difference in the likelihood of recommending ED presentation before and after viewing wearable device data was 0 (Q1 range: −0.5 to 0; Q3 range: 0 to 0.875). There were no statistically significant differences in the likelihood of recommending ED presentation before and after viewing wearable device data for any vignette (all $P>.25$). All clinicians reported that the wearable device data impacted their decision-making or confidence, and clinicians generally rated the wearable device data as helpful.

Discussion

Principal Results

The goal of this mixed methods study was to examine oncology clinicians' perspectives on integrating wearable device data into clinical decision-making and care. Overall, providers noted many potential benefits of collecting wearable device data during outpatient treatment for patients with cancer and sharing these data with clinical care teams. Survey responses helped pinpoint which wearable device data providers would most like to be notified about, with clinicians indicating that they were most interested in tracking vital sign metrics, followed by data related to falls and functioning, and then by data on sleep and activity. Clinicians thought that wearable device data might be especially useful for remotely monitoring patients at high-risk moments in their care trajectory, such as after an acute hospitalization or after starting a new outpatient treatment.

Themes from interviews highlight that wearable device data could serve several useful functions in the context of cancer care, including providing objective data to corroborate, clarify, or reconcile contradictory subjective reports; helping to identify new issues that emerge when the patient is outside of the clinic; and providing objective baseline and historical data that might serve as a foundation for the coordination of multidisciplinary cancer care. Clinicians further noted both positive and negative implications for patient-provider communication. While wearable device data could help patients with cancer take a more active role in monitoring and managing their health, clinicians also noted that the patient-facing interfaces and notifications must be thoughtfully implemented to prevent undue patient anxiety and distress. Providing information on how to interpret wearable device data, adding an additional team member to monitor notifications about changes in these data, and integrating this information into the electronic medical record were judged as being potentially moderately to very helpful for future clinical integration.

Clinicians' responses to vignettes in which clinical scenarios were presented with or without visualizations of wearable device data collected from patients further demonstrated the potential clinical value of this technology, with clinicians rating the helpfulness of the data visualizations highly and noting that the data visualizations increased confidence in their clinical recommendations even though these recommendations were not changed by the data. Even if recommendations do not shift, increased clinician confidence in decisions and recommendations may be clinically significant, with benefits that could include enhanced patient trust in clinicians, reduced time spent on clinical decision-making, and decreased clinician burnout.

Comparison With Prior Work

These results are consistent with findings from previous studies in which noncancer physicians reported that wearable device data could improve communication and symptom management [8,9]. Similarly, oncology physicians were also concerned about whether alerts might cause undue anxiety for their patients [10]. Beyond the previously documented benefits and disadvantages, providers in this study indicated which specific wearable device data would be most relevant to their clinical needs and identified the support necessary to integrate this information into their clinical workflow. Furthermore, although providers' ED recommendations did not change significantly before and after

XSL•FO
RenderX

viewing the wearable device data, they reported increases in confidence comparable to those observed in the pediatric surgery vignette study that informed this aspect of the present study [13].

Limitations

This study used multiple methods, including online surveys, semistructured interviews, and clinical vignettes augmented with visualizations of oncology research patients' wearable device data, to begin to probe cancer clinicians' perspectives on wearable devices in cancer care. Limitations of this study include the small sample of clinicians from a single academic cancer center who were interested in participating in a study about wearable devices and who may be favorably biased toward digital health. The small sample also constrained our ability to examine different perspectives across disciplines (eg, among physicians vs nurses), disease specialties, or different clinics or care facilities, and exploration of how perspectives differ across these roles and settings should be a focus of future research. The survey and interview questions were not adapted from validated instruments or pilot-tested and suffered from various conceptual and methodological weaknesses. Additionally, the vignettes were based on a convenience selection of available wearable device data from our research group and therefore focused on patients with stage IV cancer who used a Fitbit Inspire device [7]. Findings may be different if vignettes focused on patients with early-stage cancer undergoing curative treatment or if data from a different wearable device were presented. Because these vignettes were selected retrospectively from a research study, they may not reflect real-world clinical scenarios where this information would be best applied.

Despite these limitations, this work contributes to a growing body of literature on the value of wearable and other mobile sensors in clinical oncology and highlights cautious enthusiasm among clinicians about how these data could inform and improve cancer care.

Future Directions

Findings suggest that oncology providers recognize the clinical value of integrating wearable device data into their workflow and that such integration may enhance their confidence in decision-making. More work is needed to identify the threshold at which wearable device data signals increasing risk as well as the best way to communicate this risk to providers and patients to avoid straining clinical resources or increasing patient anxiety or clinician alert fatigue. Research has suggested that early comprehensive training and additional support within the care team can mitigate burnout, but further investigation is needed into how this will be structured within oncology clinics to minimize cost and burden [15]. Additionally, future studies should examine how providing clinicians with access to wearable device data impacts clinical decision-making, patient-provider communication, and patient outcomes.

Future studies exploring wearable device data integration into oncology care should also acknowledge issues related to cost and access. Disparities exist along socioeconomic lines as well as between rural and urban areas, which, if left unchecked, could result in further inequity and widen the digital divide. Those with lower incomes, less educational achievement, and those living in rural areas are less likely to own wearable devices [16,17]. Simply supplying these devices to patients may not be sufficient either, as previous work has demonstrated that demographic and clinical factors, such as non-White race and cognitive impairments, have been linked to lower adherence to wearable devices [4]. Further investigation is needed into ways to improve digital health literacy in patients with cancer, in addition to improving access, to ensure wearable device data integration does not continue to advantage only certain populations.

In conclusion, oncology providers view patient-generated wearable device data as potentially valuable in the cancer care setting. They indicated that access to this information could improve communication between providers and patients, as well as between collaborating clinicians. Displaying wearable data alongside symptom data may also be helpful in contextualizing patient and caregiver reports. While the wearable device data visualizations did not change hypothetical clinical recommendations, providers reported that the data increased confidence in their decisions. As wearable devices become more common, it becomes increasingly important to have systems in place that allow these new real-world data streams to be integrated into the oncology clinic workflow.

Abstract

Background: Patients with metastatic breast cancer (MBC) experience significant quality-of-life decrements, but there are few supportive care interventions specifically designed for this group that significantly improve quality of life. Ecological momentary assessment (EMA) and related ecological momentary interventions (EMIs) may be particularly beneficial for patients with MBC. However, no studies have previously examined the use of EMIs in the context of metastatic cancer.

Objective: The purpose of this study was to qualitatively assess experiences with EMA and preferences for intervention content and mode among patients living with MBC, with an emphasis on EMIs.

Methods: Women with MBC (n=29) were recruited from a longitudinal, observational study of quality of life using an EMA design. In-depth qualitative interviews assessed participants' perspectives on the EMA design, including its feasibility, acceptability, and relevance to participants' MBC experiences. Guided by participants' EMA data, the interviews also examined the impact of self-monitoring and possible interventions when patients reported high symptom burden and/or low quality of life. Interviews were audio-recorded, transcribed verbatim, and analyzed using open coding, axial coding, and selective coding. The codebook was developed by reviewing a randomly selected subset of transcripts (n=5) and creating inductive, data-driven codes using the raw data, which were deductively organized into overarching themes.

Results: Participants were mainly White (17/29, 59%), heterosexual (23/29, 79%), currently working (17/29, 59%), and held at least a bachelor's degree (17/29, 59%). Participants had been living with MBC for a median of 2.5 years (range 0.2 - 16.6 years). Most were diagnosed with hormone receptor-positive (23/29, 79%) and HER2-negative (21/29, 72%) breast cancer. Qualitative analysis identified 5 major themes. The participants reflected on their reasons for enrolling in the study, including interest in study activities and giving back to the MBC community (theme 1: participant engagement). Most participants found the EMA format easy to complete, and they provided recommendations for improving the design of future studies, including altering the timing and frequency of questionnaires (theme 2: feedback on study design). While less common, some participants discussed how engaging with the EMA protocol altered their experiences or behaviors (theme 3: impact of self-monitoring). Participants also discussed their reactions to seeing their EMA data, including their mixed thoughts on real-time data sharing (theme 4: responses to data). Finally, participants suggested programs and resources to improve their overall quality of life, reflecting on their interest in real-time interventions and peer-to-peer support (theme 5: recommendations for future interventions).

Conclusions: Patients with MBC are willing to use EMA methodologies for data collection on quality of life and are open to EMIs with varying content and formats. Given variations in daily functioning between and within patients, a just-in-time adaptive intervention framework may be well suited for this population.

Introduction

Metastatic breast cancer (MBC) is breast cancer that has spread to other parts of the body; it is typically considered to be treatable but incurable [1]. Approximately 5% - 10% of breast cancers are metastatic at diagnosis, and 20% - 30% of early-stage breast cancers will progress to MBC [2-4]. In the past decade, novel treatment approaches have resulted in significantly increased survival times following MBC diagnosis [5-10]. For this reason, the MBC population is anticipated to increase in the coming years; by 2030, an estimated 246,000 people in the United States will be living with MBC (a 59% increase from 2017) [11,12].

MBC symptoms, treatment side effects, and their impact on daily functioning influence quality of life (QOL) in this population [13,14]. Given the incurable nature of the disease, QOL is a priority for patients with MBC [15-17]. Interventions that improve QOL for people with MBC are vital; not only is QOL an important outcome in and of itself, but improvements in QOL may also enable patients to adhere to life-sustaining therapies [18].

However, there are few supportive care interventions that significantly improve QOL for people with MBC. A 2023 systematic review identified 11 studies testing supportive care interventions specifically designed to improve QOL among individuals living with MBC [19]—only 3 demonstrated QOL improvements. More recent trials have found that health-related QOL in patients with MBC significantly increased 6 months after the onset of a supervised exercise program [20]. Two small pilot trials, one examining the impact of brief psychotherapy [21] and another evaluating a whole-food, plant-based diet [22], demonstrated effects in some QOL domains, but not others. Thus, further research is needed to develop, test, and optimize interventions targeting QOL for patients with MBC.

Ecological momentary interventions (EMIs) may be particularly beneficial to help ameliorate QOL in patients with MBC. EMIs deliver dynamic, individually tailored treatments to patients in real time and in natural settings [23,24], using ecological momentary assessment (EMA) methodology (ie, repeated, in situ reporting) to identify optimal times to provide support. This type of adaptive intervention approach has several potential benefits over traditional "one-size-fits-all" interventions: maintaining participant engagement, sustaining continued behavior change for longer durations, and ultimately achieving greater intervention effects [25]. Given the substantial variability in QOL trajectories among patients with metastatic cancer generally [26]—and the widely acknowledged heterogeneity of the disease and treatment response in MBC specifically [27-29]—EMIs could be ideally suited to meet the needs of patients with MBC with the most QOL decrements without overburdening those who are currently stable. However, EMIs have rarely been used in cancer survivorship research [30]. To our knowledge, there are no studies examining EMIs in the context of metastatic cancer, and further information is therefore needed to inform their use within this population.

The purpose of this study was to qualitatively assess preferences for intervention content and mode among patients living with MBC, with an emphasis on EMIs. Participants were recruited from a longitudinal, observational study of QOL using an EMA design [31,32]. In-depth qualitative interviews assessed participants' perspectives on the EMA design, including its feasibility, acceptability, and relevance to participants' MBC experiences. As symptom monitoring can improve symptom control for patients with cancer [33-35], the interviews also examined the impact of self-monitoring. Finally, guided by participants' EMA data, interviews solicited suggestions for possible interventions when patients reported high symptom burden and/or low QOL.

Methods

Procedures and Participants

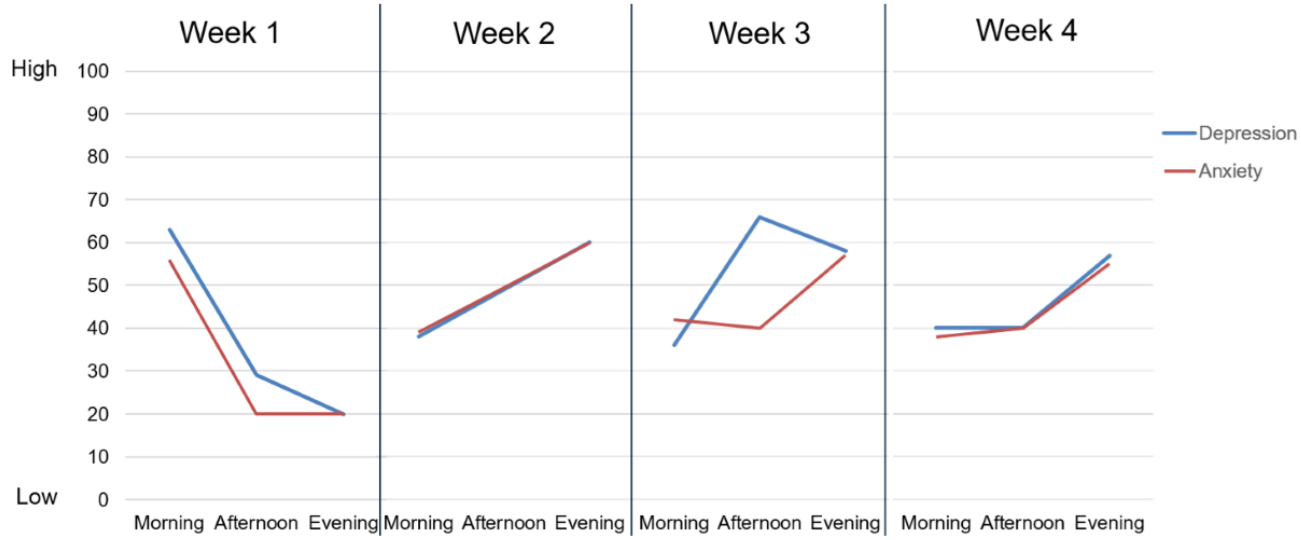
This study used qualitative exit interview data from a longitudinal study of QOL among patients with MBC. Data collection and analyses were guided by a pragmatist philosophical orientation and align with COREQ (Consolidated Criteria for Reporting Qualitative Research) [36].

Between January 2023 and April 2024, participants were recruited from 5 sites within the Georgetown Lombardi Comprehensive Cancer Center Network (in Washington DC, Maryland, and New Jersey). Eligible participants were assigned female at birth, aged 18 years and older, diagnosed with MBC, able to speak English or Spanish, and had a working telephone capable of receiving SMS text messages and accessing the internet. Study team members screened the electronic medical record to identify potentially eligible patients, obtained approval to approach participants from their treating oncologist, approached potentially eligible patients via telephone, and confirmed patient eligibility. Eligible, interested patients provided written informed consent via electronic signature on web-based consent forms. Following informed consent, participants completed a brief baseline survey and a 4-week EMA protocol. Participants completed 3 EMA prompts per day, 1 day per week (randomly assigned each week), for 4 consecutive weeks; thus, participants completed up to 12 EMA surveys. This "measurement burst" design incorporates short periods of intensive, recurrent assessment that are repeated longitudinally and spaced out over longer intervals. This design reduces participant burden while maintaining density of assessments [37,38]. EMA prompts consisted of a text message with a link to a REDCap (Research Electronic Data Capture) survey (Multimedia Appendix 1). Each survey assessed global QOL, symptom severity (depression, anxiety, pain, fatigue,

XSL•FO
RenderX

slowed cognitive functioning, appetite loss, nausea, gastrointestinal [GI] distress, and decreased libido), and positive experiences (social connectedness, peace, and joy). Participants had a 3-hour window to complete each EMA. Thus, EMA surveys enabled assessment of change in each domain over the course of the day and over the course of 1 month (the approximate length of a treatment cycle for a patient with MBC).

Upon completion of EMA data collection, participants were queried regarding their interest in and willingness to participate in an exit interview. Initially, we planned to offer the exit interview to all study participants. However, in the first 3 months of data collection, a relatively large number of participants were interested in participating in the exit interview (20/24, 83% of participants enrolled in the first 3 months). As it would not be feasible to conduct interviews and analyze qualitative data from more than 80% of study participants (target n=120), we elected to change our approach and randomly sample 15% of participants who were interested in the exit interview. Sampling for the interview was stratified by recruitment site, such that 15% of participants from each site who were interested in the exit interview were invited to participate. We engaged in constant comparative analysis [39] and conducted interviews until theoretical saturation was reached [40].



Three female members of the study team with prior training and experience in qualitative interviewing (CCC, MAVS, and JDR) conducted semistructured qualitative interviews in English or Spanish with selected participants. The interviewers did not have a relationship with the interviewees prior to their participation in the study but had sometimes interacted with the participants during the EMA phase. Interviewers reintroduced themselves and reminded participants of the rationale for the study at the start of the interview. The interviewers had foundational knowledge of MBC but not firsthand experience. They also tended to be younger than the interview participants. These characteristics may introduce bias by affecting the interviewer's application of probing questions. Potential bias was managed through postinterview debriefing with colleagues.

The interview guide (Multimedia Appendix 2) was developed by the study team in collaboration with patient advocates with MBC. We first identified broad topic areas of interest that included both feedback on their experiences in this study and the perceived acceptability of future research projects, including EMIs. Once the topic areas for the interview were identified, the group brainstormed a wide variety of probing questions that could be used to elicit additional input from participants. Thus, the resulting interviews began with open-ended questions about participants' experiences with the EMA protocol and symptom self-monitoring. After the open-ended questions, participants were shown their EMA data in graphical format (see Figure 1 for an example). Specifically, participants were shown a series of line graphs representing their responses to the EMA surveys over the 4 weeks in the study. Participants viewed graphs representing overall QOL, mental health (anxiety and depression), physical health (pain, fatigue, nausea, and GI distress), thinking and feeling (slowed cognitive functioning, appetite loss, and decreased libido), and positive experiences (social connectedness, peace, and joy). The EMA data display figures were developed by the study team and iteratively revised based on feedback from patient advocates with MBC to ensure clarity prior to their use in the interviews. For each graph, the interviewer oriented the participant to the horizontal axis, vertical axis, and legend. The interviewer also answered any questions about the data visualization. Participants were then asked about their reactions to their data, how they might change their behavior in response to these data, and their preferences for data-guided symptom management interventions.

Interviews took place via telephone or web-based video platform, based on participant preference. When interviews took place via telephone, participants were mailed or emailed the EMA data display figures and were instructed to refer to them during the telephone call. Interviews lasted 44 minutes on average (range 26‐76 minutes), were audio-recorded, transcribed verbatim, and translated to English (if necessary). The interviewer took field notes during the interviews. As participants did not consent to be recontacted, we did not conduct repeat interviews, return transcripts to participants for review, or have participants provide feedback on the findings.

Figure 1. Example ecological momentary assessment (EMA) data display figure, showing one participant's responses to EMA questions on anxiety and depression across 12 time points (morning, afternoon, and evening; 1 day per week for 4 consecutive weeks). The vertical axis represents the visual analog scale ranging from 0 to 100 and the horizontal axis represents the EMA time point. The blue lines indicate depression scores and the red lines indicate anxiety scores.

Data Analysis

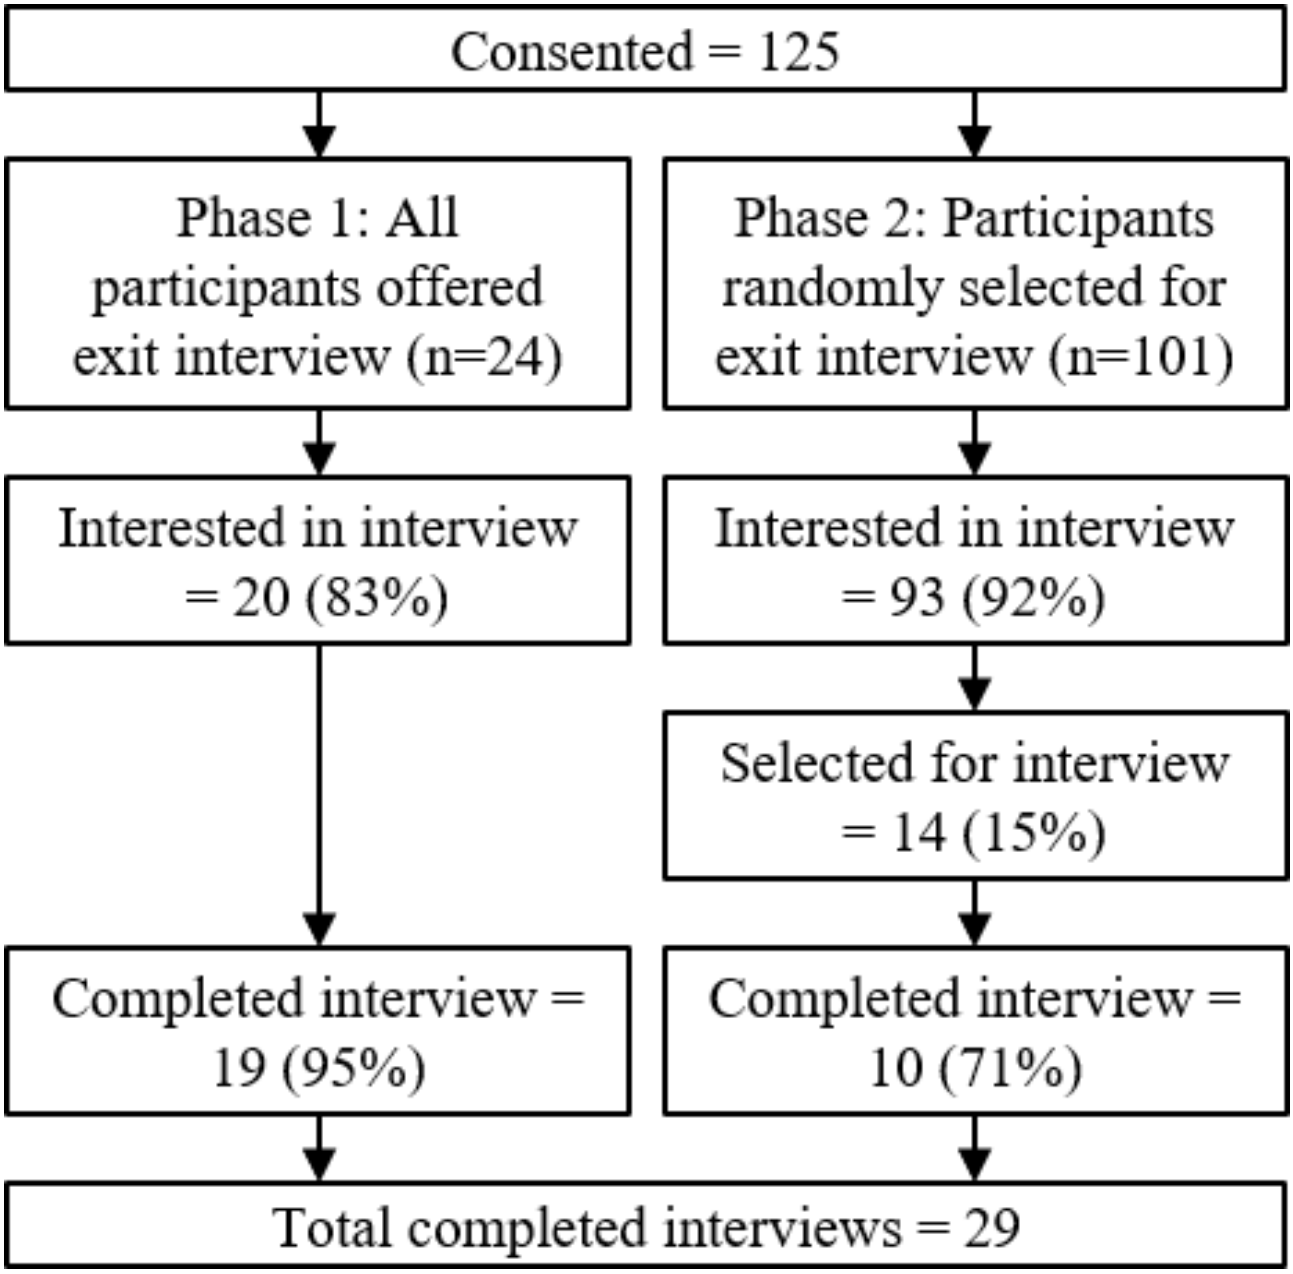
We used a combined deductive and inductive qualitative data analysis approach [41,42]. First, 3 members of the study team (CCC, MAVS, and EPT) reviewed a randomly selected subset of transcripts (n=5) and collaboratively developed a detailed codebook consisting of data-driven codes from the raw data [43]. These codes were then organized based around core concepts of feasibility and acceptability as reflected by the topic areas in the interview guide. Thus, the data-driven codes represented inductive subthemes that were deductively organized into themes based on our belief that certain core concepts exist in the data [44,45]. Following the development of the codebook, all transcripts were independently coded by 2 of 6 raters (MAVS, ZR, NK, EPT, MS, and HK). Coding disagreements were resolved through discussion with a third rater (CCC) until consensus was reached. Coding was conducted using Dedoose.

Ethical Considerations

All procedures were reviewed and approved by the Institutional Review Board at Georgetown University (institutional review board number 00005081). All participants provided written informed consent via electronic signature on web-based consent forms and confirmed ongoing consent verbally at the time of the qualitative interview. Informed consent included consent for the use of quotes in research publications. Qualitative data are deidentified to protect participant confidentiality. Participants received US $10 for completing the baseline survey, up to US $25 for completing EMA surveys, and US $20 upon interview completion. Thus, participants could earn up to US $55 for completing all study activities. Participant incentives were provided as a gift card.

Results

Participant Demographics



Of the 125 eligible patients who consented, 113 out of 125 (90%) expressed interest in the exit interview, 34 out of 113 (30%) were invited to participate in the interview, and 29 out of 34 (85%) completed the interview (Figure 2).

See Table 1 for a full description of the interview participants. The median participant age was 57 years. The majority were non-Hispanic White (17/29, 59%), currently working (17/29, 59%), and held a bachelor's degree or greater (17/29, 59%).

Participants had been living with MBC for a median of 2.5 years (range 0.2 - 16.6). Most participants were diagnosed with hormone receptor positive (23/29, 79%) and HER2 negative (21/29, 72%) breast cancer. The most common treatments received were targeted therapy (20/29, 69%) and hormone therapy (16/29, 55%); chemotherapy (7/29, 24%), immunotherapy (5/29, 17%), and radiation therapy (1/29, 3%) were less common. Most participants had an Eastern Cooperative Oncology Group performance status rating of 0 (13/29, 45%) or 1 (11/29, 38%), indicating no performance restrictions and restrictions in strenuous physical activity, respectively.

Textbox 1. Representative quotes illustrating themes 1-4.

Participant engagement

- "I like being part of a study in that I think it's good to get a wide range of how people experience cancer and everything like that, so." [Participant 16, 9 years post-MBC diagnosis, completed 12 EMA surveys]
- "These things are good experiences for people. I mean, you guys get insight and I get to think about how I actually am feeling at those times." [Participant 19, 1 year post-MBC diagnosis, completed 8 EMA surveys]
- "Well, I really respect my oncologist. So the fact that she had passed me along for it made me want to do it. And then I think looking at quality of life issues for people with metastatic breast cancer, I felt a connection to the study." [Participant 20, 9 years post-MBC diagnosis, completed 12 EMA surveys]

Feedback on study design

- "It was very easy to participate. And I haven't given it much thought because I would just do it. And it wasn't difficult in any way." [Participant 12, 5 years post-MBC diagnosis, completed 10 EMA surveys]
- "Instead of looking at overall quality of life, we are being asked to look at it in snippets of time. And I think you can get a skewed answer that way. It really depends on how the participant is looking at the question." [Participant 27, 3 years post-MBC diagnosis, completed 7 EMA surveys]
- "I think the three times in one day, I don't know if that was really needed. I would rather have done more [days] because it would key in more on if you're having a good day or a bad day. Because I can remember some of my bad days. I thought, 'Oh, I wish I had the questions.' [My answers] would be so different." [Participant 17, 2 years post-MBC diagnosis, completed 12 EMA surveys]
- "I appreciated the fact that I could take the survey on my phone, so no matter where I was, I was able to access it. That was really good." [Participant 4, 10 years post-MBC diagnosis, completed 10 EMA surveys]
- "I wish that I could have done it over email because sometimes it's hard for me to get to my phone. But I liked it when you guys texted me the night before so I knew that I would have to check my phone a few times a day." [Participant 14, 5 months post-MBC diagnosis, completed 12 EMA surveys]
- "I thought the questions were very good. They touched on a lot of different parts of your life that you really wouldn't normally think about." [Participant 17, 2 years post-MBC diagnosis, completed 12 EMA surveys]
- "Some of [the questions] didn't apply to me. I'm not sexually active, so I didn't know how to gauge that." [Participant 4, 10 years post-MBC diagnosis, completed 10 EMA surveys]

Impact of self-monitoring

- "It did make me more cognizant and mindful. It made me think, 'Is there something I can do for myself?' Having those little pauses was actually nice. And at times it made me kind of grateful in that moment that not everything was challenging." [Participant 24, 3 years post-MBC diagnosis, completed 12 EMA surveys]
- "It just made me think about what I'm going through because sometimes you just go through the day, and you don't pay much attention to what you're feeling. And this really made me think more about what's happening, and if it wasn't good, how can I change it or how could I feel different...It makes you ask yourself, 'How am I taking care of myself? Am I doing a good job or am I not?' Because that's important." [Participant 17, 2 years post-MBC diagnosis, completed 12 EMA surveys]
- "I don't think I changed [my behavior]. I think I became more mindful of things...I can't think of an instance where I was like, 'Oh, let me go do more self-care.' I think it just made me mindful of what I was doing." [Participant 6, 2 years post-MBC diagnosis, completed 11 EMA surveys]
- "I was more aware of my behavior, aware of myself like I was more conscious of how I was feeling on what I was doing. For instance, when I tell myself, 'I don't feel like exercising today,' or, 'I'm too tired to go downstairs on the treadmill,' but then I have to tell myself, 'You'll feel better. You need it.' So just things like that. It just made me more aware...It's like you're holding yourself accountable." [Participant 18, 3 years post-MBC diagnosis, completed 12 EMA surveys]

Responses to data

- "I was a little hesitant [to look at my data] because I kind of was expecting this...Unfortunately, I think this is probably pretty accurate and describes my highs and lows and the stress and overwhelm that I had been feeling...But I guess the anxiety led to more of the overwhelm, feeling alone, challenging, more depressive thoughts and feelings. So unfortunately, this is probably really, really accurate." [Participant 24, 3 years post-MBC diagnosis, completed 12 EMA surveys]
- "Overall, I try to stay very positive, but when you get granular with specific feelings and experiences and whatnot, yeah, it probably doesn't equate to the quality of life being so high...As I look at [my data], I'm like, 'Well, how the heck do you get that [high] quality of life then?' Because it just doesn't seem like anything should—none of these average to the quality of life that I thought I had. But at the end of the day—so food didn't taste good to me today and whatever, but is it really affecting my quality of life? I'm just happy to be here. Just very lucky. Very, very thankful." [Participant 25, 1 year post-MBC diagnosis, completed 11 EMA surveys]

XSL•FO
RenderX

Textbox 2. Representative quotes illustrating theme 5 and related subthemes.

Content

- "[I would like] suggestions that I could implement myself without needing assistance from someone else. Definitely things that would have the quickest effect." [Participant 3, 2 years post-MBC diagnosis, completed 11 EMA surveys]
- "You can send more tips of that meditation, of just that deep breathing...I think deep breathing makes a big difference. Even if you don't know how to meditate, to teach someone how to do the deep breathing, to help them through those anxiety attacks will help." [Participant 18, 3 years post-MBC diagnosis, completed 12 EMA surveys]
- "Maybe you can send ways to calm yourself down in the moment. Like take a step back, breathe in, breathe out, put your arms up, whatever. Things like that. Or if you need to punch a pillow or something. So it might be more intense, but it has ideas that are safe for you to get it out. Go in the bathroom and let it out. Find yourself a place or just take a pause in whatever you're doing, just different things like that." [Participant 7, 2 months post-MBC diagnosis, completed 10 EMA surveys]
- "Some kind of question to prompt thought. Like, 'When have you last eaten, or have you had some water recently? Can you get a few minutes of fresh air or talk to somebody or think of an affirmation or write something down?' Any of those kinds of things, I guess. Just something to be more mindful and practical." [Participant 24, 3 years post-MBC diagnosis, completed 12 EMA surveys]
- "I guess for nausea, to remind you of all the interventions and to make sure that you're on top of it. It's so important with nausea to stay ahead of it. Same with pain management or GI distress, really, too." [Participant 20, 9 years post-MBC diagnosis, completed 12 EMA surveys]
- "I know that there are studies about how getting out in nature lifts your spirits and exercise and that sort of thing. So maybe encouragement to do that...Or kind of preemptive solutions that might hit a larger number of people. Like, 'Oh, look, they reminded me this week that it's spring so your allergies might be worse because your immune system is compromised so do this. Exercise inside instead of jogging outside.'" [Participant 15, 8 years post-MBC diagnosis, completed 12 EMA surveys]
- "My doctors tell me that they have resources out there that will help a person. So if I was feeling depressed, I would probably want to be guided somewhere where I can talk to a mental health person, or talk to someone about a type of medication, or support groups or stuff like that. Maybe you can tell me, 'Okay. If you use this link, that can take you to where you need to get the help that you think you might need.' Because there's so much information out there. Sometimes you can't concentrate." [Participant 1, 1 year post-MBC diagnosis, completed 10 EMA surveys]

Timing

- "If you rank between this and this [on the survey], maybe they could send them to you just as a, 'Hey, you're not alone. We appreciate your feedback. And while it may not totally resolve your matter, here are some suggestions.' Right after you finish that survey for that time period or something because some people may not know what to do, just suggestions." [Participant 7, 2 months post-MBC diagnosis, completed 10 EMA surveys]
- "I feel like [it would suggest] things that I already do, which are listen to music and meditate and pray. But just, I guess, suggestions to help in the moment." [Participant 13, 1 year post-MBC diagnosis, completed 12 EMA surveys]
- "I think a prompt would be nice. [Something] that's nudging you to go and look at it, but if you don't want to, you can opt out. I think the idea of having a nudge to go look at something would be nice based off reporting something as being lower and then that kind of correlating with the app prompting." [Participant 23, 2 years post-MBC diagnosis, completed 12 EMA surveys]
- "I think it depends. That week when I was having a really tough time, I might not have been able to take another piece of advice that day. So maybe it's a follow-up on the next day...Just based on that one particular day, I might have just been like, 'No, you have no idea. Nothing is going to help me today.' But maybe the next day? Like, 'Okay. The next time you find yourself having that kind of thinking or this, why don't you maybe try one of these suggestions? Keep this in your pocket.'" [Participant 25, 1 year post-MBC diagnosis, completed 11 EMA surveys]

Format

- "If there's a website you can go to and it has different topics—'I'm feeling a lot of fatigue today. What are some of the things I can do?' You click on a button and see, 'Go outside and take a brisk walk.' Yes, practical application is what I'm looking for." [Participant 3, 2 years post-MBC diagnosis, completed 11 EMA surveys]
- "Nothing too lengthy. For me, my attention span isn't all that great...I don't mind reading but nothing that's going to take more than like 15 minutes of my time. I just get distracted and impatient." [Participant 13, 1 year post-MBC diagnosis, completed 12 EMA surveys]
- "Well, I mean, people could choose. There's websites you can go on to get free [meditation videos] and there's also websites that have some wonderful healing music on too." [Participant 9, 4 years post-MBC diagnosis, completed 9 EMA surveys]

Audience

- "It's so complicated because there are people who suffer from very difficult symptoms, who sometimes don't feel like going for a walk. But if the family supports them, encouraging them to take a break, 'Let's just walk for 15, 20, 30 minutes' that can help a lot. Because there are times when those chemotherapies are so strong, it's really difficult to tell a person, 'Go for a walk.' So, if the family supports them, or friends accompany them, maybe the person will be a little more encouraged." [Participant 29, 10 years post-MBC diagnosis, completed 12 EMA surveys]
- "My husband is not one of those people that likes to talk or even believes in therapy, but he's a people person. So he's related to some of his coworkers and things like that that have had wives or spouses that have had cancer. I know that that's helped him. I just wish that there was somebody for my kids and my husband to talk to." [Participant 7, 2 months post-MBC diagnosis, completed 10 EMA surveys]

XSL•FO
RenderX

Peer support

- "What would help? Sometimes talking to somebody...If I'm really down in the dumps, I would not call my friends, though, because they don't understand. But I would call another cancer patient. That's how I would handle it for me. I think that would help me, because I know who I can call." [Participant 8, 8 years post-MBC diagnosis, completed 11 EMA surveys]
- "I think reaching out just by phone to talk to somebody, just having a phone buddy or something like that. I think having someone to talk to would be important. Not so much to complain, but to let them know what's going on. And then maybe have the person talk about good self-care." [Participant 9, 4 years post-MBC diagnosis, completed 9 EMA surveys]

Theme 1: Participant Engagement

Participants primarily enrolled in the study because they wanted to give back to the MBC community. Participants cited an altruistic drive as motivation for joining the study, stating "it's my turn to give back a little bit" [Participant 26, 9 years post-MBC diagnosis, completed 10 EMA surveys]. Other participants expressed a desire to join the study to provide representation for specific subpopulations within the MBC community. For example, one participant stated that they enrolled in the study for "the opportunity to give some data points for women of color" [Participant 22, 2 years post-MBC diagnosis, completed 11 EMA surveys]. Furthermore, participants appreciated the study's focus on their QOL, which they felt was an understudied dimension of MBC: "This is an area where there could be more support and research and more information out there for people who are just so busy and dealing with [MBC] and living with [MBC]" [Participant 24, 3 years post-MBC diagnosis, completed 12 EMA surveys].

Participants also appreciated the low-burden nature of the study procedures. The 1-month assessment time frame meant that they "didn't have to make a big commitment" [Participant 26, 9 years post-MBC diagnosis, completed 10 EMA surveys], and the lack of financial restrictions to enroll encouraged participation because "it doesn't cost anything" [Participant 7, 2 months post-MBC diagnosis, completed 10 EMA surveys].

Theme 2: Feedback on Study Design

Most participants felt the EMA design was straightforward. Almost all participants noted that the daily assessments were simple to complete, especially given the reminders provided the day prior. One participant reflected that "It was quick and straightforward, very, very user-friendly, and very easy for somebody who could be forgetful like me and just be dealing with a lot all at once. It didn't feel like it was one more thing that I had to do, which was really nice" [Participant 24, 3 years post-MBC diagnosis, completed 12 EMA surveys].

However, some participants reflected on a lack of clarity in study activities. Several participants noted that they did not fully understand the study procedures until they were actively completing them. For example, one participant had thought that they would receive surveys daily, rather than 1 day each week. Other participants did not grasp the overarching goal of the study and/or how the design would answer the research questions. As one participant shared, "I guess I just didn't really understand what [the researchers] were looking for" [Participant 21, 17 years post-MBC diagnosis, completed 11 EMA surveys].

When asked about alternative study designs, participants suggested fewer assessments per day, with a larger response window, for multiple days in a row. Some participants had trouble responding to surveys within 3 hours. One participant noted, "Sometimes, I found it difficult to keep up with actually answering the questions in a timely manner. Just regular everyday time management sometimes didn't work out the way I needed it to" [Participant 3, 2 years post-MBC diagnosis, completed 11 EMA surveys]. Thus, allowing a longer response window could improve response rates. Generally, participants felt that the 3 surveys administered per day were more than sufficient to adequately capture their experiences that day; some noted that 1 or 2 surveys would have sufficed. However, participants frequently stated that completing surveys several days in a row would be a better reflection of their experiences. As one participant put it, "There were days that I wasn't doing well, but those weren't the days that the questions were. So in a way, I felt like it wasn't accurate to how I was feeling all the time" [Participant 17, 2 years post-MBC diagnosis, completed 12 EMA surveys].

Participants had mixed experiences with the technology used to deliver the study surveys. Some participants enjoyed completing surveys on their cell phone, as this allowed them to do the survey in any location and did not interrupt their daily plans. Other participants would have preferred email surveys because it was sometimes difficult for them to get to the phone.

Another commonly cited technology issue was the use of sliders to capture symptom data, rather than a Likert-style response scale. Participants felt that the slider did not always reflect their experiences and that inadvertently moving the slider resulted in inaccuracies in their data. Numerical answers were preferred over sliders "because, with numbers, I could have done what I wanted to tell you with more precision" [Participant 10, 1 year post-MBC diagnosis, completed 11 EMA surveys].

Relatedly, many participants wished the study had involved more open-ended questions or room for comments. One participant noted:

> *I thought it was a little too restrictive regarding the type of questions they were asking and my limited ability to be able to express what I was actually trying to think about, being forced to gauge high or low, where it would have helped me [is] if I could put in a little comment section. This is what I'm feeling. This is why I'm feeling it.* [Participant 4, 10 years post-MBC diagnosis, completed 10 EMA surveys]

Participants felt that most questions resonated with their MBC experiences, with the exception of one: libido. Several participants noted that the questions resonated with their lived experiences with MBC, with the surveys serving as both a clarifying and reflective experience. For example, one

XSL•FO
RenderX

participant reflected, "It was easy [to answer the questions] because I'm living it. So it's not really something I have to think about" [Participant 19, 1 year post-MBC diagnosis, completed 8 EMA surveys].

The one exception to this pattern was the item assessing changes in libido. This item prompted many negative reactions; participants felt "uncomfortable" [Participant 7, 2 months post-MBC diagnosis, completed 10 EMA surveys] or "sad" [Participant 16, 9 years post-MBC diagnosis, completed 12 EMA surveys] and were "sick of being asked about [it]" [Participant 15, 8 years post-MBC diagnosis, completed 12 EMA surveys]. Confusion was another common reaction. Many participants did not realize that changes in libido can be a side effect of cancer treatment and were confused about why this would be included in a study of QOL in MBC. Others understood libido "as sex" [Participant 8, 8 years post-MBC diagnosis, completed 11 EMA surveys], which led to some confusion on the premise of the question and what was being asked, with the sense that it was not relevant for their personal situation (particularly for participants who were not partnered). Participants suggested that future studies assessing libido should include a "not applicable" response option.

Theme 3: Impact of Self-Monitoring

Some participants described negative emotional responses to the study activities or procedures. For example, one participant stated they felt "upset" answering questions about their QOL on "one of the days [they were not] really feeling good" [Participant 28, 3 years post-MBC diagnosis, completed 10 EMA surveys]. Another participant described their experience in detail:

> *I mean, I'm not sure if upsetting is the right word, but it was kind of like, "I don't want to go to that space right now." Sometimes I was like, "I'm focused on something completely different, and that's going to shift my perspective." The survey itself doesn't take very long to fill out, but yeah, your mind does kind of go in that space, and you start to think about that, which is distracting, potentially, to what your current day's achievement outcomes and focus that you want it to be...when I finished the surveys or if it was a survey day, I don't think I left feeling upset. But I think, yeah, a lighter version of distressing...* [Participant 23, 2 years post-MBC diagnosis, completed 12 EMA surveys]

In other words, the survey prompt tended to interrupt participants' usual routines and, in doing so, sometimes caused distraction or distress as they reflected on their symptoms and experiences.

While participants generally expressed heightened awareness in response to the study assessments, the extent to which this resulted in behavior change varied. Several participants expressed that completing the study assessments made them feel more self-aware, and they were appreciative of the opportunity to reflect on their feelings and experiences:

> *It was amazing to actually capture my daily activities so I would be prepared to answer the questions. So I really was very focused on me and my feelings, which sometimes I will try to avoid and just stay busy. But this actually made me kind of reassess myself and see that I want to keep focusing on certain things, or just go on and enjoy life and do some of the things I wanted to do.* [Participant 5, 2 years post-MBC diagnosis, completed 6 EMA surveys]

While this reflective experience prompted some to adopt certain behavior changes—such as exercise, yoga, or cooking a meal—many participants reported no explicit behavior change as a result of study participation. As one participant stated, "I thought the survey was very helpful, but it didn't change me" [Participant 4, 10 years post-MBC diagnosis, completed 10 EMA surveys].

Theme 4: Responses to Data

Participants appreciated the opportunity to see their data at the end of the study. In reviewing their data, participants felt that they could more clearly see how it was going to be used to accomplish the goals of the study. As one participant noted:

> *I really appreciate the fact that you are sharing all the information with me, and the opportunity to know what happened at the end. So that's interesting for me because I never had that before, and I've been in a couple other studies.* [Participant 28, 3 years post-MBC diagnosis, completed 10 EMA surveys]

Many participants found their data interesting or surprising but individual reactions varied. Some participants had positive responses when presented with data that they characterized as "good," while others expressed sadness upon "seeing that [quality of life] was trending down" [Participant 16, 9 years post-MBC diagnosis, completed 12 EMA surveys]. While most participants felt that the graphs accurately reflected their weekly experiences, others commented on the inaccuracy of some data due to "user error" [Participant 1, 1 year post-MBC diagnosis, completed 10 EMA surveys]. This "user error" most frequently referred to inadvertently choosing the wrong response value on the slider (see theme 2).

Of particular note were participant reactions to their data on positive experiences, including joy, peace, and social connection. Some attributed low scores directly to their physical or mental health, or even felt that positive experiences were not possible for someone with cancer: "As my other friend with cancer and I have discussed, joy is not really much of a part of our experience. So I'm not surprised it never got over 50%" [Participant 15, 8 years post-MBC diagnosis, completed 12 EMA surveys]. However, many of the participants reported positive experiences *despite* difficulties with their physical or mental health:

> *[My] physical health has declined. I have neuropathy so bad. It's hard to hold things. My feet just dangle. I have no control over my feet. I don't even get out of my pajamas, or some days I don't even brush my teeth. But positive experiences, I do have some still. I still have my friends that call me and visit me sometimes.* [Participant 8, 8 years post-MBC diagnosis, completed 11 EMA surveys]

XSL•FO
RenderX

> *I have chronic neck pain. I have [cancerous] lesions top to bottom on every vertebra of my spine, and the worst being my cervical spine. And that's where I had the surgery last year. So it's healed. It's strong. I mean, I was almost paralyzed last year, and I'm nowhere near that. I have a normal life, except I do have chronic pain in my neck sometimes...[but] my family and my kids bring me so much peace and joy.* [Participant 13, 1 year post-MBC diagnosis, completed 12 EMA surveys]

Reactions to the idea of real-time data sharing were mixed. Interviewers asked participants how they would feel if their data were available in real time. Some participants felt that this would be beneficial:

> *I think it would have been helpful. If I could see them in real time, then I would be aware of the things that I could change and make an effort to change them. Obviously, some stuff you can't really change with pain and anxiety and stuff. That stuff is hard to change. But in terms of joy and peace, there are things you can do to try to change those.* [Participant 3, 2 years post-MBC diagnosis, completed 11 EMA surveys]

Others felt that real-time data sharing, especially in moments of high depression or anxiety, would not be helpful. Many participants shared that they "don't think [they] would have responded any differently" or changed their behaviors if they had received data in real time and preferred to "look at it all together in a month" to "get a better picture" [Participant 18, 3 years post-MBC diagnosis, completed 12 EMA surveys].

Theme 5: Recommendations for Future Interventions

Real-time interventions were of interest to most, but not all, patients with MBC with various suggestions for content and format. Participants were asked about their openness to real-time interventions in moments of high symptom burden. Many participants were open to receiving resources in real time. Suggested content for EMIs varied widely and included mindfulness, meditation, and breathing exercises; tips for emotion regulation; reminders to take medications for side effects such as pain, nausea, and GI distress; suggestions to engage in physical activity or spend time outside or in nature; affirmations and journaling; and prompts to connect with other people. Participants overall emphasized desire to see "practical application(s)" in real-time interventions to alleviate symptom burden [Participant 3, 2 years post-MBC diagnosis, completed 11 EMA surveys]. Some participants wanted real-time interventions that could "[be implemented] without the need for someone else" [Participant 3, 2 years post-MBC diagnosis, completed 11 EMA surveys]. These wishes for quick, pragmatic, and implementable interventions were consistent across participants who expressed interest in real-time interventions. In terms of the format of the intervention, participants overall expressed a preference for receiving resources via email or text message, preferably with a link to a website where they could access further information as needed. As one participant put it:

> *If you rank between this and this [on the survey], maybe they could send them to you just as a, "Hey, you're not alone. We appreciate your feedback. And while it may not totally resolve your matter, here are some suggestions." Right after you finish that survey for that time period or something because some people may not know what to do, just suggestions.* [Participant 7, 2 months post-MBC diagnosis, completed 10 EMA surveys]

Relatedly, one participant described how the frequency of real-time interventions could affect their adherence, sharing, "I like messages sporadically, something that draws my attention to it. It can't be too habitual" [Participant 24, 3 years post-MBC diagnosis, completed 12 EMA surveys]. Less commonly, some participants suggested that a responsive, but delayed, intervention would be preferable. As one participant shared:

> *That week when I was having a really tough time, I might not have been able to take another piece of advice that day...maybe the next day?* [Participant 25, 1 year post-MBC diagnosis, completed 11 EMA surveys]

Some participants saw potential benefits of EMIs for their friends and family. While most participants felt that resources should be delivered directly to the person living with MBC, a few noted that their friends and family might also benefit from resources. For example, one participant expressed a desire for "somebody for my kids and my husband to talk to" [Participant 7, 2 months post-MBC diagnosis, completed 10 EMA surveys]. Another noted that engaging friends and family members might help bolster the overall effect of the intervention, stating "if the family supports them, or friends accompany them, maybe the person will be a little more encouraged" [Participant 29, 10 years post-MBC diagnosis, completed 12 EMA surveys].

Many participants were interested in interventions that included engagement with other people with similar experiences. Participants expressed a desire to connect with other patients with MBC, particularly in moments of high distress: "If I'm really down in the dumps, I would not call my friends, though, because they don't understand. But I would call another cancer patient" [Participant 8, 8 years post-MBC diagnosis, completed 11 EMA surveys]. Some participants had been able to establish their own peer support networks but felt that providing support resources could help others. As one participant noted:

> *I think that there are people who don't know how to access those supports. So maybe [you could provide] the information for therapists or support groups. Having access to those resources, maybe places where you could access them for free.* [Participant 12, 5 years post-MBC diagnosis, completed 10 EMA surveys]

Thus, an EMI that connected patients with peers or provided resources for seeking additional support was widely seen as potentially beneficial.

Although less common, some participants were not interested in additional resources. A smaller group of participants, typically those further from MBC diagnosis, was not interested in receiving resources for managing symptoms. As one participant described, "There's nothing right now that I need

XSL•FO
RenderX

addressed. I'm already addressing it. Like I said, I've already been around the block a few times, so I've already come up with my own way if there is a way" [Participant 27, 5 years post-MBC diagnosis, completed 7 EMA surveys].

Discussion

Principal Findings

This study qualitatively explored patient experiences with EMA and their preferences for an EMI to ameliorate QOL. We identified 5 major themes from qualitative interviews: participant engagement, feedback on study design, impact of self-monitoring, responses to data, and recommendations for future interventions. These results highlight that patients with MBC are open to EMA methodologies for data collection and that EMIs can be valuable to this population.

Patients with MBC were engaged and interested in participating in this EMA study. Many patients were motivated by increasing research inclusivity for this population, underscoring the importance to participants of representativeness in research samples. These findings are consistent with other studies, which identified that altruism highly impacts patients' decisions to enroll in research studies [46,47]. Designing recruitment strategies and study methodology to emphasize inclusivity and the altruistic benefits of the research may facilitate recruitment and retention in research studies [48]. However, we also identified that several patients did not fully understand the study design and purpose of the research. This has important implications for the design and implementation of the informed consent process for future studies to ensure that all participants fully understand study procedures before enrolling. For example, future studies with complex EMA designs might incorporate evidence-based tools for improving informed consent, such as the "teach-back" method [49,50].

Furthermore, participant feedback indicated that a preferred study procedure would have included fewer surveys per day for multiple days in a row, with additional time to complete each survey. Some participants noted that their experiences did not change dramatically over the course of the day, which aligns with and builds upon our previously published quantitative analyses [31,32], demonstrating that time of day of the EMA was not significantly associated with QOL or symptom burden. Taken together, these results can help guide the design of future EMA studies that align with the preferences of the MBC community. Despite their suggestions for improving the EMA schedule, participants generally found the EMA design to be straightforward and easy to understand, similar to other studies using EMA in MBC populations. One such study looked specifically at the feasibility of using EMA for symptom burden and management and demonstrated high adherence and retention [51]. This study extends these findings to demonstrate the feasibility of using EMA to assess physical symptoms, psychological symptoms, positive experiences, and overall QOL among patients with MBC.

One unique result from this study was participant discomfort and confusion discussing libido as relevant to their MBC experience. This finding reflects a broader pattern reported in clinical settings, where the majority of women with breast cancer do not discuss the sexual health effects of cancer with their providers [52]. When conversations about sexual function do occur, they are more frequently initiated by the clinical provider [53]. Participants in this study were also confused about the definition of libido and its relevance as a side effect of many MBC treatments. More effective communication between patients and providers about sexual health is needed to increase patient knowledge [54]. Therefore, future studies should explain the rationale for assessing libido, define the term, and offer an opt-out response option to both increase participant knowledge and limit any potential participant discomfort.

Finally, these results have important implications for future interventions. While patients with MBC are open to EMIs with varying content and formats, more research is needed on the best time to intervene for each person. Intervention timing is an important avenue for future research to explore, as participants in this study varied on when they would have preferred help (ie, in moments of high distress vs the next day). Future research should also further examine patient preferences toward receiving help during moments of high distress to determine feasibility and acceptability of various options (eg, connecting with a peer vs receiving resources). We also observed variability in participant openness toward receiving their data in real time, with some participants feeling positively toward the idea and others negatively. Given this variability in preferences, a just-in-time adaptive intervention (JITAI) may be well suited for this population; JITAIs deliver personalized support in real time, typically using mobile technology, with the aim of providing the right type and amount of support at the right time and place to maximize effectiveness [55]. A JITAI for people with MBC could personalize intervention delivery based on participant and contextual factors, including participant preferences. In terms of the intervention components to be included in a JITAI framework, participants suggested a wide variety of resources, primarily targeted toward patients living with MBC but potentially also engaging family members and support people. These findings build upon previous research, as other studies also document the importance of more MBC-specific support groups to better meet this population's needs, as well as the lack of formal resources for family members and support people [56]. This study builds on this prior literature and further illuminates current gaps in interventions to improve QOL for patients with MBC.

Strengths and Limitations

This study is among the first to explore the acceptability of EMA study designs among patients with MBC, a group with significant QOL decrements and few options for tailored supportive care interventions. Our sample included participants who had been living with MBC for varying lengths of time and could therefore contribute unique perspectives on their disease. The qualitative interview design incorporated patients' EMA data, adding depth and clarity to study findings. We used a robust coding approach involving multiple coders for each transcript and discussion of discrepancies until consensus was reached, which allowed us to mitigate potential individual biases in the coding process.

XSL•FO
RenderX

However, the interpretation of these results must be informed by the study's limitations. First, interview participants represent a subset of individuals who were eligible for and agreed to participate in an EMA-based observational study of QOL. Thus, results may be subject to selection bias; participants who elected to participate in such a study may be more open to EMA and EMI or may have higher QOL than individuals who declined to participate. Second, responses may be subject to social desirability bias due to lack of anonymity during study interviews. Third, most participants were non-Hispanic White and highly educated. Although representative of patients at National Cancer Institute-designated Comprehensive Cancer Centers [57], it is possible that theoretical saturation was achieved only due to the homogenous nature of the cohort [58]. Relatedly, all participants in this study were patients at academic medical centers; their experience may not reflect the majority of patients with MBC who are seen in community oncology practices [59]. Additional research, including heterogeneous patient populations receiving care in varied settings, would increase the fidelity and usefulness of the findings presented here. Finally, this is a small, qualitative study. Future studies should quantitatively examine the feasibility and acceptability of EMI in a large, representative sample of patients with MBC.

Conclusions

This qualitative study identified that patients with MBC are willing to use EMA methodologies for data collection on QOL and that EMI could be beneficial for this population. Participants engaged well with the study design, found the EMA framework easy to understand, and would be open to EMIs. A JITAI framework may complement EMA well for this population, with the most frequently suggested interventions including MBC-specific support groups, peer navigation, and resources for family members and support people. Future research will take into consideration this qualitative participant feedback to formulate an updated EMA approach paired with a useful EMI.

Abstract

Background: Identification of metastasis status in non–small cell lung cancer (NSCLC) is a critical part of understanding disease prognosis, treatment courses, trial eligibility, and population-level cancer surveillance. However, metastasis status is inconsistently recorded in structured cancer registry fields, since manual abstraction of clinical notes is often an error-prone process. This challenge highlights an opportunity for leveraging large language models (LLMs) to conduct high-scale metastasis extraction from real-world clinical documentation.

Objective: We conducted a retrospective, multicohort comparative evaluation of 3 distinct LLMs for 2 independent classification tasks: overall metastasis presence at any site and brain/central nervous system (CNS) metastasis presence. We evaluated model performance on 2 independent NSCLC cohorts: one with registry labels and another with manual annotations. We further explored whether our methods could analyze clinical documentation and recover missing information in structured registry fields.

Methods: Patient cohorts were derived from the Winship Cancer Institute. Cohort 1 (n=579 patients; 24,887 notes across 69 note types; 2023-2025) used registry-linked metastasis fields as the reference standard. Cohort 2 (n=22 patients; 644 radiology notes; 2010-2021) was drawn from 2 completed randomized trials and used dual-annotated labels (Cohen κ: 0.93 overall metastasis; 0.88 CNS metastasis) as the reference standard. We fine-tuned the GatorTron-base encoder model for each independent binary classification task. We evaluated MedGemma-27B-text and Llama 3.1-70B using zero-shot prompting. A separate cohort of 675 patients with missing registry labels was used for an exploratory missingness-recovery analysis, validated against annotations of a random subsample. Our best-performing model was used to conduct further site-specific metastasis classification, based on available registry data.

Results: More than half (675/1260, 54%) of initially identified cohort 1 patients had missing or unknown registry metastasis labels. MedGemma demonstrated the best performance in overall metastasis classification (cohort 1: F_1-score=0.80; cohort 2 patient-level: F_1-score=1.0; cohort 2 note-level: F_1-score=0.93). For brain/CNS metastasis, Llama3 performed best in both cohorts (cohort 1: F_1-score=0.79; cohort 2 patient-level: F_1-score=0.93; cohort 2 note-level: F_1-score=0.86). The fine-tuned GatorTron model showed strong performance for classification of overall metastasis in cohort 1 (F_1-score=0.72). Error analysis indicated that several model errors reflected incomplete registry labels, ambiguous clinical language, or missing documentation. In the exploratory recovery analysis, model predictions agreed with manual annotations at an accuracy of 0.90 and F_1-score of 0.89.

XSL•FO
RenderX

Additional site-specific metastasis classification by MedGemma demonstrated high performance for liver metastasis (F_1-score=0.82) and bone metastasis (F_1-score=0.79).

Conclusions: All models demonstrated relatively high performance. The zero-shot generative models were more robust to nuanced documentation and context-dependent brain/CNS metastasis extraction. The fine-tuned encoder model demonstrated strong classification performance but may have been limited by potential inaccuracies in the registry reference standards during model training. This study further demonstrated the potential of LLMs in recovering plausible structured labels from narrative text, complementing cancer registries for metastasis ascertainment.

Introduction

Non–small cell lung cancer (NSCLC) is the leading cause of cancer-related mortality worldwide, with prognosis and treatment shaped by the presence and extent of metastatic disease at diagnosis and throughout the clinical course [1-3]. Among the most consequential and clinically complex sites of spread is the central nervous system (CNS) [4]. Brain metastasis develops in up to 50% of patients with NSCLC over the course of their disease, carrying distinct prognostic implications, driving treatment decisions, and serving as a key eligibility criterion in oncology trials [5,6]. Accurate ascertainment of metastatic status is crucial for determining eligibility for systemic therapies, radiation planning, enrollment in clinical trials, and cancer surveillance [7,8]. These realities underscore that metastasis information, particularly CNS metastasis, must be captured accurately and comprehensively.

However, metastatic status is inconsistently recorded in structured electronic health record (EHR) fields and is often dispersed across radiology reports, oncology progress notes, discharge documentation, and other free-text clinical narratives [9]. Cancer registries, the primary infrastructure for population-level cancer surveillance, rely on manual review by trained cancer registrars, an approach that is resource-intensive, subject to human error, and limited in its ability to capture disease progression documented after the initial abstraction window [10]. These gaps in data capture can have meaningful consequences. In a large National Cancer Database analysis of more than 1.2 million patients with NSCLC, 71% had missing data in at least one variable of interest, including cancer stage and treatment [11]. Missing data were especially prevalent among patients with lower 2-year overall survival, indicating that incomplete documentation may have been more prevalent for patients with severe illnesses or complex, metastatic cases [11]. Thus, studies using cancer registry data may be biased if missingness is ignored [11].

Another limitation of cancer registries is that data often reflect disease status primarily at the time of initial diagnosis and do not capture metastatic progression documented later in the clinical course [12,13]. In contrast, clinical notes provide longitudinally detailed records of disease evolution, including imaging interpretation, treatment modifications, and clinician assessments across the patient journey. Manual abstraction of clinical notes is a lengthy, resource-intensive process that is prone to human error and may not comprehensively capture disease complexities documented throughout the course of a patient's medical history [14]. These challenges highlight an opportunity for informatics approaches, namely natural language processing (NLP) methods, to enable large-scale extraction of metastasis records from real-world clinical documentation, improving accuracy and comprehensiveness of existing structured data sources [15].

There has been rapid evolution of NLP methods in the field of clinical information extraction. Early rule-based methods leveraged medical ontologies to create structured rules for detection of relevant information in unstructured text [16]. This method continues to be used today, particularly for text filtering and standardization [17]. Rule-based methods have previously demonstrated high precision and interpretability but with limited ease of implementation and generalizability to notes beyond the study context [18,19]. Their limited generalizability is characterized by their dependence on specific linguistic patterns, along with requiring specialized human expertise to create custom rules [20]. These rules can be affected by the unique documentation style and phrasing of the data used [20]. Machine learning (ML) approaches demonstrated improvement over rule-based systems due to their ability to automatically learn linguistic patterns and complexities rather than solely capturing patterns based on predefined rules [21]. Transformer-based ML models, specifically, have demonstrated strong performance in real-world data and can be fine-tuned for use in various clinical contexts [21]. Transformers pretrained on clinical and medical data have further demonstrated immense promise in detecting semantic interactions and complex, varied phrasing in clinical text [22,23]. These models, further optimized on smaller clinical cohorts, have been shown to outperform traditional NLP and ML approaches, including regular expression-based text searches and classic supervised learning approaches [24]. However, lower performance has been observed when applying models, including transformer-based, rule-based, and classic ML methods, to heterogeneous note types or switching institutions from which the notes are sourced [21,23]. Furthermore, differences in vocabulary and documentation style can be seen to lower performance in these models [21,23]. More recently, generative large language models (LLMs), including both domain-adapted and general-purpose instruction-tuned variants, have demonstrated strong performance on a range of clinical extraction tasks [11,25-27]. However, because generative LLMs produce free, unconstrained text rather than directly predicting

XSL•FO
RenderX

predefined labels, additional prompting and/or postprocessing may be required to standardize their outputs [28]. These additional steps may introduce variability in output formatting and interpretation, whereas BERT-based classifiers map inputs directly to a fixed label set [28]. These models also require a substantial amount of memory, which can detract from widespread use in clinical settings [23].

Despite this progress, critical gaps remain, particularly in the types of clinical text analyzed for extraction tasks. First, a recent systematic review of LLM applications in clinical medicine found that over three-quarters of included studies did not conduct analyses on real EHR data, relying instead on simulated clinical scenarios or synthetic notes [29]. This limits the generalizability of findings to the nuanced documentation encountered in routine oncology practice. Second, few studies have directly compared fine-tuned domain-adapted encoder models, for supervised classification, against instruction-tuned generative models, particularly for information extraction from real-world oncology notes [23,28]. Third, and particularly for NSCLC, brain and CNS metastasis extraction is underexamined as a distinct NLP task, despite its clinical importance. Given the complex language and the plethora of terminologies used to document different sites of CNS metastasis, this extraction task further tests the ability of NLP methods or LLMs in detecting and distinguishing between nuanced phrases and site-specific verbiage.

To address these gaps, we examined 2 research questions. First, how accurately can LLM-based methods classify the presence of overall metastasis and site of metastasis from real-world clinical notes? Second, can these models recover clinically relevant metastasis information that is missing from structured registry data? Metastasis status recorded in structured registry fields is a crucial part of observational cancer research and trial recruitment, so systematic undercapture propagates into every downstream use. A pipeline addressing this gap would operate retrospectively on documentation already in the EHR. In cancer registry abstraction, where metastasis status is currently determined by manual chart review, it would prescreen notes and help identify candidate documentation for abstractors. In trial eligibility screening, it would flag patients whose metastasis status is absent or incomplete in structured fields and who may be misclassified during cohort identification. In both cases, the model narrows what a human reviews rather than deciding the classification.

Methods

Study Design and Setting

We conducted a retrospective comparative evaluation of 3 LLM-based methods for extracting (1) overall metastasis at any site and (2) brain/CNS metastasis from real-world clinical notes in patients with NSCLC. We leveraged 2 cohorts with distinct but complementary roles in model development and validation, in addition to a dataset with missing metastasis records to explore the LLM's capabilities for data recovery. All analyses were conducted under a waived-consent protocol approved by the Emory University Institutional Review Board.

Data Sources and Cohorts

Cohort 1: Primary Registry-Linked Development Cohort

Overview

Cohort 1 was used for model development and internal validation. It was derived from the Winship Cancer Registry, which is linked to the Georgia Comprehensive Cancer Registry. Inclusion was restricted to patients for whom Winship Cancer Institute was the institution of record for diagnosis and/or first-course treatment, with both registry data and linked clinical notes available from 2023 through 2025.

Cohort Construction and Exclusions

Initial data extraction yielded 1260 patients with NSCLC with 62,191 notes across 81 note types and 12,174 encounters. Patients were excluded from model development if at least one registry metastasis field was missing (n=663) or labeled unknown with no confirmed positive site (n=12), yielding 585 patients with 24,908 notes across 69 note types. Six additional patients were excluded from model development and validation because their available notes contained no cancer-relevant clinical content (eg, administrative telephone encounters only), yielding a final development cohort of 579 patients with 24,887 notes across 69 note types for overall metastasis analysis. Three additional patients with unconfirmed brain metastasis registry records were excluded from the brain/CNS metastasis analysis, yielding a cohort of 576 patients. The full cohort selection process is illustrated in Figure 1. Demographic characteristics, following initial data extraction and cohort selection, are described in Table 1.

XSL•FO

Figure 1. Flowchart of selection of cohort 1 following initial data extraction.

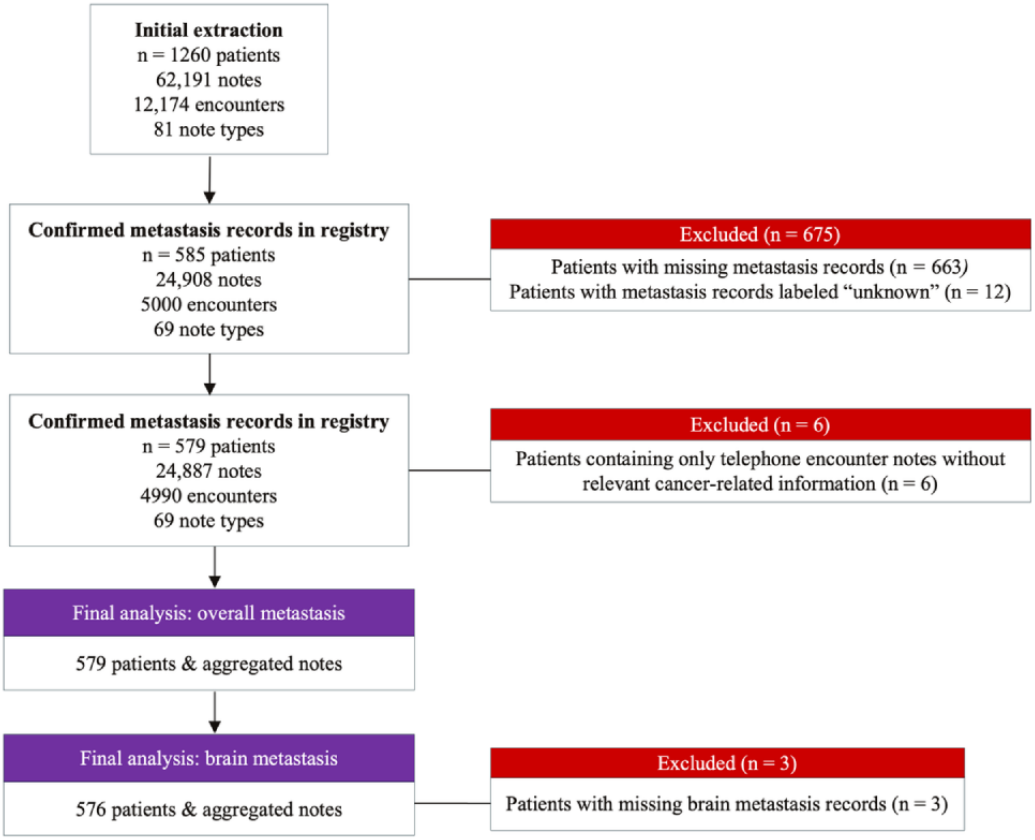

Table 1. Cohort 1 demographic characteristics.

	Total patients identified (n=1260)	Patients included in analysis (n=579)
Age at diagnosis (years), median (IQR)	72 (65-79)	73 (66-79)
Male, n (%)	670 (53.2)	273 (47.1)
Race, n (%)		
White	599 (47.5)	279 (48.2)
Black or African American	516 (40.9)	220 (38)
Asian	72 (5.7)	37 (6.4)
Other	20 (1.7)	13 (2.2)
Unknown	53 (4.2)	30 (5.2)
Ethnicity, n (%)		
Hispanic	27 (2.1)	14 (2.4)
Non-Hispanic	1147 (91)	521 (90)
Unknown	86 (6.8)	44 (7.6)

Reference Standard

We used the Winship Cancer Registry as our reference standard, which reports site-specific metastasis (liver, brain, bone, lung, distant lymph nodes, and other distant sites). Using these fields, we created our binary outcome label to identify overall metastasis. This label, encompassing all metastasis sites, was derived as follows: patients with at least one site-specific positive metastasis record were classified as metastasis-positive; patients with all-negative records were classified as metastasis-negative, and patients with at least one missing (n=663) or unknown (n=12) field, in the absence of a confirmed positive, were classified as metastasis unknown and excluded from model development. The registry brain metastasis field was used directly as the reference standard for brain metastasis analysis.

Note Inclusion Window

Because registry metastasis fields primarily capture disease status at initial diagnosis, clinical note inclusion was restricted to a window spanning 30 days before through 30 days after each patient's formal cancer diagnosis date. This window maximized

XSL•FO
RenderX

temporal correspondence between notes and registry labels. All note types within this window were eligible, including radiology reports, discharge summaries, progress notes, consultation notes, provider communication, nursing documentation, and other note types. The full distribution of notes across all note types is detailed in Table S1 in Multimedia Appendix 1.

Cohort 2: Independent Temporal Validation Cohort

To assess model generalizability across an earlier documentation period, we assembled an independent cohort of 22 patients with NSCLC whose records were extracted retrospectively from 2 completed randomized clinical trials conducted between 2010 and 2021. Trial enrollment required systematic imaging, resulting in dense radiology documentation in the historical records of these patients. A total of 644 radiology notes, including computed tomography, magnetic resonance imaging (MRI), X-ray, and other imaging reports, were extracted. Notes were not restricted to a diagnosis-adjacent window, and registry records were not used as the reference standard, since they did not capture documented metastatic progression. Manual note-level annotations served as the reference standard labels for this cohort (see ”Manual Annotation of Cohort 2” section). All models were applied to this cohort without retraining to serve as further external validation. Characteristics of both cohorts are provided in Table 2.

Table 2. Overall cohort characteristics.

	Cohort 1: primary registry-linked	Cohort 2: temporal validation
Reference standard	Cancer registry	Manual annotation
Documentation period	2023-2025	2010-2021
Total patients with NSCLC[a] identified, n	1260	22
Patients with missing/unknown registry metastasis records, n (%)	675 (54)	0 (0)
Patients included in analysis, n		
Overall	579	22
Brain/CNS[b]	576	22
Clinical notes included in analysis, n	24,887	644
Note types	Heterogeneous (69 types)	Radiology only
Patients with overall metastasis, n (%)	239 (41)	22 (100)
Patients with brain/CNS metastasis, n (%)	89 (15)	8 (36)

[a]NSCLC: non–small cell lung cancer.

[b]CNS: central nervous system.

Missingness-Recovery Dataset

The 675 patients excluded from primary model development, due to at least one missing or unknown registry metastasis record, represented 54% of the initial cohort 1 extraction pool. A total of 12 of these patients had unknown brain metastasis records. Notes from these patients were retained for a downstream exploratory analysis. This dataset was used solely to assess whether our methods could recover structured metastasis information absent from registry fields. No reference standard was available for this group, and model predictions were qualitatively reviewed by selecting a small random sample of patients and manually assessing their clinical notes, which were aggregated to the patient level. (see “Exploratory Downstream Missingness-Recovery Analysis” section). This analysis is reported to describe the feasibility of our methods and not as a primary performance evaluation.

Clinical Note Preprocessing

Prior to model input, all clinical notes were preprocessed through a keyword-based filtering pipeline to reduce noise while retaining clinically relevant content. Keywords were drawn from the publicly available Clinical Event Recognizer (CLEVER) dictionary, which contains clinical synonyms for oncology-relevant terms, supplemented by custom oncology-specific terms developed by the study team [30]. Representative CLEVER terms included “metastasis,” “widespread disease,” and “stage IV,” among other words and phrases. Custom additions included “high grade” and “malignant mass,” in addition to other words. All keywords used for preprocessing are available in Table S2 in Multimedia Appendix 1. For notes containing at least one keyword match, only sentences containing keywords were retained. For notes without any match, the full note text was preserved. This step was applied strictly as a noise-reduction measure to eliminate sentences irrelevant to the patient’s disease course. In cohort 1, all notes from each patient were aggregated at the patient level before preprocessing and model input, consistent with the patient-level registry reference standard. In cohort 2, notes were processed and input individually.

Manual Annotation of Cohort 2

Two trained abstractors, both of whom have a background in public health and biomedical informatics, independently annotated radiology notes from cohort 2 under the supervision of a board-certified oncologist. A standardized schema targeted 2 binary note-level labels: (1) overall metastasis present vs absent and (2) CNS metastasis present vs absent. Annotators

XSL•FO
RenderX

were instructed to label both explicit evidence (eg, "brain metastases confirmed on MRI") and contextually implied evidence strongly suggestive of current metastatic disease, such as imaging findings or treatment references indicating metastatic involvement.

Annotators were provided with two forms of each note: (1) the preprocessed text on which the label was assigned, and (2) the complete original note available for additional context. A predefined annotation schema was used to assign two binary note-level labels: (1) overall metastasis present vs absent, and (2) CNS metastasis present vs absent (Supplemental Material 1 in Multimedia Appendix 1). Disagreements were resolved by discussion or oncologist adjudication. Annotation proceeded in 4 iterative rounds of increasing size (n=10, 100, 200, and 334 notes), with interannotator agreement assessed and discrepancies reconciled after each round. Final agreement, quantified by Cohen κ values across all rounds of annotation, was 0.93 for overall metastasis and 0.88 for CNS metastasis, indicating high agreement (Table 3). Final labels were assigned based on unanimous consensus or oncologist suggestion.

Annotators reviewed each note in full before assigning a label. Explicit evidence of metastasis presence was often contained within a single sentence such as "hepatic lesions consistent with metastatic spread," "brain metastases confirmed on MRI," or "malignant pleural effusion," and one such statement was sufficient for a positive label. A metastasis negative label could be determined either by explicit evidence of a metastasis-negative test result or by absence of metastasis-positive language in the note. Metastasis negative labels therefore required review of the complete note. Annotators were also instructed to label positive imaging findings or treatment references indicating metastatic involvement as metastasis positive. Findings in which the documenting clinician expressed uncertainty, such as a lesion described as suspicious or worrisome for metastasis without confirmation, were labeled negative. Because evidence of metastasis was distributed across multiple phrases within a note, and because the negative class required complete review of the note to establish absence of metastasis-positive language, annotators did not mark individual text spans and instead assigned note-level labels based on the full note.

Table 3. Interannotator agreement for cohort 2.

Annotation round	Overall metastasis, Cohen κ	CNS[a] metastasis, Cohen κ
Round 1 (n=10)	1	1
Round 2 (n=100)	0.92	0.80
Round 3 (n=200)	0.92	0.85
Round 4 (n=334)	0.93	0.91

[a]CNS: central nervous system.

Model Development and Inference

We evaluated three pretrained LLMs representing distinct architectures: (1) GatorTron-base, (2) MedGemma-27B-text-it, and (3) Llama 3.1-70B [31-33]. Selection was restricted to open-weight models so that all inference could be performed within our institutional Health Insurance Portability and Accountability Act (HIPAA)–secure environment without transmitting protected health information externally, allowing for reproducibility at other institutions. Within this constraint, models were chosen to represent the approaches currently used for clinical extraction: a clinically pretrained encoder applied with supervised fine-tuning, a general-domain instruction-tuned generative model applied zero-shot, and a medically pretrained model of the same generative type.

GatorTron is a transformer encoder pretrained on more than 90 billion words of deidentified clinical text, biomedical literature, and other English text [31]. Encoder architectures are well suited to sequence classification using real-world EHR data, and our registry-derived metastasis fields provided labels sufficient for supervised fine-tuning [34]. Additionally, a comparative analysis of pretrained biomedical models reported that GatorTron's ability to learn nuanced clinical information within unstructured clinical text makes it suitable for clinical extraction tasks, compared to other BERT-based models [35]. Prior published comparisons have also demonstrated comparable performance between the GatorTron-base and GatorTron-large models. He et al [36] evaluated both GatorTron-base and GatorTron-large on clinical temporal relation extraction, finding that GatorTron-base with hard prompting achieved the highest micro F_1-score (89.54%), exceeding GatorTron-large (88.06%). Standard fine-tuning of GatorTron-base achieved a micro F_1-score of 85.95% [36]. Peng et al [37] similarly reported strong performance of GatorTron-base across tasks, including clinical concept extraction and medical relation extraction, achieving F_1-scores of 0.89 and 0.96, respectively, on the 2018 n2c2 dataset [38]. Given this comparable performance and the lower computational cost required for deployment, GatorTron-base was selected for this study.

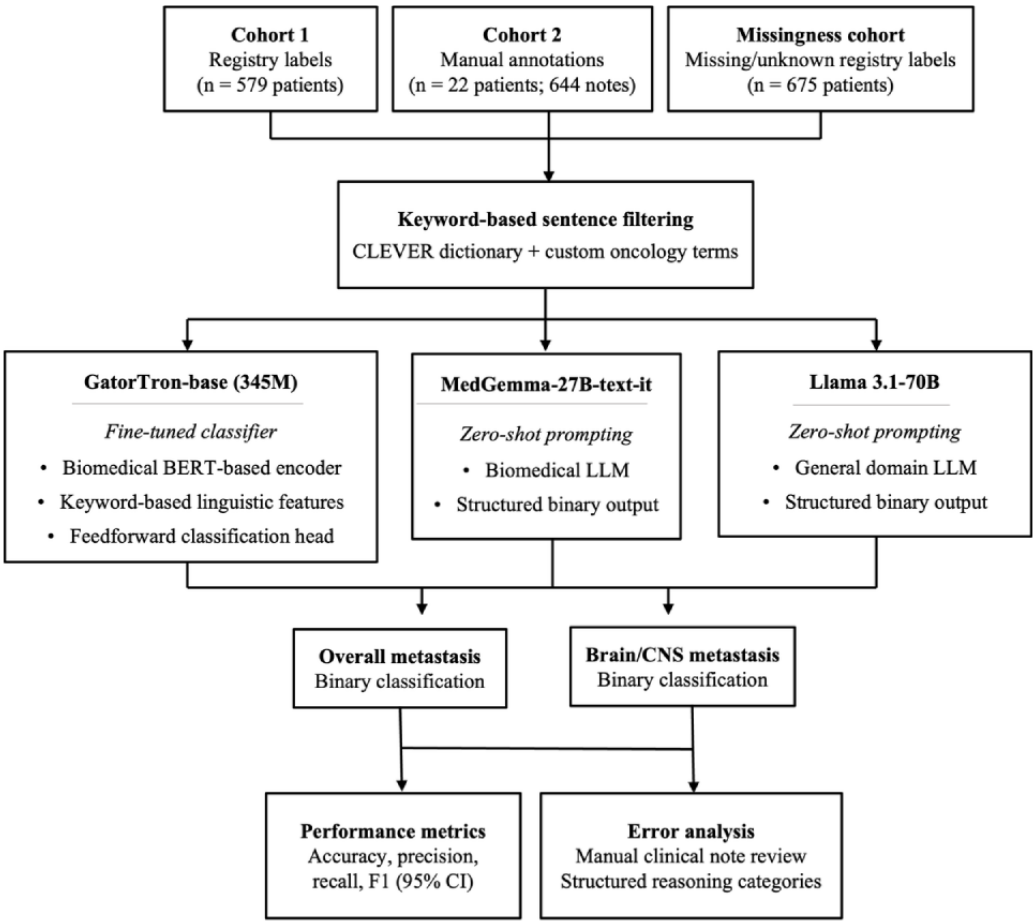
We began by benchmarking the non–fine-tuned GatorTron-base model (345M parameters) for binary classification of overall metastasis on a subset of cohort 1. This initial benchmarking yielded random chance predictions (F_1-score=0.46), indicating a need for further fine-tuning on our institutional cohort [31]. We fine-tuned 2 separate GatorTron-base models for binary classification of overall metastasis (train: n=463, 80%; test: n=116, 20%) and brain/CNS metastasis (train: n=461, 80%; test: n=115, 20%). To mitigate label noise arising from ambiguous phrasing in clinical note text, training incorporated extraction of key linguistic features in the clinical text. First, a list of metastasis-relevant terms, from the CLEVER dictionary, was used to capture mentions of metastasis presence. For fine-tuning of brain/CNS metastasis classification, these terms

XSL•FO
RenderX

were expanded to include brain/CNS site-specific verbiage. Next, NegEx-based negation detection was implemented to handle negated metastasis mentions [38]. Finally, a curated list of uncertainty expressions (eg, “suspicious for metastasis” and “may represent metastasis”) was implemented to handle unconfirmed metastasis mentions. These features were encoded as binary indicators.

Notes in the 80% train set were further partitioned into an 80% train set (overall metastasis: n=370; brain/CNS metastasis: n=369) and 20% validation set (overall metastasis: n=93; brain/CNS metastasis: n=92), stratified based on the binary outcome label. Since clinical notes were aggregated at the patient level prior to preprocessing, the unit of analysis was the aggregated patient document. Following preprocessing, cohort 1 documents averaged 7082.3 tokens in length (median 3382, IQR 1179–8795; range 12-87,293). Summary statistics of note lengths per cohort and average number of notes per patient are provided in Tables S3 and S4 in Multimedia Appendix 1. Patients were first divided into a model training set (80%) and a held-out test set (20%: overall metastasis n=116, brain/CNS metastasis n=115). The training set was then partitioned into training (80%: overall metastasis n=370; brain/CNS metastasis n=369) and validation (20%: overall metastasis n=93; brain/CNS metastasis n=92) subsets, with all splits stratified on the binary outcome label. GatorTron accepts a maximum input of 512 tokens, so documents were tokenized and segmented into overlapping 512-token chunks with a stride of 128 tokens, yielding a mean of approximately 19 chunks per patient document.

We trained a custom classifier head that concatenated the 3 linguistic features, described above, into a single feature vector. This feature vector, along with the text representation generated by GatorTron, was input into a feedforward neural network, which incorporated contextual and rule-based information to generate a binary prediction of metastasis presence. The 20% validation set was used to identify the optimal probability threshold for metastasis classification by evaluating thresholds between 0 and 1 and selecting the probability value that optimized the F_1-score per patient. Final inference was conducted on the 20% hold-out test set (overall metastasis: n=116; brain/CNS metastasis: n=115). Final patient-level predictions were assigned based on the maximum probability predicted across chunks corresponding to each patient’s note. Predictions on cohort 2 were generated using the final fine-tuned model without further retraining. Probability thresholds were optimized on the cohort 1 validation set and applied directly to cohort 2. Optimizing thresholds on cohort 2 would have required its outcome labels and would therefore no longer constitute independent validation. Applying the cohort 1 threshold maintained a consistent decision rule across cohorts and allowed evaluation of whether the approach transfers to an independent cohort with different note characteristics without cohort-specific fine-tuning.



MedGemma-27B-text-it is a biomedical variant of Google’s Gemma model, optimized for medical text and image understanding [32]. Prior literature has demonstrated MedGemma’s ability to perform clinical information extraction from unstructured medical notes using prompt-based strategies, supporting its application in clinical information extraction tasks [39]. However, given MedGemma’s recent release at the time of this study, there was limited evidence of its use in oncology notes for cancer-related information extraction, reflecting a knowledge gap that this study sought to address. We evaluated the 27 billion parameter instruction-tuned text model in a zero-shot setting using structured prompts that instructed the model to classify whether the provided note text documented the target condition and to return a constrained binary response (“Metastasis: YES” or “Metastasis: NO”). Greedy decoding was used, in which stochastic sampling was disabled (do_sample=False), such that the highest probability token was selected at each generation step. A fixed maximum output length was imposed to constrain the models’ responses. Prompt templates are provided in Supplemental Materials 2 and 3 in Multimedia Appendix 1.

Llama 3.1-70B-Instruct is a general-domain open-source LLM developed by Meta, trained on a large-scale corpus of general text and optimized for instruction-following [40]. Given that the prior 2 models were pretrained on biomedical data, evaluation of the Llama model allows for an understanding of the capability of general-domain models to comprehend dense clinical text. Furthermore, the Llama model has previously been shown to outperform BERT-based models and successfully conduct structured extraction tasks from clinical notes [23]. Therefore, its evaluation in this study, alongside GatorTron and MedGemma, may challenge current notions that encoder biomedical models are superior for clinical extraction tasks [23]. Llama3 was evaluated using an identical zero-shot prompt structure to MedGemma, decoding configuration, and constrained binary output format as MedGemma for both extraction tasks. Because the two are similar in architecture and prompting strategy and differ primarily in their pretraining, their comparison is informative about whether medical-domain pretraining is associated with better performance on this task.

Since the encoder model was fine-tuned while the generative models were prompted zero-shot, this study is an evaluation of distinct NLP approaches for metastasis classification rather than a direct comparison of model architectures. A pipeline depicting an overview of note preprocessing and inference is provided in Figure 2. All model weights were obtained from Hugging Face and deployed locally on an institutional, HIPAA-secure computing infrastructure [41-43]. All analyses were implemented in Python 3.10. All code is available on GitHub [44]. Models were run on a high-performance cluster with an AMD EPYC 9254 Processor (24 CPU cores/48 CPU threads), 348 GB RAM, and 2 NVIDIA RTX 6000 Ada Generation GPUs (48 GB VRAM per GPU), and 60 TB of NVMe-backed local scratch space in /tmp. The computational job used to run these models was allocated 2 CPU cores, 128 GB RAM, and 2 GPUs. Training time for the GatorTron model took 32 minutes on the training cohort (n=463). Inference time for all 3 models was approximately 4.5 minutes per model on the test sets (n=116), averaging approximately 2.3 seconds per note.

Data Partitioning and Model Evaluation

GatorTron fine-tuning and testing were conducted on cohort 1. MedGemma and Llama3 did not undergo fine-tuning and were instead evaluated under a zero-shot prompt setting. Cohort 1 evaluations for all models were conducted on the 20% test set used in the evaluation of the fine-tuned GatorTron model (overall metastasis: n=116; brain metastasis: n=115).

Cohort 2 served as an independent, out-of-sample test set for all 3 models. Since note-level manual annotations served as the reference standard for cohort 2, model evaluation was conducted at both the note-level (n=644) and the patient-level (n=22). Patient-level reference standards were derived by aggregating note-level annotations, such that if any note of a patient is labeled metastasis positive, the patient-level label is metastasis positive. For each model, cohort, and prediction level, we computed accuracy, precision, recall, and F_1-score. The 95% CIs were estimated using bootstrapped resampling with 10,000 iterations. All metrics were reported separately for the overall metastasis and brain/CNS metastasis tasks.

Furthermore, to assess whether our methods extend beyond aggregated metastasis status, we additionally evaluated our best-performing model on 3 site-specific classification tasks based on available metastasis fields in the cancer registry: bone, liver, and distant lymph node metastasis. The evaluation used the same held-out test set (n=116).

Error Analysis

For the best and poorest performing models on each extraction task in the development cohort, all misclassified cases were examined qualitatively. Clinical notes from each error were manually reviewed and assigned to one of four prespecified error categories: (1) incorrect model prediction despite obvious note content; (2) ambiguous clinical text, in which metastatic status was uncertain or unconfirmed by imaging, laboratory testing, or biopsy; (3) correct model prediction with an erroneous registry label; or (4) missing clinical text, in which relevant documentation was likely absent from the available note. Category definitions and representative examples are provided in Table 4.

XSL•FO
RenderX

Table 4. Structured reasoning categories used in qualitative analysis of prediction errors.

Error category	Description	Example
Incorrect prediction	The model assigned an incorrect prediction despite clear indication of positive or negative metastasis presence in the clinical note text.	• "Suspected metastasis confirmed to be benign meningioma." • In this case, the note explicitly confirms negative metastasis, but the model predicts a positive case.
Ambiguous text	The clinical note text has unclear confirmation of metastasis presence. The note expresses uncertainty of metastasis presence without documented confirmation via imaging, laboratory test, or biopsy. The clinical note text may also indicate suspicion of an additional primary cancer, which the model predicts as metastasis.	• "Brain metastasis cannot be ruled out." • "There are several malignant nodular lesions." • If no imaging, laboratory test, or biopsy confirmation is documented, the model may predict the incorrect label.
Correct prediction and incorrect registry label	In some cases of false positive predictions, the available clinical note demonstrates clear mentions of metastasis presence, either indicating an error in the registry label or an update in the patient's cancer diagnosis not reflected in the registry.	• "Biopsy results confirm osseous mets." • If this confirmation is documented around the time of initial cancer diagnosis but is not reflected in the cancer registry, this may reflect an error in the registry label.
Missing clinical text	In some cases of false negative predictions, the available clinical note does not clearly state any mention of metastasis. Therefore, rather than a failure of the model, these errors indicate the possible presence of additional notes, unavailable to us, which may have included metastasis information.	• If the registry indicates metastasis to a specific site, but there is no language in the clinical note relevant to metastasis, metastasis testing, or even mention of the site, the model prediction will not align with the registry label.

Exploratory Downstream Missingness-Recovery Analysis

The best-performing model for each extraction task was applied to the 675 patients in the missingness-recovery dataset. This analysis was conducted to evaluate the feasibility of leveraging our models to recover metastasis information from narrative text. To assess predictive performance, random samples of 10 predicted-positive and 10 predicted-negative cases were drawn. Their notes were manually reviewed and labeled prior to viewing model predictions to ensure unbiased assessment. Concordance between manual labels and model predictions was then evaluated. Given the small validation sample, findings are exploratory rather than definitive of our model performance.

Ethics Approval

This study was approved by the Emory University Institutional Review Board (protocol 2025P010922) under the expedited review process, with a complete waiver of informed consent and HIPAA authorization.

Results

Cohort Characteristics

Among 1260 patients with NSCLC identified from the Winship Cancer Registry and linked to clinical notes, restricted to analytic cases diagnosed and/or treated at Emory, metastasis status was missing or recorded as unknown in 54% (675/1260) of patients. Cohort 1 included 579 patients with complete registry metastasis data and 24,898 clinical notes; 41% (239/579) had metastasis at any site, and 15% (89/579) had brain metastasis at diagnosis. Cohort 2 included 22 patients and 644 radiology notes. All patients had metastasis at any site, and 36% (8/22) had CNS metastasis. At the note level, 51% (328/644) of notes were positive for metastasis and 11% (71/644) for CNS metastasis. Keyword-based preprocessing reduced mean document length by approximately 71% in both cohorts, from 24,193 to 7082 tokens per aggregated patient note in cohort 1 and from 364 to 107 tokens per note in cohort 2 (Table S3 in Multimedia Appendix 1).

Model Performance: Overall Metastasis Extraction

All models demonstrated strong performance (Table 5). In cohort 1, MedGemma achieved the highest F_1-score (0.80), followed by Llama3 (F_1-score=0.76) and fine-tuned GatorTron (F_1-score=0.72). In cohort 2, all models achieved high patient-level scores, which was expected given the dense radiological documentation and the presence of metastasis in all patients. At the note level, MedGemma achieved the highest F_1-score (0.93), followed by Llama3 (F_1-score=0.88) and GatorTron (F_1-score=0.76). The optimal probability threshold for overall metastasis classification was 0.58.

Model Performance: Brain/CNS Metastasis Extraction

In cohort 1, Llama3 achieved the highest F_1-score (0.79), followed by MedGemma (F_1-score=0.76) and GatorTron (F_1-score=0.50). In cohort 2, Llama3 achieved the highest F_1-scores (patient-level F_1-score=0.93; note-level F_1-score=0.86). MedGemma achieved comparable note-level performance (F_1-score=0.86) with a lower patient-level score (F_1-score=0.70). GatorTron achieved a patient-level F_1-score of 0.72 and a note-level F_1-score of 0.50. The optimal probability threshold for brain/CNS metastasis classification was 0.40. Performance metrics for brain/CNS metastasis are provided in Table 6.

Error Analysis

Prediction errors from the best and poorest performing models for each classification task in the held-out test set of cohort 1 (overall metastasis n=116; brain/CNS metastasis n=115) were qualitatively analyzed and assigned to a category of reasoning. Corresponding predictions from the other 2 models were assessed in parallel.

Overall Metastasis Prediction

GatorTron

GatorTron generated 14 false negative predictions and 16 false positive predictions. Less than half of the errors generated (n=13) were due to incorrect model errors, all of which were predicted correctly by MedGemma and Llama3. The primary reason for other errors was ambiguous phrasing in the clinical text (n=10), in which clinical documentation indicated "suspicious," "concerning," or "probable" metastasis without clear confirmation through laboratory test results. Another reason was that the model correctly generated positive predictions (n=4), despite a metastasis-negative registry label. In these cases, patient notes explicitly mentioned a diagnosis of metastatic cancer, which was not reflected in the registry but identified by our model. Finally, multiple false negative cases (n=3) were due to missing clinical text. A detailed error analysis is provided in Table S6 in Multimedia Appendix 1.

MedGemma

For prediction of overall metastasis, MedGemma generated 8 false negative predictions and 15 false positive predictions. In 9 instances, the model generated correct positive predictions despite conflicting registry records. Errors also occurred due to missing clinical text (n=6) and ambiguous clinical text (n=6; 4 false positive and 2 false negative predictions). Finally, the model produced one false positive prediction and one false negative prediction, both categorized as incorrect and predicted correctly by Llama3 and GatorTron. A detailed error analysis is provided in Table S7 in Multimedia Appendix 1.

Brain/CNS Metastasis Prediction

GatorTron

For brain/CNS metastasis, GatorTron generated 7 false positive predictions and 7 false negative predictions. Most errors were caused by incorrect predictions (n=10), all of which were predicted correctly by MedGemma and Llama3. Other errors were due to missing text (n=3) and ambiguous text (n=1). A detailed error analysis is provided in Table S8 in Multimedia Appendix 1.

Llama3

Llama3 generated 4 false negative predictions due to missing clinical text and one false positive prediction, which was determined to be incorrect. The incorrect false positive prediction was predicted correctly by MedGemma and GatorTron. A detailed error analysis is provided in Table S9 in Multimedia Appendix 1.

Site-Specific Metastasis Extraction

Since MedGemma was the best-performing model for overall metastasis, we further examined its site-specific metastasis classification performance (Table 7). Performance for bone metastasis (F_1-score=0.79) and liver metastasis (F_1-score=0.82) was comparable to that observed for overall metastasis classification. Performance for distant lymph node metastasis was lower (F_1-score=0.29), reflecting high recall (0.87) with low precision (0.18) at a prevalence of 1.7%.

Table 7. Performance metrics and 95% CIs for site-specific metastasis prediction.

Model and metastasis site (n=116)	Prevalence[a]	Accuracy (95% CI)	Precision (95% CI)	Recall (95% CI)	F_1-score (95% CI)
MedGemma-27B-text-it					
Bone	0.16	0.93 (0.88-0.97)	0.79 (0.58-0.95)	0.79 (0.59-0.95)	0.79 (0.62-0.91)
Liver	0.12	0.96 (0.91-0.99)	0.80 (0.57-1.0)	0.86 (0.64-1.0)	0.82 (0.64-0.96)
Distant lymph nodes	0.02	0.92 (0.87-0.96)	0.18 (0.00-0.45)	1.0 (0.00-1.0)	0.31 (0.00-0.62)

[a]Proportion of test-set patients with registry-recorded metastasis at the specified site (n=116).

Exploratory Missingness-Recovery Analysis

We evaluated whether models could recover metastasis information among 675 patients with at least one missing or unknown registry label (including 12 with unknown brain metastasis status). Using the best-performing model for overall metastasis, MedGemma classified 302 of 675 (44.7%) patients as metastasis-positive, closely resembling the prevalence of metastasis in cohort 1 (239/579, 41%). To assess validity, a random sample of 20 cases (10 predicted positive and 10 predicted negative) was manually annotated prior to viewing model results. Agreement with model predictions yielded accuracy=0.90 and F_1-score=0.89. Two false positive errors were identified in the prediction of overall metastasis due to several ambiguous phrases regarding suspicion of metastasis without clear confirmation. For brain/CNS metastasis, all 12 patients with unknown registry status were manually annotated as negative and correctly classified by Llama3.

Discussion

Principal Findings

LLM-based methods demonstrated strong performance for extracting overall and CNS metastasis from real-world NSCLC clinical notes, with performance varying by task and evaluation setting. Additional exploratory analyses suggest that clinically meaningful information about metastasis can be recovered from narrative documentation when structured registry data are missing. These findings highlight a core limitation of current oncology data systems. Cancer registries, while essential, are

XSL•FO
RenderX

temporally limited and incomplete, whereas clinical notes can provide longitudinal, detailed documentation of disease evolution. LLMs offer a practical mechanism to extract clinically relevant information within routine documentation, complementing structured data.

Earlier studies have largely focused on single cohorts or limited note types, particularly radiology reports and discharge summaries [24,25]. By leveraging a registry-linked cohort with heterogeneous oncology documentation, we provide a more realistic evaluation of real-world performance. Furthermore, few studies have evaluated and compared distinct NLP strategies, including clinically pretrained encoder models and large instruction-tuned generative models, on the same task [8,11,12]. In our study, baseline performance metrics demonstrated that the generative models (Llama3 and MedGemma) achieved higher performance in classifying both overall and brain/CNS metastasis presence, respectively, compared to the fine-tuned GatorTron model. Upon further inspection of model errors, generative models and fine-tuned encoder models appeared to serve complementary strengths, where certain prediction errors made by one model were correctly predicted by another. Additionally, while GatorTron was fine-tuned on clinical notes using linguistic features, Llama 3.1 and MedGemma were evaluated under zero-shot prompting strategies. Therefore, rather than a direct comparison of model architectures, this study showcases distinct LLM-based strategies for metastasis classification of clinical notes. CIs for several estimates overlap substantially, particularly for brain/CNS metastasis in cohort 1 and across tasks in cohort 2, and differences in reported scores should not be interpreted as establishing that one approach outperforms another.

Fine-tuned encoder models show promise for classifying metastasis presence and identifying potentially inaccurate registry records based on clinical note text; however, they may be sensitive to discrepancies present in their input data. Instruction-tuned generative models, even in a zero-shot prompt setting, demonstrate holistic understanding of clinical note text without this limitation, which may explain the differences in model performance in this study.

In this multicohort evaluation, we make 3 principal observations. First, metastasis information was substantially incomplete even within a cancer registry-linked dataset, with more than half of patients lacking definitive structured metastasis labels. Second, model performance varied, with the instruction-tuned generative models demonstrating holistic understanding of complex clinical language and the fine-tuned encoder model demonstrating strong classification performance but likely hindered by potentially inaccurate registry labels during training. Third, LLMs appear adept at correcting inaccurate registry records and recovering missing data.

Our first observation in this study is the high prevalence of missing data in structured metastasis labels, representing 54% (675/1260) of the patients identified in our initial extraction of cohort 1. This study extends prior clinical NLP work in important ways. While cancer registries serve as the gold standard for cancer surveillance, future studies may seek to use more curated real-world datasets for more robust model fine-tuning. Though inaccuracies and missingness in the cancer registry may have inhibited the fine-tuned encoder model from more accurately distinguishing between positive and negative metastasis cases, our model still demonstrated the ability to correct inaccurate data based on clinical text documentation. The use of metastasis labels from the cancer registry presents both an advantage and a challenge to fine-tuning our GatorTron model. Our cohort size (n=579 patients for overall metastasis; n=576 patients for brain/CNS metastasis) was comparable to prior work that fine-tuned the same model for metastasis extraction, which leveraged manually annotated computed tomography reports from 550 patients [45]. That work, however, manually annotated labels at the report level. Because registry metastasis fields are recorded at the patient level, each of our labels applied instead to an aggregated document (mean 7082, SD 9841 tokens) drawn from 69 distinct note types in which metastatic disease may be expressed in different forms. This heterogeneity better reflects real-world documentation but provides weaker supervision for a fine-tuned model, and it is intrinsic to registry-linked data. We did not evaluate performance as a function of training set size and therefore cannot determine whether the fine-tuned model was data-limited. The zero-shot models required no labeled data and were not subject to these constraints; their comparable or higher performance suggests that zero-shot approaches may be better suited to settings where only patient-level reference labels are available.

Our second observation in this study is that model performance patterns underscore that no single approach is uniformly optimal. Encoder models align well with structured labels; however, discrepancies in registry records may influence model outputs. In contrast, generative models appear more robust to heterogeneous, implicit, and context-dependent clinical language, which is particularly relevant for CNS metastasis, where documentation is often indirect and radiology-driven. This difference in performance may be attributed to the ability of generative models to better identify nuanced and complex site-specific language used in the documentation of brain/CNS without the influence of structured registry labels. Furthermore, GatorTron's prediction of brain/CNS metastasis may have been inhibited by the class imbalance in brain/CNS metastasis cases during model fine-tuning, whereas this class imbalance was not impactful in a zero-shot prompting setting. These results support a use-case-specific deployment strategy rather than a single-model solution.

Our third observation in this study is that LLM-based extraction appears to be adept at correcting and recovering incomplete metastasis data in structured registry fields. Our error analysis indicated that many discrepancies were due to data limitations in reference labels or available clinical documentation rather than explicit model failure. Differences in registry labels compared to clinical documentation, missing clinical text, and ambiguity in clinical language accounted for most errors. In several cases, model predictions were clinically plausible despite conflicting with registry labels, underscoring the imperfect nature of structured ground truth in oncology datasets. Both the error analysis and exploratory missingness recovery analysis provide an initial signal that NLP may augment registry accuracy

XSL•FO
RenderX

and completeness. The error analysis identified several positive metastasis cases that were not reflected in the registry labels, despite clinical documentation near the time of initial diagnosis. The exploratory missingness recovery analysis demonstrated high accuracy in recovering missing metastasis labels, based on manual review of a subset of notes. While preliminary, this suggests that clinically relevant signals embedded in narrative documentation can be systematically recovered. These findings have direct clinical and operational implications. NLP-based extraction can support cancer registry workflows by prioritizing high-yield cases and improving completeness. It may also enable more accurate cohort construction and clinical trial screening, where metastasis status, particularly CNS involvement, is a key eligibility criterion.

Our study contributes to the current field of clinical NLP in a few key ways. First, previous metastasis extraction studies have predominantly focused on single document types, namely radiology reports and discharge summaries, while our evaluation included 69 distinct note types [24,25,45]. The incorporation of heterogeneous clinical documentation more closely reflects the setting in which LLM-based cancer abstraction would be deployed. It also provides more robust evidence of each model's ability to comprehend and extract structured data from complex, varied clinical language. Second, we evaluated not just distinct LLMs but distinct modeling approaches for metastasis extraction. Recent literature has begun to compare different LLM-based approaches for clinical note extraction, including encoder-only, decoder-only, and prompt-based instruction-tuned LLMs in zero-shot and few-shot settings [37,46]. Such comparisons have not previously been reported for metastasis extraction. Because models were evaluated using different adaptation strategies, this study does not permit a direct comparison of model architectures, but it does provide an evaluation of distinct LLM-based methodologies for clinical note extraction. Third, we used both registry data and human annotations as reference standards, in cohort 1 and cohort 2 respectively. This allowed model performance to be assessed against existing structured registry fields while independently evaluating it against human annotation. Metastasis status was missing or recorded as unknown for 54% (675/1260) of registry-linked patients in the source population, consistent with reports of incomplete and discordant registry documentation [47].

Our error analysis further indicated that many apparent model errors reflected gaps in the registry rather than misclassification, illustrating the limitations of registry-derived labels as a reference standard for model development. Finally, despite these inconsistencies, LLM-based approaches may support the recovery of missing or incorrect registry labels: in the exploratory recovery analysis, predictions for patients with missing registry values agreed with manual annotation at accuracy 0.90 and F_1-score 0.89. Few studies have used LLM-based methods to assess the recovery of information missing from structured registry fields.

Our study has several limitations. First, cohort 1 (the primary development cohort) relied on cancer registry labels that contain limitations, including accuracy of label and inability to capture metastatic progression. Thus, discordance between registry labels and model predictions does not necessarily indicate model error, since the reference standard itself may be imperfect. Furthermore, there is a possibility that, though documentation spanned one month before and one month after initial diagnosis, metastasis cases diagnosed within one month after initial cancer diagnosis were not updated in the registry.

Second, cohort 2 was small and derived from clinical trial populations with dense radiologic follow-up, which may limit generalizability to routine care settings. All models demonstrated higher performance in cohort 2, likely due to the minimal heterogeneity of note types. Radiology notes are likely to contain dense documentation of metastatic disease presence, which may have contributed to improved model performance in cohort 2. Moreover, all patients in cohort 2 had overall metastasis, so patient-level metrics for that task do not reflect the models' ability to distinguish metastasis-positive from metastasis-negative patients. The note-level evaluation is therefore the more informative measure of discriminative performance in this cohort, and patient-level results should be interpreted as complementary rather than as an indication of the model's discriminative ability. Note-level metrics may, themselves, be optimistic, since each patient contributed multiple notes that often contained similar or repeated phrasing and are therefore not independent observations.

Third, the performance metrics of cohort 2 require further contextualization, given its small cohort size and class imbalance in the patient-level evaluation. Since all patients were found to have metastasis, the patient-level performance metrics do not demonstrate the models' ability to distinguish between metastasis-positive and metastasis-negative patients. Additionally, the note-level performance metrics may reflect a biased overestimation of the models' ability to classify metastasis presence. Each patient contributed multiple notes, which may have contained similar or repeated phrasing, likely leading the model to assign identical metastasis predictions for multiple notes based on similar language seen across notes.

Fourth, the use of different reference standards across cohorts (registry-based at the patient level in cohort 1 vs manual note-level annotation in cohort 2) complicates direct comparison, particularly given differences in temporal scope and definition of CNS metastasis. Certain prediction errors made by the models on cohort 1 may have been a result of incorrect registry labels. Since the ground truth label was more reliable in cohort 2 notes, model performance may have appeared to be better in this cohort.

Fifth, models of differing underlying architectures were evaluated in distinct ways, wherein GatorTron was fine-tuned, while generative models were evaluated in a zero-shot setting. Additionally, encoder models with extended context windows, compared to GatorTron, such as those built on the ModernBERT architecture, have since become available and can process inputs of up to 8192 tokens. Such models would accommodate most documents in this cohort without the chunking and max-pooling strategies used in our study. Evaluating whether long-context modeling improves performance of metastasis classification would be a useful extension of this work. The difference in

XSL•FO
RenderX

computational requirements across the 3 models is a crucial consideration for deployment of these models in real-world clinical settings. The Llama 3.1 70-billion-parameter model has larger memory requirements compared to the GatorTron 345-million-parameter model, and this difference should be considered when inference is run on constrained hardware. Model selection in real-world clinical settings should consider this trade-off between performance and computational requirements.

Sixth, the keyword-based preprocessing strategy may have excluded relevant contextual information, potentially limiting sensitivity to implicitly expressed metastasis. Seventh, the study was conducted at a single institution, and broader external validation is needed. Finally, the missing recovery analysis was exploratory and based on a small sample. A larger-scale validation should be conducted to further evaluate the potential of recovering missing metastasis records. Similarly, site-specific evaluation was informative for bone and liver metastasis but not for distant lymph node metastasis, where prevalence in the test set was 1.7%, and the resulting estimates were unstable. Our estimates demonstrated a high presence of false positive predictions, so future evaluations of site-specific metastasis at infrequently documented sites would require a much larger test set.

Several factors affect the generalizability of our findings. Both patient cohorts were specific to one health care institution, and all patients were diagnosed with NSCLC. These constraints pose a challenge in assessing the models' generalizability to cohorts at other institutions and with other cancer types, and clinical terminologies and documentation practices may differ elsewhere. Our study design does, however, offer 2 features relevant to interpretation. First, the variation in clinical note types allows the model evaluations to be more representative of real-world EHR documentation. Second, the use of 2 cohorts from different documentation periods, with different reference standards, provided a second evaluation setting and a preliminary view of model performance across distinct clinical language and documentation styles. Cohort 2 was small (n=22), drawn from a clinical trial population with dense radiologic follow-up, and comprised entirely of metastasis-positive patients, so it does not by itself establish generalizability of our methods. It provides a second evaluation setting with an independent reference standard and a different documentation period, but its size and composition prevent its results from generalizing to routine care. Additionally, the patient-level estimates in this cohort carry wide CIs. Similarly, the missingness-recovery analysis was validated against manual annotation of 20 cases, demonstrating the feasibility of our methods but not sufficient to estimate recovery performance with precision. Therefore, the results of the error analysis should be regarded as preliminary. Both findings require confirmation in larger and more diverse cohorts in order to demonstrate the reliability of these methods in other settings.

Conclusion

In this study, the instruction-tuned generative models, evaluated in a zero-shot setting, performed best at classifying metastasis. The high degree of missing metastasis data, even within a cancer registry-linked cohort, underscores a key limitation of structured oncology data and highlights the value of note-based ascertainment. Exploratory analyses further suggest that metastasis information documented in clinical narratives can be partially recovered when structured fields are incomplete. These findings support the use of NLP to complement cancer registry data for metastasis ascertainment, cohort identification, and trial screening, while requiring further validation before broader use.

Acknowledgments

Patient cohort identification was conducted by the Winship Cancer Institute's Data and Technology Applications Shared Resource (WinDATA). Clinical note extraction for select patients was conducted by Emory University's Medical Informatics and AI Core team.

Claude Sonnet 4.6 (Anthropic) was used between April 7-13, 2026 to suggest fixes for Python code errors or improvements to code. Any changes made to our code based on Claude's suggestions were manually verified. Claude was also used occasionally to rephrase sentences.

Abstract

Background: With increasing numbers of survivors with cancer, the importance of patient-centered information provision and communication to alleviate psychological burdens, such as anxiety and depression, is growing. However, substantial individual differences exist in patients with cancer information–seeking behaviors and use of support services, and few studies have comprehensively examined cognitive and psychological factors such as treatment status, sex, trust in information sources, and patient-provider relationships.

Objective: This study aimed to integrate the theory of planned behavior and the patient-provider relationship model to identify latent subgroups among Japanese survivors with cancer using information-seeking behaviors, difficulties in information seeking, trust in information sources, and intentions to use psychosocial support services recommended by medical institutions.

Methods: A CHERRIES (Checklist for Reporting Results of Internet E-Surveys)–compliant cross-sectional web survey was conducted in December 2024 with 350 Japanese survivors with cancer (at least 1 year post diagnosis, either undergoing treatment, or within 5 years after completing treatment). Exploratory factor analysis examined items such as difficulties in information seeking, trust in information sources, and assessment of relationships with physicians. Using the resulting factor structure and sociodemographic and clinical characteristics, latent class analysis was conducted. Differences between classes were examined using the chi-square test, Kruskal-Wallis test, and post hoc analyses.

Results: Latent class analysis classified participants into 3 groups: women under observation, men under observation, and patients under treatment. In the women under observation group, evaluation of the reliability of information from nonmedical institutions was significantly higher than in the male group (χ^2_2 =12.30; *P*=.002). Although information-seeking behavior among men under observation was relatively limited, their evaluation of relationships with physicians was significantly higher than that of the treatment group (χ^2_2 =12.20; *P*=.002). The proportion of men who regarded promoting communication with doctors and health care professionals as a benefit of using support services was also significantly higher than that of women (χ^2_2 =12.57; *P*=.002 and Class 2 > Class 1; *P*=.001). In the treatment group, searches for information on life during treatment (χ^2_2 =7.22; *P*=.03), use of the Cancer Consultation Support Center (χ^2_2 =17.31; *P*<.001), and use of the National Cancer Center website (χ^2_2 =7.59; *P*=.02) were significantly higher than among men under observation. The treatment group also reported greater difficulty in seeking information (χ^2_2 =11.90; *P*=.003).

Conclusions: Information-seeking behaviors, trusted sources, and perceived difficulties differed by sex and treatment stage among Japanese survivors with cancer. Patients undergoing treatment showed high information needs but greater difficulty in seeking information, suggesting reduced perceived behavioral control. Men under follow-up emphasized relationships with physicians, whereas women relied more on nonmedical information sources. These findings indicate that psychosocial support and information provision should be optimized according to patient-provider communication patterns.

Introduction

Currently, approximately 20 million people worldwide are newly diagnosed with cancer each year [1], and this number is expected to reach 35 million by 2050 [2]. In Japan, the number of new patients with cancer is projected to reach approximately 4 million between 2035 and 2039 [3]. Owing to advances in treatment methods and early detection, many individuals diagnosed with cancer are now long-term survivors, and the number of people classified as survivors with cancer who live with and beyond cancer is increasing [4]. Regardless of treatment status, survivors with cancer tend to face various difficulties, including physical, mental, economic, social, and emotional challenges [5]. In particular, the prevalence of psychological stress, such as anxiety and depression, is high, making it extremely important to address their emotional needs [6,7]. Against this background, health care professionals are expected to provide appropriate information and high-quality communication so that patients can confidently make decisions about their diagnosis, prognosis, and treatment options [8].

The most frequently reported unmet nonmedical need among patients with cancer is information [9]. Accurate knowledge of the disease and its treatment affects psychological well-being, quality of life, and satisfaction with treatment [10]. However, the quality of information, access to it, and the individual's level of understanding pose challenges. Improving the quality of the information provided and accurately identifying patient needs also leads to better communication between patients and physicians [11,12]. Nonetheless, many survivors with cancer report that the medical terms and explanations used by health care professionals are difficult to understand, resulting in insufficient information and communication [13,14]. Therefore, while patient-centered communication [15,16]—which enhances the reliability of information for survivors with cancer—is important, dissatisfaction may not stem solely from a simple lack of communication but may instead be intricately related to individual cognitive and psychological factors, which need to be elucidated.

Given this background, we conducted a pilot study using content analysis of free-text responses regarding the use of psychosocial support services among survivors with cancer aged 40 years and older [17]. The results suggested that factors such as trust in support providers, expectations for emotional regulation, difficulty in verbalizing emotions, a desire for independence, the personality of support providers, clarity of consultation procedures, and awareness and dissemination of services are related to the use of support services [17]. These findings suggest that the usage of psychosocial support services may be influenced not only by access and information deficiencies but also by individual cognitive and behavioral characteristics, including personal values. Thus, it is necessary to introduce a theoretical framework to comprehensively and quantitatively capture these complex factors.

The theory of planned behavior (TPB) has been widely used to explain behavior change among patients with chronic illnesses [18,19]. According to the TPB, behavioral intention is formed by 3 factors: "attitude," "subjective norms," and "perceived behavioral control" [20]. However, because the behavior of patients with chronic illnesses is influenced not only by internal cognitive factors but also by external factors such as the living environment, support networks, and health care systems, in this study we integrated external and relational factors, such as the living environment, support networks, and health care systems of survivors with cancer, into the TPB framework to deepen our understanding of the formation of behavioral intentions.

When addressing communication between patients and health care professionals, which is a central focus of this study, the patient-provider relationship model [21] is important. This model explains the impact of the relationship between health care professionals and patients on health outcomes, such as survival, treatment and recovery, relief of symptoms and distress, emotional well-being, and pain control. Communication functions are classified into relationship-oriented functions, which emphasize strengthening the therapeutic relationship and responding to emotions, and task-oriented functions, which involve exchanging information, decision-making, supporting self-management, and managing uncertainty [21].

Previous research has often examined information-seeking behaviors and the use of support services among survivors with cancer on the basis of single attributes, such as treatment phase or sex [22-24]. There have been limited attempts to comprehensively typify diverse individual behavioral characteristics and psychological factors and theoretically clarify their backgrounds. Therefore, in this study, we aimed to fill this gap by using latent class analysis (LCA) to identify behavioral patterns and by examining the characteristics of these patterns from the perspectives of the TPB and the relationship-oriented and task-oriented functions of the patient-provider relationship model.

On the basis of the above theoretical framework, we focused on the following two research objectives in this study:

1. To identify latent groups that can be typified from the viewpoint of the TPB regarding information-seeking behavior of survivors with cancer, trust in information sources, difficulties faced while seeking information, and use of psychosocial support services.
2. To examine how the identified latent groups are characterized from the perspectives of the relationship-oriented and task-oriented communication functions of the patient-provider relationship model and to clarify the contextual factors behind information-seeking behaviors and the use of support services.

Methods

Research Design

This cross-sectional survey was conducted on the basis of the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) [25] (Checklist 1).

The questionnaire, created in Japanese, consisted of 21 screens and 52 items on the website and was designed to be answerable within 25 minutes (Multimedia Appendix 1). To prevent missing data, all questions were set as mandatory in the web-based

XSL•FO
RenderX

questionnaire. To eliminate duplicate responses, any responses that matched IP address, sex, age, and place of residence were considered to be from the same respondent, and only the first response was included in the analysis.

Questions regarding patients with cancer information-seeking behavior were developed with reference to previous studies [26] that aimed to clarify the information needs and difficulties encountered when searching for information and using psychosocial support services among patients with ovarian cancer, as well as the patient experience survey [27] conducted by the National Cancer Center. During development, 3 researchers with experience in medical research and survey studies involving individuals with diseases examined whether each question appropriately reflected the research objectives and theoretical framework from the perspective of content validity and revised the questions for clarity of wording and to minimize respondent burden.

First, 12 items on sociodemographic information (including sex, age, place of residence, and occupation) and clinical information (including type of cancer, cancer stage, treatment status, and recurrence or metastasis) were collected using a single-choice format during the screening phase. This allowed for the collection of basic attribute information to uniquely classify each respondent. In addition, as a basic indicator related to information seeking, "device used to gather information" (1 item) was assessed using a single-choice format.

For information-seeking behavior regarding cancer, we started with the question "Have you ever searched for information about cancer?" Four multiple-choice checkbox items were used: "sources of cancer-related information," "social networking service (SNS) or apps used for collecting cancer-related information," and "advantages of psychosocial support and information-gathering services recommended by medical institutions." For these questions, mutually exclusive options such as "did not search," "do not wish to obtain information," "do not use SNS or apps," and "not applicable" were provided to ensure consistency in responses.

Furthermore, skip logic was introduced: if a respondent answered "did not search" to the question "Have you ever searched for information about cancer?" they were not required to answer questions about "sources of cancer-related information," "devices used to collect information," or "SNS or apps used for collecting cancer-related information," and were instead directed straight to the question about "difficulties in information seeking." Additionally, even if respondents had searched for information, if they selected either "do not wish to obtain information" or "do not use SNS or apps," they were not asked to answer the question about the "device used to gather information."

For the intention to use psychosocial support and information provision services recommended by medical institutions (corresponding to "behavioral intention" in the TPB), a yes or no question—"use of hospital-recommended apps and services for counseling support and information gathering"—was used (1 item). Only participants who answered "Yes" were able to proceed to the subsequent question on "advantages of psychosocial support and information-gathering services recommended by medical institutions."

"Difficulties in information seeking" consisted of 7 items, "trusted information sources" consisted of 8 items, and "evaluation of interpersonal relationships between patients and health care providers" consisted of 9 items. To reduce the respondent burden, these were presented in a matrix format and measured using a 5-point Likert scale.

To assess personality traits, the Japanese version of the 10-Item Personality Inventory (TIPI-J) [28], which uses 10 items and a 7-point Likert scale, was used. The TIPI-J measures the Big Five personality dimensions—extraversion, agreeableness, conscientiousness, neuroticism, and openness—with 2 items each and has shown high internal consistency: extraversion (α=.92), agreeableness (α=.85), conscientiousness (α=.82), neuroticism (α=.91), and openness (α=.86) [28]. The TIPI-J has also been shown to be associated with the emotional and cognitive health of patients with brain tumors [29], making it a valid indicator for this study.

To ensure accessibility and usability, a test page simulating the survey environment was created before the actual survey to confirm that the question display and skip logic functioned accurately.

Targeting and Survey Distribution

The survey was conducted privately by Asmarc Inc (a Japanese marketing research company) from December 10 to December 12, 2024. The company operates an online research panel with over 16 million registered members. After agreeing to the membership terms, registered members completed preliminary and final registration, during which they provided basic demographic information, such as age, sex, place of residence, employment status, and medical history.

The survey was conducted using the D-style web and Monitas platforms (Asmarc Inc) and was conducted using a list of available questionnaires. The eligibility criteria for this study were based on patient-reported outcome criteria for survivors with cancer 1 - 5 years after diagnosis [30]. Participants were required to be between 20 and 89 years of age at the time of the survey, to have been diagnosed with cancer at least 1 year prior, and to be either currently undergoing treatment or within 5 years of completing treatment. The following exclusion criteria were applied: participants who reported their treatment status as "before cancer treatment" or "other," those who had been diagnosed with cancer less than 1 year prior, and those for whom more than 10 years had passed since the end of treatment.

The sample size was calculated using cancer incidence statistics in Japan [31] as the reference population. Assuming a 90% CI and a 5% margin of error, the required sample size was estimated to be approximately 270 participants. This calculation was performed using the *pwr* package (version 1.3-0) in R. The *pwr* package was originally developed by Stéphane Champely and is currently maintained by Helios De Rosario. Considering a previous recommendation that at least 300 participants are desirable for conducting LCA [32], the minimum target sample size for this study was set at 300 participants.

Statistical Analysis

In this study, only data for participants with responses to all questions were included, and statistical analyses were performed using R (version 4.3.2; R Foundation for Statistical Computing). Sociodemographic information was stratified on the basis of the use of psychosocial support services, specifically by responses of "Yes" or "No" to "use of hospital-recommended apps and services for counseling support and information gathering." Descriptive statistics were calculated for each group. The sociodemographic information included sex, age, place of residence, occupation, and "device used to collect cancer information." Cancer-related information consisted of "cancer stage," "cancer type," "presence or absence of recurrence," "presence or absence of metastasis," "current treatment status," "time of cancer diagnosis," and "time of cancer treatment completion." Place of residence was recategorized into 6 categories: Hokkaido and Tohoku, Kanto, Chubu, Kinki, Chugoku and Shikoku, and Kyushu and Okinawa. To simplify the classification of cancer types, lung cancer and small cell lung cancer were grouped as lung cancer; esophageal, gastric, small intestine, and colorectal cancers were grouped as gastrointestinal cancer; liver, biliary tract, and pancreatic cancers were grouped as liver, biliary tract, and pancreatic cancer; kidney cancer and cancers of the renal pelvis and ureter and urethra, and bladder cancer were grouped as kidney, ureter, and bladder cancer; ovarian, endometrial, and cervical cancers were grouped as gynecologic cancer; leukemia, malignant lymphoma, and multiple myeloma were grouped as hematologic cancer; and brain tumors, head and neck cancer, thyroid cancer, cancer of unknown primary, skin cancer, and malignant melanoma were grouped as other. For information-seeking behaviors of patients with cancer, descriptive statistics were calculated regarding "having searched for information about cancer," "sources of cancer information," "SNS and apps used to gather cancer information," and "benefits of using psychosocial support and information-gathering services recommended by medical institutions." To understand the relational structure among items, analyses were conducted using tetrachoric correlations. Exclusive options such as "did not search" for "having searched for information about cancer," "did not want to obtain information" for "sources of cancer information," "do not use SNS or apps" for "SNS and apps used to gather cancer information," and "not applicable" for "benefits of using psychosocial support and information-gathering services recommended by medical institutions" were excluded from the statistical analyses. For the TIPI-J, descriptive statistics were calculated, and the relational structure among the items was examined using polychoric correlations.

Structural Validity of the Exploratory Factor Analysis

Exploratory factor analysis (EFA) was conducted according to the reporting standards proposed by Watkins [33]. EFA was chosen to identify the underlying factor structure. The measurement scales used were "behavioral barriers experienced when collecting information about cancer," "reliable information sources," and "relationships with doctors, medical professionals, and society." Each item was rated on a 5-point Likert scale ranging from 1 to 5. The appropriateness of conducting EFA was confirmed using the Bartlett test of sphericity [34]. The criteria for determining the number of factors included the Kaiser criterion of eigenvalues greater than 1 [35] and the minimum average partial (MAP) method [36]. Eigenvalues exceeded 1 up to the fifth factor (fifth factor=1.26), and the MAP exhibited its lowest value (0.03) at the fifth factor; therefore, a 5-factor solution was adopted. To choose the factor extraction method, multivariate normality was examined using the Mardia test [37]. Because skewness (skewness=62.14; P<.01) and kurtosis (kurtosis=613.96; P<.01) were significant, multivariate normality was rejected, and a method that did not assume normal distribution was required. Moreover, because the items used in this study were ordinal scales based on a 5-point Likert scale, factor analysis using the minimum residual method with a polychoric correlation matrix, which is suitable for ordinal data, was adopted [38,39]. Oblimin rotation [40] was used for simplification and theoretical convergence. Because oblique rotation was used, pattern coefficients of ≥0.37 were judged to be theoretically meaningful loadings, and coefficients of ≥0.40 were considered the primary criterion [41] for substantial interpretation. Cross-loadings of ≥0.3 were examined for interpretative caution. Internal consistency was determined using Cronbach α and McDonald ω, and factors with a reliability of ≥0.7 [42,43] and theoretical significance were judged as appropriate. The analysis was conducted using the *psych* package (version 2.6.2) in R. The *psych* package was developed and is maintained by William Revelle [44].

The LCA

In this study, we hypothesized that information-seeking behaviors and the use of psychosocial support services among survivors with cancer are not uniform and that multiple latent profiles exist. To identify these subgroups on the basis of statistical modeling, we used LCA [45]. Unlike traditional distance-based cluster analysis, LCA estimates latent structures using probabilistic models, allowing for objective model comparisons using information criteria, making it well suited for identifying latent profiles [46]. The analysis followed the reporting standards of Weller et al [47], and the optimal number of latent classes was determined on the basis of statistical fit indices and theoretical interpretability [48]. For the measurement variables, we recoded variables to ensure estimation stability, categorizing age, occupation, treatment status, and information-gathering devices. To examine the indicators included in the LCA, we conducted a polychoric correlation analysis and included 10 variables—sex, age, employment status, cancer type, stage, recurrence, metastasis, treatment status, time since completing treatment, and information-gathering devices—which were confirmed to have intervariable correlations of ±0.3 or higher. Model fit was assessed primarily using Bayesian information criterion (BIC), adjusted Bayesian information criterion (aBIC), and consistent Akaike information criterion (cAIC), and the model with the smallest value was selected as a candidate. Entropy was checked, with ≥0.8 considered acceptable and ≥0.9 considered ideal [48]. For the final model selection, we carefully evaluated whether each class had a sample size of n>50 or >5% of the total sample and whether each class profile was clinically meaningful. The R *poLCA* package (version 1.6.0.1), developed by Drew A Linzer and Jeffrey B Lewis, was used for the analysis [49].

XSL•FO
RenderX

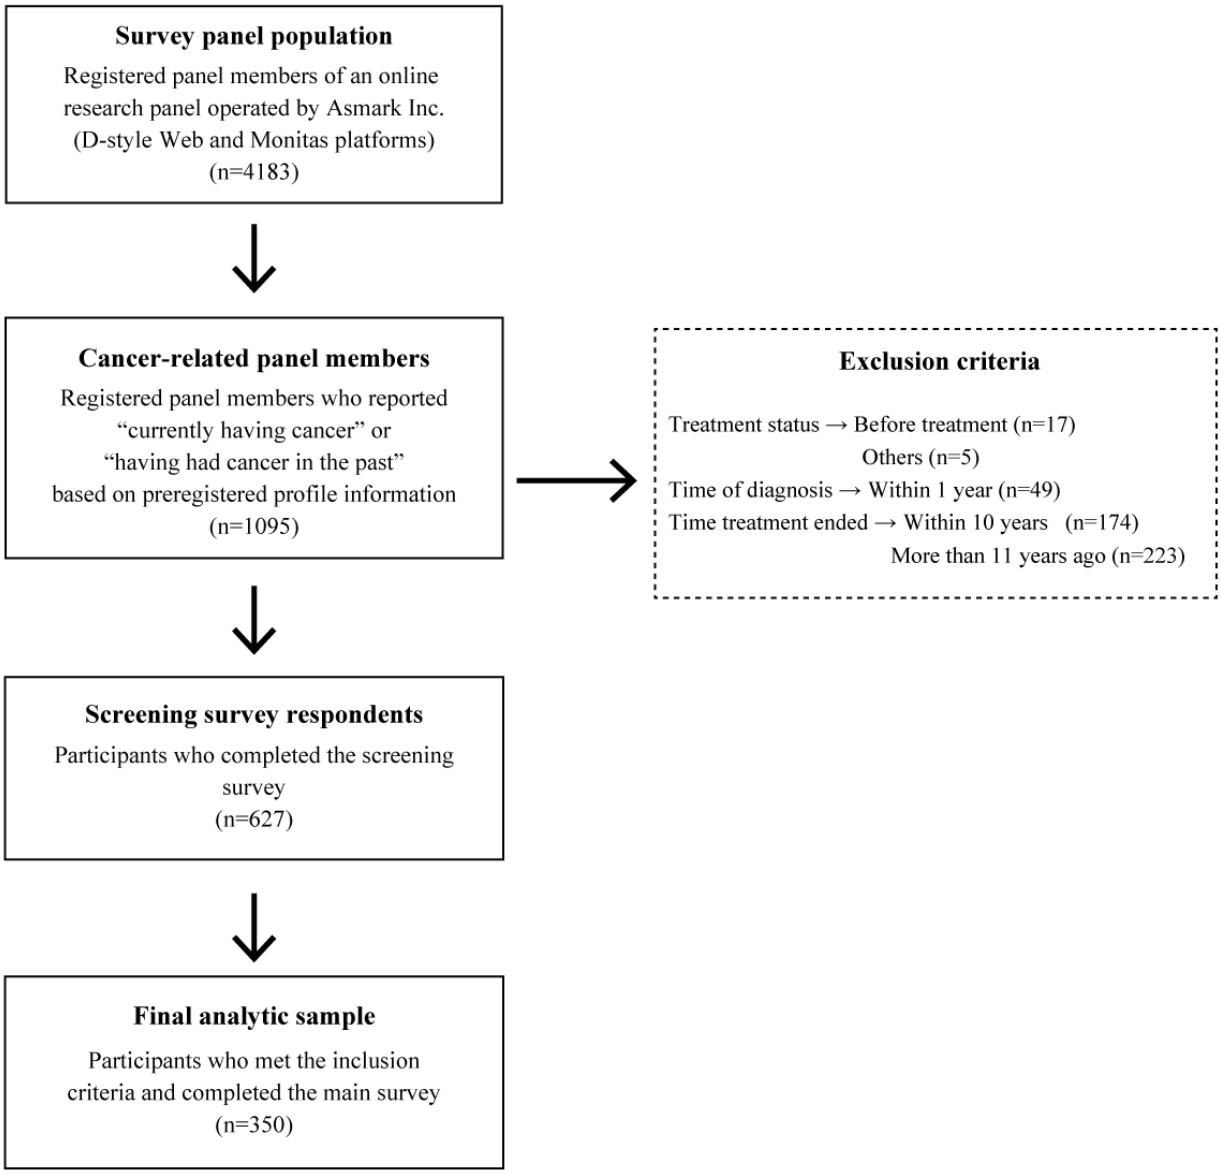
Multiple Comparison Tests Between Identified Latent Classes

We examined the differences in each survey item among the latent classes. The variables compared included "counseling support and information gathering through apps and services recommended by the hospital," "survey items related to cancer," "sources of information about cancer," "SNS and apps used to gather cancer information," and "advantages of using psychosocial support and information-gathering services recommended by medical institutions," as well as the factors identified in the EFA and the TIPI-J. To assess statistical significance, we adopted nonparametric testing methods with a significance level of $P<.05$. For binary items, we used the chi-square test for independence, and for ordinal items, we used the Kruskal-Wallis test. For items where significant differences were observed, we conducted residual analysis for binary items and the Wilcoxon rank-sum test ($P=.02$) for ordinal items as post hoc analyses using the Bonferroni correction and evaluated the association between the latent classes and each survey item.

Ethical Considerations

This study was approved by the Research Safety and Ethics Committee of Tokyo Metropolitan University of Industrial Technology (approval no 23020). The survey was conducted in compliance with the Declaration of Helsinki and relevant ethical guidelines, and only those who provided informed consent participated in the study. The collected data were securely stored in a password-protected database that was accessible solely to the research team. Participants were compensated with reward points according to the regulations of each platform. The allocation and exchange of points were managed exclusively by the survey company, and the research team was not informed about individual point allocations. Participants who responded via the D-style web platform received 2 points for the preliminary survey and 15 points for the main survey, totaling 17 points upon completing both surveys. Participants who responded via the Monitas platform received 2 points for the preliminary survey and 9 points for the main survey, totaling 11 points upon completing both surveys.

Results



Participant Characteristics

Of the 4183 members registered on the D-style web and Monitas platforms, 1095 individuals who indicated in their preregistration information that they "currently have cancer or have had cancer in the past" were selected for the screening survey. Of these, 627 individuals responded (participation rate: 57.3%). Among the respondents, 350 met the eligibility criteria for the main survey and proceeded to participate (transition rate: 55.8%). Accordingly, the final analysis included 350 survivors with cancer (350/1095, 31.9%; Figure 1).

The survey participants comprised 175 men and 175 women (175/350, 50%). The average age was 57.9 (SD 10.8) years. The largest age group was 60 - 69 years (138/350, 39.4%), followed by 70 - 79 years (89/350, 25.4%). Regarding occupation, the most common response was unemployed (108/350, 30.9%), followed by company employees (84/350, 24%). Most participants resided in the Kanto region (156/350, 44.6%). Regarding clinical characteristics, the most common types of cancer were breast cancer (93/350, 26.6%) and gastrointestinal cancer (91/350, 26%). Many patients were at an early stage, with stage 1 accounting for 156 of 350 (44.6%) participants. Regarding treatment status, more than half had completed treatment and were undergoing regular follow-up visits at the hospital (202/350, 57.7%). Smartphones (193/350, 55.1%) were the most commonly used devices to gather information about cancer. In contrast, 105 of 350 (30%) participants reported that they did not search for information. Regarding the use of hospital-recommended apps and services for counseling support and information gathering, 282 of 350 (80.6%) participants answered "yes," and 68 of 350 (19.4%) participants answered "no." Among participants who reported that they did not search for information in response to the question about devices used to gather information about cancer (105/350, 30%), most also reported "yes" regarding the use of hospital-recommended apps and services for counseling support and information gathering (91/105, 86.7%), with only 14 of 105 (13.3%) reporting "no." Of those who answered "yes," 161 of 282 (57.1%) had completed treatment and were under regular follow-up, and 72 of 282 (25.5%) were receiving outpatient or home medical care. Smartphones were the most commonly used devices to gather information about cancer (161/282, 46%; Table 1).

Information-Seeking Behavior of Patients With Cancer

Topics Researched Regarding Cancer

The most frequently researched topic related to cancer was “my disease,” which accounted for 75.7% (265/350) of responses. This was followed by “about treatment” (68.6%, 240/350) and “progress and prognosis” (55.4%, 194/350). “Treatment costs” accounted for 38.9% (136/350) of responses, “life during treatment” for 36% (126/350), and “other patients’ treatment and daily life” for 27.1% (95/350). Regarding correlations between categories, “life during treatment” had a strong positive correlation with “about my own condition” (ρ=0.7) and “progress and prognosis” (ρ=0.64). “Other patients’ treatment and daily life” showed a moderate positive correlation with “about my own condition” (ρ=0.61).

XSL•FO
RenderX

Sources of Cancer Information and Use of SNS and Apps

The most common source of cancer-related information was "internet/SNS" (58.9%, 206/350), followed by "doctors, nurses, and other medical staff" (50.6%, 177/350). Other sources included "newspapers, magazines, and books" (17.7%, 62/350), "family, friends, and acquaintances" (15.7%, 55/350), "National Cancer Center website" (15.4%, 54/350), and "cancer counseling support center" (7.4%, 26/350). Regarding correlations between categories, a moderately strong correlation (ρ=0.69) was observed between "newspapers, magazines, and books" and "television and radio," Among the SNS and apps used, YouTube (Google LLC) was the most common (13.4%, 47/350), followed by blogs (10%, 35/350), LINE, provided by LY Corporation (7.4%, 26/350), and X (formerly Twitter, provided by X Corp; 6%, 21/350). These items exhibited positive correlations with each other (ρ=0.48-0.6).

Benefits of Using Psychosocial Support and Information-Gathering Services Recommended by Health Care Institutions

The most commonly identified benefits of psychosocial support services or apps were "being able to obtain reliable information" (59.7%, 209/350) and "deepening knowledge about illness and treatment" (58.6%, 205/350), with more than half of the respondents emphasizing the quality and understanding of information. "Receiving information and support tailored to one's own symptoms or situation" was cited by 45.4% (159/350) of patients, and "facilitating communication with doctors or medical staff" was cited by 29.4% (103/350) of patients. Regarding correlations between items, a strong positive correlation (ρ=0.71) was found between "deepening knowledge about illness and treatment" and "receiving information suited to one's own symptoms or situation." "Easy to operate and user-friendly" showed a moderate positive correlation with both "deepening knowledge about illness and treatment" (ρ=0.61) and "facilitating communication with doctors or medical staff" (ρ=0.6; Table 2 and Multimedia Appendix 2).

TIPI-J

The mean scores reported by respondents were highest for neuroticism at 8.62 (SD 2.47), followed by openness at 8.24 (SD 2.43), extraversion at 7.65 (SD 2.6), and conscientiousness at 7.15 (SD 2.29). Agreeableness exhibited the lowest value among the 5 traits, at 5.84 (SD 2.03). A Shapiro-Wilk test [50] was conducted to assess the distribution of each scale, and the results were significant for extraversion (W=0.98; P<.001), agreeableness (W=0.95; P<.001), conscientiousness (W=0.98; P<.001), neuroticism (W=0.98; P<.001), and openness (W=0.98; P<.001), indicating that the data were not normally distributed. The correlations among the subscales were uniformly low (r=−0.43 to 0.37; Multimedia Appendix 2).

XSL•FO
RenderX

EFA Results

The Bartlett test of sphericity was conducted to assess the applicability of factor analysis. On the basis of the results, the null hypothesis that the correlation matrix is an identity matrix was rejected (χ^2_{210}=5425.91; P<.001), indicating that there was a sufficiently robust correlation structure among the items. The Kaiser-Meyer-Olkin statistic was 0.81, confirming sampling adequacy and determining that factor analysis was appropriate. The number of factors was determined on the basis of eigenvalues, MAP, and theoretical consistency. Eigenvalues exceeded 1 up to the fifth factor (factor 1=6.33, factor 2=4.27, factor 3=2.56, factor 4=1.86, and factor 5=1.26), and the cumulative contribution of the 5-factor solution was 67.83%. MAP decreased with the addition of more factors and improved up to the fifth factor. In addition to these results, considering that the measurement included several conceptual domains such as "difficulties in information seeking," "support and consultation for care," "relationship with the physician," "trust in information from medical institutions and specialized websites," and "trust in information from outside medical institutions," a 5-factor solution was adopted.

Factor 1 included items reflecting difficulties encountered in the process of seeking cancer-related information (factor loadings: 0.54-0.9) and was named "difficulties in information seeking." Factor 2 included items related to continued employment before treatment, concerns about appearance, convalescence, precautions in daily life, and workplace considerations (factor loadings: 0.42-0.74) and was interpreted as "evaluation of support for cancer care." Factor 3 included items on the primary physician's knowledge and experience, ease of consultation, and trust in information provided by physicians (factor loadings: 0.67-0.81) and was named "evaluation of the relationship with the physician." Factor 4 included trust in information from cancer-specialized or hospital or pharmaceutical company websites (factor loadings: 0.73-0.85) and was named "evaluation of the reliability of information from medical institutions and cancer-related websites." Factor 5 included trust in sources of information outside medical institutions, such as family and acquaintances, other patients, and social networking sites (factor loadings: 0.47-0.76) and was named "assessment of the reliability of information from nonmedical institutions."

The item "I had to visit several websites" loaded on both Factor 1 (0.60) and Factor 4 (0.33), and "the most reliable source is information from the physician" loaded on both Factor 3 (0.67) and Factor 4 (0.32). The internal consistency of the factors ranged from α=.75 to .9 and ω=0.78 to 0.92, with small interfactor correlations, the highest being between Factors 2 and 3 (r=0.47), justifying the treatment of the 5 factors as independent subconcepts (Table 3).

LCA Results

In determining the number of latent classes, models with 2-6 classes were estimated, and BIC was used as the primary index with comparisons to aBIC and cAIC. The 3-class model had the lowest BIC (5734.74) and cAIC (5805.74) and demonstrated high classification accuracy with an entropy of 0.95. Although the 4-class model had the lowest aBIC (5465) and similarly high entropy (0.96), both BIC and cAIC worsened (BIC=5766.37 and cAIC=5861.37). For models with 5-6 classes, the information criteria further increased, suggesting model overfitting. In finalizing the model, it was confirmed that each class had a sample size of n>50 or >5% of the total and that the class profiles were clinically interpretable. On the basis of minimum BIC and cAIC values and high classification accuracy, the 3-class model was selected as the final model (Table 4).

Table . Model selection criteria.

After fitting the model, the results for the 3 classes identified by the LCA were as follows. Class 1 comprised 95 individuals, all of whom were female (95/95, 100%). Most patients in Class 1 were between the ages of 50 and 69 years, with 35 of 95 (36.8%) aged 50 - 59 years and 31 of 95 (32.6%) aged 60 - 69 years. Regarding treatment status, 74 of 95 (77.9%) patients were undergoing regular follow-up after completing treatment, while 21 of 95 (22.1%) were in the follow-up stage without needing to visit a medical facility. On the basis of these treatment characteristics, this class was categorized as the "group of women under observation." Breast cancer was the most common cancer type (52/95, 54.7%), followed by gynecological cancers (19/95, 20%). In terms of cancer stage, more than half of the patients were classified as stage 1 (56/95, 58.9%). Of the 95 patients, recurrence was observed in 8 (8.4%) and metastasis in 4 (4.2%). Regarding employment status, 51 of 95 (53.7%) patients were employed. For information-seeking behavior, 43 of 95 (45.3%) patients answered, "I do not use devices to gather information about cancer." Among those who gathered information, smartphones were used by 39 of 95 (41.1%) patients; however, overall, information-seeking behavior was limited compared with that of patients in the other classes.

Class 2 comprised 163 individuals, the majority of whom were male (141/163, 86.5%). Most patients in Class 2 were aged 60 years or older, with 144 of 163 (88.3%) patients in this range; 76 of 163 (46.6%) patients were aged 60 - 69 years, and 68 of 163 (41.7%) patients were ≥70 years. Regarding treatment status, 128 of 163 (78.5%) patients were under regular observation after completing treatment, while 35 of 163 (21.5%) were in the follow-up stage without requiring hospital visits. These features led to this class being categorized as the "group of men under observation." The most common cancer was gastrointestinal cancer (69/163, 42.3%), followed by prostate cancer (29/163, 17.8%). Most cases were classified as early stage, with 76 of 163 (46.6%) patients at stage 1 and 37 of 163 (22.7%) patients at stage 2. Recurrence occurred in 21 of 163 (12.9%) patients, and metastasis occurred in 14 of 163 (8.6%) patients. These proportions were higher than those in Class 1 but lower than those in Class 3. Regarding employment, 92 of 163 (56.4%) patients were not employed. The device most commonly used for information seeking was a smartphone (104/163, 63.8%), and 31 of 163 (19%) patients answered "I do not use devices to gather information about cancer"; this proportion was lower than that among participants in the other classes.

Class 3 comprised 92 individuals, all of whom were undergoing treatment (92/92, 100%). There were 59 (64.1%) females and 33 (35.9%) males, with the majority aged between 50 and 69 years (50 - 59 years: 25/92, 27.2% and 60 - 69 years: 31/92, 33.7%). Breast cancer was the most common cancer (41/92, 44.6%), followed by gastrointestinal (10/92, 10.9%) and prostate cancers (10/92, 10.9%). This class had a higher proportion of advanced cancers, with stage 4 accounting for 25 of 92 (27.2%) patients. Recurrence was observed in 33 of 92 (35.9%) patients and metastasis in 37 of 92 (40.2%) patients. Both proportions were higher in Class 3 than in the other 2 classes. Regarding information-seeking behavior, 50 of 92 (54.4%) patients used smartphones, but 31 of 92 (33.7%) patients answered "I do not use devices to gather information about cancer." Given these features, this class was defined as the "group under treatment" (Figure 2 and Multimedia Appendix 2).

Figure 2. Class-specific conditional probabilities of sociodemographic and clinical characteristics identified by latent class analysis.

Results of the Comparison Among the 3 Groups

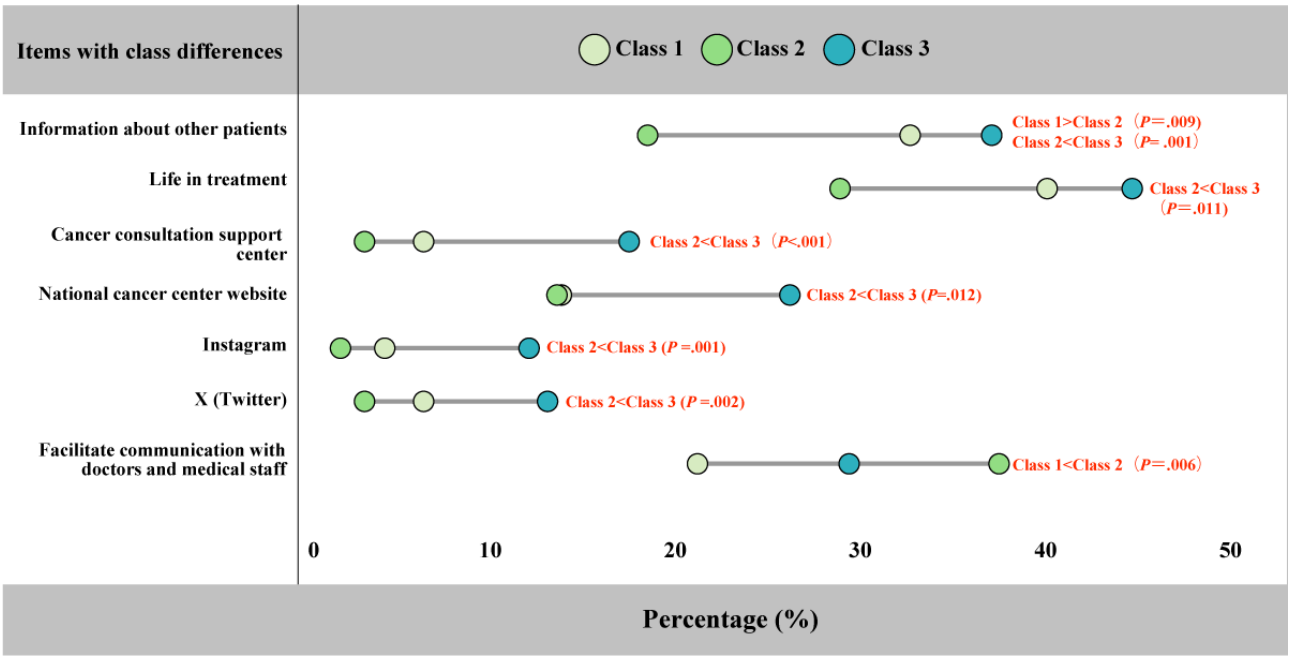
All results were obtained from post hoc analyses. Regarding "use of hospital-recommended apps and services for counseling support and information gathering," no significant differences were found. As shown in Figure 3, regarding "things I've researched about cancer," the results revealed that "information about other patients" was significantly lower in Class 2 than in the other classes (χ^2_2 =12.22; *P*=.002, post hoc test: Class 1 > Class 2; *P*=.009, and Class 2 < Class 3; *P*=.001). Regarding "life during treatment" (χ^2_2 =7.22; *P*=.03 and post hoc test: Class 2 < Class 3; *P*=.01), Class 3 was significantly higher than Class 2. Regarding "sources of cancer information," "Cancer Consultation Support Center" (χ^2_2 =17.31; *P*<.001 and post hoc test: Class 2 < Class 3; *P*<.001) and "National Cancer Center website" (χ^2_2 =7.59; *P*=.02 and post hoc test: Class 2 < Class 3; *P*=.01) were significantly higher in Class 3 compared with Class 2. Regarding "SNS and apps used to gather cancer information," "Instagram" (χ^2_2 =12.57; *P*=.002 and post hoc test: Class 2< Class 3; *P*=.001) and "X (Twitter)" (χ^2_2 =9.55; *P*=.008 and post hoc test: Class 2 < Class 3; *P*=.002) were significantly higher in Class 3 compared with Class 2. Regarding "blog" (χ^2_2 =5.82; *P*=.054), no significant differences were found between classes after the post hoc test. For "benefits of using psychosocial support and information-gathering services recommended by health care institutions," regarding "facilitate communication with doctors and medical staff" (χ^2_2 =12.57; *P*=.02 and post hoc test: Class 1 < Class 2; *P*=.006), Class 2 was significantly higher than Class 1 (Figure 3 and Multimedia Appendix 2).

According to Figure 4, for "Factor 1: difficulties in information seeking" (χ^2_2 =11.9; *P*=.003 and post hoc test: Class 2 < Class 3; *P*=.007), Class 3 showed a significantly higher value than

XSL•FO
RenderX

Class 2. For "Factor 3: evaluation of the relationship with the physician" (χ^2_2 =12.2; *P*=.002 and post hoc test: Class 2 > Class 3; *P*=.002), Class 2 had a significantly higher value than Class 3. For "Factor 5: assessment of reliability of information from nonmedical institutions" (χ^2_2 =12.3; *P*=.002 and post hoc test: Class 1 > Class 2; *P*=.002), Class 1 showed a significantly higher score than Class 2. Regarding the TIPI-J, agreeableness (χ^2_2 =6.7; *P*=.04) and neuroticism (χ^2_2 =8.8; *P*=.01) did not show significant differences after the post hoc test (Figure 4 and Multimedia Appendix 2).

Figure 3. Results of multiple comparison analysis using the independent chi-square and post hoc tests.



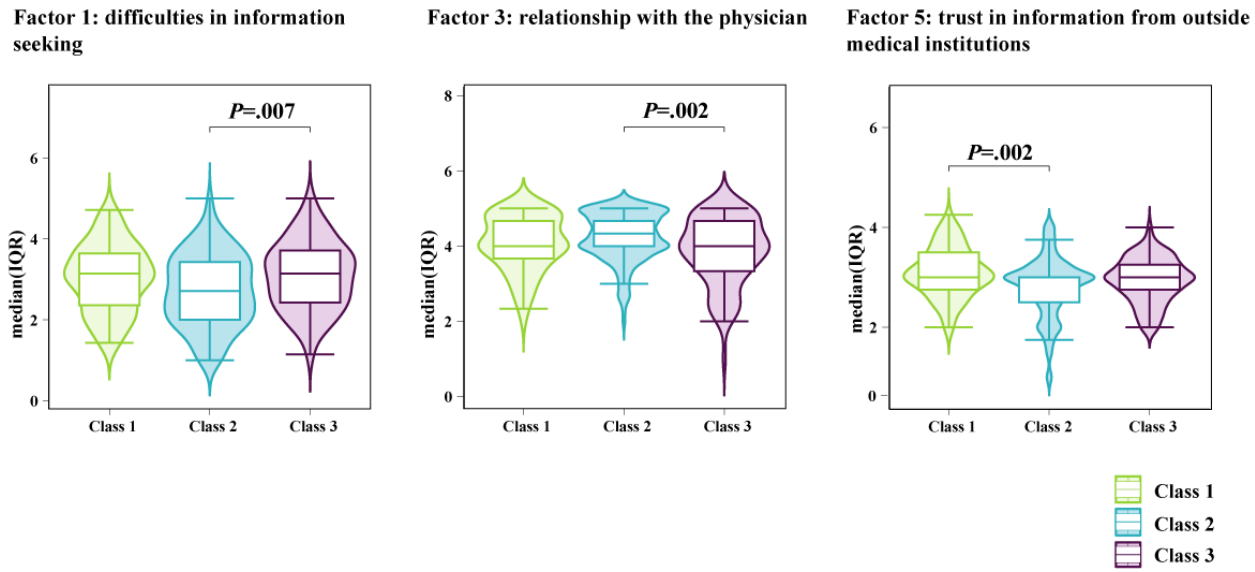


Figure 4. Results of multiple comparison analysis using the Kruskal-Wallis test and the Wilcoxon rank-sum test.

Discussion

Principal Findings

The results revealed that age distribution and cancer type composition among the respondents in this study were generally consistent with trends in Japan's national cancer statistics [31]. In addition, more than 80% of respondents indicated that they would like to use psychosocial support services or apps if recommended by medical institutions. Furthermore, in the results of the LCA, the "female under observation" group showed a high level of trust in "Factor 5: assessment of the reliability of information from nonmedical institutions," whereas the "male under observation" group was less proactive in gathering information but placed a high value on "Factor 3: evaluation of the relationship with the physician" and "facilitate communication with doctors and medical staff," indicating that they prioritize relationships with health care professionals. The "under treatment" group was the most active in collecting

XSL•FO
RenderX

information, frequently using "information about other patients," "life during treatment," "Cancer Consultation Support Center," and "National Cancer Center website." However, the "Factor 1: difficulties in information seeking" score was also high, suggesting that treatment status and gender may influence barriers to gathering information and differences in trusted sources.

Comparison With Previous Work

This study suggests that integrating the 3 factors from the TPB (ie, "attitude," "subjective norms," and "perceived behavioral control") with the "relationship function" and "task-oriented function" from the patient-provider relationship model is associated with a stronger intention to use psychosocial support services and hospital-recommended apps. Within the TPB framework, hospital recommendations may consistently shape behavioral intentions as a form of subjective norm. Previous studies have also reported that recommendations from health care providers strongly influence information-seeking behavior and support service usage among patients with cancer [51], and the results of this study are consistent with these findings.

Looking at each group, the male group under follow-up showed a high evaluation of their relationship with physicians and a strong trust in physician-provided information, with subjective norms in the TPB being particularly dependent on physicians. Previous research has also shown that male patients with cancer place a high value on trustworthiness and sincerity in their interactions with health care providers [52]. Furthermore, in the male follow-up group, the relationship function based on trust in physicians appears to play a central role, possibly serving as a prerequisite for accepting psychosocial support services and information provision.

In contrast, the female group under follow-up showed relatively higher trust in "information from other patients" and nonmedical sources, suggesting that peer-derived experiential knowledge plays an important role in forming attitudes in the TPB. Earlier studies, particularly those focusing on patients with breast cancer, have reported that peer support contributes to acquiring information and alleviating anxiety about recurrence [53-55], which is consistent with the current findings. For this group, it is also possible that task-oriented functions, such as managing uncertainty and decision support, are supplemented outside health care institutions. By providing opportunities for exchange with other patients or sharing experiential information, health care providers may help translate behavioral intentions into action.

The "under treatment" group displayed the highest level of active information-seeking behavior among the 3 groups, but also the greatest difficulty in seeking information. In terms of the TPB framework, while "behavioral intention" to seek information or use psychosocial services was high, "perceived behavioral control" appeared to be low. From the perspective of the patient-provider relationship model, it was suggested that the task-oriented functions for exchanging information and managing uncertainty, and the relationship functions providing reassurance and emotional support, may not be sufficiently aligned with patients' needs. Survivors with cancer undergoing treatment have strong information needs and clear intentions to seek information but may lack sufficient self-efficacy to understand the information and make decisions, leading to increased difficulty. Prior studies have also reported that patients with cancer in advanced or treatment phases experience heightened anxiety from online information [56], lack of social support beyond the internet, and negative treatment experiences [57]. Such negative experiences can decrease patients with cancer's self-efficacy and trust in their digital skills, making information seeking a heavy burden. Therefore, for survivors with cancer undergoing treatment, clarifying reliable information sources and having health care providers organize and supplement information is crucial for alleviating the psychological burden associated with information-seeking.

Strengths and Limitations

The strength of this study lies in its analysis of information-seeking behaviors of survivors with cancer and usage of psychosocial support services, grounded in the 3 components of TPB, as well as the communication functions of relationship-oriented and task-oriented functions in the patient-provider relationship model. By using EFA to identify factors and subsequently using LCA to classify multiple subgroups, this study systematically captured the behavioral intentions underlying information-seeking activities. This approach identified diverse needs among subgroups—needs that are often difficult to capture by a simple comparison of attributes—regarding trusted sources of information and communication tendencies among survivors with cancer. In particular, differences in the levels of trust in information sources between men and women during the follow-up period highlight the importance of personalized information provision, offering practical insights for future patient support service design. However, this study involved several limitations that should be considered. First, although the target sample size was achieved and trends were found to partially align with national cancer incidence statistics, the sampling was not stratified by age or cancer stage. Consequently, there was a bias toward survivors in stages 1 and 2, whereas the proportion of survivors in stages 3 and 4, or those who experienced recurrence or metastasis, was relatively low. Given the imbalances in cancer type, age group, and stage, caution is warranted regarding the generalization of the study findings to all survivors with cancer. Second, this was a cross-sectional study aimed primarily at identifying tendencies in types of information-seeking behaviors and thus cannot establish causal relationships related to various factors and backgrounds associated with each survey item. Detailed factor analyses and longitudinal studies are necessary to elucidate how information-seeking behaviors and perceptions evolve over time. Third, because this study focused on differences by treatment status and gender, socioeconomic factors such as income, education, and digital literacy were not included in the survey. However, these factors may also influence information-seeking behaviors and the use of support services, suggesting that future research should comprehensively examine these variables. Fourth, the questionnaire used in this study was developed on the basis of previous research and theoretical frameworks. However, because no formal pilot testing or test-retest reliability verification was conducted before the survey, the temporal stability of the measurement could not

XSL•FO
RenderX

be assessed. This represents a limitation, and caution is required when interpreting the results. In the future, a comprehensive psychometric evaluation, including test-retest reliability and measurement invariance, will be necessary.

Conclusions

This study clarified how information-seeking behaviors among survivors with cancer differ depending on treatment status and sex. By applying the TPB and patient-provider relationship models and using EFA, LCA, and multiple comparison analyses, we identified subgroups of patients with cancer with different behavioral characteristics. Our findings provide valuable insights for designing necessary approaches to promote personalized psychosocial support services and information provision for patients, as well as for improving the user interfaces of products and services that support patients psychologically and socially. Future research should focus on the realities of information provision and communication between patients with cancer and health care professionals, as they relate to individualized support for middle-aged and older survivors with cancer. Further exploration from multifaceted perspectives, including health care providers' recognition of information delivery and patients' acceptance of information, is expected to lead to the development and improvement of personalized and patient-centered communication approaches in the future.

Abstract

Background: Quality of life (QoL) questionnaires are used in many disease areas to measure the burden that a disease causes for patients, which help provide insights into disease impact, identify unmet medical needs, and inform patient-centered drug development and value assessment for treatments. The collection of data imposes both a significant burden on patients as well as effort on health care personnel, thus incurring high costs for the health care system. Given that patients share detailed information about their condition and treatment experiences on social media and patient forums, an important research question is to what extent information about QoL can be obtained from patients' online forum posts to potentially complement information obtained from questionnaires.

Objective: This study aimed to assess how much QoL information can be gained from the analysis of posts by patients in online health care communities and whether this information is rich enough to estimate individual patient's QoL based on their posts. We conducted this feasibility study in the context of breast cancer as it is the most prevalent cancer in the female population.

Methods: We recruited 134 female patients diagnosed with breast cancer on the Inspire patient online forum, who voluntarily participated in our feasibility study. They filled in the EORTC (European Organisation for Research and Treatment of Cancer) QLQ-C30 and QLQ-BR23 questionnaires consisting of 30 general questions and 23 additional breast cancer–specific questions and provided consent to analyze their posts and comments on the online forum (756 posts and 19,478 comments). Posts were coded manually to identify parts of the text providing answers to 1 of the aforementioned 53 questions.

Results: The data annotation yielded a substantial agreement (mean Fleiss κ of 0.5, SD 0.28). Overall, we found answers in the coded data for 50 out of 53 EORTC QLQ-C30 and QLQ-BR23 questions. The information coded in the posts reliably predicted the answers given in the questionnaires (F_1-score=0.7), with even better results when grouping similar questions (F_1-score=0.8 for fine-grained and 0.9 for coarse-grained grouping). The 5 questions that were most frequently answered on the basis of the coded posts were "Did you feel ill or unwell?" (304 of 2683 annotated posts and comments), "Did you worry?" (105 posts and comments), "Have you had pain?" (104 posts and comments), "Did you feel tense?" (85 posts and comments), and "Were you limited in doing either your work or other daily activities?" (77 posts and comments).

Conclusions: Our feasibility study shows that there is valuable QoL-related information in posts of online patient communities, which can potentially serve as an innovative low-burden QoL monitoring approach. Future research should consider how these insights can be used to complement existing QoL instruments and whether the process of extracting QoL-related information can be automated.

Introduction

Quality of life (QoL), as defined by the World Health Organization, encompasses physical, mental, and social well-being beyond the mere absence of disease [1]. Assessing QoL is essential in health care, providing insights into disease impact, identifying unmet medical needs, and informing patient-centered drug development and value assessment for treatments. Traditionally, QoL is measured using patient-reported outcome questionnaires, such as the widely used EORTC (European Organisation for Research and Treatment of Cancer) QLQ-C30 for patients with cancer [2]. These standardized tools facilitate comparisons across patient groups and with the general population.

However, QoL assessments are often time-consuming and administratively burdensome for both patients and health care providers [3-7]. Efforts to streamline data collection have explored digital and computer-supported approaches [6-8]. Given the increasing use of social media and online patient communities for sharing health experiences, a key question arises: Can patient-generated online content serve as a proxy or complementary source for QoL data collection? While not a replacement for structured surveys, social media data may provide real-time, cost-effective insights into patient well-being, preferences, and treatment experiences.

Previous research has leveraged social media to assess disease burden and treatment experiences across conditions, such as Parkinson disease [9,10], Sjögren disease [11], chronic obstructive pulmonary disease [12], and mental disorders [13,14]. Some related work also analyzed patient posts compared to a specific QoL ground truth, but on an aggregated level. For example, Zivanovic et al [15] compared Twitter data with official QoL data of the city of Bristol. Similarly, Cotté et al [16] also investigated cancer-specific forums and QoL data, but with a focus on immune checkpoint inhibitors and not the QoL impact for individual users. Therefore, studies have yet to systematically evaluate whether individual QoL data can be reliably extracted from online patient discussions.

To explore this, we conducted a study with patients diagnosed with breast cancer from the Inspire patient online forum, assessing whether online forum posts contain relevant QoL information. Breast cancer remains the most commonly diagnosed cancer in women, with over 2.3 million new cases in 2020 [17]. QoL is a critical concern for patients diagnosed with breast cancer and survivors, who frequently experience significant impairments [18-21].

In our study, patients diagnosed with breast cancer completed standard QoL questionnaires (EORTC QLQ-C30 and QLQ-BR23), while their online posts and comments were manually coded to determine the presence of QoL-related content. We then assessed the prevalence of QoL discussions and their correlation with questionnaire responses. Our research focuses on the following questions:

- RQ1: Do patient online forum posts contain QoL-related information?
- RQ2: Which QoL questions from EORTC QLQ-C30 and QLQ-BR23 are most frequently addressed in online posts?
- RQ3: How well do these online discussions align with individual patients' QoL questionnaire responses?

This study aims to determine whether patient-generated content from online health communities can complement traditional QoL assessments, potentially offering a scalable, low-burden alternative for understanding patient well-being.

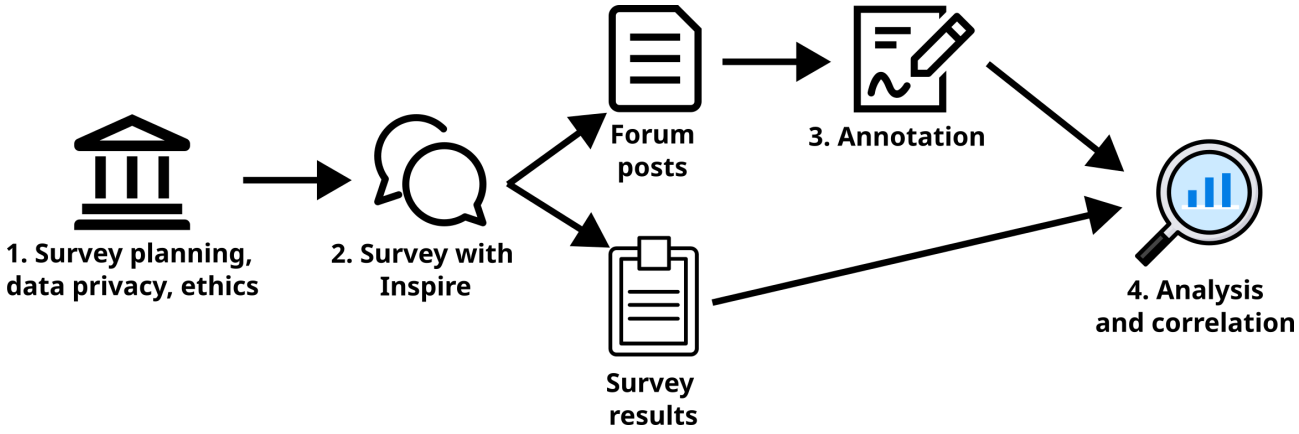
Methods

Overall Structure

This feasibility study aimed to assess the presence of QoL information in online discussions by patients diagnosed with breast cancer. Breast cancer was selected due to its high prevalence, and data were collected from patient-generated content on the Inspire patient online forum. Patient communities on this forum are organized by condition, including "breast cancer" and "advanced breast cancer," where each thread of natural peer-to-peer conversation consists of an initial post and subsequent comments. An overview of the workflow followed in this study is given in Figure 1.

To compare patient-reported QoL in online posts with structured assessments, we (the authors of this study) administered the QLQ-C30 questionnaire by the EORTC [2] and its breast cancer–specific module, QLQ-BR23. These validated instruments provided a reference (ground truth) against which the content of online discussions could be analyzed.

Participants were recruited from the "Breast Cancer" and "Advanced Breast Cancer" communities on Inspire. Eligibility criteria included female patients diagnosed with breast cancer, age 18 years or older, residency in the United States, and at least 1 post or comment in the respective Inspire communities.



Residency in the United States was included due to Inspire being based in the United States.

The EORTC QLQ-C30 questionnaire was used to assess general QoL in patients with cancer. It comprises 30 items grouped into 5 functioning scales, a global health status/QoL scale, 3 symptom scales, and 6 single-item measures. Scores range from 0 to 100, with higher functioning scores and lower symptom scores indicating better QoL. Normative values for this instrument have been previously established [22,23]. The breast cancer–specific module, EORTC QLQ-BR23, consists of 23 items categorized into 8 scales: systemic therapy side effects, hair loss, arm symptoms, breast symptoms, body image, future perspective, sexual functioning, and sexual enjoyment. Response options align with those of the EORTC QLQ-C30.

The final survey also included demographic questions, such as year of birth, US state of residence, gender, sex at birth, insurance type, and residential setting (urban, suburban, rural, or other). The survey required approximately 5 to 10 minutes to complete and was conducted between May and June 2024.

Figure 1. Overview of the study workflow from planning survey conduction to data analysis. The online survey using the EORTC QLQ-C30 and QLQ-BR23 questionnaires was conducted between May and June 2024 with patients diagnosed with breast cancer posting in the Inspire patient online forums. EORTC: European Organisation for Research and Treatment of Cancer.

Ethical Considerations

Our study has been approved by the Ethics Committee of Bielefeld University under application number 2023 - 216-W1. A filled CHERRIES (Checklist for Reporting Results of Internet E-Surveys) [24] checklist can be found in Checklist 1. Informed consent was obtained from all participants, granting permission to analyze their posts and comments for this study. The collected data, especially the survey responses, are not publicly shared and only available to the authors of the study. Additionally, the data are stored in encrypted form only. All eligible community members were invited to participate (ie, convenience sampling), with the first 100 respondents receiving a US $20 gift card as compensation.

Annotation and Coding Process

The objective of the coding process was to identify text spans within collected posts and comments that could correspond to responses in the EORTC QoL questionnaires. To achieve this, we implemented an annotation schema similar to named-entity recognition, where each of the 53 QoL questions served as a label. Unlike traditional named-entity recognition, which identifies entities, such as persons or organizations [25,26], our approach used QoL-related labels to tag relevant text segments.

In addition to assigning labels corresponding to each QoL question, we introduced supplementary labels to capture both reported presence and absence of symptoms: “positive” or “negative.” Coders applied these labels alongside question-specific tags to indicate whether a response reflected a favorable or unfavorable QoL experience. Furthermore, an “Exact match” label was used to denote text spans that provided precise or highly relevant answers, while standard labels without this addition were applied to responses that were partial or vague.

The annotation schema and guidelines were developed in a 2-phase process. In the first phase, 3 annotators labeled 30 posts using a preliminary schema. After completing this pilot phase, the results were reviewed, and minor refinements were made. For instance, the label “Did you feel ill or unwell?” was designated for general QoL descriptions that did not fit into other, more specific categories. The annotators were explicitly trained to only use the fallback label when they could not find any other label that fits better, and this was also added to the annotation guidelines (Multimedia Appendix 1). Compliance with these rules was ensured by closely checking fallback annotations during the beginning of the annotation process of the full data. These pilot annotations were subsequently excluded from the final dataset.

In the second phase, the full annotation process commenced, with no further modifications needed. Additionally, posts and comments from the last 6 months (relative to each user’s participation date) were labeled to indicate whether they referred to past events. This distinction was critical for evaluating the correlation between forum data and survey responses, as older event descriptions may not accurately reflect a patient’s current QoL. Filtering out such posts allowed for a more precise alignment between forum-derived insights and survey-based QoL assessments.

Measuring Information Consistency Between Online Posts and Survey Responses

To assess the alignment between information shared in online posts and responses in the structured questionnaires, we applied classification metrics commonly used in machine learning. The coding scheme and questionnaire responses were simplified into a binary format, mapping each piece of information from posts and survey answers to either a “positive” or “negative” response. The intended meaning of “positive” here is that the corresponding question would be answered with “yes,” thus indicating the presence of symptoms or other issues. Analogously, “negative” corresponds to answering the question with “no,” indicating the absence of symptoms or other issues. Specifically, the answer categories “a little,” “quite a bit,” and “very much” were classified as “positive,” whereas “not at all” was categorized as “negative.” This enabled the computation of key classification metrics as follows:

- True positives (TP): Instances where both the online post and the corresponding questionnaire response indicate a “positive” answer (eg, a user stating, “I had so much pain last week!” and selecting “yes” for the survey question, “Have you had pain?”).
- False positives (FP): Cases where an online post is labeled as “positive,” but the corresponding survey response is

XSL•FO
RenderX

"negative" (eg, a user stating, "I am so worried!" but responding "no" to the question, "Did you worry?").
- True negatives (TN): Instances where both the online post and the survey response indicate a "negative" answer (eg, a user stating, "I do not have any pain!" and selecting "no" for the survey question, "Have you had pain?").
- False negatives (FN): Cases where an online post is labeled as "negative," but the corresponding survey response is "positive" (eg, a user stating, "I did not worry at all last week!" but selecting a "positive" response in the survey question, "Did you worry?").

If no labeled data existed for a specific user and QoL question, that user did not contribute to the TP, FP, TN, or FN calculations for that question. This approach allowed us to evaluate how well the available data could predict survey responses.

Using the TP, FP, TN, and FN values, we computed standard machine-learning classification metrics, including precision (TP/[TP + FP]), recall (TP/[TP + FN]), and F_1-score as harmonic mean between precision and recall, that is, 2× precision × recall/(precision + recall) [27]. Given that data sparsity increases when analyzing results at the individual user level across all 53 survey questions, we explored grouping similar survey questions based on the EORTC scoring manual. This resulted in 2 levels of categorization: (1) fine-grained grouping: based on detailed QoL question clusters (Table 1) and (2) coarse-grained grouping: functional (questions 1-7, 20-27, 39-46), symptoms (questions 8-19, 28, 31-38, 47-53), and global health (questions 29 and 30).

These groupings enabled more robust analyses by reducing sparsity and improving interpretability of the correspondence between online forum discussions and structured survey responses.

Table . Fine-grained grouping based on the EORTC[a] QLQ-C30 and QLQ-BR23 scoring manual[b].

Group	Question IDs
Global health	29, 30
Physical functioning	1, 2, 3, 4, 5
Role functioning	6, 7
Emotional functioning	21, 22, 23, 24
Cognitive functioning	20, 25
Social functioning	26, 27
Fatigue	10, 12, 18
Nausea and vomiting	14, 15
Pain	9, 19
Dyspnea	8
Insomnia	11
Appetite loss	13
Constipation	16
Diarrhea	17
Financial difficulties	28
Systemic therapy side effects	31, 32, 33, 34, 36, 37, 38
Upset by hair loss	35
Arm symptoms	47, 48, 49
Breast symptoms	50, 51, 52, 53
Body image	39, 40, 41, 42
Future perspective	43
Sexual functioning	44, 45
Sexual enjoyment	46

Results

General Statistics

The collected dataset comprises 20,204 posts and comments from 2006 to 2024, with 580 posts and comments originating within the 6 months preceding the end of the study. The distribution of posts per user follows a long-tail pattern, as illustrated in Figure 2, with absolute values presented in Table 2). As shown in Figure 2, the majority of contributions are comments rather than original posts. Table 3 shows that our data cover a broad spectrum of patients diagnosed with breast cancer, both in terms of age and distance between survey and breast cancer diagnosis.

Figure 2. Posts per user, with 123 users on the x-axis and the (log-scaled) number of posts on the y-axis, differentiating between combined posts and comments in light blue and comments only in dark blue. Users without posts or comments were disregarded. The online survey using the EORTC QLQ-C30 and QLQ-BR23 questionnaires was conducted between May and June 2024 with patients diagnosed with breast cancer posting in the Inspire patient online forums. EORTC: European Organisation for Research and Treatment of Cancer.

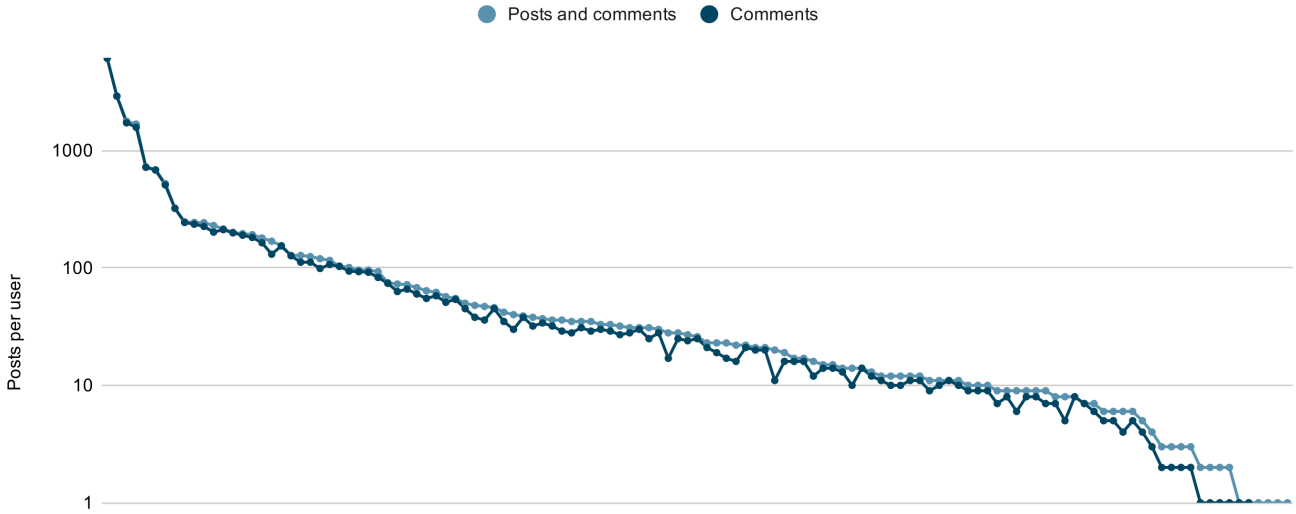

Table . Overview of the number of posts per user[a].

Number of posts and comments	Number of users
1	6
2-10	28
11-100	63
101-1000	22
>1000	4

[a]The online survey using the EORTC QLQ-C30 and QLQ-BR23 questionnaires was conducted between May and June 2024 with breast cancer patients posting in the Inspire patient online forums.

The average post length is 408.4 (SD 366.8) characters. A total of 134 participants were enrolled in the study, of whom 11 did not contribute at least 1 post or comment, resulting in 123 participants meeting the inclusion criteria.

For annotation, the last 6 months of data (580 posts and comments) were labeled by 3 annotators, with an average annotation time of 15.9 (SD 10.3) hours per annotator. The last 24 months of data (an additional 2103 posts and comments) were labeled by 2 annotators, requiring an average of 76.5 (SD 12.7) hours per annotator. In total, 2683 posts were annotated. Fourteen posts contained QoL-related information referring to someone other than the posting user. These posts were annotated but excluded from statistical evaluation.

Of the 2669 annotated posts and comments included in the final dataset, 613 (23%) contained at least 1 label corresponding to a QoL question. When considering only the last 6 months, the proportion was higher at 37.4% (217 out of 580 posts), indicating that approximately one-third to one-fourth of all posts contained QoL-relevant content.

Table . Statistics of self-reported demographic data of survey participants[a].

Data category	Mean (SD)	Minimum	Maximum
Age	68.2 (11.5)	27	116
Age at diagnosis	55.7 (12.6)	26	103
Years since diagnosis	13.1 (9.4)	0	45

[a]The online survey using the EORTC QLQ-C30 and QLQ-BR23 questionnaires was conducted between May and June 2024 with patients diagnosed with breast cancer patients posting in the Inspire patient online forums.

Among the 53 QoL questions, 50 were labeled at least once, with the most frequently occurring questions summarized in Table 4. The most commonly assigned label was "Did you feel ill or unwell?," with 301 annotations, representing 11% (n=301) of all posts and 57.3% (n=47) of users who actively posted during the study period. It has to be noted that this is used as a fallback label for the case where posts or comments contain information which is clearly QoL-relevant, but no other better-fitting label could be found. An example for this is when patients describe some very specific or very vague symptoms that do not correspond well to any other question (eg, "the symptoms increased a lot"). The next most frequently annotated questions were "Did you worry?" (105 annotations) and "Have you had pain?" (102 annotations), both capturing broad categories of patient discomfort. The overall label distribution is visualized in Multimedia Appendix 2.

Table . Top 10 most frequent labels with respect to number of posts they are annotated in for all annotated posts (most recent 24 months)[a].

Question	Number of posts	Portion of posts, %	Number of users	Portion of users, %
Did you feel ill or unwell?	301	11	47	57.3
Did you worry?	105	3.9	26	31.7
Have you had pain?	102	3.7	32	39
Did you feel tense?	84	3.1	21	25.6
Were you limited in doing either your work or other daily activities?	77	2.8	18	22
Were you tired?	55	2	18	22
Have you felt nauseated?	51	1.9	18	22
Were you worried about your health in the future?	41	1.5	16	19.5
Have you lacked appetite?	32	1.2	5	6.1
Did you feel depressed?	32	1.2	14	17.1

[a]"Portion of posts" refers to the percentage of posts with the corresponding label relative to all posts of that time period. Similarly, "Portion of users" refers to the number of users who have posts annotated with that label relative to all users who posted in that time period. The online survey using the European Organisation for Research and Treatment of Cancer (EORTC) quality of life questionnaires (QLQ) QLQ-C30 and QLQ-BR23 was conducted between May and June 2024 with patients diagnosed with breast cancer posting in the Inspire patient online forums.

Annotator Agreement

As every post and comment within the most recent 2 years was annotated by 2 or 3 annotators, the interannotator agreement can be calculated via Fleiss κ values [28]. This measure aids in determining to which degree annotators agreed on which text segments or posts answered that question at least partially. We only consider the basic labels corresponding to the questions for the calculation of interannotator agreement, ignoring the additional labels "negative" and "exact match," and handle each question separately, as this fits best with the setting assumed by the Fleiss κ metric for interannotator agreement.

We calculated the Fleiss κ for 2 different levels of annotation granularity, that is, on word and on post or comment level, respectively. The word level reflects the actual annotations, that is, the text segments created during annotation, whereas the post level is a simplification aggregating all annotations of a post such that the annotations only have to agree on whether the whole text answers a specific question or not, but not where exactly.

The top and bottom 10 Fleiss κ values for the most recent 6 months of data are provided in Table 5, together with the absolute numbers of posts in which the corresponding question has been answered.

It can be observed that many frequently occurring labels exhibit solid to high annotator agreement, for example, "Have you lost any hair?" has a Fleiss κ value of 0.7 for word units and even 1.0 for post units while being present in 26 posts in total. Even the fallback label "Did you feel ill or unwell?" with 285 labeled posts has Fleiss κ values of 0.6 and 0.7 for word and post granularity, respectively.

Most questions in the lower range of Fleiss κ values have a very low number of labeled posts. The 6 questions with the lowest

XSL•FO
RenderX

observed agreement of 0.0 together only account for 14 posts in total, so these appear to be cases where the annotators do not agree whether the label is applicable. Further investigating the data, the most disagreement is caused by vaguely formulated posts for which a label could but does not necessarily have to apply. For example, for labels, such as "Did you have any pain in your arm or shoulder?," issues can range from just vaguely described body areas to mentions of certain diseases or syndromes, which are closely connected to pain in that area, without pain being explicitly mentioned. Although we cannot give real posts as examples for data privacy reasons, we summarized prototypical posts to illustrate the reasons for disagreement. For "Did you have any pain in your arm or shoulder?," annotators disagreed for posts, such as "I take that medication for 5 years now and started to have problems with hand-foot syndrome some time ago," as hand-foot syndrome itself is not an explicit mention of pain and can occur with or without pain [29]. Similarly, annotators disagreed for posts, such as "In the last months I had cramps in different parts of my hand from time to time." Another label with low annotator agreement was "Have you had skin problems on or in the area of your affected breast (e.g., itchy, dry, flaky)?," for example, for posts like "I try to avoid foods with high folic acid as much as possible as they can cause pain in the arms for some of us. For the dryness, I use some ointment all the time," as it is not very clear what part of the body "dryness" refers to.

Table . Annotator agreement for the 10 questions with the highest agreement and 10 questions with the lowest agreement (Fleiss κ, the most recent 6 months of data before the survey) using word units and post units[a].

Question	Fleiss κ (word units)	Fleiss κ (post units)	Labeled posts
Top 10			
Did you have headaches?	1.0	1.0	3
Have you had difficulty remembering things?	0.9	1.0	3
Have you lacked appetite?	0.9	0.9	15
Did you have hot flushes?	0.8	0.8	9
Have you lost any hair?	0.7	1.0	26
To what extent were you sexually active? (with or without intercourse)	0.7	1.0	6
Did you feel ill or unwell?	0.6	0.7	285
Have you had diarrhea?	0.6	0.9	10
Do you have any trouble taking a short walk outside of the house?	0.6	0.7	19
Were you tired?	0.6	0.8	35
Bottom 10			
Have you had skin problems on or in the area of your affected breast (eg, itchy, dry, and flaky)?	0.2	0.3	11
Have you vomited?	0.2	0.5	2
Do you have any trouble taking a long walk?	0.2	0.3	7
Did you have any pain in your arm or shoulder?	0.2	0.4	11
How would you rate your overall health during the past week?	0.0	0.0	1
Did you need to rest?	0.0	0.0	1
Was it difficult to raise your arm or to move it sideways?	0.0	0.0	1
Did pain interfere with your daily activities?	0.0	0.0	3
Did food and drink taste different than usual?	0.0	0.0	6
How would you rate your overall quality of life during the past week?	0.0	0.0	2

[a]The online survey using the European Organisation for Research and Treatment of Cancer (EORTC) quality of life questionnaires (QLQ) QLQ-C30 and QLQ-BR23 was conducted between May and June 2024 with patients diagnosed with breast cancer posting in the Inspire patient online forums.

Correlation Results Between Annotated Data and Survey Data

We estimate the correlation between the information provided by the authors to QoL aspects and the data provided in the questionnaires by computing F_1-score as described in the "*Measuring Information Consistency Between Online Posts and Survey Responses*" section. Table 6 shows the F_1-scores and total annotations for the 10 most frequently annotated questions based on data originating from the most recent 6-month period and compares these numbers to the corresponding values for 24 months.

As observed from Table 6, all of the 10 most frequently answered questions can be predicted reliably with an F_1-score of 0.6 or higher for the last 6 months of data. For 7 of the 10 questions, the F_1-score is even 0.8 or higher. The lowest score of 0.6 is achieved for the most frequent question, that is, "Did you feel ill or unwell?" This specific question is also used as a fallback label for utterances, which do not fit in any other category, thus increasing prediction difficulty compared to other labels. Even when considering a much larger time period of 24 months, the F_1-scores for these questions do not drop below 0.5, with some even increasing.

XSL•FO
RenderX

Although the observed F_1-scores are high for many questions, for example, "Were you tired?" or "Were you worried about your health in the future?" with each of an F_1-score of 1.0, for some questions, the available data get sparse and the data sparsity increases even further when considering single users or shorter time spans, leading to lower F_1-scores in some cases, for example, for "Have you vomited?" (F_1-score of 0.2 with 2 labeled posts in 6 months of data). One way of reducing data sparsity is to consider a larger time span. However, this comes at the cost of posts and comments with a larger temporal distance from the survey date being potentially less relevant with respect to the QoL at that time. However, in Table 6, despite the inclusion of older posts, we can observe solid to high F_1-scores (0.6-1.0, mean 0.8, SD 0.1) for all 10 most frequently answered questions. This shows that including posts from dates outside the time period asked for in the QoL surveys can still be useful.

Table . F_1-scores for the 10 most frequently annotated questions, describing how well annotations predict the actual answers given in the survey, considering the last 6 and 24 months of data, which are not filtered by time deviation[a].

Question	F_1-score (6 mo)	Total annotations (6 mo)	F_1-score (24 mo)	Total annotations (24 mo)
Did you feel ill or unwell?	0.6	127	0.7	222
Did you worry?	0.8	36	0.9	47
Did you feel tense?	0.9	33	0.8	40
Have you had pain?	0.8	28	0.8	74
Were you tired?	1.0	14	0.9	50
Have you felt nauseated?	0.7	14	0.5	34
Has your physical condition or medical treatment interfered with your social activities?	0.7	13	0.7	13
Has your physical condition or medical treatment caused you financial difficulties?	1.0	12	1.0	12
Were you worried about your health in the future?	1.0	11	1.0	15
Have you lost any hair?	0.8	10	0.8	29

[a]The online survey using the European Organisation for Research and Treatment of Cancer (EORTC) quality of life questionnaires (QLQ) QLQ-C30 and QLQ-BR23 was conducted between May and June 2024 with patients diagnosed with breast cancer posting in the Inspire patient online forums.

As some questions occur sparsely, we group the answers from the posts and the questionnaires into the groups "Symptomatic" and "Functional" used in the EORTC scoring manual. The results for the grouped questions are shown in Table 7.

The only group in Table 7 having annotations available and exhibiting a lower F_1-score than 0.7 for the last 6 months is "cognitive functioning," which comprises only 2 questions, that is "Have you had difficulty in concentrating on things, like reading a newspaper or watching television?" and "Have you had difficulty remembering things?" All other groups show very promising results, with over half of the groups having scores of 0.9 or higher. Groups of questions for which there were no annotations in the data, that is "Appetite loss," "Global health," "Insomnia," "Sexual enjoyment," "Sexual functioning," and "Upset by hair loss," have been omitted in the table. Even when considering much older data from the last 24 months as well, F_1-scores do not drop below 0.5, with many scores even increasing, underlining the relevance of older data.

For 6 months of data, a total of 31 users have shared posts containing QoL information with on average 10.8% (SD 9.8%) of the 53 QoL questions answered. For the full 24 months of annotated data, there are 46 users with QoL-relevant posts, with 10.8% (SD 10.1%) of the questionnaire questions answered on average.

[b]Not applicable.

Discussion

The goal of this feasibility study is to investigate whether we can reliably gain QoL information from posts of patients in online communities. To this end, we have introduced a new methodology that examines the content of posts in relation to data from QoL surveys completed by the same cohort of patients whose posts we have access to. This has allowed us to not only assess how frequently users post information that is relevant to QoL, but also measure the degree to which this information corresponds to the answers to the corresponding questions in the questionnaires. This methodology is novel, as it has not previously been applied to analyzing whether information shared by patients online can reliably estimate individual QoL data. We have provided evidence that this methodology is sound, showing that the information can be coded at good levels of agreement and that there is some objective "ground truth" in the information shared by patients online that can be consistently interpreted as providing answers to the survey questions. With regard to RQ1, we can say that patient online forum posts indeed contain QoL-related information. The questions most frequently addressed in those posts (RQ2) are "Did you worry?" "Did you feel tense?" and "Have you had pain?" Moreover, the online posts align well with the actual QoL questionnaire responses (RQ3), achieving an F_1-score of 0.7, with even better results when grouping similar questions (F_1-score =0.8 for fine-grained and 0.9 for coarse-grained grouping).

In particular, Fleiss κ values were nonnegative with "Did you have headaches?" achieving the highest score of 1.0. Only 6 out of 53 questions showed agreement values of 0, with the mean Fleiss κ value being 0.5 (SD 0.28), indicating moderate to solid agreement among the annotators, especially considering the complexity of the task.

We have further quantified the degree to which patients share information that can be mapped to questions from the EORTC QLQ-C30 and QLQ-BR23 questionnaires.

XSL•FO
RenderX

From the total of 2669 annotated posts and comments, 613 (23%) answered at least 1 question from the used EORTC questionnaire. For the last 6 months (since the end of the survey), even 217 out of 580 posts (37.4%) contain QoL-relevant information. As these numbers might be affected by selection bias (indicated by older posts containing less QoL-relevant information), they should be seen more as upper bounds compared to scenarios where the data of an arbitrary patient are investigated.

We have further shown that there is a substantial correlation between the information that participants have provided in their online posts and the survey responses. We have proposed to rely on standard evaluation metrics as used in machine-learning research to estimate the correctness of the information provided by participants in their online posts compared to their answers to corresponding questions in the questionnaires.

The average score for the most recent 6 months of data across all 33 questionnaire questions that had answers in the respective data was an F_1-score of 0.7, indicating that posts and comments containing QoL-relevant information can reliably predict questionnaire answers. Similarly, from the patient level, an average of 63.4% (SD 33.5%) of the estimated answers to the questions is correct. This indicates a high predictive power of forum posts which contain QoL information.

When grouping similar questions together, we even get a mean F_1-score of 0.8 (SD 0.154) for fine-grained grouping and a mean F_1-score of 0.9 (SD 0.01) for coarse-grained grouping when applying the time deviation filtering, excluding posts and comments talking about events and experiences from an unspecified or distant past. Without filtering, we get mean F_1-scores of 0.7 (SD 0.353) without grouping, 0.8 (0.158) with fine-grained grouping, and 0.9 (SD 0.051) with coarse-grained grouping.

The most frequently answered questions (RQ2) include “Did you worry?,” “Did you feel tense?,” “Have you had pain?,” “Were you limited in doing either your work or other daily activities?,” “Were you tired?,” “Have you felt nauseated?,” “Were you worried about your health in the future?,” “Have you lacked appetite?,” and “Did you feel depressed?” These questions are not particularly specific to breast cancer, thus indicating patients typically discuss their QoL online more on a general level or in such a specialized manner that none of the EORTC questions fit well as shown by the high number of “Did you feel ill or unwell?” occurrences.

One inherent problem of the collection and analysis of the questionnaire data is related to missing data, as often patients do not fill out all information. In our case, the rate of completeness for the survey data was 100%, as the completion of all questionnaire items was required. Two questions of the form “If you were/had …” allowed choosing “no answer,” which, however, we do not consider missing data but instead a different way to answer the question.

However, not all questions were answered in posts of all patients. For patients who have shared QoL-relevant information in their posts, only about 10.8% (SD 9.8%) of the questions could be answered by information given in the posts. This means that the available data are typically not sufficient to answer all questions of the EORTC QoL questionnaire, but at least some parts can be reliably extracted for each patient. We also investigated ways to deal with data sparsity by grouping questions and considering longer time periods, which help to get more insights into the QoL without losing too much reliability.

Overall, our results show that users of online communities, such as Inspire, indeed post information about their QoL, providing important information that can be consistently and objectively mapped to the categories of standard questionnaires.

Our results have important implications. First, the results suggest that we could potentially seek answers to questions that are typically not included in standardized QoL questionnaires. Furthermore, there are nuances in the posts of patients that are not directly captured by the questionnaires. On one hand, the topics that patients do or do not bring up in online discussions may indicate which topics are currently the most important for that patient, potentially referring to specific aspects of the relatively broad areas covered by the QoL questionnaires. On the other hand, this can provide insights into areas, which are not covered by the QLQ because they are unique to that patient (eg, due to certain living circumstances). This hints at the potential of our methodology to complement data obtained from standard QoL questionnaires.

Comparison With Prior Work

In recent years, there have been numerous studies investigating whether QoL-related information can be gained from unstructured data sources. However, our work differs from related approaches in substantial ways.

For one, our approach leverages different types of data considered. We considered social media posts from dedicated health care online communities or more precisely the breast cancer forum of Inspire. Other work has focused on clinical reports [30,31] or health records [31,32], which, in spite of also having unstructured elements, considerably differ in terms of content and style from social media data. Among similar approaches considering social media, many approaches have sourced Twitter data [13,15,33-37], in contrast to the specific health care online community data that we used. An exception is the work by Leung et al [38,39] who have used data from cancer support groups. However, their data originate from chats moderated by health care professionals instead of posts from organic, forum-like online communities. Their study had a narrower focus by studying signs of emotional distress in patients participating in the online discussions instead of the broader focus of capturing QoL-related information in our study. An overview of how social media contents can be analyzed for health care is given by Fu et al [40].

Our study has aimed to gain insights into the QoL of individual patients based on their posts in health care communities. In contrast, the goal of many other studies is to discover aggregate trends for a certain geographic segment of the target population [13,15,36]. Other studies are interested in population-wide trends and effects related to how a disease, intervention, or treatment

XSL•FO
RenderX

affects patients in general, instead of estimating values for specific users [9,11,12,37,41-52]. Such population-wide analyses can support the creation of conceptual models of a disease [9,42], whereas other studies have focused on general and individual health [33], recognition of discussions about health services [53], or emotional distress in participants of online chats [38,39].

Some studies have been conducted in relation to existing QoL questionnaires. For example, Tapi Nzali et al [54] have also used the EORTC QLQ-C30 and QLQ-BR23 questionnaires, aiming at identifying general topics that patients diagnosed with breast cancer discuss in relation to EORTC questionnaires. Gries and Fastenau [52] have relied on items in the EORTC QLQ-C30 and QLQ-MY20 questionnaires to investigate concepts of interest, symptoms, and impacts discussed by patients with multiple myeloma on a specific health care social media platform. These studies analyze general trends rather than predicting QoL for individual patients.

Renner et al [55] annotated data from 19 health-related forums using the Short Form Health Survey SF-36 [56] and Euro Quality of Life 5 Dimensions [57], but they did not compare and contrast survey responses with the information in patient posts as we do.

There are few studies that have analyzed the information posted by patients in relation to ground truth QoL data as available in the existing QoL questionnaire data. For example, Zivanovic et al [15] have compared Twitter data originating from the city of Bristol with official QoL data for this city. They analyzed the data on an aggregate level for the whole city rather than for individual patients as we do. Twitter has also been used by Sarma et al [35] who compared information obtained from Tweets with ground truth data of Centers for Disease Control Healthy Days Questionnaire [58]. The questionnaire used is much shorter than the one used in our study, providing a less detailed view on patients' QoL. Cotté et al [16] have compared data from cancer-specific forums with data obtained from the Functional Assessment of Cancer Therapy-General [59] and EORTC QLQ-C30 questionnaires. Their main focus has been on investigating the impact of immune checkpoint inhibitors, but not investigating the QoL impact for individual users.

Although this work focuses on breast cancer, related work covers a wide range of diseases. These diseases include Parkinson disease [9,10], amblyopia [41], presbyopia [42,49], cancer [16,30,48,51], dry eye disease [43], chronic ocular pain [44], Sjögren disease [11], chronic obstructive pulmonary disease [12], systemic lupus erythematosus [45,60], immunoglobulin A nephropathy [46], complement 3 glomerulopathy [47], atopic dermatitis [50,61], obesity [36], depression [62], and (general) mental health [13,14].

In summary, our work advances the field by paving the way for a new option to monitor patients' QoL. As elaborated in the previous section, analyzing forum posts with respect to QoL questions can be used to complement existing instruments for assessing QoL, helping to focus on the most relevant aspects of patients' QoL as well as to discover areas potentially not covered by existing instruments in detail. Additionally, possible ways to automate the process of identifying QoL-relevant information in online posts using, for example, artificial intelligence methods, pose an interesting path of future research.

Limitations

Despite carefully annotating the data and collecting ground truth data through a survey, our work has multiple limitations, which are briefly discussed in this section.

In our study, the investigated population has been limited to those active on the Inspire platform. However, many other online patient communities exist, and both the frequency of QoL-relevant utterances as well as their predictive power might be different.

Similarly, the fact that older posts in our dataset discuss QoL-relevant topics less often indicates that selection bias might be present in our data, as patients currently interested in QoL might be more likely to have participated in our study. Thus, our results have to be considered more like an upper bound to the possible insights about patients' QoL from posts in online forums.

Moreover, we also found signs of recall bias in the data. For example, we found that some patients talked about how much they worried about different topics shortly before participating in the study, but then answered that they did not worry at all. The occurrence of such phenomena has not been systematically investigated in this work and might thus have an impact on the results.

Certain highly intimate topics, such as aspects related to sexuality or body image, were rarely discussed in the forum posts. Given the public nature of the data, which is to be expected, however, it represents a limitation in terms of depth and scope of insights that can be obtained from such a dataset. Compared to one-on-one interviews, forum data may provide a less comprehensive picture of patients' concerns in these areas.

Finally, data sparsity and unequal distribution of posts and comments among forum users are typical problems when considering social media. As illustrated by the long-tail distribution in Figure 2, there are a few users with many posts and comments in our dataset, but the majority of users have much fewer posts available. The degree to which we can obtain QoL information is thus dependent on the posting behavior of a particular user. Statistics and numbers presented in this work thus have to be interpreted as upper bounds for the potential to extract QoL information from a randomly chosen user of the Inspire communities. Similarly, due to the general data sparsity, labels that are scarcely covered by our data sample might be present more prominently for other users, which have not been part of our study, and analogously, labels with many occurrences in our data might be more rare to find for other users.

Conclusions

This study has investigated the feasibility of gaining insights about QoL from posts of patients in online forums. Toward this goal, we have recruited patients diagnosed with breast cancer from Inspire. These patients have filled the EORTC Quality of Life Questionnaire and allowed us to analyze their posts and comments in relation to their answers given in the questionnaire. By this, we have been able to compare the information provided

XSL•FO
RenderX

in their posts with the answers provided in the questionnaires. Our key findings are that between 23% and 37.4% of patients' posts contain information that can be mapped to at least one of the questions of the questionnaire. Furthermore, we could show that the QoL information in posts is reliable, corresponding to a large extent to the answers given in the questionnaire. Our findings thus show that the information shared by patients in online posts can contribute to a better understanding of how the disease affects their QoL.

While the information provided by patients in posts shared in online forums cannot replace the collection of data via questionnaires, it represents a low-cost, low-burden alternative to collect insights about QoL effectively. Most importantly, the information in posts can help us to discover aspects related to disease burden and QoL that are not captured by existing questionnaires. This could even provide guidance on how survey instruments could be extended to cover those aspects that are most burdensome to patients.

Future work should investigate how exactly the information provided by patients online can complement existing QoL assessment methodologies. A further line of research relates to how the information can be extracted automatically, in order to avoid having to scan and read thousands of posts. Given the current state of research on information extraction, this seems to be a promising avenue to investigate. Additionally, first experiments conducted in this direction yielded promising results.

All in all, our work contributes to the foundation for a novel low-burden alternative for monitoring patients' QoL and complementing existing QoL instruments. Moreover, this opens up interesting new avenues of research on how to automate the process including using artificial intelligence methods and thus further lowering the burden for both patients and clinical staff.

Acknowledgments

The authors thank the European Organisation for Research and Treatment of Cancer for giving them the permission to use their questionnaires QLQ-C30 and BR-23 (request IDs 96009 and 102328). They also thank Antonia Frank for her help with annotating the data and developing the annotation guidelines. No generative artificial intelligence tools were used to write this paper.

Funding

This work is partially funded by the Ministry of Culture and Science of the State of North Rhine-Westphalia under grant number NW21-059A (SAIL). The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to data privacy reasons.
