Contents

Reviews

The Impacts of Social Marketing Campaigns on Breast Cancer Awareness and Screening: Scoping Review (e88568)
Sahar Abduljawad. . . . 12

The Longevity of Mobile Apps for Cancer Recovery: Scoping Review (e82448)
Kenneth Färnqvist, Luisa Thiele, Sophie Johnsson, Pernilla Lagergren, Anna Schandl. . . . 33

Empathic AI for Patient-Centered Cancer Care: A Scoping Review of Patient Navigation, Support, and Clinical Practice (e82336)
Brianna White, Gabriela Aitken, Janet Zink, Parnian Kheirkhah Rahimabad, Fekede Kumsa, Soheil Hashtarkhani, Rezaur Rashid, Saba Kheirinejad, Tyra Girdwood, Christopher Brett, Robert Davis, David Schwartz, Arash Shaban-Nejad. . . . 42

The Application of eHealth in Symptom Management of Patients With Breast Cancer During Endocrine Therapy: Scoping Literature Review (e92030)
Chengjia Gu, Lili Shen, Shiyu Zhang, Nan Zhang. . . . 56

Multiturn Large Language Model–Based Conversational Agents for Patients With Cancer and Caregivers: Scoping Review (e96241)
Yeongrok Jeong, Hyejeon Cha, Eunyoung Suh. . . . 69

Interventions to Reduce Fear of Cancer Recurrence Among People With Cancer: Scoping Review (e81579)
Niu Li, Cynthia Wensley, Lisa Reynolds, Wal Baraza, Tatiana Leyton, Andrew Jull. . . . 84

Advanced Clinical-Based Technologies for Monitoring Physical Function in Breast Cancer Survivors: Scoping Review (e77894)
Mahtab Azhdar, Adalberto Loyola-Sanchez, Amber Wardrop, Martin Ferguson-Pell. . . . 114

Measurements and Digital Technology Solutions to Monitor Physical Activity in Patients With Pediatric Cancer: Scoping Review (e73889)
Greta Jermolenko, Guna Semjonova, Aija Klavina, Evita Dubinina, Keita Augstkalne, Klavs Balamovskis-Kalnins, Alina Cesuna, Emil Syundyukov, Dace Bertule, Madara Blumberga, Ilze Kundzina. . . . 129

AI-Enhanced Predictive Analytics to Optimize Tele-Oncology Implementation in Rural Settings: Scoping Review (e78005)
Laiba Husain, Megan Mullins, Bella Etingen, Raaed Zafar, Mediha Siddiqui, George Jackson. . . . 171

XSL•FO
RenderX

Digital Health Interventions and Psychosocial Outcomes in Women With Breast Cancer: Systematic Review (e96858)
Rocío Zúñiga-Tapia, Mercè Boixadós, Eulàlia Hernández Encuentra. . . . 202

Use of AI to Predict and Support Medication Adherence in Patients With Breast Cancer: Systematic Review (e80128)
Massimo Pezzolato, Viktorya Voskanyan, Ilaria Cutica, Chiara Marzorati, Gabriella Pravettoni. . . . 222

Viewpoints

Internet of Things–Enhanced Mathematical Oncology: Conceptual Framework for Adaptive Cancer Care Modeling (e73997)
Adeniyi Onasanya, Ramona Kyabaggu, Daryl Hepting. . . . 149

AI Agents for Multimodal Oncology Diagnosis: Toward Transparent and Traceable Clinical Decision Support (e103545)
Liuyang Yang, Liyu Shan, Xiangmei Yao, Renbin Zhao, Zengzheng Li, Shuai Feng, Yajie Wang. . . . 161

Practical Recommendations for Implementing Remote Patient Monitoring for Patients Receiving Bispecific Antibodies for Multiple Myeloma (e95949)
Cindy Varga, Eric Schaefer. . . . 1695

Original Papers

Perspectives of Adolescents and Young Adults, Caregivers, and Health Care Providers on Regional Cancer Care: Qualitative Study (e85096)
Joanne Tay, Mohammad Jarrar, Telford Yeung, Jessica Kichler. . . . 188

Improving Long-Term Adherence to Endocrine Therapy Among Breast Cancer Survivors: Development of a Multiscale Modeling and Intervention System (e68255)
Manuel Gonzales IV, Cristian Garcia-Alcaraz, Navreet Kaur, Anna Baglione, Sarah Livermon, Laura Barnes, Kristen Wells. . . . 243

Feasibility and Implementation of an eHealth Dashboard for the Remote Monitoring of Dutch Patients With Chronic Myeloid Leukemia: Multimethods Approach (e76096)
Lynn Verweij, Julie Swillens, Sanne Metsemakers, Yolba Smit, Esri Wener, Geneviève Ector, Rosella Hermens, Nicole Blijlevens. . . . 262

Cultural Adaptation of a Web-Based Ostomy Care Intervention for Hispanic Patients With Cancer and Caregivers: Mixed Methods Study (e70354)
Xiaomeng Wang, Lixin Song, Amy Vondenberger, Fei Yu, Jia Liu, Roxana Delgado, Robert Svatek, Natalia Rodriguez, Lurheinna Rivera, Mark Bonnen. . . . 280

New Technologies and Digital Health Tools in Patients With Solid Tumors and Hematological Malignancies: Cross-Sectional Multicenter Survey Study (e58823)
Alberto Lopez-Garcia, Carola Diaz-Aizpun, Beatriz Gallego-Diaz, Carolina Miranda-Castillo, Maria Yuste-Platero, Pilar Beltran-Alvarez, Cristina Carames-Sanchez, Jesus Garcia-Foncillas, Pilar Llamas-Sillero, Marta del Olmo-Rodriguez, Jorge Short-Apellaniz, Bernadette Pfang, Javier Arcos-Campillo, Raul Cordoba. . . . 298

Evaluation of GPT-5 for Esophageal Cancer Staging Using Fluorodeoxyglucose Positron Emission Tomography Maximum-Intensity Projection Images: Comparative Pilot Study (e86630)
Hiroki Maruyama, Yoshitaka Toyama, Yuya Araki, Kentaro Takanami, Masato Ito, Yumi Nakajima, Kei Takase, Takashi Kamei. . . . 307

Revealing the Physician's Task Conceptualization in Melanoma Treatment: Qualitative User Experience Study (e79294)
Eva Hartmann, Alisa Küper, Jessica Swoboda, Catharina Beckmann, Georg Lodde, Elisabeth Livingstone, Dirk Schadendorf, Sabine Sachweh. 3 2 4

Implementing UK Oncology Nursing Society–Informed Digital Symptom Triage With Episode-Based Review in Routine NHS Acute Oncology: Service Evaluation (e92586)
Mohamed Mohamed Azhar, Rishabh Ray, Sagar Sharma, Hiten Chauhan, Margaret Robinson, Yetunde Owoseni, Anupama Vijay, Sadaqat Hussain. . . . 339

Cost-Effectiveness of AI-Powered Decentralized Production for Advanced Therapies in the Hospital–Generated Chimeric Antigen Receptor T-Cell Therapy for Multiple Myeloma From a German Hospital Perspective: Early Health Technology Assessment Study (e92253)
Iris Boot, Anna Weltin, Ysanne de Graaf, Hubertus Vrijhoef. . . . 352

Detection of Cervical Nodal Metastasis in Oral Squamous Cell Carcinoma Using Elastic Scattering Spectroscopy: Ex Vivo Diagnostic Modeling Study (e103960)
Waseem Jerjes, Zaid Hamdoon, Dara Rashed, Colin Hopper. . . . 365

Exploring the Readiness for Digital Health Literacy Transformation and Intervention Preferences From the Perspectives of Patients With Cancer, Caregivers, and Health Care Professionals: Qualitative Interview Study (e77738)
Hind Mohamed, Turki Alanzi, Jon Salsberg, Mudathir Mohamed, Dervla Kelly. . . . 390

Real-World Evidence of Treatment Outcomes in Small Cell Lung Cancer: A Bayesian Mixed Effects and Competitive Risk Approach (e84042)
Luca Marzano, Asaf Dan, Adam Darwich, Luigi De Petris, Salomon Tendler, Rolf Lewensohn, Jayanth Raghothama, Sebastiaan Meijer. . . . 406

Piloting a Clinical Decision Support System for Unintended Weight Loss in Primary Care: Mixed Methods Study on Early Cancer Detection (e90885)
Javiera Martinez-Gutierrez, Sophie Chima, Barbara Hunter, Alex Lee, Lucas De Mendonca, Deborah Daly, George Fishman, Fong Lim, Benny Wang, Craig Nelson, Brian Nicholson, Jo-Anne Manski-Nankervis, Jon Emery. . . . 426

Explainable Machine Learning–Based Prediction of Progression-Free Survival in Prostate Cancer: Retrospective Cohort Study (e91510)
Hein Tun, Lin Naing, Owais Malik, Muhammad Abdullah, Thu Ta, Hanif Rahman. . . . 444

Scan, Screen, Support—A Digital Pathway for Assessing Supportive Care Needs in Oncology: Implementation Study (e82392)
Theres Fey, Nicole Thurner, Ulrike Haidn, Friederike Mumm, Birgit Haberland, Rachel Wuerstlein, Sebastian Theurich, Georg Wolfrum, Marie-Louise Troidl, Susan Müller, Claudia Bausewein, Timo Schinköthe, Volker Heinemann, Nicole Erickson. . . . 457

Patient Perspectives on AI-Powered Medical Robots in Breast and Prostate Cancer Care: Qualitative Study (e69710)
Mahiya Habib, Janet Ellis, Aaron Palachi, Melissa Korman, Tatjana Kay, Karen Barlow, Jordana DeSouza, Rosanna Macri, Abdullah Alabousi, Mehran Anvari. . . . 474

Monitoring Steps and Heart Rate Using a Withings Smartwatch in Children and Adolescents With Cancer: Validation Study (e77766)
Emma den Hartog, Marta Fiocco, Patrick van der Torre, Wim Tissing, Emma Verwaaijen. . . . 489

Online Intervention on Lung Cancer Screening Among High-Risk Individuals: Pilot Intervention Study (e89823)
Fang Lei, Feifei Huang, Yufang Guo, Sun Kim, Yang Liu. . . . 503

Large Language Models for Breast and Cervical Cancers Communication: Mixed Methods Evaluation Study Assessing Linguistic Quality, Safety, and Accessibility (e82971)
Agnik Saha, Victoria Churchill, Anny Rodriguez, Ugur Kursuncu, Muhammed Idris. . . . 516

Generative AI Chatbots as Digital Adjuncts for Sexual Health Information After Prostate Cancer in Men Who Have Sex With Men: Auto-Netnographic Study (e81745)
Mats Christiansen, Henrik Eriksson, Lisbeth Fagerström. . . . 532

Patients' Attitudes and Beliefs Toward Artificial Intelligence Use in Cancer Care: Cross-Sectional Survey Study (e81346)
Marco Santos Teles, Karolina Bryl, Susan Chimonas, Atif Khan, Andrew Epstein, Bobby Daly, Han Xiao, Jun Mao. . . . 541

Leveraging Innovative Electronic Health Record Data to Characterize Social Determinants of Health Among Survivors of Cancer in Persistent Poverty Areas: Cross-Sectional Study (e81054)
Shiori Tanaka, Laura Rogers, Lisa Zubkoff, Lori Bateman, Wendy Demark-Wahnefried, Gabrielle Rocque, Sejong Bae, Maria Pisu, James Booth, Carrie Howell. . . . 548

Digital and Paper-Based Hospital Workflows and 60-Day Mortality in Acute Leukemia: Retrospective Natural Experiment (e71306)
Christian Ramos Peñafiel, Álvaro Cabrera García, Carolina Balderas Delgado, Rocío Luna Tentle, Andrea Milán Salvatierra, Nora Godínez Cubillo, Gustavo Acosta Altamirano, Rosa Sánchez Conejo, Adán Gallardo Rodríguez. . . . 566

Assessing the Accuracy, Completeness, and Reference Quality of GPT-4 and Google for Gynecologic Cancer Information: Comparative Quantitative Study (e76471)
Alexandra Smick, Martins Ayoola, Rajeshree Rajpara, Isabel Lazo, Dana Chase. . . . 580

Experiences of Informal Caregivers Facing Cancer While Caring for Someone With Dementia: Qualitative Interview Study (e93688)
Elizabeth Travis, Mollie Price, Millie Slessor, Jacqueline Crewe, Laura Ashley. . . . 590

Identification of Early Signs of Mental Health Disorders in Older Survivors of Cancer Using Patient-Generated Health Data: Observational Study (e75050)
Georgios Petridis, Antonios Billis, Georgios Meditskos, Athina Tsanousa, Paraskevas Lagakis, Juan Naranjo, José Zenóglio de Oliveira, Vania Tavares, Panagiotis Bamidis. . . . 602

Fear of Cancer Recurrence Before Treatment in Patients Newly Diagnosed With Breast Cancer: Cross-Sectional Study (e89346)
Yun Ding, Huiting Zhang, Qiaoling Zhong, Lijuan Zhang, Huiying Qin. . . . 618

Pathways and Roadblocks in Navigating Online Cancer Communities: Qualitative Study Among Young Adult Cancer Survivors (e79893)
Qi Chen, Erin Donovan, Leyi Zhou, Lailea Noel, Barbara Jones. . . . 630

Benefits and Challenges of a Digital Exercise and Mind-Body Program During Active Cancer Treatment: Qualitative Study of Patients' Perceptions (e80075)
Karolina Bryl, Sierra Silverwood, Krupali Desai, Kelsey Schobert, Xiaotong Li, Susan Chimonas, Jun Mao, Erin Gillespie. . . . 645

Surrogate Decision-Making by Family Caregivers for Hyperthermic Intraperitoneal Chemotherapy in Gastric Cancer: Qualitative Study in a High-Volume Chinese Center (e80471)
Zheng-Ke-Ke Tan, Dan-Ni Li, Kui Jia, Wen-Zhen Tang, Xin Chen, Li Yang. . . . 660

Cancer Information Burden Among US Cancer Survivors Using Health Information National Trends Survey 2022 and 2024: Cross-Sectional Study (e101310)
Jingjing Gao, Sharon Munroe, Yue Zhang, Jason Windett. . . . 674

Predictors of Telehealth Use Among Cancer Survivors: Retrospective Study (e87403)
Jasskiran Kaur, Jeffrey Zhong, Carley Mitchell, Annie Zhang, Qian Wang, Melinda Hsu. 690

Cardiovascular Symptom Tracking Among Patients With Cancer in Cardio-Oncology Care: Qualitative Study Using the Capability, Opportunity, Motivation–Behavior (COM-B) Framework (e100279)
Roberto Benzo, Macy Tetrick, Rujul Singh, Sara St George, Vanina Pavia Aubry, Peter Washington, Anvitha Gogineni, Sanam Ghazi, Olivia Preston, Daniel Addison. 702

Factors Associated With the Use of the Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology (LETSGO) mHealth App in Routine Follow-Up After Gynecologic Cancer Treatment: Observational Study (e89918)
Zaklina Tarabar, Elin Børøsund, Sindre H Fosstveit, Sveinung Berntsen, Milada Hagen, Ingvild Vistad. 719

Assessment of Physical Activity Engagement and Promotion Among Cancer Survivors in Cardio-Oncology Care: Qualitative Study (e104332)
Macy Tetrick, Daniel Addison, Rujul Singh, Sara St. George, Vanina Pavia, Anvitha Gogineni, Peter Washington, Sanam Ghazi, Olivia Preston, James Fisher, Roberto Benzo. 734

Quality, Empathy, and Readability of AI Chatbot Responses to the Survivorship Needs of Adolescents and Young Adults With Melanoma: Evaluation Study (e84234)
Jordan Jafarnia, Priscilla Haff, Reece Moore, Alyssa Osheim, Katherine Riley, Sabrina Zheng, Michael Roth, Madeleine Salge, Kelly Nelson.
7 5 1

Stakeholder Perspectives on Cancer Survivors' Return to Work and Well-Being: Qualitative Interview Study (e89954)
Sara Fällman, Katarina Wijk, Anna Efverman, Linda Eklund, Per Fessé, Sven Trygged, Maria Fjell. 765

Correlates of Fitness Tracker Ownership and Use in Cancer Survivors: Cross-Sectional Survey (e92876)
Roberto Benzo, James Fisher, Macy Tetrick, Rujul Singh, Alex Osei, Jessica Krok-Schoen, Brett Nickerson, Electra Paskett, Ali Kargarandehkordi, Sachin Kumar, Sara St George, Michael Rayo, Frank Penedo, Peter Washington. 781

Symptom Management Following Radioactive Iodine Treatment in Adults With Thyroid Cancer: Usability Evaluation and Proof-of-Concept Study (e84151)
Alaina Carr, Angela Jenkins, Valeria Gómez, Janine Lorenzo, Ryan Moclair, James Pocchia, Devansh Gandhi, Kristen Miller, Kristi Graves, Jacqueline Jonklaas. 799

Clinical Feasibility of Six Inflammatory Markers for Predicting the Mortality of Patients With Cancer: Longitudinal Study (e99410)
Kangwei Wang, Ce Shi, Dingchao Xia, Ya Lin. 813

Immunotherapy Safety in Thymic Epithelial Tumors: Disproportionality Analysis of the Food and Drug Administration Adverse Event Reporting System (e76908)
Ruilian Chen, Hanrui Chen, Lingling Sun, Yang Cao, Lizhu Lin. 828

Identifying Hemophagocytic Lymphohistiocytosis and Describing Outcomes Using Computable Phenotypes: Retrospective Cohort Study (e87347)
Suheyla Ocak, Martin Yi, Agata Wolochacz, Ida Mehrdadi, Ahmed Naqvi, Sumit Gupta, Lillian Sung, Adam Yan. 843

Predicting Overall Survival in Patients With Multiple Primary Lung Cancer: Nomogram Development and Validation Study (e87275)
Wenzhi Luo, Kengliang Rao, Hongjia Chen, Cailian Hu, Shengming Liu, Jing Wang, Dongdong Zhang, Li Chen. 854

Using Latent Dirichlet Allocation Topic Modeling to Uncover Latent Research Topics and Trends in Renal Cell Carcinoma: Bibliometric Review (e78797)
Javier De La Hoz-M, Karime Montes-Escobar, Carlos Salas-Macias, Martha Fors, Santiago Ballaz. 869

Abstract

Background: Promotional activities, such as social marketing approaches, are important for raising cancer awareness and increasing breast cancer screening participation. Such interventions are designed to facilitate change and maintain positive health behaviors at both the community and society level. With the growing use of these promotional activities in public health, it is pertinent to map available studies to inform future evaluations and the development of effective interventions.

Objective: This study aimed to review existing studies on how social marketing interventions have been used to promote breast cancer screening and early diagnosis. The specific objectives were to assess the characteristics of social marketing interventions aimed at promoting breast cancer screening, identify the methodological approaches used in evaluating the interventions, identify the outcomes used to measure the impact of social marketing interventions for breast cancer screening, and assess the impacts of social marketing interventions when promoting breast cancer screening.

Methods: A comprehensive literature search was performed in 6 electronic databases to identify qualitative and quantitative evaluations of social marketing interventions targeting breast cancer screening and early diagnosis. Titles and abstracts were reviewed independently by two reviewers, followed by data extraction and verification. The methodological quality was evaluated using the Cochrane Handbook for Systematic Reviews of Interventions. Outcomes were categorized using an adapted version of key performance indicators and metrics related to social media use in health promotion.

Results: Overall, 15 research articles were eligible and analyzed. The 4 types of social marketing interventions identified were health professional and educational strategies, social media or mass media campaigns, community outreach campaigns, and video-based marketing. The predominant intervention source was public health government bodies, followed by regional health services, cancer charities, and educational institutions. Most interventions were designed to influence breast cancer screening behaviors by raising awareness through advertisements, educational interventions, and fundraising activities. Most interventions reached a large audience (>500 people), but participants had mixed awareness and perceptions toward social marketing strategies, and the outcomes were shaped by demographic factors such as cultural backgrounds, age, education, marital status, and occupation. Knowledge gaps, cost concerns, and the lack of physician recommendations also constituted key barriers to screening uptake. Behavior change outcomes were sparingly assessed in most interventions, thereby contributing to limited understanding of mechanisms affecting screening uptake.

Conclusions: Available evidence suggests that social marketing interventions may enhance breast cancer screening and early diagnosis. However, robust evaluations of these interventions and assessment of behavior change outcomes could be performed in future research by using well-established evaluation frameworks and reporting guidelines. Developers and funders of these campaigns should also consider using an evaluation plan before conducting the actual campaign.

KEYWORDS

social marketing; social media; breast cancer; awareness; diagnosis; screening

Introduction

Social marketing campaigns (SMCs) are widely accepted approaches and tools for enhancing public awareness of diseases and altering health behaviors [1]. SMCs entail applying marketing principles to facilitate actions in the pursuit of efficient, effective, fair and sustained social transformation, both individually and collectively [1,2]. According to Thompson and Heinberg [3], social marketing applies marketing strategies to develop interventions that enhance individual and societal well-being.

XSL•FO
RenderX

Despite the similarity to conventional commercial marketing in terms of strategic approach and goal [4], SMCs emphasize voluntary behavioral change and broader benefits directed toward the community and society [1,5]. By shifting from simply providing information, SMCs assist66 with designing a comprehensive, target-centric experience that makes health behaviors highly desirable and easily adopted [1]. Although the product of commercial marketing is specific, social marketing products or services are mostly invisible and conceptual.

Social and health interventions can be enabled by using advertising techniques that promote related commercial products [1]. Typical examples of social marketing include disaster relief and recovery [6], organ donation [7], campaigns promoting recycling [8], and health promotion programs delivered via social media platforms . Social media has become extremely popular, estimated to be used by more than one-half of the global population [[9]. Hence, apart from being widely used for public engagement, it has increasingly extended into social marketing strategies for driving public health interventions [10]. Such integrations can shape behavior by targeting emotional and cognitive responses, triggering discussions, and altering social norms. In addition, the combination of social marketing and social media approaches allows rapid dissemination of health information, at a low cost, to a large audience of people across wide geographical locations [11].

In this article, the term “intervention” refers to a spectrum of activities ranging from national awareness-raising public health campaigns to targeted activities that use social marketing approaches to deliver information to specific audiences, specifically to enhance breast cancer screening decisions and uptake. The effectiveness of these social marketing strategies may differ depending on the approach used, whether official, emotive, or persuasive. The source of the message is pivotal in its persuasiveness, as sources that hold higher status and are familiar to the recipient are more likely to be recalled and internalized [12].

Accumulated evidence suggests that raising awareness and promoting the prevention of cancers has several challenges. The barriers to cancer screening uptake among susceptible individuals can be resolved via interventions that educate people about the benefits of early detection and screening [5,10]. Promotional activities, such as social marketing approaches, are critical for raising cancer awareness and likely to increase screening participation among high-risk persons, thereby reducing related morbidity and mortality rates [10]. The goal of promotional activities is to facilitate change and maintain positive health behaviors at the community and society levels.

In terms of breast cancer, the level and impact of social marketing strategies on screening decisions and uptake are underreported despite the extensive barriers to screening and adherence in vulnerable populations [13,14]. Nevertheless, empirical studies have demonstrated the effects of awareness programs on health behaviors for other diseases and disorders. Examples include the strong empirical evidence on the reduction of smoking prevalence and promotion of smoking cessation following mass media campaigns [15]. It is estimated that public health campaigns designed to address coronary heart disease have led to a 30% reduction in cholesterol in the past 3 decades [16].

Given these social marketing effects, the potential benefits of awareness raising and promotional activities on breast cancer screening should not be underestimated, thus warranting further investigation. Many scholars have attempted to explore the effectiveness of promotional campaigns in raising awareness and motivating screening for breast cancer and other cancers [17,18]. The outcomes from these studies have varied. The perceived credibility of breast cancer information is shaped by factors such as education, socioeconomic status, age, health attitudes, health status, and cultural background [19,20].

Moreover, despite the increasing advocacy for promotional campaigns, there is little evidence to support their efficacy in improving breast cancer screening and early diagnosis. Review publications describing the various approaches in which social marketing strategies are used to promote breast cancer screening and how such interventions might foster behavior change are lacking. Previous scoping and systematic reviews looking at a range of interventions for breast cancer screening focused on social media-based and mobile health (mHealth) technology [5]. However, the use of social marketing interventions for public health is rapidly evolving, reflecting the need for a broader mapping of available studies to inform future evaluations and the development of effective interventions.

This study aimed to review existing studies on how social marketing interventions have been used to promote breast cancer screening and early diagnosis. The specific objectives were to assess (1) the characteristics of social marketing interventions aimed at promoting breast cancer screening, including methodological approaches and outcomes measures, and (2) the impacts of social marketing interventions on promoting breast cancer screening. By emphasizing nonclinical initiatives, this study reviewed SMCs with the potential to be implemented at the community level to promote breast cancer screening and preventive behaviors.

Methods

Study Design

This scoping review was conducted in accordance with PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [21] and guided by the scoping review framework by Arksey and O’Malley [22]. The review focused on the use of social marketing interventions for promoting breast cancer screening and positive behavioral changes in vulnerable populations. The review was designed to address the following research questions: (1) What are the characteristics of social marketing interventions that aim to promote cancer screening? (2) What methodological approaches have been used to evaluate the interventions? (3) What are the outcomes used to measure the impact of interventions? and (4) What are the impacts of social marketing interventions in promoting breast cancer screening?

Search Strategy and Search Terms

A comprehensive literature search was conducted in 6 electronic databases: Web of Science, PubMed, EBSCOhost (via

XSL•FO
RenderX

CINAHL), MEDLINE, PsycINFO, and Scopus. The search included studies using quantitative, qualitative, and mixed methods designs to ensure a broad retrieval of relevant literature. To focus on recent advancements and growing research on social marketing strategies for breast cancer screening uptake and preventive behaviors, the search was limited to articles published between 2010 and 2025.

The literature search was performed from August 2025 to October 2025. In addition to the database search, snowballing techniques were applied, including backward reference checking (screening reference lists of selected articles) and forward reference searching using the "cited by" function in Google Scholar. These manual searches were performed to retrieve possible articles that might be missed from the electronic databases. Aligning with the research objectives, the following 6 key search components were identified: (1) breast cancer; (2) screening or testing; (3) SMC, promotional activities, or advertisement; (4) social media, mass media, or mass communication; (5) intention to screen or test; and (6) behavior change or preventive behavior.

Alternative keywords were used for each component and combined using the Boolean operators "OR" within categories and "AND" between categories. Boolean operators were not applied in Google Scholar. Additionally, a truncation symbol (*) was used where applicable to capture word variations, as detailed in Tables 1 and 2.

Table . Search strategy for the literature review in the following databases: Web of Science, PubMed, EBSCOhost (CINAHL Complete), Scopus, MEDLINE, and PsycINFO.

Main keywords	Search strings
Breast cancer	"Breast cancer" OR "Breast cancer patients" OR "Women with Breast Cancer"
Screening, testing	"Breast cancer screening" OR "Breast cancer testing" OR "Screening" OR "Testing
Social marketing campaign, promotional activities, advertisement	"Social marketing" OR "Campaign" OR "Promotion" OR "Advert"
Social media, mass media, mass communication	"Social media" OR "Mass media" OR "Mass communication" OR "Communication"
Intention to screen, test	"Intention to screen" OR "Intention to test"
Behavior change, preventive behavior	"Behavior change" OR "Preventive behavior"

Study Selection and Screening

The study included patients with breast cancer and those at risk who had participated in interventions involving any type of social marketing strategy, such as health promotion activities and community awareness programs. Titles, abstracts, and full-text articles were screened using PDF content to ensure alignment with the study objectives. Selected articles were subsequently stored in a Zotero database for reference management.

Eligibility Criteria

Articles were included if they met the specific criteria outlined in Table 3, which included the language and publication period, study design, intervention and outcomes, and target population. Meanwhile, studies not fulfilling the criteria listed in Table 3, not published in English, not focusing on breast cancer patients, or not involving cancer survivors or health professionals were excluded. Review articles, online materials, conference proceedings, nonoriginal articles, and articles that evaluated static internet pages, such as blog posts, were also excluded.

Table . Criteria and description considered for eligible studies.

Criterion	Description
Language and publication period	Original research articles or short communications written in English, published between 2011 and 2024
Study design	Interventional studies, including quantitative, qualitative, and mixed methods
Intervention and outcomes	Studies had to examine social marketing interventions/campaigns/programs and address at least one of the following outcomes: breast cancer screening, early diagnosis, preventive practices, or help-seeking for potential breast cancer symptoms.
Target population	Studies had to focus on women with breast cancer or high-risk populations.

Screening Process and Data Extraction

Title and abstract screening were conducted by 2 researchers, followed by full-text assessment for eligibility. Disagreements were resolved through consensus, with a third reviewer serving as a mediator. An interrater reliability analysis was performed for title and abstract screening, and an acceptable level of agreement was achieved (Cohen α=0.72). Data extraction was

XSL•FO
RenderX

conducted independently by 2 research assistants to ensure accuracy and consistency. The lead researcher predefined the key data points to be recorded. A structured data extraction form was used, capturing the following details: authors' names, research objectives, study location and design, population of interest, interventions applied, and main findings. Any discrepancies during data extraction were resolved using the same consensus approach described in the screening process, with a third reviewer providing mediation when necessary.

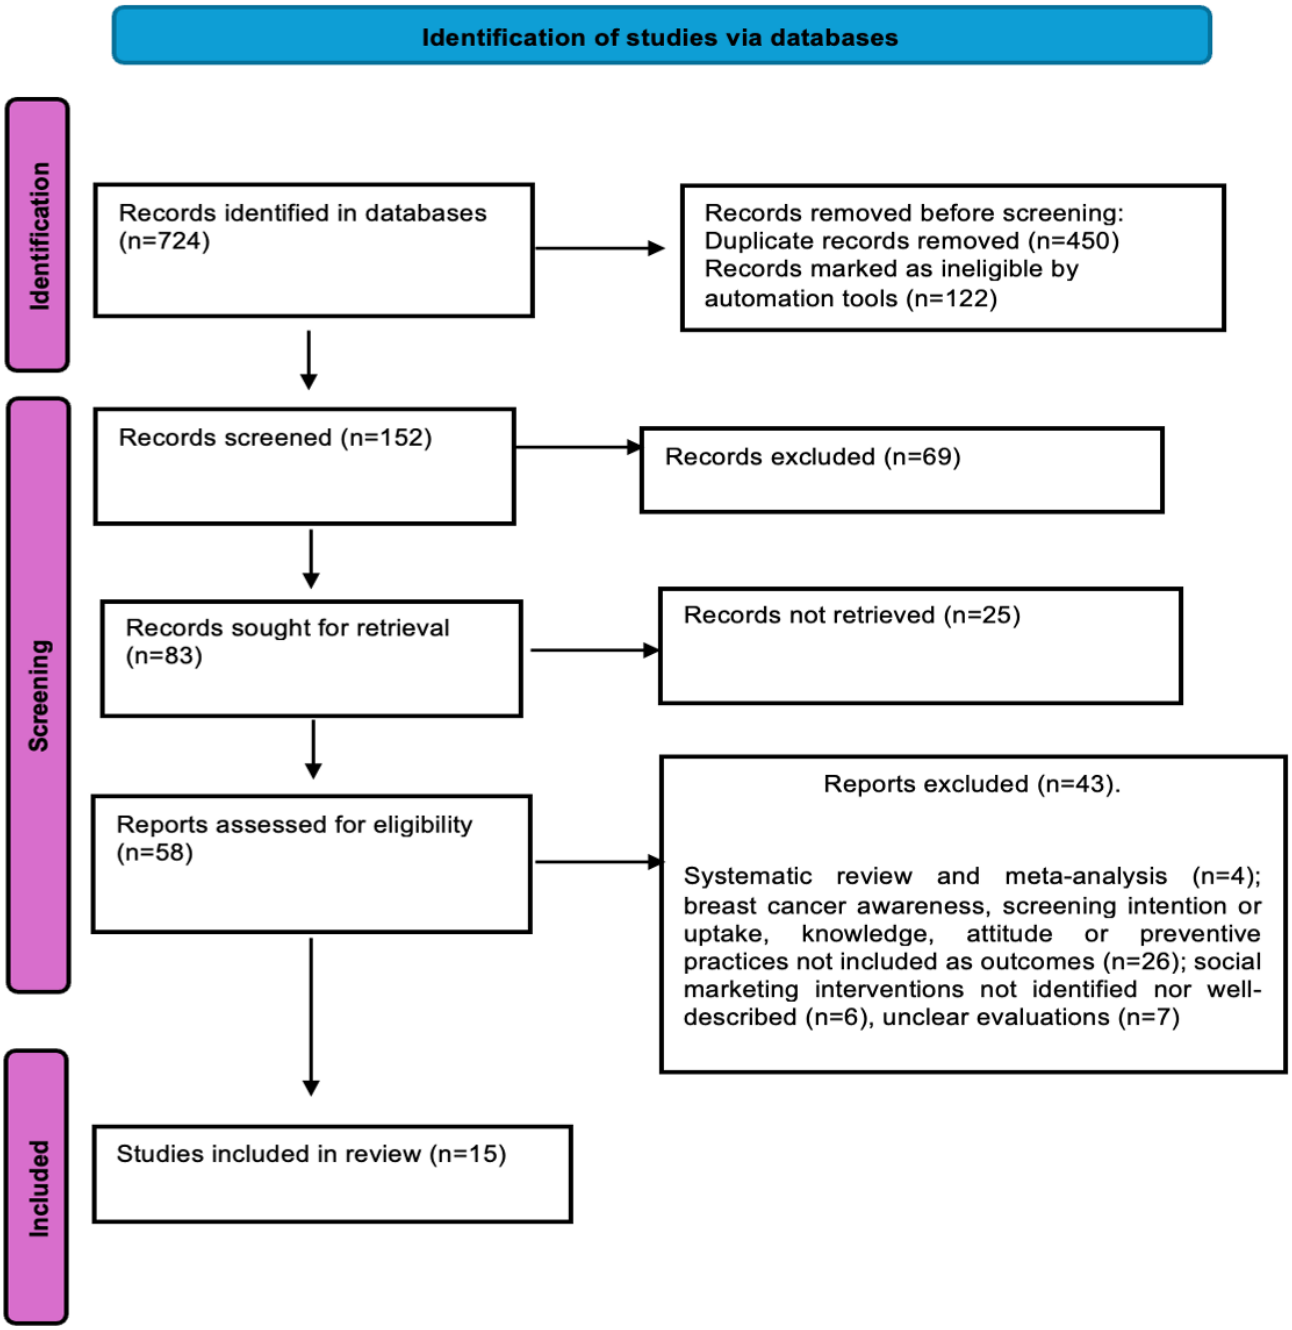
Assessment of Risk of Bias

Although quality appraisal is not always required in scoping reviews due to the diversity of study designs [23], this review used a risk of bias assessment given its specific focus on social marketing strategies or programs for women with breast cancer and high-risk groups. The methodological quality of each study was evaluated using the Cochrane Handbook for Systematic Reviews of Interventions [24]. The assessment considered 5 key domains: sequence generation, allocation concealment, adjustment for confounders, blinding, completeness of data, and selective reporting.

Data Synthesis

The extracted data and outcomes from the reviewed studies are shown in Table 3. We categorized the outcomes using an adapted version of key performance indicators and metrics related to social media use in health promotion [25]. The main aspects include insights, exposure and reach, and various levels of engagement. Information on the design, theoretical foundation, and delivery methods of interventions was also extracted from the reviewed studies. Furthermore, information regarding the potential mechanisms by which social marketing interventions shape behavior change was gathered by using the behavior change technique (BCT) taxonomy described by Michie et al [26].

The extracted data were analyzed using a narrative approach and thematic analysis, as recommended for scoping reviews. An inductive approach was used to identify and synthesize key themes based on the main findings from each study. The data synthesis process involved familiarization and coding, performed independently by 2 research assistants. The next step entailed developing the themes, whereby systematic coding was used to generate overarching themes. The last stage was validation and consensus, in which all the themes were reviewed by the authors to ensure consistency with the extracted data. Discrepancies were also resolved through discussion. All data management and analysis procedures were conducted using Excel (Microsoft Corp).



Results

Search Results

The literature search retrieved 724 articles from 6 databases. More than one-half (572/724, 79%) of the results were removed before screening, as 450 were identified as duplicates and 122 records were marked as ineligible. Upon title and abstract screening, 69 records were excluded. In the final stage, 15 of the 58 articles were eligible and included in the qualitative and thematic analysis. The reasons for excluding 43 full-text articles are outlined in Figure 1.

XSL•FO
RenderX

Figure 1. Flowchart of the scoping review literature search and screening process.

Studies and Participants' Characteristics

Table 4 outlines the characteristics of the reviewed studies. All the articles were original studies published in peer-reviewed journals. Most of the studies were conducted in the United Kingdom (n=4), and 1 each was conducted in Greece, Malaysia, Romania, Saudi Arabia, the United Arab Emirates, India, the United States, Israel, Turkey, China, and South Korea. In terms of study design, 4 studies were either single or multicenter randomized controlled trials (RCTs), 4 were quasi-experimental designs, 4 comprised a combination of cross-sectional surveys and pre- and posttest designs, 2 were case studies, and 1 article involved content analysis and in-depth interviews.

Table . Characteristics and main findings from the 15 studies on social marketing campaigns.

Search number	Reference	Objective	Study design, sample population	Sample population	Mode of delivery	Specific instruments and interventions	Main findings
1	[18]	To examine the effects of a TV-led breast cancer mass media campaign on the awareness of breast cancer–related factors and intention to engage in preventive behaviors	3 campaigns performed over 2 weeks: precampaign, followed immediately by campaign wave 1 and campaign wave 2 in the northeast of England	572 in the precampaign; 576 in wave 1; 552 in wave 2	Cancer charity	TV advertisements showing the connection between breast cancer and alcohol consumption, with a voiceover communicating the various types of cancer caused by alcohol; target online audience also reached via advertisements shown on promoted posts on Facebook	Awareness of breast cancer and readiness to engage in preventive behaviors increased significantly postcampaign (45% increment) compared with the precampaign level, especially after wave 2. Awareness of alcohol as a cancer risk factor and support for related policies increased significantly between surveys.
2	[27]	Effects of an early presentation (PEP[a]) intervention on breast cancer knowledge, skills, and motivation for early presentation into care among older women	Randomized controlled trial	867 women 67 - 70 years old attending a breast cancer screening program	Regional health services	PEP intervention using a 10-minute interaction with a radiographer	At 2-year follow-up, the intervention increased the proportion of participants who were aware of breast cancer and ready to perform early screening compared with those in usual care (21% versus 6%; OR[b] 8.1, 95% CI 2.7% - 25.0%)
3	[28]	Phase 2 assessment of the impact of a brief health professional–delivered intervention on breast cancer awareness and prevention intention among older women	Multicenter clinical trial; mammographers trained to deliver a brief health intervention for older women (n=495) in 4 screening centers, with 1 used as a control (no intervention); breast cancer awareness and prevention intention assessed at baseline and 1 month postintervention	875 older women (no intervention)	Regional health services	The intervention was based on the English National Health Service Breast Screening Program, designed to equip women to present early with breast symptoms, as a critical aspect of the concluding invited mammogram at an estimated age of 70 years.	A total of 27 mammographers were trained. Overall, breast cancer awareness increased 7-fold at 1 month in older women exposed to the intervention relative to a 2-fold increase in the control group (OR 15.2, 95% CI 10.0 to 23.2).

XSL•FO
RenderX

Search number	Reference	Objective	Study design, sample population	Sample population	Mode of delivery	Specific instruments and interventions	Main findings
4	[29]	To identify the breast cancer screening advertisements preferred by women at risk of breast cancer	A hybrid study design, comprising content analysis and repertory grid interviews; first approach: identified pertinent messages mostly promoted in breast cancer screening advertisements; interview aimed to elucidate women's perceptions regarding the messages; 13 different breast cancer screening advertisements presented to assess level of authoritativeness, credibility, emotional appeal, and persuasiveness; conducted in Greece	32 women	Charity body, celebrities	13 breast cancer screening advertisements	Some women found some of the breast cancer screening promotional messages, including award-winning advertisements, offensive and failed to connect with the visual design of these adverts. Respondents were more motivated to perform screening when exposed to positive advertisements, capturing reliable data on breast cancer data and endorsements from celebrities who genuinely support the cause.

RenderX

Search number	Reference	Objective	Study design, sample population	Sample population	Mode of delivery	Specific instruments and interventions	Main findings
7	[14]	To assess the efficacy of an institutional breast cancer health campaign on the knowledge, attitudes, and practices of female employees	Cross-sectional descriptive study. in Saudi Arabia	290 female workers from various university departments	University	A group-based breast cancer awareness campaign, supported with posters, brochures, lectures and advertisements, followed by an online self-administered questionnaire	Knowledge and positive attitudes toward breast cancer increased significantly postintervention; participants who had previously attended any prior breast cancer health campaign scored higher knowledge (mean 7.45, SD 0.98) and attitude (mean 5.30, SD1.48) scores than those who had never attended (knowledge: mean 6.10, SD 1.10; attitude: mean 4.10, SD 1.41); to facilitate screening behavior, counseling services and the promotion of existing breast cancer screening are necessary; diverse, culturally sensitive strategies tailored to younger and older women are recommended in future interventions.

XSL•FO
RenderX

Search number	Reference	Objective	Study design, sample population	Sample population	Mode of delivery	Specific instruments and interventions	Main findings
8	[32]	To ascertain the effects of breast cancer awareness programs on the use and uptake of breast screening among women in the United Arab Emirates	Cross-sectional study in the United Arab Emirates using a content-validated interviewer-administered questionnaire	959 women aged ≥20 years	University	—[c]	One-third of the participants (31.7%) had attended awareness programs, and attendance was influenced by younger age, higher education, and being single (P<.001); screening was performed by 38.3% of participants who had ever attended any breast cancer awareness programs than nonattendees (13.3%; P<.001); important barriers included knowledge gaps, cost concerns, and the lack of physician recommendations.
9	[33]	To evaluate the impact of a video-based intervention on the knowledge of breast cancer risk factors, symptoms, and attitudes toward screening practices	A quasi-experimental design in Bihar, India	267 rural-dwelling women	Regional health services	Intervention entailing serial exposure to validated YouTube Hindi videos focusing on educating respondents on breast cancer, changing attitudes toward screening methods, and encouraging healthy prevention practices	Knowledge level of risk factors, symptoms, and breast cancer screening increased significantly (100%) at 3 months post-intervention. Attitude towards breast self-examination improved significantly in 58% of women, 16.5% for clinical breast examination, and 9.7% for mammogram. Breast self-examination practices improved significantly in 60% of women. Associated factors of breast cancer awareness include education, age, and occupation.

15	[39]	To promote screening mammography and correct breast cancer myths among women living in an urban community in Korea	A multicity, multicomponent community intervention trial, with surveys at baseline and 7 months later in South Korea	480 women	Public health government bodies	The intervention city was equipped with a community outreach and clinic and pharmacy-based in-reach strategies; the community campaign emphasized the efficacy of screening mammography for detecting masses that are not reachable; messages were tailored to correct myths about breast cancer and screening mammography.	A 20.4%-point decrease in the myths regarding the association between breast size and cancer, a 19%-point decrease in myths about the cost of mammography, and a 14% increase in the intention to perform screening mammography. In the intervention city, about a 23% increase in the proportion of participants at the action stage of the transtheoretical model, but such improvement was either lacking or inconsistent in the control city.

[a]PEP: Promoting Early Presentation.

[b]OR: odds ratio.

[c]Not available.

[d]CBPR: community-based participatory research.

[e]EPPM: extended parallel process model.

The sample size of participants in the studies ranged from 32 to 1945 with a total of 10,287 women enrolled in the intervention groups and 1164 in the control groups accross the 15 studies. The participants' ages were presented in 8 studies, with a minimum age of ≥20 years to a maximum age of 70 years old. Most studies used >40 years old as the eligibility criterion.

Characteristics and Methodological Approaches Used in Social Marketing Interventions

This section presents findings regarding the first objective, focusing on the characteristics of social marketing interventions in the context of breast cancer screening. Specifically, the results are described based on intervention source and types; underpinning theories; insights, exposure, and reach; and outcome measures.

Intervention Source and Types

Public health government bodies were the predominant intervention source (8/15; 53%), followed by regional health services (3/15, 20%), cancer charities (2/15, 13%) and a university (2/15, 13%). The interventions can also be broadly divided into national (n=10) and regional (n=5) breast cancer awareness campaigns, as well as targeted (n=9) and untargeted types (n=6). National breast cancer awareness campaigns refer to those performed to enhance breast cancer screening and awareness among the general public. Meanwhile, regional types focus on a specific region or community. Targeted interventions encompassed those that used well-defined activities to disseminate breast cancer screening and awareness information to specific groups, whereas untargeted types refer to interventions delivered to the general public without specifically focusing on breast cancer.

Overall, 4 types of social marketing interventions were identified: (1) video-based marketing (n=2) [18,33], (2) health professional and educational strategies (n=5) [14,15,27,28,32], (3) community outreach campaigns (n=3) [34,36,39], and (4) social media or mass media campaigns (n=5) [30,31,37,38,40]. Thus, the majority of studies involved social marketing strategies incorporating health professional and educational approaches, followed by social media and outreach campaigns.

Behavior Change Theories Used in Interventions

Five studies provided insight into the theories that informed the development and implementation of the intervention. The predominant models considered were the health belief model [30,35,36], the transtheoretical model [39], and the extended parallel process model of persuasion [38].

All interventions were designed to influence breast cancer screening behaviors, such as improving attendance at cancer

XSL•FO
RenderX

screening, performing self-examination, and adhering to recommended prevention practices. This was achieved by disseminating information on breast cancer screening and raising awareness through advertisements, educational interventions, and promotional or fundraising activities.

The interventions shaped behavior change by informing participants or vulnerable people regarding the health consequences of breast cancer, specifically by providing videos, posters, advertisements, brochures, modules, and links to cancer charity and public health websites to access information about screening, risk factors, and symptoms. The interventions delivered information from well-established and credible sources, such as cancer charities, national and regional government health organizations, and university or institutional bodies, but certain information from untrusted individuals, users, or celebrities was deemed less credible [18]. Interventions that used social comparisons, individuals' approval, and social support to motivate cancer screening were reported in 4 studies. Examples included sharing messages of support from organizations, the public, cancer survivors, charities, and celebrities [18,31,35,36,39].

Insights, Exposure, and Reach

Different exposures were used in line with the type of intervention. Some of the studies provided detailed information on the exposure and the reach achieved by the social marketing interventions. One of the interventions with the largest reach involved 2 waves of a social campaign performed over 2 weeks with 1200 participants in the northeast of England. The target online audience was also reached via advertisements shown on promoted posts in Facebook [18]. A similarly large audience was reached by studies conducted in the United Arab Emirates [32], reaching 959 women aged ≥20 years; Turkey [35] with 20 trained peer educators and each educating approximately 200 women; and more than 450 attendees in a series of campaign events organized to build a breast cancer resource hub for Black women in the United Kingdom [37]. In Malaysia, about two-thirds of the participants identified at least one of the campaign materials used for the intervention, and the probability of being reached during the campaign was lower among Chinese women (odds ratio [OR] 0.25, 95% CI 0.15 to 0.40) and those aged >70 years (OR 0.47, 95% CI 0.23 to 0.94) relative to Malays and younger women [30].

A few studies shared insights into participants' views on the acceptance of social marketing strategies as an approach to delivering breast cancer awareness and screening information [18,37]. However, 1 study revealed that some women perceived that some breast cancer screening promotional messages, including award-winning advertisements, were offensive and did not represent the benefits or messages portrayed in the advertisements [29].

Outcome Measures

Descriptively, 5 studies reported outcomes relating to breast cancer awareness [18,27,28,30,40]; 6 studies reported outcomes for early cancer screening and preventive behaviors [27,31,35,38,39,40]; 4 studies reported outcomes related to perceptions regarding social marketing strategies for prompt cancer screening [29,30,34,37]; 6 studies reported outcomes regarding knowledge, attitudes, and practices toward breast cancer screening [14,32,33,35,36,39]; and 4 studies reported on the predictors of breast cancer awareness and screening [14].

Impacts of Social Marketing Interventions

Breast Cancer Awareness

Martin et al [18] used TV advertisements to explore the relationship between breast cancer and alcohol consumption, supported with voice notes and Facebook posts on different types of cancer caused by consuming alcohol. The intervention led to a significant postcampaign increase (45% increase) in breast cancer awareness compared with the precampaign level. In Malaysia and Romania, culturally adapted and mass media campaigns (TV, radio, print media, and social media) led to significantly higher levels of awareness among participants who recognized the campaign than nonrecognizers [30]. However, the true effects of these social marketing interventions on breast cancer awareness remain uncertain given the methodological limitations, particularly the use of a 1-group pre and postdesign and the lack of underpinning theories.

Meanwhile, more reliable findings were observed in 2 RCTs [27,28]. A multicomponent intervention, comprising Promoting Early Presentation (PEP) and a 10-minute interaction with a radiographer, improved breast cancer awareness by 2-fold (OR 8.1, 95% CI 2.7% - 25.0%) compared with participants in usual care at the 2-year follow-up [27]. A similar intervention based on the English National Health Service Breast Screening Program for older women (approximately 70 years old) was associated with a 7-fold increase in breast cancer awareness (OR 15.2, 95% CI 10.0 to 23.2) relative to a 2-fold increase in the control group. These results suggest that a multicomponent intervention incorporating SMCs and health promotional activities is more effective at upscaling breast cancer awareness. However, clinical trials comparing these various approaches are required to test the hypothesis.

Breast Cancer Screening and Preventive Behaviors

The significant effects of SMCs on early breast cancer screening and preventive behaviors were revealed in 3 intervention trials [27,38,39]. The PEP intervention investigated by Forbes et al [27] among vulnerable women in the United Kingdom led to an 8-fold increase in participants' readiness to perform early screening. The intention to perform breast cancer self-examination also improved following the provision of messages about the risks and precautions of breast cancer across different media outlets [38]. Likewise, community outreach and clinic and pharmacy-based in-reach strategies led to a 14% and 23% increase, respectively, in the intention to perform screening mammography and the proportion of participants at the action stage [39].

A few studies were designed to shape participants' perceptions and positive behavioral change toward breast cancer screening via community outreach campaigns [34], social media or mass media campaigns [29,37], and health professional and educational strategies [14,32]. Yfantidou and Skandali [29] conducted a qualitative interventional study by presenting breast cancer screening advertisements to 13 participants, followed

XSL•FO
RenderX

by interviews to capture their perspectives on the promotional activities. Some of the breast cancer screening and promotional activities were considered offensive and failed to connect with the visual designs; however, the participants were motivated to perform screening when exposed to positive advertisements capturing reliable data on breast cancer and endorsements from highly respected celebrities. Williams et al [37] used a similar intervention involving a series of virtual educational and cancer screening events used to build a breast cancer resource hub for Black women. As a result, most participants (>85%) perceived the SMC to be very helpful and supportive, leading to a 9% increase in the proportion of those likely to visit health care centers for mammogram screening.

Some of the studies in this category, particularly those involving health professional and educational strategies [32,35,37] and community outreach campaigns [36,39], highlighted a positive relationship between improved knowledge and a positive perception toward breast cancer screening. The video-based social marketing used by Sinha and Sharma [33] in a regional study in India also reported significant improvements in participants' knowledge of risk factors, symptoms, and breast cancer screening, leading to positive attitudes toward breast self-examination. Direct comparisons between these interventions is challenging given the different approaches. More importantly, the evidence from these studies is weak given the qualitative or quasi-experimental design and the use of an online survey for follow-up assessment [35].

Factors Influencing the Primary Outcomes

The factors influencing breast cancer screening awareness were investigated by 4 articles. Alomairy et al [14] found that cultural backgrounds shaped younger and older women's attitudes toward breast cancer screening services. Abdulla et al [32] and Sinha and Sharma [33] reported that younger age, higher education, occupation, and being single improved the likelihood of attending breast cancer awareness programs, with knowledge gaps, cost concerns, and the lack of physician recommendations constituting the major barriers. The performance of breast awareness practices and clinical breast examinations was associated with having a lower level of religious beliefs and better understanding of the importance of screenings [36]. In contrast, none of the demographic variables influenced improvement in symptom awareness scores among Malaysian women who were exposed to a culturally adapted and mass media campaign (TV, radio, print media, and social media) [30]. These findings reflect the multifactorial nature of breast cancer screening behaviors and the need for tailored social marketing interventions.

Discussion

Principal Findings

Most articles on social marketing interventions assessed breast cancer awareness and screening intentions using a mixture of experimental and observational study designs to measure exposure, reach, and impacts on investigated outcomes. A few studies revealed that national and regional breast cancer awareness campaigns and targeted interventions might improve cancer awareness, screening intentions, and uptake. The available evidence also suggests that exposure, reach, and engagement attained by these interventions differed by age, gender, educational level, and users' ethnicity.

Although several reviews have been published on interventions to address cancer screening and prompt diagnosis, to the best of our knowledge, this scoping review is the first attempt to focus on social marketing interventions to improve breast cancer screening, awareness, early diagnosis, and presentation to care. The findings add to the existing knowledge pool by reflecting the data paucity and robust clinical trials exploring the level of engagement, mechanisms of behavior change, and attendance at screenings specifically designed for women with breast cancer and high-risk groups. It is difficult to attain high engagement levels given the challenge with accessing timely observational data on breast cancer screening attendance [40,41]. This is further complicated by the fact that social marketing interventions are usually designed without provision for evaluation and impact metrics [42]. A similar situation was observed in the scoping review conducted by Plackett et al [5], whereby the authors commented, based on expert validation of emerging themes, that campaigns are designed rapidly without room for evaluation.

Immediate changes are difficult to measure since cancer screening and early diagnosis are long-term goals, which is in sharp contrast to the primary design of SMCs. More comprehensive evaluations that reflect outcomes of behavior change and engagement could be achieved by developing an evaluation framework that integrates components of behavior change theories [43]. Nevertheless, it is difficult to equivocally demonstrate that a specific campaign is primarily responsible for a change in behavior or outcome, in addition to the organizations' limited resources and time to perform evaluations. Such assessments could, however, be conducted in campaigns involving collaboration with public health and institutional bodies.

In this review, we attempted to use the BCT taxonomy to delineate the various BCTs used in social marketing interventions to shape participants' health behaviors, including social support, incentives, and equipping vulnerable populations with health information. The health belief theory was the framework predominantly used to develop the investigated interventions. According to BCTs, providing actionable health information about breast cancer symptoms and risk factors could have stronger and direct positive effects on behavior change. The BCTs used in breast cancer campaigns, such as sharing personal stories, could help create social support and influence public opinion, thereby encouraging help-seeking behaviors, increasing screening uptake, and improving health outcomes. Future interventions could explore these assumptions, particularly how national and regional social marketing strategies might facilitate positive behavior change and the most important messages required in such interventions.

This scoping review revealed the degree to which social marketing interventions addressed inequalities in breast cancer screening, awareness, and early diagnosis. The available evidence suggests a low reach and engagement with ethnic minorities [1,30], which is mainly associated with limited access

XSL•FO
RenderX

to breast cancer screening, stigma, and low engagement with social media and SMCs [44,45]. This inequality is further exacerbated when the information is not culturally adapted [46]. The low uptake of screening and awareness may also stem from the lack of campaign role models that are highly respected and resonate with ethnic minorities [18].

Inequalities in the use and impacts of SMCs were also identified in terms of age, educational level, marital status, and occupation. Younger age, higher education, being employed, and being single improved the odds of exposure to breast cancer awareness programs and perceived benefits toward screening services [14]. These results align with recent data on social marketing and media use in the United Kingdom and high-income countries by age and gender [47]. The finding underscores the need for specific campaign strategies preferred by target users and those more likely to facilitate broad engagement.

Future interventions involving social marketing approaches should assess inequalities in exposure, reach, and engagement, as well as consider the effectiveness directly in relation to the target groups. Designing interventions toward populations with a disproportionate disease burden could address health inequalities observed in breast cancer screening and early diagnosis. This could be achieved by shifting from broad, "one-size-fits-all" approaches to audience-segmented interventions that effectively tackle systemic barriers. Social marketing strategies involving mass and social media can shift the "product" from fear-inducing to capacity-building, relatable, and manageable actions [48]. Educational-related barriers could be addressed by incorporating language and cultural nuances, partnering with community leaders, and designing messages that align with cultural beliefs and mitigating local cancer myths [49].

Meanwhile, inequities introduced by unemployment could be tackling systemic and hidden costs. Examples include campaigns that promote screenings related to tangible solutions, such as free and accessible mammography centers in local communities. These marginalized groups could also be further reached by expanding distribution channels beyond digital spaces, focusing on physical and trusted touchpoints [48]. Other possible channels to address the aforementioned inequities include leveraging trusted intermediaries to deliver face-to-face messaging and engaging the support ecosystem while considering the role of family structures in health care decisions [5].

Based on the syntheses of the 15 articles, most SMCs and interventions had significant impacts on breast cancer screening awareness and preventive behaviors. Overall, the findings are consistent with previous reviews on the use of social marketing strategies in HIV testing and related outcomes [49], whereby a consistent pattern of positive results were observed. Nevertheless, effectiveness seems to differ depending on specific elements used in the intervention, such as mass media, social media, and recognizable figures. Methodological limitations also need to be considered when interpreting the findings.

For instance, 2 RCTs [27,28] incorporating SMCs and health promotional activities led to significant improvement in upscaling breast cancer awareness, with a large effect size. These promising results may stem from the efficacy of such campaigns at enabling the transition from mere information to behavioral change. By integrating health promotional activities such as culturally tailored education, the intervention directly addresses psychosocial barriers, strengthens self-efficacy, and encourages proactive health actions [50]. Moreover, a comprehensive marketing mix is established by collaborating with stakeholders to tackle barriers such as accessibility and cost [14].

Social media or mass media and community outreach campaigns [39] were also instrumental at enhancing breast cancer awareness. These campaigns combined broad reach and localized, culturally tailored messaging as well as mitigated specific barriers to care such as stigma and fear. As a result, women were empowered to identify symptoms early and encouraged to visit screening centers [30,39]. However, the actual effect size of changes in breast cancer awareness could not be ascertained given the low-quality research designs. Promising results were also reported in a few qualitative interventional studies involving social media or mass media campaigns [29,37]. Positive advertisements capturing reliable data on breast cancer and endorsements from highly respected celebrities were perceived more positively, leading to proactive health actions. Celebrities can upscale breast cancer awareness and promote positive attitudes toward screening by leveraging their massive reach to destigmatize the cancer, break obstacles, and act as crucial relatable models for early diagnosis [51]. Involving recognizable figures bridge gaps between the general public and complex medical information, translating awareness into life-saving actions [52].

Video-based marketing was primarily used as the source of intervention in 2 studies [18,33], with both reporting greater awareness and improved knowledge and attitudes toward breast cancer screening postintervention. This approach was effective at bypassing literacy barriers, capturing attention, and directly inspiring proactive health behaviors because they rapidly translate complex health information into accessible, emotionally resonant and culturally adaptable formats [53].

Nevertheless, the evidence from the studies needs a deeper assessment and to be interpreted cautiously. Direct comparisons between the interventions was challenging given the different study designs and interventional approaches. However, the large effect sizes reported for SMCs incorporating health promotional activities suggest that these elements are effective at upscaling breast cancer awareness and positive screening decisions. This is further supported by the robust research designs used in the reviewed studies [14]. Community outreach and mass media campaigns also showed promising results in terms of breast cancer awareness and preventive behaviors, with the inclusion of recognizable figures providing additional benefits [54]. Meanwhile, evidence from video-based marketing approaches is weak, and the incorporation of other proven marketing elements may be required to optimize their effects.

Overall, the reviewed studies depict the importance of identifying SMCs and delivery methods that strongly resonate with the target audience [55]. Significant efforts are required to achieve audience segmentation and formative research with the target market for planning and branding the campaign. A

XSL•FO
RenderX

catchy slogan and name are critical components of effective SMCs, but the information was lacking in most studies. As a result, it is unclear whether these important elements contributed to the promising outcomes reported in the reviewed studies.

Quality appraisal also revealed that only 2 clinical trials (RCTs) had a robust design. Based on the weak study designs, it is difficult to conclusively infer that the SMCs led to improved breast cancer awareness, screening uptake, and early diagnosis or presentation into care. Although the use of different approaches and evaluation methods provided a clear picture of the population's exposure to the SMC and the participants' awareness levels, a standardized approach is required to facilitate robust comparisons between campaigns in terms of effectiveness and economic benefits. We acknowledge the diverse nature of target populations when conducting SMCs, but a standardized reporting of exposure and impact is crucial for significant progress to be achieved in this unique field of public health.

Limitations

Research into social marketing in public health interventions is rapidly growing, and this scoping review presents only the current and available evidence for social marketing interventions. Only articles written in English were included in our review, thereby neglecting information from relevant interventions either conducted in non-English speaking countries or not written in English. This limitation affects the generalizability of the review findings. Many of the SMCs used combined interventional approaches and sources, possibly contributing to the positive outcomes in terms of breast cancer awareness and screening participation.

Given the lack of a standardized protocol for report evaluations of social marketing interventions, the data synthesis was based on the outcomes measured and reported in the reviewed studies. In other words, some degree of reporting bias might be present in the included studies. The exclusion of gray literature may also introduce some bias, as only articles retrieved from selected databases and peer-reviewed journals were analyzed. The quality appraisal highlighted moderate to weak study designs in 13 of the 15 articles. We did not perform a meta-analysis due to the heterogeneity between the studies, particularly in terms of study designs, delivery methods, type of social marketing interventions, and diverse outcomes. Developing a reporting protocol based on available frameworks for evaluating social marketing research should be considered in future research endeavors.

Conclusion

This scoping review revealed that behavior change outcomes were sparingly assessed in most evaluations of social marketing interventions to improve breast cancer awareness, screening, and early diagnosis. The limited evidence reflects various types of social marketing interventions, ranging from community outreach to health professional and educational strategies, social media or mass media campaigns, and video-based marketing, which may improve breast cancer awareness and intended and actual screening uptake. Robust evaluations of these interventions could be performed in future research by using well-established evaluation frameworks and reporting guidelines. This will assist with capturing behavior change outcomes and elucidating their underlying mechanisms. Specific users or engaged individuals should be identified, and measures should be used to ascertain whether some health inequalities could be addressed by social marketing interventions. Developers and funders of these campaigns should also consider using an evaluation plan before conducting the actual campaign. Such evaluation plans may consider using feasible mixed methods and quasi-experimental designs. This is crucial to ensuring that campaign exposure and impact are measured adequately, as well as identifying the specific elements responsible for the observed behavioral change.

Abstract

Background: The number of cancer survivors is steadily increasing worldwide, leading to an increased demand for long-term follow-up and supportive care. Many survivors face ongoing physical and psychosocial issues that highlight the need for innovative management approaches. Mobile health apps offer potential benefits by facilitating patient-led follow-up, self-management, and more efficient use of health care resources. Although the market for cancer-related mobile apps has grown rapidly, their sustainability and scientific basis remain unclear. In the European Union, the Medical Device Regulation (MDR), in effect since May 2021, introduced stricter criteria for classifying medical devices, including certain software apps. While aiming to improve patient safety, the MDR could pose challenges for small companies and academic developers, potentially limiting the availability of such apps. No scoping review has delineated changes in active apps before and after implementation of the legislation regulating medical devices.

Objective: This scoping review aimed to evaluate the current availability and longevity of English-language mobile apps supporting cancer recovery, with a specific focus on changes before and after the implementation of the European Union MDR, and to assess the extent to which these apps are supported by clinical evidence.

Methods: Searches were conducted in mobile app stores (Apple's App Store and Google Play) and literature databases (MEDLINE, Embase, Cochrane Library, and Web of Science), using predefined terms. Mobile apps targeting cancer recovery and published articles on their effectiveness were included. Two reviewers independently extracted data. A descriptive analysis was conducted to report trends in mobile device app availability and updates over time.

Results: A total of 151 mobile apps were identified in 2018. However, by 2024, only 45 of 151 (30%) were still available. Among these, 25 of 151 (17%) were updated within the past 2 years. During the search in December 2024, 1 new mobile app supported by scientific evidence was discovered. This mobile app was developed to assist cancer survivors in managing insomnia through cognitive behavioral therapy. Rapid turnover and a potential lack of sustainability in the mobile health app market for cancer survivors were evident, with most mobile apps identified in 2018 no longer available by 2024.

Conclusions: This review revealed a limited number of publicly available mobile apps that support cancer recovery. The longevity of existing mobile apps is limited, potentially because of regulatory and financial barriers. Prioritizing rigorous effectiveness trials, addressing implementation barriers, and developing sustainable business models are essential to ensure the long-term availability and success of mobile health apps in cancer survivorship care.

KEYWORDS

cancer; symptoms; neoplasm; mobile health; cancer survivorship

Introduction

Globally, the total number of new instances of cancer is steadily rising, but treatment and survival rates are also consistently improving. Thus, the prevalence of people having undergone cancer treatments is rapidly increasing [1]. Currently, there are approximately 12 million cancer survivors in Europe [1]. Survivors often have regular health care follow-up appointments

XSL•FO
RenderX

for many years, or even lifelong [2]. Hence, providing adequate cancer care is a significant challenge because of increasing demand [3]. The role of regular outpatient appointments after treatment completion has been criticized because of the lack of scientific evidence supporting their benefits and the anxiety and distress they could bring patients [4]. In contrast, some data indicate that patient-initiated follow-up appointments may be more valuable for patients and the health care system [5]. Structured clinical follow-up remains an essential component of survivorship care, with digital tools increasingly regarded as complementary rather than substitutive approaches. This complementary role highlights the need for scalable, accessible, and resource-efficient follow-up models, including mobile health apps that can enhance access to and reduce the burden on health care systems and foster patient empowerment [5,6].

While structured follow-up remains important, many patients who have completed curative-intent treatment for cancer experience incomplete recovery, with persistent physical and psychosocial problems [7]. These facts highlight the need to consider novel management strategies for cancer survivors. Use of modern communication tools, such as smartphones and engaging in patient-driven follow-up, may offer a successful way forward to improve cancer survivorship and promote more cost-effective use of health care resources [5,6]. In recent years, the market for mobile apps has grown rapidly [8], and many initiatives focusing on cancer patients have become available [9]. Nevertheless, the annual number of mobile apps created to assist individuals living with and beyond cancer does not correspond to the existing evidence of their usefulness and effectiveness [10,11]. The rapid pace of app development has outstripped the evidence base, creating a gap that researchers are now trying to address and highlight as an evaluation crisis in the field [12].

The content of mobile apps for cancer management available on the market can be divided into five main categories: (1) communicating cancer information, (2) planning and organizing cancer care, (3) interacting with others (including health care professionals and others affected by cancer), (4) enacting management strategies and adjusting to life with or beyond cancer, and (5) receiving feedback about cancer management, for example, by sharing self-monitoring reports with health care professionals [13]. For instance, almost 40 apps have been proposed to aid skin cancer detection [14]. Some apps aim to help cancer patients keep track of their treatment and therefore include functions such as schedules and treatment-related information, as well as symptom tracking. The majority of these apps have not been scientifically developed or classified as medical devices [11].

Numerous cancer mobile apps are available on the market; however, the current availability of these apps remains uncertain. The survival of an app is contingent on financial, political, and regulatory factors [15]. Apps solely used as research tools can often be sustained through research funding. Conversely, apps intended for commercial use or integration into sectors such as health care usually require ongoing external financing, which may lead to discontinuation due to struggles to secure such support. Furthermore, political decisions (eg, national reimbursement policies, procurement rules, or regulatory priorities) also influence the adoption of apps or similar software in health care, which can pose challenges for researchers [15].

The Medical Device Regulation (MDR) is a specific European Union regulation affecting the classification and approval of medical devices, including software apps [16]. The introduction of the MDR, which became applicable in May 2021, has significant implications [16]. For instance, software that provides a responsive functionality, such as offering self-care advice based on self-reported values, such as health-related quality of life was, from that date, classified as a medical device (MDR class IIa) [16]. This classification necessitates a costly and time-consuming validation process that forces these apps to comply with stringent rules for classification, technical documentation, clinical evaluation, and postmarket surveillance to remain on the market. Although the MDR has been established to enhance patient safety and create a more robust regulatory framework, it presents challenges, particularly for smaller companies and academic contexts with limited resources. The increased regulatory burden and associated costs may disproportionately affect these entities, potentially reducing the number of mHealth apps available on the European Union market [17].

No scoping review has delineated the changes in active apps before and after the implementation of the MDR. This study aimed to describe the longevity (ie, whether apps identified in 2018 remained accessible in 2024) of English-language mobile apps before and after implementation of legislation regulating medical devices by examining (1) the availability of these apps in mobile app stores and (2) the extent to which they are supported by scientific evidence.

Methods

Our review was reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines (Checklist 1) [18]. We used the InSynQ list for items relevant to scoping reviews [19]. Quality assessment and risk of bias were not evaluated because the primary aim was to identify mobile device app measures, consistent with scoping review recommendations [18]. An internal study protocol was established before conducting the study. Because the protocol was not publicly registered, it is available from the corresponding author on reasonable request.

Information Sources and Search for Apps

To investigate the longevity of these apps, we examined cancer-related mobile apps available since September 2018, as identified in the study by Adam et al [13], and compared them with our search conducted in December 2024. Accordingly, all mobile apps from Adam et al's [13] study were included in separate analyses. However, different inclusion and exclusion criteria were applied to address the 2 additional research questions, and multiple approaches were used to identify available apps with supporting literature.

Search Strategy and Screening

First, on December 2, 2024, we searched Apple's App Store and Google Play to identify currently available cancer recovery

XSL•FO
RenderX

mobile apps. We explored both the apps still available from Adam et al's [13] study and additional apps identified through our search. Two researchers (KF and SJ) performed the searches, resolving discrepancies through discussion or consulting with a third author (AS). The search strategy described by Adam et al [13] was used. Specifically, we used the exact same keywords from the original review ("cancer," "cancer survivor," and "cancer survivorship") and conducted 2 searches using an iPhone and a Samsung phone to search Apple's App Store and Google Play, respectively.

Second, a literature search was conducted to understand which cancer recovery apps were supported by scientific evidence. Searches were conducted in MEDLINE, Embase, the Cochrane Library, and Web of Science databases. The literature search was conducted on October 4, 2022, and updated on August 15, 2024. Medical Subject Headings (MeSH) and free-text terms were identified for each search concept. The full search strategies, including all MeSH and free-text terms, are provided in Multimedia Appendix 1. For mobile apps beyond those identified in the study by Adam et al [13] but found in our December 2024 search, we explored the literature in PubMed using free-text searches for the app names. We also conducted Google searches using the names of apps identified by Adam et al [13].

We developed and pilot-tested the abstract and full-text review criteria that reflected our inclusion and exclusion criteria. For pilot testing, the reviewers assessed 10% of abstracts and full-text articles. Any discrepancies were discussed within the research group and, if necessary, the process was updated accordingly. Two researchers (KF and SJ) independently evaluated the literature search results according to the eligibility criteria using Rayyan web-based software [20]. Discrepancies were resolved through discussion or consultation with a third author (AS). Initially, titles and abstracts were screened for eligibility, followed by a full-text review of articles deemed to align with the eligibility criteria. The search strategy was developed in MEDLINE (Ovid) in collaboration with librarians at the Karolinska Institute University Library. MeSH and free-text terms were identified for each search concept. The search strategy was then translated into the other databases using the Polyglot web-based tool [21].

No language restrictions were applied to the database searches. However, studies not written in English were excluded during screening due to limited translation resources. Articles published before 2010 were excluded. The strategies were peer-reviewed by another librarian prior to execution. Deduplication was performed as described by Bramer et al [22]. A final step was added to compare the DOIs.

Third, a snowball search was conducted to check references and citations of eligible studies identified through the database searches using the Citationchaser web-based tool [23].

Eligibility Criteria

Study Inclusion Criteria

As this was a scoping review, we aimed to include all relevant study designs that provided quantitative measures of impact. We considered experimental studies of any size that reported at least 1 measure of efficacy or effectiveness of a mobile app. Only studies published from 2010 onwards were eligible.

Study Exclusion Criteria

Observational studies, qualitative studies, editorials, reviews, opinion articles, case studies, research protocols, trial registrations, conference summaries, and papers published as abstracts were excluded. Studies that reported only qualitative measures were excluded. Due to limited resources, studies not written in English were excluded.

Population Inclusion Criteria

This study included primary studies of adult cancer survivors (18 years or older) who had completed treatment with curative intent before participating in the study.

Population Exclusion Criteria

Individuals with incurable diseases or those at the end of life were excluded. Studies that included patients younger than 18 years were excluded, even if the mean age was greater than 18 years. Studies that included patients with childhood cancer, who were subsequently included as adults, were also excluded.

Intervention Inclusion Criteria

We included all studies that examined smartphone apps designed for cancer survivors, with content presented in English that reported at least 1 measure of efficacy or effectiveness. The duration of the intervention had to be at least 6 weeks to ensure the intervention period was long enough to assess meaningful change in quantitative outcomes. Eligible studies required 1 treatment arm (or the treatment arm in single-arm studies) to consist solely of the mobile app or the mobile app in addition to usual care (as defined by the study authors).

Intervention Exclusion Criteria

We did not consider mobile apps used solely to identify or diagnose specific cancer types, provide general cancer information, manage hospital appointments or medication schedules, supply tools for health care professionals or caregivers, or support patients before or during treatment. Web-based apps were not included. Apps exclusively designed for tablets were also excluded because of their lower accessibility and use rates compared with mobile phones among the general population. Lastly, we excluded apps involving person-to-person interactions, such as cognitive behavioral therapy (CBT) or general counseling, as it would increase costs and resource demands.

Mobile App Characteristics Inclusion Criteria

Beyond apps identified by Adam et al [13], additional apps were eligible if they were available in one of the mobile app stores (Apple's App Store or Google Play) and supported by evidence that met the study eligibility criteria. The eligibility of apps was evaluated using the cancer survivorship care quality framework [24], which required that the app address at least 1 of the following domains: surveillance and management of physical effects, psychosocial effects, or chronic medical conditions.

XSL•FO
RenderX

Mobile App Characteristics Exclusion Criteria

Apps were excluded if they did not address any survivorship domain defined in the cancer survivorship care quality framework or did not meet the availability and evidence requirements described above.

Data Charting Process

During the study planning phase, a checklist for data extraction was developed (see Multimedia Appendix 1). We developed data extraction forms to collect relevant information from each article. The forms were piloted on 5 apps, and any discrepancies were discussed within the research group. Two researchers (KF and SJ) independently extracted relevant data (from mobile app stores and papers), except for the information on the app intervention (as described in mobile app stores), which was extracted by one reviewer (KF) and verified by another reviewer (SJ). This approach was deemed most acceptable, as the information on mobile app stores was transcribed in a free-text format and could not be extracted in precisely the same manner between reviewers. Any disagreements were resolved through discussion or by seeking input from a third reviewer (AS) when needed. The shortest follow-up was set at 6 weeks. We included all studies that investigated smartphone apps designed for cancer survivors that reported at least 1 measure of efficacy or effectiveness. We took this approach because we wanted to investigate not only existing mobile apps on the market but also apps that could potentially affect survivorship. The following information was collected from each study or the mobile app:

- Trial details (sample size, first author's name, publication year, country, funding)
- Participant information (type of cancer)
- Mobile app specifics (name of the app, availability in app stores, latest update of the app, intervention characteristics [as described in mobile app stores], cancer survivorship care quality framework domain covered)

Synthesis of Results

This scoping review used a narrative approach aligned with the research objectives to summarize the results. The data are presented in tabular and narrative formats, offering a comprehensive overview of the findings.

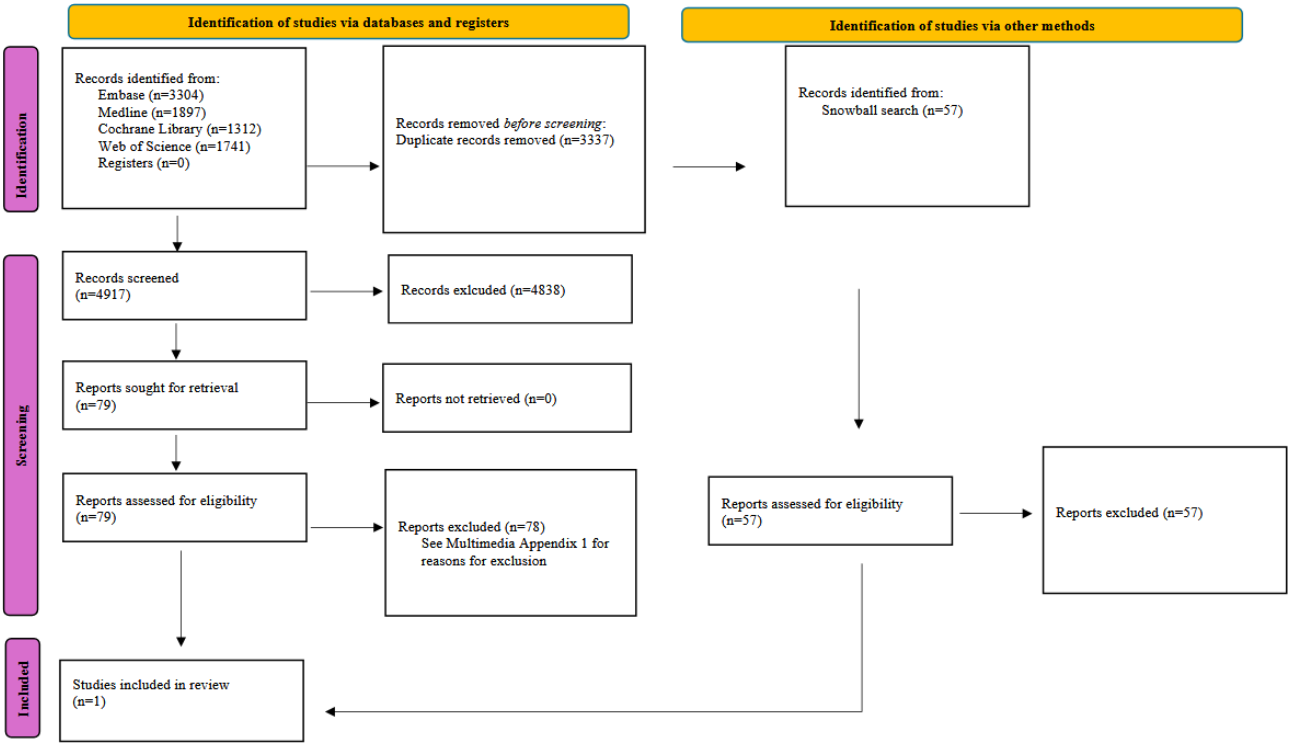
Patient and Public Involvement

The extensive involvement of patients and their caregivers in our Surgical Care Science research partnership group [25] was integral to the study design. Their contributions encompassed proposing research questions and informing study methodologies. Feedback from these stakeholders on the study's findings was actively solicited, and insights derived from group discussions were incorporated into the Discussion section.

Results

Mobile Apps Found in App Stores

In the study by Adam et al [13], 151 mobile apps were identified. Of these, 45 of 151 (30%) were still available on either Apple's App Store or Google Play in December 2024. A total of 16 of 151 mobile apps (11%) were updated in 2024, and 25 of 151 apps (17%) were updated between 2023 and 2024. In our search in Apple's App Store and Google Play in December 2024, we found 1 new app from 2024 that fulfilled our eligibility criteria [26]. This mobile app was developed to assist cancer survivors in managing insomnia through CBT. Detailed descriptions of all identified apps are provided in Multimedia Appendices 2-4.



In the December 2024 Google Play search, we identified 225 search results for "cancer," 52 for "cancer survivor," and 3 for "cancer survivorship." In Apple's App Store, we obtained 175 results for "cancer," 20 for "cancer survivor," and 10 for "cancer survivorship." The searches for "cancer survivor" and "cancer survivorship" did not render any unique results but were covered by the initial search for "cancer" both in Google Play and in Apple's App Store. The search did not yield any additional mobile apps. However, 1 additional mobile app was found in the literature search (Multimedia Appendix 4) [26]. The reasons for excluding apps included that they were exclusively for clinicians (n=51); were fundraising apps (n=6); were not exclusively for the treatment period (n=11); did not fulfill any of the cancer survivorship care quality framework domains (n=66); were conference apps (n=6); were for children's cancer only (n=6); were games (n=4); were covered by Adam et al [13] (n=24); were apps for obtaining a diagnosis (n=23); were not supported by evidence (n=1); had no content related to cancer (n=164); and were not English (n=38).

Literature Supporting Apps

The initial search conducted in 2022 yielded 6238 papers, and the updated search conducted in 2024 yielded 2016 new papers. A total of 3337 duplicate papers were removed. After reviewing the literature, only 1 article was included in this study. That study evaluated a mobile app developed to help cancer survivors manage insomnia through CBT. It offers a self-guided, 7-week program featuring sleep hygiene education, personalized sleep plans, relaxation techniques, and motivational interviewing. Users can track their sleep metrics and receive tailored advice to address their negative beliefs about sleep. A single-arm interventional study involving 30 participants significantly improved insomnia severity among cancer patients [26]. Figure 1 shows a PRISMA flowchart of the search strategy. See Multimedia Appendix 2 for reasons for exclusion.

XSL•FO

Figure 1. Flow diagram of search strategy (adapted from Page et al [27]).

Discussion

Principal Findings

This scoping review aimed to evaluate the durability of English-language mobile apps intended to aid cancer patients' recovery after treatment and to determine the level of scientific evidence supporting their effectiveness. In 2018, 151 mobile apps were available, of which 45 of 151 (30%) were still available as of December 2024. Remarkably, only 16 of 151 mobile apps (11%) were updated by 2024. In addition, we found 1 new app by December 2024.

Strengths and Limitations

To ensure the scientific rigor of this scoping review, we conducted a comprehensive literature search using 4 electronic databases, an additional snowball search to check the references and citations of eligible studies, and a broad search strategy. The review also used Apple's App Store and Google Play, which have almost 100% coverage of the mobile app market [21]. The review followed the PRISMA guidelines for scoping reviews [18] and was methodologically robust, with an independent blinded selection of studies and data extraction (except for extraction for interventions).

However, our scoping review had some limitations. To make the review more pragmatic, we focused on mobile apps available in app stores that followed at least 1 of the cancer survivorship care quality framework domains and had supporting evidence for effectiveness without cointerventions (excluding usual care). We also excluded face-to-face interactions within the app because of the cost and implementation challenges in real-world health care settings, which have been shown to hinder mobile app survival [28]. This meant that several trials and apps were excluded. Consequently, the data used in this review do not represent the entire market. This methodology does, however, draw attention to the scarcity of cancer recovery–focused mobile apps that are available for download from mobile app stores and have some scientific backing for their efficacy.

We also conducted searches using computers and tablets to determine whether the results differed owing to the algorithms provided by the manufacturers. We noticed that the search results differed depending on who conducted the searches, when they were conducted, and the devices used for the search (eg, tablets, computers, or phones). For example, when using a web browser, the maximum number of search results for Apple's App Store was 50, whereas for an iPhone, it was 250.

However, we consider the search terms to be accurate and representative of how a typical user searches for a mobile app related to the topic examined in this review. Finally, a limitation of searching for apps with associated studies is that the nomenclature must likely be included to identify them. Consequently, scientific support may exist for some apps, even though we did not find it.

Implementation Challenges

Proponents of mHealth assert that its primary advantages include improved efficacy, reduced expenditure, and expeditious delivery of health care with minimal risk [29]. Nevertheless, it is not evident how digital health technologies can complement the need for in-person care interactions and health care expenses [30]. Some research findings suggest that digital interventions may contribute to increased physical activity levels. However, the outcomes regarding psychological effects remain inconclusive. Notably, the evidence supporting these findings is limited [9].

Adherence is a well-known and complex problem that can affect the outcomes of mobile app interventions [31]. Although

XSL•FO
RenderX

developers have created a purportedly optimal app, its efficacy is contingent upon the health care sector's willingness or reluctance to integrate it into existing practices [32]. Adopting new technologies in health care settings often faces challenges owing to resistance to change and concerns about workflow disruption. Health care providers may be hesitant to integrate new mobile apps into their practice if they perceive them to be time-consuming or potentially compromise patient care [9,28]. The involvement of health care professionals in the development and implementation processes is crucial for overcoming barriers. This approach ensures that the technology addresses specific requirements and integrates effectively with existing workflows [33].

The implementation of mobile apps in health care settings presents several challenges. Strict regulations, such as the MDR in Europe, have increased development costs and complexity, potentially limiting the availability of apps, particularly from smaller enterprises [16]. Financial limitations also pose a major hurdle, as sustaining high-quality health care apps requires substantial resources [17]. Additionally, technical obstacles, adoption resistance, and insufficient evidence hinder the effective integration of mobile apps into health care environments [28]. These challenges underscore the necessity for careful consideration and strategic planning to overcome these barriers and ensure successful implementation.

Most mobile apps identified in the study by Adam et al [13] are no longer available, highlighting their rapid turnover and potential lack of sustainability in the mobile health app market for cancer survivors. This high attrition rate raises concerns regarding the continuity of the research process using these digital tools, as they frequently depend on research funding [34]. Research grants may be derived from taxpayer funds, and given the research inefficiencies observed in this area, action must be taken to enhance the sustainability of these apps and avoid research waste [35]. Implementing mobile apps in health care settings would optimize the allocation of public funds instead of merely conducting pilot studies and subsequently discarding apps. Despite the emergence of new mobile apps, overall scientific evidence supporting their effectiveness remains limited [11]. Several studies suggest that apps may reduce health care use related to disease management (eg, fewer clinic visits, hospital admissions, or unplanned contacts) and the overall financial burden of the disease; however, the cost-benefit relationship remains contentious due to high development and implementation costs, as well as limited user adoption [36]. These 2 critical factors must be established when proposing a change in the care-setting environment [37,38].

Conclusions

Despite the well-documented rapid growth of mobile health apps in the health care market, this scoping review found that there appear to be few publicly accessible, frequently updated, evidence-based apps for cancer recovery that are supported by clinical evidence. Even though many apps are available, the longevity of care recovery apps is very low. In addition, the rapid pace of mobile device app development has outstripped the evidence base, creating a gap that researchers are now trying to address while highlighting an evaluation crisis in the field. Ensuring sustained availability of mobile health apps necessitates heightened emphasis on more robust effectiveness trials, addressing barriers to implementation, and developing sustainable business models. Although some cost-effectiveness evaluations of mobile health apps exist, there is a clear need for more comprehensive and standardized assessments within care settings.

Acknowledgments

We thank Narcisa Hannerz and Sabina Gillsund from the Karolinska Institute University Library for their assistance in developing and peer reviewing the literature search strategies. We are also grateful to the members of the Surgical Care Science patient and caregiver partnership group for their valuable input on the study design and interpretation of the findings.

Funding

This work was supported by Region Stockholm (ALF project RS2021-0822), Sjöberg Foundation contract number 2024-01-04:06; The Swedish Research Council contract number 2023-02178, and the Swedish Cancer Society (230665 FE). The funders had no involvement in the study design, data collection, analysis, interpretation of results, or writing of the manuscript.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files in Multimedia Appendices 1-4. No additional datasets were generated. The full search strategies and extracted application-level data are provided in the supplementary files in Multimedia Appendices 1-4. The study protocol is available from the corresponding author upon reasonable request.

Abstract

Background: Artificial intelligence (AI) is rapidly reshaping oncology, offering advancements in clinical care and patient support. A growing area of interest is the integration of empathic AI: systems integrating clinical precision with emotional intelligence to support medical decision-making and the emotional and psychosocial well-being of patients and caregivers.

Objective: This review aimed to explore the role of empathic AI in cancer care, with a focus on its applications in patient education, clinician support, and emotional care. It also evaluated the ethical, cultural, and implementation challenges associated with its integration into clinical practice in oncology.

Methods: A systematic search of literature was conducted in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines. Peer-reviewed papers published between January 2018 and January 2025 were identified through a search of PubMed, Scopus, and IEEE Xplore, and citation tracking. Eligible studies focused on applications of empathic AI in oncology. A total of 44 studies were included and analyzed thematically across 3 core clinical domains: tailored communication and education, diagnostics and care plan optimization, and emotional and psychosocial support.

Results: Empathic AI demonstrates the potential to improve cancer care by enhancing patient education, clinical decision-making, and emotional support. Common applications include personalized education for patients and providers, support for diagnostic and therapeutic decisions, and tools designed to recognize and respond to patient distress. Several studies noted improved patient engagement and reduced clinician burden. However, concerns were identified regarding overreliance on AI systems, cultural insensitivity, and patient privacy.

Conclusions: Empathic AI represents a promising advancement in patient-centered oncology, integrating emotional intelligence into clinical care. Its successful implementation will require careful attention to ethical, cultural, and clinical considerations to ensure health equity, trust, and safety in AI-assisted cancer care.

(JMIR Cancer 2026;12:e82336) doi:10.2196/82336

KEYWORDS

empathic AI; oncology; cancer care; patient-centered care; AI in health care; digital health; health equity; artificial intelligence

Introduction

Artificial intelligence (AI) has become increasingly embedded in medical practice over the past decade, enhancing care capabilities from the development of personalized health libraries and innovative patient education strategies to disease screening, diagnostics, and treatment planning [1-4]. These technologies are reshaping how care is accessed, delivered, and experienced. In oncology, AI models are being developed to standardize and improve the consistency and quality of care, offering new ways to support both clinicians and patients in navigating complex diagnostic and treatment pathways [5].

XSL•FO
RenderX

These technologies provide timely, accurate, and accessible information that can empower patients and caregivers, supporting engagement, comprehension, and autonomy throughout the cancer care continuum [6-8].

For example, AI has rapidly become a critical adjunct for medical image analytics, demonstrating that computer models can achieve state-of-the-art tumor detection, segmentation, extraction, and classification across a wide range of cancer types [9]. These advancements in AI in health care have improved diagnostic accuracy and enabled earlier cancer detection, allowing clinicians to initiate timely, evidence-based interventions. Beyond imaging, AI supports personalized oncology through predictive models that generate tailored treatment recommendations based on individual patient demographics, genomics, and clinical profiles [10]. These technologies have ushered in a new era of precision health and medicine [11], specifically impacting the field of oncology, informing care strategies that range from recurrence prediction and surgical planning to emotional assessment. By integrating psychosocial considerations into clinical decision-making, AI holds promise not only for improving treatment efficacy but also for enhancing overall quality of life [10]. This progress may help address systemic gaps in access to emotional support and culturally responsive communication, which have been long-standing public health challenges in cancer care.

However, despite these advances, the integration of AI into emotionally sensitive domains such as oncology introduces a new set of unresolved ethical, relational, and epistemological challenges [12]. The emotional toll of a cancer diagnosis underscores the critical need for empathetic care. Empathy, long considered a distinctly human element of care, has historically been difficult to replicate through technology. Yet recent advancements suggest that AI systems may approximate emotional attunement, recognize distress, and respond in ways perceived as empathic and compassionate [13]. In this context, empathic AI refers to technologies designed to detect and respond to users' emotional states to foster interactions that feel emotionally responsive and humanlike [13].

This review examines the role of empathic AI in cancer care, with a focus on its potential to enhance patient-centered, holistic treatment. We synthesize current advancements, challenges, and ethical considerations to inform the development of empathic AI systems that support both clinical effectiveness and emotionally responsive care. Given the distinct emotional, ethical, and communicative demands of oncology, this review underscores the need for a field-specific framework to guide the safe, equitable, and meaningful integration of empathic AI into cancer care delivery. From a public health perspective, thoughtful integration can inform scalable interventions, guide equitable policy design, and improve outcomes for historically underserved populations.

Methods

Search Strategy

The initial review of literature incorporated peer-reviewed studies that were identified on January 6, 2025, from PubMed, published between January 2018 and January 2025. This timeline was adopted to ensure that the review focuses on the most recent advancements and innovations in the use of empathic AI in cancer care as technological developments are rapidly evolving. Our search terms were used based on the thesaurus and keywords including AI, empathic, empathy, emotion, emotional intelligence, cancer, tumor, and oncology. Terms and keywords were combined to comprise search phrases, allowing for a more sensitive search. Search phrases included "artificial intelligence" OR "AI" AND "empathic" OR "empathy" OR "emotion" OR "emotional intelligence" AND "cancer" OR "oncology".

Following peer review, the search strategy was expanded to strengthen database scope. An updated search was conducted in Scopus and IEEE Xplore on January 1, 2026, using the same search terms and inclusion criteria, and newly identified studies were screened and extracted using the same procedures as the original search. Studies identified through the updated search were fully integrated into the descriptive and thematic analyses, and totals reflect the combined results of both search phases.

Eligibility Criteria

Studies were included for review if they met the following eligibility criteria: (1) published from January 2018 to January 2025, (2) explored the relationship between empathic AI and cancer care, and (3) available in the English language. Studies were excluded if they were not original research or were not peer-reviewed.

Study Selection, Data Extraction, and Analysis

The initial electronic database search yielded 78 results, which were collectively screened by 2 reviewers (GA and JZ) using the eligibility criteria. Following the abstract and full-text screening, 64 studies were eliminated because they did not meet the inclusion criteria. To expand the scope of relevant literature, a snowballing technique was used, where key studies identified during the initial search were used to trace additional sources through references and citations. This process led to the identification of 15 additional studies, enhancing the comprehensiveness of the review. A third reviewer (BW) verified the full set of included and excluded studies, cross-referencing decisions with the original criteria and extraction tables. Any uncertainties or inconsistencies were discussed collaboratively among the 3 reviewers to ensure a consistent and transparent review process. Study quality indicators (ie, peer-review status, study design, and sample size) were collected during data extraction to contextualize findings and mitigate potential sources of bias.

Terminology

Throughout this review, we use the term "empathic AI" as an umbrella descriptor for AI systems designed to recognize, respond to, or adapt to users' emotional states in health care contexts. Closely related terms such as empathetic AI or emotionally intelligent AI appear sparingly and only when reflecting terminology used in the source literature. These terms are treated as conceptually overlapping within this review, and their use does not imply substantive distinctions in system function or intent.

Results

Overview

As shown in Figure 1, a total of 44 studies met the inclusion criteria for review. Study characteristics are summarized in Table S1 in Multimedia Appendix 1 [14-57]. The included literature spans from June 2018 to January 2025, reflecting the evolution of empathic AI applications in cancer care over time. A synthesis of key applications, thematic domains, and representative findings across the included studies is shown in Table 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram of study selection process.

Table . Summary of key findings by clinical domain of empathic artificial intelligence in cancer care.

Domain	Key applications	Representative findings	Included references
Tailored communication and education	• Chatbots delivering emotionally calibrated, context-aware patient education • LLMs[a] and NLP[b] tools supporting empathic provider communication • Real-time summary tools and simulation-based training	• Improved patient comprehension, reduced distress, and greater engagement in care • Enhanced clinician ability to convey complex or difficult information empathetically • Reduced provider burnout and communication fatigue	[14-51]
Enhanced diagnostics and treatment planning	• Integration of clinical and emotional data for diagnostics and care planning • AI[c]-assisted screening, documentation, and decision-making • Tailored treatment strategies based on emotional state, literacy, preferences, and trust	• Increased diagnostic accuracy and efficiency • More personalized and emotionally attuned treatment plans • Improved adherence, patient satisfaction, and provider-patient trust	[17,18,20,22,23,25-27,31,34,37-43,45-47,50-54]
Emotional and psychosocial support	• NLP and affective computing to detect distress and offer emotional responses • Chatbots and support tools applying positive psychology principles • LLMs and cofacilitators offering caregiver guidance • VR[d] interventions and NLP tools for end-of-life discussions	• Reduced anxiety, isolation, and emotional distress in patients • Enhanced emotional support and resilience for caregivers • Improved mood, stress reduction, and support in palliative and end-of-life contexts	[14-17,19-36,38,39,41-51,53-56]

[a]LLMs: large language models.

[b]NLP: natural language processing.

[c]AI: artificial intelligence.

[d]VR: virtual reality.

Thematic analysis was conducted through a qualitative synthesis of the studies shown in Table S1 in Multimedia Appendix 1. Each paper was reviewed to extract key concepts, use cases, and reported outcomes relating to the application of empathic AI in cancer care. To organize these findings meaningfully, we used an inductive approach, identifying patterns that emerged directly from review of the data. These patterns were then organized into three overarching clinical domains: (1) tailored communication and education, (2) enhanced diagnostics and treatment planning, and (3) emotional and psychosocial support. The domains were refined iteratively as themes reoccurred across studies, allowing grouping of findings into categories that reflect the diverse roles of empathic AI in cancer care.

Tailored Communication and Education

Tailored communication and educational interventions emerged as a central theme across the majority of included studies, underscoring the potential of empathic AI to deliver information that is both clinically relevant and dynamically attuned to the emotional and cognitive needs of both patients and providers.

Tailored Patient Education

Empathic AI systems supporting personalized patient education were reported in 86% (38/44) of studies, highlighting growing adoption of these technologies to enhance informational access and emotional resonance in patient care. These tools tailor educational content to individual patient contexts, including diagnosis, treatment phase, emotional state, and cognitive load. Chatbots and AI cofacilitators were most often used to simplify complex medical concepts, offer condition-specific coping strategies, and reduce distress through emotionally calibrated messaging.

For example, Greer's *Vivibot* chatbot leveraged a positive psychology framework to support emotional regulation in young adult cancer survivors, resulting in reduced anxiety and high user satisfaction [14]. Studies by Leung et al [15,16] evaluated AI cofacilitators that adapted group-based educational content in real time based on participant mood and interaction dynamics, enhancing cohesion and engagement. Similarly, Chaix et al [17] and Siglen et al [18] reported that chatbot-delivered education improved adherence to treatment regimens and facilitated greater engagement in shared decision-making. By modifying tone,

XSL•FO
RenderX

language, and complexity in real time, AI tools improved patient comprehension and engagement.

Chen et al [19] evaluated the use of AI chatbots such as GPT-3.5, GPT-4, and Claude AI to generate high-quality, empathetic, and readable responses to cancer-related questions posed by patients on social media. The study found that AI-generated responses, particularly those from Claude AI, outperformed those from oncologists in terms of empathy, clarity, and emotional resonance, suggesting that AI chatbots can serve as effective tools for enhancing patient education and communication. Other studies specifically highlighted the role of empathic AI in expanding access to reliable, emotionally attuned health information among historically underserved or low-literacy populations [20,21]. These findings position AI as a tool to enhance patient education equity, particularly in contexts where human resources are limited, or in settings where patients may be hesitant to ask questions directly.

Recent studies further extend this work by demonstrating how generative AI tools tailor educational content based on patient demographics, clinical context, and informational needs, including evaluations of ChatGPT and other large language models (LLMs) responding to cancer-related questions and decision-making scenarios [22-25].

However, concerns about misinformation, cultural insensitivity, and overreliance on AI-generated outputs were raised across multiple studies [26-28]. These findings emphasize the importance of clinical oversight and algorithmic guardrails. Scalability and safety remain central to the integration of AI-mediated education in oncology as these tools move closer to frontline deployment.

Tailored Provider Education

Empathic AI was also used to support tailored provider education in 52% (23/44) of studies, reflecting a growing interest in leveraging AI to enhance clinical decision-making and support emotionally intelligent communication. These tools were positioned as cognitive extenders, offering context-specific recommendations on treatment protocols, synthesizing complex medical data, and facilitating more empathic responses during patient interactions. As 1 study highlighted, this may be particularly important in high-stress oncology settings for reducing clinician burnout and compassion fatigue [29].

Several studies examined the use of LLMs to help clinicians better understand caregiver perspectives, enabling the cocreation of more responsive group interventions [30,31]. Providers received AI-generated conversation summaries or context-sensitive prompts, which improved their ability to convey difficult information with empathy and precision. Others found that AI-generated patient-facing responses were rated significantly higher in quality, clarity, and empathy than those written by clinicians under time pressure, pointing to the potential of AI to support consistency in emotionally attuned communication [21,28,32]. One study comparing physician and AI chatbot responses with patient inquiries on social media found that AI replies were preferred 78.6% of the time [32].

Furthermore, De Silva et al [33] explored the use of machine learning and natural language processing (NLP) to analyze patient interactions in online cancer support groups. By identifying patient-reported behaviors, emotions, and treatment decisions, AI tools provided valuable insights into patient decision-making, emotional dynamics, and care preferences. The findings highlighted how AI-driven insights could help clinicians better understand behaviors, decisions, side effects, and emotional cues within support groups to derive actionable insights for patient-centered care. Recent work has also explored hybrid and simulation-based approaches, including live-chat models emphasizing digital clinical empathy [34] and virtual patient systems designed to train clinicians in empathic and end-of-life communication [35,36]. Other studies explored the use of empathic AI for real-time feedback and simulation-based training, with AI tools positioned not just as repositories of information but as companions in ethical and emotional reasoning [26,27].

These findings underscore the potential of AI to cultivate emotionally intelligent clinician communication. Nevertheless, integration challenges remain. Several studies raised concerns about how increasing reliance on AI may shift the balance between algorithmic input and clinical judgment, prompting debate about the potential erosion or recalibration of clinical intuition. While some view this shift as a loss, others argue that AI could enhance intuition by providing real-time feedback and mitigating cognitive biases [21,37]. Although AI may reduce cognitive load and offer scalable training solutions, its ability to cultivate true empathic capacity remains contested, which raises important questions for future research and professional development strategies.

Enhanced Diagnostics and Treatment Planning

The decision-making use of empathic AI in cancer care was explored across several areas, from diagnostics to care plan optimization. In total, 70% (31/44) of the included studies addressed the use of empathic AI in the clinical space, with approximately half examining both diagnostics and treatment planning. Studies in this theme revealed how AI systems are increasingly integrated into clinical decision-making, optimizing care goals and improving patient outcomes.

Diagnostics and Decision-Making Support

Empathic AI systems have been shown to support clinicians in making more accurate diagnoses and treatment decisions. Among the studies reviewed, 43% (19/44) discussed how AI is being used to aid in diagnostic reasoning and clinical interpretation. By integrating emotional intelligence with clinical data, these tools help enhance the accuracy of patient assessments, considering both clinical factors and the emotional context of the patient's situation. For example, ChatGPT has been used to assist in the interpretation of personalized breast cancer screening studies with 80% accuracy while reducing clinician workload by 70% [38]. Similarly, these algorithms have supported individualized radiation therapy dosage planning [39], enhancing diagnostic efficiency and precision in a patient-centered manner. While these applications are technically oriented, the authors emphasize that "using AI and combining it with human wisdom, empathy, and affection will be the method of choice for further fruitful development of tomorrow's

XSL•FO
RenderX

senology" [38], highlighting the envisioned role of empathy even within data-driven clinical tools [40,52].

Furthermore, NLP models have been used to analyze patients' decision-making behaviors and emotions [33,41], allowing clinicians to understand patients better and tailor their recommendations accordingly. When it comes to clinical documentation, AI-powered notes written by OpenAI's ChatGPT 3.5 and GPT 4.0 have been found to be more personalized and empathetic [42]. Together, these functions of AI platforms create not only a precise and tailored patient experience but also one that is more patient-specific. While AI integration into the clinical realm is in its infancy, it has a definite role in enhancing patient care delivery and optimization.

Care Plan Optimization

Several studies examined how AI-driven systems can optimize care plans by considering both medical and psychosocial factors. In total, 61% (27/44) of studies addressed how AI enhances patient-centered decisions and care. Specifically, these AI tools assist in tailoring treatment regimens that account for individual patient preferences and emotional well-being, ensuring a more holistic approach to cancer care. For example, AI models such as the Vik chatbot, designed to support patients with breast cancer[17], can personalize conversations and treatment recommendations based on a patient's literacy level and personal context. This helps patients make informed decisions and improves treatment adherence [57]. Others emphasize the influence of AI-generated guidance on treatment decision-making in advanced or complex cancer contexts, including variability in tone, content, and recommendations that may shape patient choices [22,52]. Furthermore, multiple studies examining chatbots showed that patients are capable of trusting machines [27], including the Rosa chatbot focused on breast cancer gene testing embedded into an app for patients with breast and ovarian cancer [18]. AI can, therefore, be used to detect distress and other emotions as shown by the results of using an AI-based therapy group cofacilitator [16], which allows physicians to tailor their patient-to-provider interactions accordingly, resulting in more patient-centered care. Through these functions, AI platforms foster stronger patient-provider relationships in the clinical landscape [43].

Studies included in this theme demonstrate that AI enhances patient-provider communication and real-time emotional support, leading to optimized care plans. Although concerns regarding machine privacy remain, these studies support the use of AI systems as copilots or cofacilitators in clinical decision-making to enhance the holistic work of physicians.

Emotional and Psychosocial Support

Another prominent theme in the studies was the emotional and psychosocial support that empathic AI can offer to both patients and caregivers. To underscore the importance and timeliness of this theme, the vast majority of studies (40/44, 91%) alluded to applications of the technology involving patient or caregiver emotional support. These AI systems are increasingly seen as tools for alleviating stress, providing reassurance, and offering emotional guidance during challenging cancer journeys.

Patient Emotional Support

Several studies focused on the ways empathic AI can provide emotional comfort to patients, offering them a sense of companionship and reducing feelings of isolation. A large majority of studies reviewed (40/44, 91%) highlighted the use of empathic AI in the service of patient emotional support. By using NLP and affective computing, AI systems were able to recognize and respond to emotional cues, providing timely encouragement or referrals to professional counseling services [53,54]. Likewise, Mårell-Olsson et al [44] demonstrated that socially intelligent agents can address nonmedical needs in pediatric populations by reducing feelings of isolation, supporting coping, and facilitating participation in daily activities.

The evaluation of the ability of various recently released AI chatbots to produce easily understandable, medically relevant, culturally appropriate, and empathetic responses to oncology patient queries was a key focus of many of the included studies [19,32,45,46]. While chatbots may be more easily applied to diagnostics, treatment, and monitoring [26], progress on interpersonal-type communications is being made, despite challenges noted on the algorithmic development side [45]. As a sign of how far these chatbots have come, one social media–based study found that nonhuman responses were rated higher on every measure by expert health care evaluators, including empathy and quality, and greatly preferred to the clinician responses [32]. Others further illustrate these applications through immersive and affect-aware interventions, including AI-driven virtual reality (VR) therapy for anxiety and depression [47,48] and sentiment-aware conversational agents designed to detect and respond to emotional distress [49].

In another notable example, the unique emotional needs of teen and young adult patients with cancer were addressed by the delivery of positive psychology skills via the Vivibot chatbot [14]. As this age group typically experiences heightened anxiety and depression posttreatment completion, this kind of intervention fills a previously unmet need [55].

Caregiver Support

Empathic AI also plays a critical role in supporting caregivers, who often experience high levels of stress and burnout. Unsurprisingly, 52% (23/44) of studies were also concerned with addressing aspects of caregiver emotional support. AI applications were found to offer tailored resources, emotional support, and coping strategies, helping caregivers manage their own well-being while supporting their loved ones through cancer care. For example, AI-based cofacilitators for online cancer support groups were shown to provide targeted emotional support for both patients and their caregivers in response to the detection of emotional distress [16]. Also, as patient care is a complex endeavor involving an interconnected team of clinicians, patients, and caregivers, the use of empathic AI chatbots can be at the center of an integrated and holistic approach to support [26,43,50]. Additional evidence highlights AI-supported environments that indirectly or explicitly assist caregivers through shared decision-making and emotional scaffolding, particularly in advanced cancer contexts [22,34].

XSL•FO
RenderX

Of particular interest is the potential of LLMs as providers of real-time, individually customized, and up-to-date medical information, with their concomitant risks and benefits, to allow for informed, complex, and empathic decision-making among caregivers for oncology patients [30]. A more speculative take on AI technologies in health care argues that the next step may well be social robots imbued with artificial empathy as the caregivers of the future [20]. Ultimately, any of these configurations may be thought of as hybrid intelligent human-AI care systems.

Palliative and End-of-Life Care

In palliative and end-of-life care settings, empathic AI has been particularly effective in providing compassionate communication and emotional support, with 30% (13/44) of studies referencing the use of AI in these contexts. These systems help both patients and health care providers navigate sensitive conversations, ensuring that care remains patient-centered and aligned with individual values during the final stages of life. For instance, the VR psychological support tool used in the SafeSpace study [51] sought to integrate guided relaxation exercises and compassionate mind training for oncology patients afflicted with a range of cancer types, including those under palliative care. Statistically significant improvements were found in the psychological measures of mood and emotional well-being, with overall reductions in stress levels demonstrated due to the safe and soothing environment simulated by the intervention. Simulated VR travel to memorable places was another unique application of empathic AI that boosted physiological and mental health outcomes, particularly depression and anxiety, for patients with terminal cancer[51]. Other researchers have used NLP approaches, such as analyzing emotion intensity or identifying psychosocial challenges, to address end-of-life discussions with patients with cancer and provide them with targeted resources specific to their stage of the cancer journey [22,24,35,36,41,56].

Discussion

Principal Findings

This review demonstrates that empathic AI is emerging as a powerful and transformative force within oncology, with broad clinical applications from education to diagnostics and treatment planning to emotional support. As such, empathic AI has the potential to enhance not only the efficacy and accuracy of care but also its psychosocial dimensions. We found that the majority of studies focused on patient support, with 85% (38/44) addressing tailored patient education and 91% (40/44) addressing patient emotional and psychosocial support. While less frequently represented, a subset of studies also explored applications in diagnostics and decision-making support (19/44, 43%) and palliative and end-of-life care (13/44, 30%), highlighting additional areas where empathic AI is beginning to gain traction. Across domains, evidence illustrates that AI systems are increasingly being used to address long-standing gaps in cancer care delivery. These technologies are reconfiguring traditional models of care into more adaptive, responsive, and patient-centered frameworks.

It is important to distinguish between human empathy and algorithmic or “simulated” empathy. While human empathy arises from lived experience, relational context, and moral judgment, empathic AI operates through pattern recognition, affective cue detection, and response optimization [58]. These systems do not “feel” empathy but rather approximate empathic behaviors through language, timing, and contextual sensitivity. This positions empathic AI to be understood not as a substitute for human connection but as a decision support and interaction support that may enhance communication, accessibility, and emotional scaffolding within clinician-led care.

A consistent theme throughout the examined literature is the redefinition of what it means to deliver holistic care. Empathic AI enables care that integrates clinical precision with personalized emotional support, bridging a gap that has long challenged providers operating under time and resource constraints. This convergence is particularly critical in oncology, where patients face complex treatment pathways intertwined with profound emotional and existential burdens. Across studies, LLMs and chatbot technologies were used to adapt educational content to user-specific contexts, including cancer type, treatment stage, emotional state, and cultural or linguistic preferences.

To bring these capabilities into everyday practice, clinicians can adopt empathic AI in targeted, workflow-compatible ways. For example, LLMs can be embedded into electronic health record systems to generate on-demand phrasing suggestions for emotionally sensitive conversations, such as treatment failure or end-of-life planning. Moreover, AI cofacilitators can personalize group therapy or education sessions in real time by responding to emotional cues. Additionally, sentiment analyses or AI-generated chat summaries can be used to brief providers ahead of visits, helping them tailor communication strategies to patient needs. AI’s ability to contextualize medical information, detect distress, and respond with calibrated empathy suggests that these systems can complement and bolster human care, particularly in emotionally charged settings such as diagnosis disclosure, palliative care, and end-of-life decision-making.

Evidence from this review further suggests that empathic performance in digital oncology settings is not solely a function of model sophistication but of interactional design and workflow integration. Studies measuring cancer-related live chat environments and simulation-based systems highlight that digital clinical empathy requires intentional strategies (ie, timely acknowledgment, authenticity, appropriate boundary setting, and contextual responsiveness) and may be best sustained through hybrid models that combine AI-enabled support with human oversight [34-36].

Moreover, the high levels of user satisfaction reported in interventions such as Vivibot [14], Vik [17], Rosa [18], and social media–based studies [19,32,57] underscore that patients are receptive to receiving education, treatment planning, and emotional support from AI systems. These findings raise important implications for the clinical role of AI in extending the reach and impact of human oncology care, rather than simply imitating it. Rather than merely mimicking human interaction,

XSL•FO
RenderX

empathic AI can help scale patient-centered care by offering timely, emotionally calibrated support, especially in scenarios where time constraints or emotional fatigue may limit provider capacity. Notably, findings from this review suggest that patients may sometimes prefer AI-generated responses over those from physicians when it comes to clarity, empathy, and accessibility [19,29,32]. Such findings challenge traditional assumptions about the limitations of machine-delivered care and suggest a potential reimagining of the therapeutic relationship. In oncology, clarity, emotional tone, and trust are particularly sensitive. For clinicians, this emerging preference signals an opportunity to align care delivery models with patient communication expectations. AI can serve as a buffer, or even a bridge, between emotionally overwhelmed patients and time-constrained providers. Empathic AI-mediated tools may help close gaps in emotional availability, ensure message consistency, and reduce the interpersonal strain that often accompanies sensitive care discussions.

Empathic AI also holds potential to reshape the patient-to-provider relationship. For patients, AI expands access to personalized education and emotional support, democratizing information and empowering users to take an active role in their treatment. This is especially significant for historically underserved populations or individuals with low health literacy, who may benefit most from scalable, emotionally attuned technologies. However, emerging evidence indicates that patient engagement with empathic AI tools is strongly shaped by trust, digital literacy, perceived usefulness, privacy concerns, and the extent to which AI systems are meaningfully connected to clinicians and care pathways. This highlights implementation success dependent as much on sociotechnical context as on model performance [25].

From a provider perspective, AI serves as both a diagnostic and treatment decision support system and a partner in empathic communication. AI-generated conversation summaries, real-time feedback, and emotion-sensitive prompts can enhance provider-patient dialogues and reduce burnout by offloading cognitive and emotional labor, such as the analysis of patient decision-making and emotions provided by the PRIME-2 (Patient Reported Information Multidimensional Exploration version 2) framework [46]. However, these benefits come with caution. The risk of overreliance on AI-generated outputs and the potential erosion of clinicians' empathic instincts raise critical concerns about long-term implications for professional development and patient trust.

Despite the promise of empathic AI, several challenges must be addressed before these systems can be safely and effectively deployed in clinical settings. The question of algorithmic empathy remains unresolved. Evidence suggests that generative AI responses to cancer-related decision-making scenarios may vary by patient demographics and clinical framing, with inconsistencies in tone, content, and guidance that could differentially influence patient perceptions and treatment decisions, underscoring the need for careful validation and health equity–focused oversight [22,24]. While AI can simulate or mimic affective responses and detect emotional cues, true empathic understanding rooted in shared experience remains uniquely human. As such, AI should be positioned as a decision support tool, not as a replacement for traditional, physician-led care. Overreliance on AI in emotionally sensitive encounters could lead to depersonalization or erosion of therapeutic rapport between patient and provider, particularly if patients perceive machine-generated responses as inauthentic or misaligned with their values.

Models trained on nonrepresentative data may also risk reinforcing racial, cultural, and linguistic biases, leading to emotionally inappropriate or even harmful interactions. In oncology, where communication must be attuned to cultural norms, family dynamics, and existential concerns, these missteps could carry particularly high stakes. Specifically, loss of trust in providers and institutions is detrimental to cancer care, as trust remains the foundation of health care in sensitive and difficult situations and among vulnerable populations. Safety is further complicated by the risk of misinformation or emotionally manipulative outputs. Moreover, sociocultural dynamics shape both the reception and use of empathic AI. Concepts of empathy, emotional expression, and caregiving may vary considerably across cultures; what is perceived as compassionate in one context may be viewed as intrusive or inappropriate in another. Developers must engage patients, caregivers, and clinicians from diverse backgrounds in early design to ensure cultural alignment and application for all populations.

Ensuring that AI systems provide reliable, culturally sensitive, and context-appropriate support will require robust algorithmic guardrails, clinician oversight, and rigorous validation. Without these safeguards, empathic AI may inadvertently exacerbate existing health disparities among marginalized populations already facing barriers to emotionally supportive care.

The findings of this review underscore the value of hybrid clinical care models, wherein humans and machines complement each other, termed human-AI symbiosis [39]. While empathic AI systems show promise in extending the reach of clinicians, personalizing education, and offering emotional scaffolding for patients and caregivers, their successful integration into clinical workflows remains dependent on several critical factors. Effective implementation will depend on careful design, robust training data, and a commitment to maintaining the human essence of medicine. Given the rapid pace of model development and evolving user expectations, adoption should proceed cautiously, with a focus on adaptability and long-term clinical usefulness. Moving forward, research must explore the longitudinal impacts of empathic AI interventions, develop integration frameworks grounded in ethical and cultural humility, and assess performance across diverse populations and care settings. Interdisciplinary collaboration will be essential to ensure that future systems are not only intelligent and accurate but also trustworthy, equitable, compassionate, and responsive to real-world clinical needs. To support practical interpretation, Table 2 summarizes key challenges associated with empathic AI in oncology alongside potential mitigation strategies identified across the included literature.

XSL•FO
RenderX

Table . Challenges, risks, and mitigation strategies for empathic artificial intelligence in cancer care.

Challenge	Description	Potential mitigation strategies
Algorithmic empathy versus human empathy	Empathic AI[a] systems simulate empathic behaviors through pattern recognition and affective cue detection but lack lived experience, moral reasoning, and relational accountability. This raises concerns about authenticity, depth, and appropriateness of emotional responses in sensitive oncology contexts.	Position empathic AI as decision support and interaction support rather than replacement for human care; embed clinician oversight and escalation pathways; and explicitly communicate AI's role and limitations to patients to preserve trust and relational integrity.
Reliability, trust, and interpretive risk	Empathic AI-generated responses may vary in tone, emotional sensitivity, or guidance depending on prompt structure, clinical framing, or patient demographics, potentially shaping patient perceptions, fostering over trust or skepticism, and influencing clinical decision-making.	Implement algorithmic guardrails and standardized response calibration; conduct bias and consistency audits across subgroups; intentionally design user interfaces to reinforce clinician accountability; use scenario-based validation prior to deployment in emotionally sensitive use cases; and provide clinician training on appropriate AI use.
Misinformation risk	Generative AI systems may produce fluent, confident, but clinically incorrect or incomplete responses, which can be particularly harmful in oncology decision-making and end-of-life contexts.	Maintain human-in-the-loop validation for high-stakes outputs; restrict autonomous response generation in diagnostic and treatment contexts; and integrate citation requirements, uncertainty signaling, and clinician review mechanisms.
Equity, bias, and cultural alignment	Training data may encode structural inequities or fail to account for cultural variation in emotional expression, caregiving norms, and communication styles, resulting in emotionally inappropriate or inequitable interactions.	Use participatory and co-design approaches with diverse patients, caregivers, and clinicians; prioritize inclusive datasets; localize language, tone, and interaction styles; and conduct ongoing health equity and subgroup performance audits.
Privacy, data governance, and emotional data sensitivity	Empathic AI systems often process highly sensitive emotional, psychosocial, and behavioral data, increasing risks related to privacy, consent, and secondary data use.	Establish robust data governance frameworks; apply privacy-by-design principles; ensure secure infrastructure and role-based access controls; and clarify consent processes for emotional and conversational data use.
Workflow integration and clinician burden	Poorly integrated AI tools may increase cognitive load, disrupt clinical workflows, or generate alert fatigue, undermining adoption and trust.	Design workflow-compatible tools aligned with clinical routines; pilot implementations in real-world settings; and iteratively refine systems based on clinician feedback and usability testing.

[a]AI: artificial intelligence.

Strengths and Limitations

This review offers a comprehensive analysis of empathic AI in cancer care, yet several limitations should be noted. First, this review included studies available only in English language, which may limit the generalizability of findings to global health care contexts. Cultural variations in emotional expression, communication styles, and attitudes toward AI are likely to influence both the development and reception of empathic AI systems. Furthermore, although a snowballing technique was used to enhance inclusivity, the reliance on peer-reviewed literature indexed in PubMed may have excluded relevant studies published in interdisciplinary journals, conference proceedings, or gray literature, particularly those from fields such as human-computer interaction or behavioral science.

Another limitation relates to the rapidly evolving nature of AI technologies. Given the pace of advancement in the field, some of the models and interventions included in this review may already be outdated or replaced by more sophisticated systems. While this pace of innovation reflects momentum in the field, it also complicates assessments of clinical readiness. Current tools may not yet meet the usability, safety, or integration standards required for large-scale adoption, underscoring the need for ongoing evaluation in real-world settings.

However, this fast-paced innovation can also be viewed as a strength, as the continual refinement of AI models suggests that future iterations will likely be more accurate, more empathetic, and better integrated into clinical workflows. By capturing a broad timeline of development from 2018 to early 2025, this review not only reflects the field's foundational growth but also establishes a baseline against which future progress can be measured.

It is also important to note that included studies were methodologically heterogeneous, encompassing diverse designs, populations, interventions, and outcome measures. The absence of standardized metrics for evaluating empathic performance limits direct comparison across studies, although this heterogeneity reflects the early and exploratory nature of the field.

Additionally, there was no standardized metric for evaluating "empathy" in AI-generated interactions across studies. This inconsistency complicates efforts to compare effectiveness across interventions. Some studies used patient satisfaction or

XSL•FO
RenderX

emotional resonance as proxies, while others relied on subjective expert evaluation. At the same time, emerging work in sentiment modeling and empathic conversational agent development suggests early methodological movement toward quantifying affective signals, although approaches remain heterogeneous and not yet clinically standardized [49,53,54]. Future research should focus on a shared operational definition of empathic AI performance to establish clear benchmarks for clinical implementation.

Public Health Implications

With careful design and oversight, empathic AI has the potential to advance public health by expanding access to emotionally responsive care and addressing structural gaps in patient-provider communication, trust, and psychosocial support. These technologies could help bridge long-standing inequities by reaching historically underserved populations facing linguistic, geographic, or cultural barriers to care. In resource-limited settings, empathic AI may also reduce clinician burden, promote continuity of care, and strengthen system resilience by extending the reach of essential health services.

In oncology, empathic AI platforms could deliver timely, culturally sensitive, and emotionally attuned support to help mitigate disparities in diagnosis, treatment adherence, and survivorship. By enhancing provider communication and tailoring care to diverse patient needs, these systems can counteract the effects of systemic bias and institutional mistrust. Integration into care settings may also enable early detection of patient distress and improve referral pathways to behavioral health and palliative services, offering a scalable means of bridging mental and physical care.

Implementation of empathic AI in low-resource or global health contexts may offer affordable, scalable strategies to support patient-centered cancer care where human capital is limited. As digital health infrastructure continues to evolve, empathic AI should be recognized not only as a clinical innovation but as a system-level tool for strengthening communication-centered models of care that foster patient engagement, empowerment, and trust. By capturing data on emotional needs, communication gaps, and engagement patterns, these tools may also inform more responsive, equity-driven public health surveillance and planning.

Conclusions

Empathic AI holds immense promise to revolutionize cancer care by enabling a more patient-centered, holistic, and emotionally sensitive approach. Oncology presents distinct emotional and ethical challenges, making it a uniquely high-stakes setting for the application of empathic AI. With thoughtful development and implementation, these tools can help close communication gaps, improve diagnostics and treatment decision-making, and support the emotional well-being of both patients and caregivers.

The creation of empathic AI–driven portals for patients and providers, for example, can improve engagement and satisfaction, expand access to culturally tailored education, and personalize treatment planning. These tools can and should be applied across the oncologic care continuum from identifying at-risk patients, to supporting treatment navigation and recovery, to helping patients and caregivers cope with the emotional burden of a cancer diagnosis. While this review highlights early promise and high user receptivity, clinical integration must be guided by rigorous validation, ethical oversight, and a deep understanding of real-world workflows and health system readiness.

Empathic AI should be viewed as an adjunct to human-centered care, not as a replacement for current practices and procedures. Clinicians must lead its implementation to ensure that empathy, trust, and clinical excellence remain central to oncologic practice. To support responsible adoption, health care systems should proactively invest in the infrastructure required to evaluate and scale these tools. Modular pilot programs such as leveraging LLMs to coauthor patient education materials, deploying chatbot cofacilitators in support groups, or using NLP tools to identify patients in emotional distress can help pave the way to widespread implementation. Other practical applications include automated phrasing assistance in clinical documentation, simulation-based training for difficult conversations, and tools to detect and mitigate caregiver burnout.

This review highlights the distinct value and complexity of applying empathic AI in oncology, where sensitivities differ markedly from other clinical contexts. The findings underscore the need for an oncology-specific framework that identifies key emotional touchpoints, proposes clinical use cases, and integrates safeguards to mitigate ethical and psychosocial risks. With continued advancement, empathic AI can help foster a health care environment that is both emotionally attuned and operationally efficient—particularly in cancer care, where emotional resonance and communication quality are as vital as clinical accuracy. The path forward requires rigorous validation, interdisciplinary collaboration, and an unwavering commitment to equity and patient voice. As we move toward the next generation of cancer care, the thoughtful integration of empathic AI offers an unprecedented opportunity to reimagine how we deliver care.

Abstract

Background: Endocrine therapy is a fundamental treatment for hormone receptor–positive breast cancer. However, treatment-related symptoms may lead to poor adherence and premature discontinuation, adversely affecting clinical outcomes. eHealth technology interventions have been widely applied as potential tools to support patient education, symptom management, and adherence.

Objective: This review aimed to evaluate the application, effectiveness, and limitations of eHealth technologies in symptom management among patients with breast cancer undergoing endocrine therapy.

Methods: A systematic literature search was conducted across 9 databases, including MEDLINE Complete, Academic Search Complete, PubMed, and CINAHL Ultimate, covering studies published between February 2015 and February 2025. Keywords included “breast cancer,” “endocrine therapy,” and “ehealth,” along with synonyms and related terms. Eligible studies examined the use of eHealth interventions in patients with breast cancer undergoing endocrine therapy. From 1352 records, 30 (2.2%) studies were included after screening and full-text review.

Results: The 30 included studies comprised 13 (43.3%) randomized controlled trials, 7 (23.3%) single-arm studies, 3 (10%) retrospective analyses, 2 (6.7%) observational studies, 3 (10%) mixed methods studies, and 2 (6.7%) qualitative studies. eHealth interventions, primarily mobile apps, telemonitoring systems, and SMS text messaging, demonstrated benefits in short-term symptom management, such as reductions in hot flashes, joint pain, anxiety, and sexual distress and improved medication adherence. However, evidence regarding long-term adherence and quality of life outcomes remains inconsistent. Considerable heterogeneity existed in study designs, adherence measures, and intervention components. Nurses were considered key contributors in implementing and monitoring eHealth interventions.

Conclusions: eHealth interventions show promise in improving symptom management and short-term adherence among patients with breast cancer receiving endocrine therapy. Methodological limitations and variability across studies restrict the strength of conclusions. Future research should prioritize long-term outcomes, standardized measures, and integration into routine clinical practice while incorporating perspectives from multiple stakeholders.

(JMIR Cancer 2026;12:e92030) doi:10.2196/92030

KEYWORDS

eHealth; endocrine therapy; symptom management; Preferred Reporting Items for Systematic Reviews and Meta-Analyses; PRISMA; patient with breast cancer

Introduction

Breast cancer is heterogeneous, with approximately 80% of cases classified as hormone receptor positive [1,2]. Adjuvant endocrine therapy (AET), primarily selective estrogenic receptor modulators and aromatase inhibitors, is a standard treatment for patients that significantly reduces the risk of recurrence and mortality [3-5]. Clinical guidelines recommend 5 to 10 years of AET [6-8]. Despite its clinical benefits, adherence to endocrine therapy remains suboptimal. Studies indicate that up to one-third of patients discontinue treatment within 5 years, often due to treatment-related adverse effects, inadequate information, comorbidities, or patient preferences [9,10]. Common adverse effects include hot flashes, joint pain, osteoporosis, sexual dysfunction, weight gain, sleep disturbances, depression, anxiety, and cognitive impairment [6,11]. These symptoms can impair quality of life (QOL) and contribute to nonadherence, ultimately affecting prognosis [12].

XSL•FO
RenderX

Therefore, effective symptom management is critical for improving adherence and clinical outcomes.

The World Health Organization has introduced the Global Strategy on Digital Health, emphasizing the integration of information and communications technologies to improve health outcomes [13]. In this review, eHealth refers to the use of digital tools such as mobile apps, SMS text messaging, telemedicine platforms, web-based portals, wearable devices, and electronic patient-reported outcome systems for real-time symptom monitoring, medication reminders, patient education, automated alerts, and remote self-management support [14]. Over the last 2 decades, eHealth has been increasingly used to support symptom monitoring, patient education, and remote care delivery [15]. Previous research has demonstrated the value of eHealth in chronic disease and cancer management, including symptom tracking, adherence support, and self-management [16,17].

Patients with breast cancer have used eHealth technologies for issues such as pain, sleep disorders, lymphedema, psychological distress, and chemotherapy side effects [18-22]. However, no comprehensive scoping review has synthesized evidence specifically on eHealth applications for symptom management during endocrine therapy. This review addresses that gap by evaluating the current evidence on effectiveness, strengths, limitations, and implementation considerations to inform clinical practice.

Methods

Search Strategy

This review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Checklist 1) to ensure thorough search quality and standardized processes [23,24]. Nine databases were searched: MEDLINE Complete, Academic Search Complete, CINAHL Ultimate, Health Source: Nursing/Academic Edition, APA PsycInfo, PubMed, Scopus, Embase, and Web of Science. The search used combinations of terms for “breast cancer,” “endocrine therapy,” and “eHealth” supplemented with synonyms, academic terms, abbreviations, and related terminology. Boolean operators (“AND” and “OR”) were applied to combine terms for search strategy construction systematically. Limits included English-language, peer-reviewed articles focusing on the application of eHealth in breast cancer and published between February 2015 and February 2025. The full search strategy is detailed in Table 1.

Table . Summary of the search strategy for the literature review.

Domain	Description
Search keywords	
Breast cancer	“Breast Neoplasms” OR “Breast Tumor,” OR “Breast Cancer” OR “Mammary Cancer” OR “Malignant Neoplasm of Breast” OR “Breast Malignant Neoplasm” OR “Malignant Tumor of Breast” OR “Breast Malignant Tumor” OR “Cancer of Breast OR Mammary Carcinoma, Human” OR “Human Mammary Neoplasms”
Endocrine therapy	“endocrine therapy” OR “endocrine treatment” OR “aet” OR “hormone therapy”
eHealth	ehealth OR e-health OR telecare OR telemedicine OR telehealth OR “digital health” OR mHealth OR teletherapy OR “smartphone App” OR “smartphone application” OR “health apps” OR “remote monitoring” OR “mobile app” OR “mobile application” OR “wearable devices” OR telemedicine OR tele-care OR telecare OR “Medicine, Virtua” OR “Tele Referral” OR tele-referrals OR tele-referral OR “Virtual Medicine” OR “Health, Mobile” OR “Mobile Health” OR telehealth OR “Electronic App” OR “Electronic Application” OR “Application, Mobile” OR “mobile phone” OR “smartphone” OR “text-, electronic-“ OR “multimedia-message” OR “electronic mail” OR “phone applications” OR “computer” OR “podcast” OR “videos” OR “internet” OR “website” OR “chatroom” OR “message board” OR “activity tracker” OR “electronic health” OR “mobile health” OR “telemedicine”
Other search parameters	
Search limits	2015-2025
Type of material searched	English-language peer-reviewed scholarly articles
Databases searched	EBSCOhost databases (Academic Search Complete, Health Source: Nursing/Academic Edition, CINAHL Ultimate, MEDLINE Complete, and APA PsycInfo), PubMed, Scopus, Web of Science, and Embase

Eligibility Criteria

Studies were eligible for inclusion if they were empirical research articles that examined the application of eHealth interventions specifically for symptom management or related outcomes, including medication adherence and QOL, among patients with breast cancer undergoing endocrine therapy in either the early or advanced disease stages. Exclusion criteria

XSL•FO
RenderX

included animal studies, research protocols, review articles, conference abstracts, non–English-language publications, and studies that focused exclusively on other cancer treatments rather than endocrine therapy.

Study Selection and Data Extraction

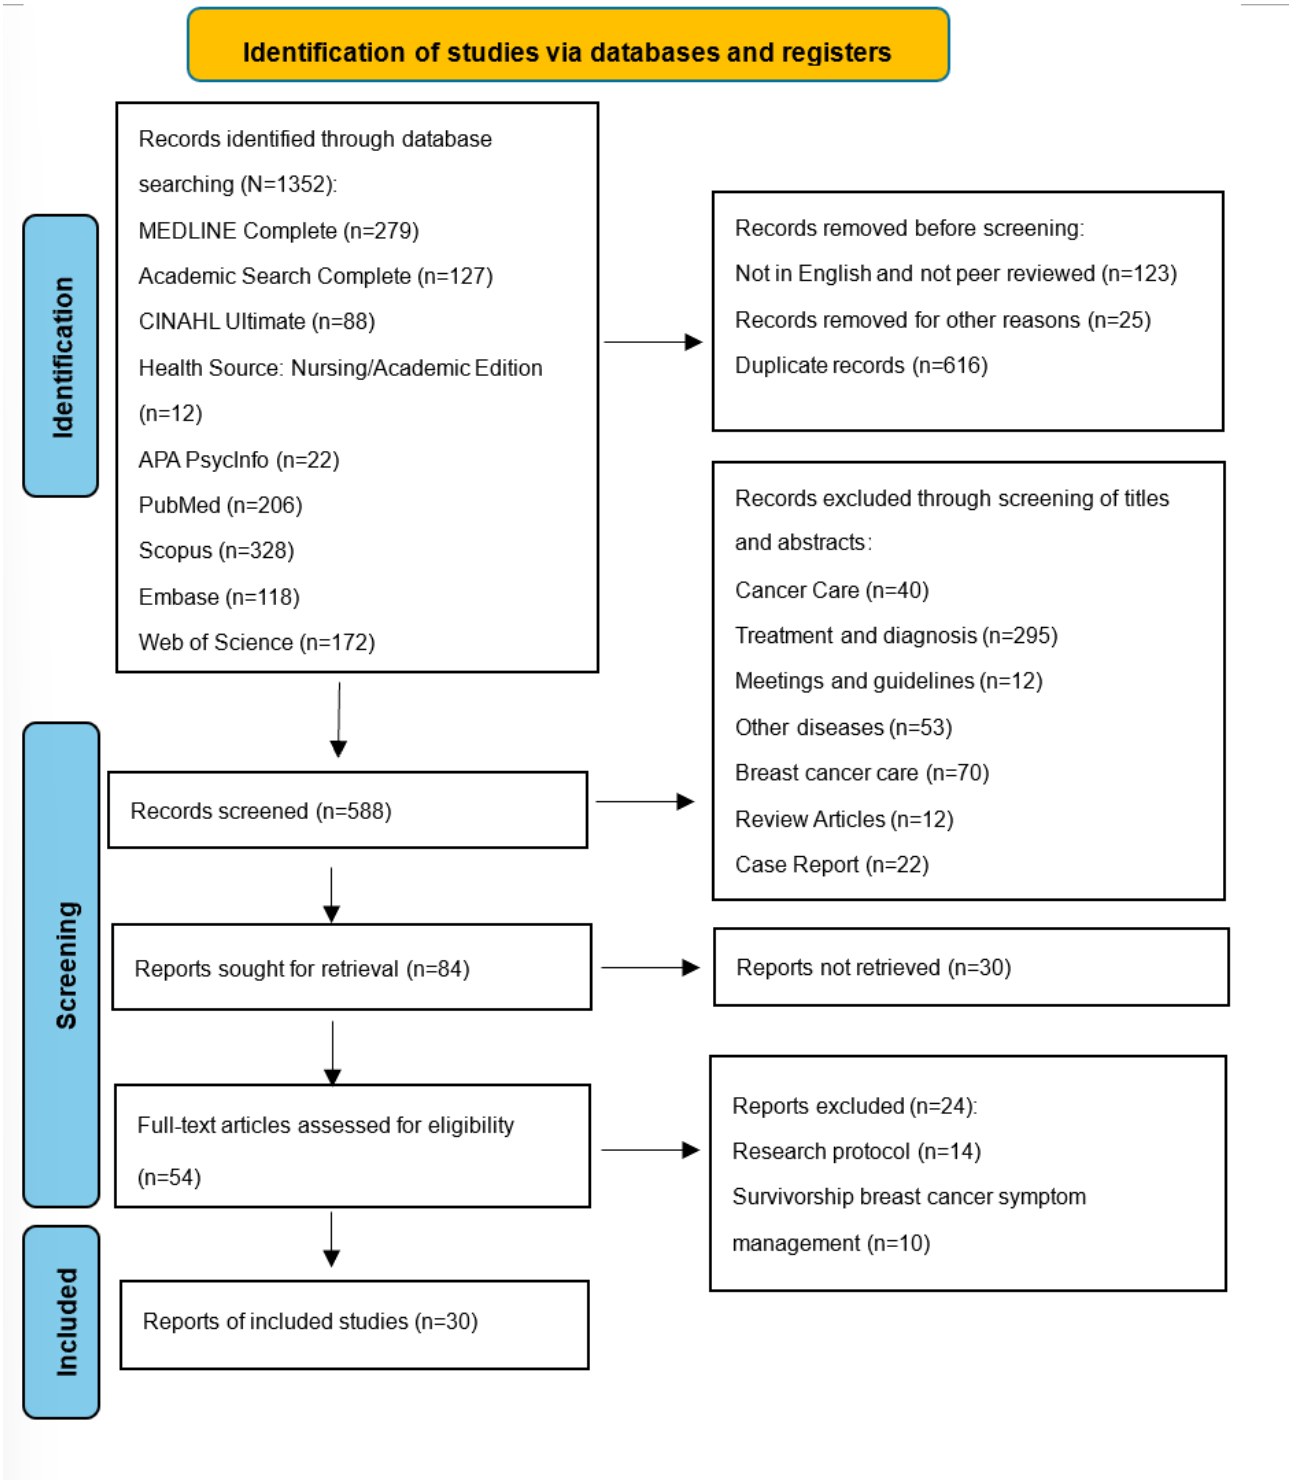
A total of 1352 records were retrieved from the 9 databases, and 148 (10.9%) were removed based on the predefined inclusion and exclusion criteria. The remaining 1204 records were imported into the Zotero software (version 7; Corporation for Digital Scholarship), where 616 (51.2%) duplicates were removed. Among the remaining 588 records, title and abstract screening resulted in the exclusion of 504 (85.7%) studies, primarily due to irrelevant populations (non–breast cancer or non–endocrine therapy; n=295, 58.5%), irrelevant focus (chemotherapy only, screening, or survivorship care without endocrine therapy; n=110, 21.8%), nonempirical content (reviews, protocols, and abstracts; n=59, 11.7%), or focus on other diseases (n=40, 7.9%). Subsequently, of the remaining 84 records, 30 (35.7%) were excluded because the full texts could not be retrieved. Full-text assessment was then performed on the remaining 54 articles, of which 24 (44.4%) were excluded because they described only study protocols or were conducted on survivors of breast cancer without a specific focus on endocrine therapy. Ultimately, 30 articles met all eligibility criteria and were included in this review (see Table S1 in Multimedia Appendix 1 [25-54] for details). Data extracted included study design, participant characteristics, intervention details, outcomes (symptom management, adherence, QOL, and patient experiences), and key findings.

Risk-of-Bias Assessment

Two oncology nurse researchers assessed the risk of bias in randomized controlled trials (RCTs) using the Cochrane risk-of-bias tool independently [55]. Discrepancies, if any, were resolved by a third reviewer. Due to heterogeneity in designs, interventions, and outcome measures, no meta-analysis was performed. The Critical Appraisal Skills Programme checklists were used to evaluate methodological quality across study types [56].

Data Synthesis

Findings were synthesized thematically into three main aspects: (1) effectiveness and limitations of eHealth for symptom management and adherence, (2) the role of nurses, and (3) patient experiences and impact on QOL.



Results

Overview

The 30 selected studies included 13 (43.3%) RCTs, 7 (23.3%) single-arm studies, 3 (10%) retrospective analyses, 2 (6.7%) observational studies, 3 (10%) mixed methods studies, and 2 (6.7%) qualitative studies. Most studies (n=17, 56.7%) were conducted in the United States, followed by Sweden (n=3, 10%); Japan and the United Kingdom (n=2, 6.7% each); and Germany, Turkey, Singapore, South Korea, and China (n=1, 3.3% each). Three key themes emerged from the review: (1) effectiveness and limitations regarding symptom management and adherence to endocrine therapy, (2) nurses' role in eHealth interventions, and (3) experiences of patients with breast cancer with eHealth tools and the impact on QOL. The PRISMA flow diagram is presented in Figure 1.

Effectiveness and Limitations of eHealth in Symptom Management

eHealth interventions, including mobile apps, telemonitoring, and SMS text messaging, facilitated timely self-reporting of symptoms and triggered alerts for health care providers. In total, 10% (3/10) of the studies allowed patients to self-report and record symptoms using mobile apps [29-31], whereas another 13.3% (4/30) of the studies used questionnaires to record patients' symptoms [32-35], allowing for real-time data capture and proactive management.

A total of 20% (6/30) of the studies reported positive effects on symptom control using eHealth [36-41]. One RCT combining an educational website with telephone counseling significantly reduced sexual difficulties, distress, and anxiety compared with usual care [36]. Another RCT using a mobile education program with nurse reminders improved physical well-being, pain, emotional functioning, and endocrine-related symptoms at 3 months [57]. Teleconferencing interventions in 2 RCTs enhanced self-efficacy and reduced hot flashes and depression [41,42]. A longitudinal study of remote tai chi sessions via an app demonstrated reductions in joint pain, anxiety, and hot

XSL•FO
RenderX

flashes after 12 weeks [38]. An app-based intervention in advanced endocrine treatment improved arm symptoms, cognitive function, anxiety, and depression [39]. The mobile app integrated daily exercise logging, medication adherence tracking, Fitbit activity data synchronization, personalized goal setting, educational modules on hormonal therapy side effects, and weekly progress visualizations, with automated feedback and nurse coach messaging. These eHealth tools enabled more accurate and timely symptom tracking, supporting personalized care plans and reducing symptom burden in the short term (typically 1 to 6 months) [29,31,35,42]. However, most studies focused on short-term outcomes and specific subgroups, such as patients with poor AET adherence [41], recent sexual activity [36], or aromatase inhibitor–induced arthralgia [38], limiting the generalizability of the findings. Patients with breast cancer on endocrine therapy often experience complex, interacting symptom clusters [22]; few interventions (1/30, 3.3%) addressed this holistically.

Medication Adherence

Medication adherence is commonly defined as taking medication as prescribed; nonadherence includes delays, dose deviations, or premature discontinuation [58]. Previous studies have shown that eHealth interventions have a significant impact on medication adherence in patients with chronic diseases and those taking medication for mental health conditions [59-61]. Medication adherence is addressed solely in relation to its direct correlation with effective symptom management; premature discontinuation is a subsequent result of inadequately controlled symptoms. Therefore, studies showing improved adherence were interpreted strictly as evidence of effective symptom control rather than as a separate end point.

Retrospective studies indicated 5-year adherence rates of 48% to 53%, primarily due to adverse events and symptoms [43-45]. Access to practical information, active monitoring of side effects, and effective medication reminders have been suggested to improve adherence [62]. A total of 16.7% (5/30) of the studies found that digital health tools, including SMS text messages, mobile apps, and emails, that incorporated symptom education, self-monitoring, and alerts, improved medication adherence [31,32,34,46,47]. Another 16.7% (5/30) of the studies reported benefits from reminder-based educational interventions [30,39,48,49]. However, other studies reported inconsistent results. In total, 15.4% (2/13) of the RCTs with 1- and 3-year follow-ups on SMS text messaging found no significant differences in adherence [33,50]. One retrospective study with telephone follow-up showed no long-term benefit [45], and one RCT on a mobile program reported no improvement despite educational modules [40]. Medication adherence was measured across several aspects: prescription fill rates of more than 80% [32,39], self-reports [31], estrogen level monitoring, and discontinuation rates (Table 2). The heterogeneity in measures and data collection and analysis methods contributed to variability in the findings. Improvements were mainly evident in short-term studies; long-term data remain limited, highlighting the need for sustained interventions.

Nurses' Role in eHealth for Symptom Management

Nurses were the primary implementers in most interventions, leveraging eHealth to enable real-time symptom assessment, 2-way communication, prioritization of high-risk cases, and referrals [63-66]. A total of 13.3% (4/30) of the studies found that nurses enabled 2-way communication and referral by prioritizing high-risk symptoms [32,34,40,47]. Nurses sharing information through eHealth tools could improve both patient satisfaction and the quality of care [52,53]. Nurses delivered education via SMS text messages, app modules, and teleconferences, enhancing patients' self-management skills and symptom control [29,33,37,41,67]. Moreover, the included interventions used dynamic, standardized, and structured assessments of both cognitive and somatic symptoms, which new data indicate are superior to conventional static questionnaires for earlier detection of clinically relevant changes and timely intervention [67].

Nurse involvement improved care efficiency, multidisciplinary collaboration, and resource use [68-70]. In total, 10% (3/30) of the studies, which were nurse led, showed that nurse-led approaches improved high-quality health care and reduced high-cost contacts and outpatient visits [46,47,53]. However, challenges included increased workload, role ambiguity, and the need for process adaptation [69,71]. Most evidence reflects patient perspectives; fewer studies (2/30, 6.7%) examined nurses' or physicians' acceptance and barriers. Cost-effectiveness evaluations were largely absent, underscoring the need for health economic analyses.

XSL•FO
RenderX

Patients' Experiences With eHealth Tools and the Impact on QOL

In this review, patients generally expressed high satisfaction and acceptance of SMS text message reminders [32,50], teleconferencing [37], and mobile apps [29,54], citing ease of use, helpful information, and improved self-management (satisfaction often of >90%). Combined tools such as videoconferencing applications and wearables further enhanced satisfaction, and many patients were willing to continue using them [38,47,62]. A total of 20% (6/30) of the studies examined QOL impacts. Four of these studies reported significant improvements in various domains such as physical, emotional, or endocrine-specific typically after 1 to 6 months of using eHealth tools such as mobile apps with reminders or tele-education [31,39,51,52]. One study providing tele-education showed significant improvements in patients' QOL after a 3-month intervention [52]. Another study used a teleconference education format and demonstrated significant improvement in patients' QOL after 24 weeks of intervention [51]. However, 2 RCTs found no significant differences in QOL: one study implemented a mobile app with SMS text message reminders and follow-up assessments at 6 and 12 months [40], whereas the other integrated the app with a patient e-reporting intervention and assessed QOL at 3 months after the intervention [35].

Heterogeneity and variations in QOL study results likely stem from differences in QOL instruments [31,35,37,39,40] (Table 3). Various QOL measurement scales may yield different results when evaluating due to differences in study design, cultural appropriateness, and assessment dimensions [72-74]. The assessment of QOL in survivors of breast cancer requires a multidimensional approach encompassing physical, psychological, social, and spiritual well-being, indicating that the use of a single assessment tool may not fully capture the heterogeneity in their QOL trajectories [75]. This review found that eHealth interventions effectively improved patients' QOL in the short term. However, the long-term effects and trends for patients with breast cancer undergoing endocrine treatment remain to be thoroughly researched and explored.

Table . Summary of questionnaires assessing quality of life (QOL) in the literature review.

[c]EORTC QLQ-BR23: European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire–Breast Cancer Module.

[d]FACT-B: Functional Assessment of Cancer Therapy–Breast.

However, several limitations remain in sample selection when examining patients' experience with eHealth interventions. In terms of sample inclusion, the mixed methods study by Jacobs et al [37] of patients with high levels of anxiety involved

XSL•FO
RenderX

predominantly White patients with high symptom burden. Additionally, the single-arm study by Gomaa et al [38] only included patients who reported joint pain. Some studies (4/30, 13.3%) predominantly selected patients who were younger, White individuals, more educated, and economically privileged [32,38,40,47]. In terms of sample size, 2 mixed methods studies and 1 single-arm study lacked a control group. They had small sample sizes of 15 [29], 10 [54], and 39 [47]. Furthermore, several studies with low response rates (3/30, 10%) were noted [46,52,53]. The main reasons for this problem included lack of personalized interventions, poor user interface design, time constraints, technical difficulties, and privacy issues [32,47,49]. Therefore, the characteristics of nonresponding patients and patients who declined to be enrolled may introduce selection bias.

Discussion

Principal Findings

This is the first scoping review to synthesize evidence on eHealth applications specifically for symptom management in patients with breast cancer undergoing endocrine therapy, incorporating effectiveness, adherence, nurse roles, patient experience, and QOL. Interventions varied (mobile apps: 8/30, 26.7%; SMS text messaging: 5/30, 16.7%; telemedicine: 6/30, 20%; online portals: 3/30, 10%; hybrid electronic patient-reported outcomes+wearables: 2/30, 6.7%; remote tai chi: 1/30, 3.3%) but shared fundamental features: real-time data capture, threshold-triggered alerts, and remote feedback. Short-term benefits for symptom burden were consistent across app- and telemedicine-based approaches, although direct comparisons were limited. This comprehensive perspective not only facilitates an in-depth understanding of the mechanisms and actual effects of eHealth interventions but also provides valuable reference information for future clinical practice and research.

This review demonstrated eHealth's efficacy in symptom monitoring and short-term management, with some positive effects on psychological symptoms and potential indirect benefits for adherence. However, many studies of symptom monitoring and management (4/30, 13.3%) applied single-arm designs with short follow-up periods, and adherence outcomes relied heavily on self-report, introducing bias [30-32,39]. The RCTs included in this review often lacked blinding, and interventions frequently targeted single symptoms or specific subgroups, overlooking complex symptom clusters and socioeconomic factors [33,40,47,48,50]. Nevertheless, this review found that eHealth interventions could improve patients' medication adherence and short-term symptom management. However, current research relies heavily on one-sided quantitative data from patients while neglecting to assess the early warning systems of physicians and nurses.

This review revealed that nurses played a pivotal role in implementation, education, and coordination, contributing to efficiency and patient engagement. However, challenges such as workload, role clarity, and limited exploration of health care providers' perspectives persist. Patient experiences were largely positive with high satisfaction, but generalizability is constrained by limited studies and equipment requirement issues [76,77]. QOL improvements were evident in the short term but inconsistent in the long term, partly due to measurement heterogeneity. In addition, most existing studies have examined the roles and functions of physicians and nurses in eHealth interventions primarily from the patient's perspective. However, as the primary implementers of these technologies, health care providers' own acceptance of eHealth tools and the barriers they encounter in daily practice remain underexplored.

This review indicates that eHealth interventions are generally associated with favorable patient experiences, high uptake rates, and positive short-term effects on QOL among patients with breast cancer receiving endocrine therapy. Prior literature similarly underscores this population's expressed need for digital support. Nevertheless, several limitations constrain the generalizability of these findings. Many quantitative studies (4/30, 16.6%) featured small, relatively homogeneous samples, often restricted to participants with the necessary devices and digital access [31,38,39,49]. Low response rates to eHealth applications in some studies (6/30, 20%) further restricted applicability across diverse populations. These issues can hinder timely symptom detection and intervention for certain patient groups. Moreover, few studies have thoroughly explored patients' specific needs in terms of tool design, particularly with respect to cultural adaptability.

The strengths of this review lie in its comprehensive literature search and the inclusion of diverse study designs, including RCTs, single-arm studies, retrospective analyses, observational studies, mixed methods studies, and qualitative research. Quality appraisal was conducted using the Critical Appraisal Skills Programme checklists, and the complementary nature of these methodologies, where RCTs help establish causality and qualitative studies provide rich insights into patient experiences, enhances the overall credibility of the synthesis. However, notable limitations were evident in the primary studies. Most (23/30, 76.6%) lacked adequate sample diversity and representativeness. In addition, the evidence base was heavily skewed toward high-income countries, with minimal data from low- and middle-income settings or rural areas, thereby limiting global applicability and scalability. Although the use of theories, models, and frameworks has been shown to strengthen the scientific rigor and explanatory depth of digital health research [78], only 13.3% (4/30) of the studies in this review were explicitly guided by such frameworks. Furthermore, most of the included RCTs (10/13, 76.9%) lacked blinding of participants or researchers, and 26.7% (8/30) of the studies used single-arm designs without control groups, both of which increase the risk of bias and reduce the robustness of the findings. In addition, the search period ended in February 2025, which may have omitted more recent high-impact publications. The restriction to English-language peer-reviewed articles may also have excluded relevant studies published in other languages. Despite these constraints, eHealth interventions demonstrate considerable potential to reduce symptom burden and improve adherence during endocrine therapy. Future research should prioritize long-term efficacy, greater equity in access, multi-stakeholder perspectives, and integration into routine

XSL•FO
RenderX

oncology workflows to maximize real-world impact and sustainability.

Conclusions

eHealth interventions offer promising support for symptom management and short-term adherence among patients with breast cancer receiving endocrine therapy, with generally high patient acceptance. Nurses are central to successful implementation. However, evidence is limited by methodological heterogeneity, short follow-ups, inconsistent long-term outcomes, and a lack of diversity. By addressing individualized patient needs and incorporating experiences from multiple stakeholders (patients, physicians, and nurses), eHealth tools can be optimized to reduce symptom burden, improve adherence, and enhance clinical outcomes. Future studies should prioritize rigorous designs, standardized measures, long-term follow-up, and equitable implementation to realize the full potential of digital health in oncology care.

Abstract

Background: Large language model (LLM)–based conversational agents are increasingly used in health care, yet their capacity to support genuine multiturn dialogue remains underexplored. In oncology, where patients and caregivers experience complex informational and emotional needs throughout the disease trajectory, conversational agents may support information provision, symptom consultation, and emotional assistance. However, research specifically examining multiturn conversational agents designed for patients with cancer and informal caregivers remains limited.

Objective: This scoping review aimed to map the research landscape of LLM-based multiturn conversational chatbots developed for patients with cancer and informal caregivers, focusing on system design, intervention purposes, evaluation approaches, safety considerations, and transparency of LLM-related components.

Methods: This scoping review followed the Joanna Briggs Institute methodology and PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines. Six databases—PubMed, Embase, Scopus, Web of Science, CINAHL, and PsycINFO—were searched for studies published between January 2022 and January 2026, with supplementary searches conducted in IEEE Xplore Digital Library and ACM Digital Library in May 2026. Studies were included if they described LLM-based chatbots designed for patients with cancer or informal caregivers that supported multiturn conversational interaction. Two reviewers independently conducted the study selection and data extraction.

Results: Eight studies met the inclusion criteria. Most studies focused on prototype development, with limited research evaluating clinical outcomes. ChatGPT-based models were the most commonly used LLMs, and retrieval-augmented generation techniques were applied in several studies. Chatbots were primarily designed for emotional support or information provision. Evaluation approaches varied widely, including response quality, psychological outcomes, and user experience. However, no studies evaluated interaction-level characteristics such as conversational continuity or context retention, and only 2 studies reported any conversational memory mechanism. Reporting on safety risks, mitigation strategies, prompt design, model parameters, and adherence to LLM reporting guidelines was often limited or absent.

Conclusions: This scoping review identified only 8 studies on LLM-based multiturn conversational chatbots for patients with cancer and informal caregivers. The field remains at an early stage, characterized by prototype-oriented development, heterogeneous design and evaluation approaches, and inconsistent safety and transparency reporting. Future development should prioritize genuine conversational capability, safety management, and transparent reporting.

KEYWORDS

chatbot; large language model; LLM chatbot; conversational agent; artificial intelligence; generative artificial intelligence; generative AI chatbot; cancer; neoplasms

Introduction

Large language models (LLMs) represent an advanced subset of natural language processing (NLP), capable of generating contextually appropriate responses through probabilistic text generation [1]. Chatbots using LLMs can generate responses in multiturn interactions while maintaining context, without relying on predefined rules or response scenarios [2,3]. Such capability distinguishes them from traditional rule-based NLP-based chatbots, revealing fundamental differences in design principles and conversational approaches [4,5]. This generative nature, however, introduces novel risk structures that are more pronounced than those in rule-based NLP systems [6,7].

XSL•FO
RenderX

Following the proliferation of LLMs, LLM-based conversational agents for diverse purposes—such as patient education, symptom consultation, emotional support, and treatment decision-making assistance—are rapidly emerging in the medical field, with accumulating evaluation studies [8]. In mental health and chronic disease management, LLM-based conversational agents have increasingly been developed to improve patient outcomes, demonstrating clinical benefits across conditions including depression, anxiety, eating disorders, and diabetes [9-11].

In oncology, where information needs and uncertainty are high during diagnosis and treatment, the potential application of LLM-based conversational agents is gaining attention [12,13]. For patients with cancer and informal caregivers, whose communication, informational, and emotional needs evolve throughout the disease course, multiturn interactions are a critical characteristic necessitating treatment as an independent analytical category [14,15]. Chatbot studies applying diverse LLMs, such as ChatGPT, are rapidly proliferating in this context, alongside advances in development frameworks including retrieval-augmented generation (RAG), knowledge graphs, and LangChain. However, existing literature tends to focus on performance comparisons at the single-turn question-answer level, making it difficult to distinguish and understand the design and evaluation characteristics specific to patient-directed conversational agents [16].

Multiturn conversational interaction refers to systems that maintain context by integrating the current message and previous conversation history when generating responses [17,18]. Yet, in LLM-based conversational agents for patients with cancer or informal caregivers, multiturn capability is rarely evaluated or explicitly implemented in practice, despite being considered inherent to conversational agents.

Simultaneously, LLMs carry safety risks, including hallucinations and responses that may pose psychological risks to vulnerable patients [6,7,19]. Although expert oversight and escalation systems have been suggested as mitigation strategies, systematic reporting of safety risks and mitigation approaches in LLM-based oncology chatbot studies remains limited.

Furthermore, if reporting on LLM-specific components—such as prompts, model settings, and external knowledge integration methods—is insufficient, reproducibility and interpretability may be limited [20]. Reporting guidelines, such as TRIPOD-LLM (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis–Large Language Models) and CHART (Chatbot Assessment Reporting Tool), have been developed to address this concern [21,22]; however, the extent to which LLM-based chatbot studies in oncology adhere to these guidelines remains unclear.

Several reviews have examined related topics in oncology. Wang et al [23] focused primarily on rule-based systems predating the LLM era. Chen et al [24] evaluated the medical accuracy of LLM-based chatbots in oncology across diagnostic and management tasks, but centered on single-turn performance rather than patient-facing conversational interaction. Jiang et al [25] synthesized conversational agent interventions in cancer care without restricting to LLM-based systems, identifying LLMs as a key emerging technology to enhance personalization and sustained engagement. To our knowledge, none of these reviews specifically examined the unique characteristics of LLM-based chatbots such as system design, safety, and transparency in the context of multiturn conversational interaction with patients with cancer and informal caregivers.

Therefore, this scoping literature review aims to identify the overall research landscape of LLM-based conversational chatbot studies developed for patients with cancer and their caregivers and sets the following research questions:

1. What types of LLM-based conversational chatbots have been developed for patients with cancer and caregivers, and what are their key design elements?
2. What are the primary intervention goals of the developed LLM-based chatbots?
3. How and at what level were LLM-based chatbots evaluated?
4. What safety risks were reported for LLM-based chatbots, and what mitigation strategies were used?
5. To what extent were the key LLM-related components of the chatbot development process transparently reported to support reproducibility?

Methods

This scoping systematic review was conducted according to the Joanna Briggs Institute (JBI) scoping systematic review methodology [26] and reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines (Checklist 1) [27]. The protocol for this study was preregistered in the Open Science Framework (OSF) [28], and a critical appraisal of individual studies was not performed.

Search Strategy

Search Sources

A pilot search for relevant literature was conducted in 3 databases—PubMed, Embase, and Scopus—from January 20, 2026, to January 31, 2026. Based on the pilot search results, the search strategy and inclusion or exclusion criteria were refined. An expanded search was then conducted from February 9, 2026, to February 13, 2026, across 6 databases initially: PubMed, Embase, Scopus, Web of Science, CINAHL, and PsycINFO. IEEE Xplore Digital Library and ACM Digital Library were subsequently searched on May 10, 2026, to ensure comprehensive coverage of computer science and AI literature.

Search Terms

Search terms were designed to comprehensively identify studies on LLM-based interactive chatbots targeting patients with cancer and their informal caregivers. The search query comprised four blocks: (1) cancer, (2) conversational agent or chatbot, (3) LLM or generative AI, and (4) patient or informal caregiver. Each block combined controlled vocabulary (eg, MeSH/EMTREE) with free-text terms using AND operators. The same search structure was applied across all databases; the full search terms for each database are presented in Multimedia Appendix 1.

XSL•FO
RenderX

Study Eligibility Criteria

This review included peer-reviewed journal articles and conference proceedings, encompassing various research designs such as experimental studies, observational studies, mixed methods studies, system development and evaluation studies, and review studies. Conversely, literature lacking systematic research design or results reporting, such as editorials, opinion pieces, and conference abstracts, was excluded. The literature was limited to English-language articles published between January 2022 and January 2026.

Participants

The participants for this scoping review were defined as studies addressing LLM-based chatbots developed primarily for patients with cancer and their informal caregivers, including family members, spouses, and other unpaid supporters involved in the care of patients with cancer. Participants were restricted to adult patients with cancer and adult caregivers. Studies including pediatric participants were included in this review if adult patients were also a primary focus.

Concept

The core concept of this review was interactive chatbots developed using LLMs. Multiturn conversational interaction was operationally defined as systems designed to support iterative dialogue, including those that (1) explicitly generate responses based on previous conversational context, (2) are architecturally configured to enable context-maintaining exchanges, or (3) are developed with the explicit intent of facilitating ongoing conversational interaction with users. Conversely, conversational systems implemented solely using rule-based NLP techniques or predefined response scenarios were excluded from this study's scope. Additionally, single-turn chatbots evaluated solely for accuracy, readability, and so forth, without presupposing interaction, were excluded.

Context

The purpose of this review is to identify the overall research landscape of LLM-based conversational chatbot studies developed for patients with cancer and their caregivers. Therefore, as it systematically organizes the purpose, design approach, application environment, and evaluation methods of the technology, it includes studies conducted in various contexts such as hospitals, homes, and online.

Study Selection

This systematic review identified relevant studies from databases, removed duplicates, performed an initial screening based on titles and abstracts, and reviewed full texts to determine final inclusion according to the predefined inclusion and exclusion criteria. Two researchers (YJ, HC) independently performed the literature screening and full-text review. Disagreements in selection were resolved through discussion and consensus. To ensure efficiency and transparency in the selection process, the web-based systematic review program Rayyan (Rayyan Systems Inc.) was used. The selection process and results were reported using the PRISMA-ScR flowchart.

Some included studies were identified as borderline cases. Given the limited number of studies explicitly addressing multiturn LLM-based conversational agents in oncology, an inclusive approach was adopted to comprehensively capture the emerging research landscape in this field. The initial judgments of each author and the consensus process for all included studies are documented in Multimedia Appendix 2.

Data Extraction and Data Synthesis

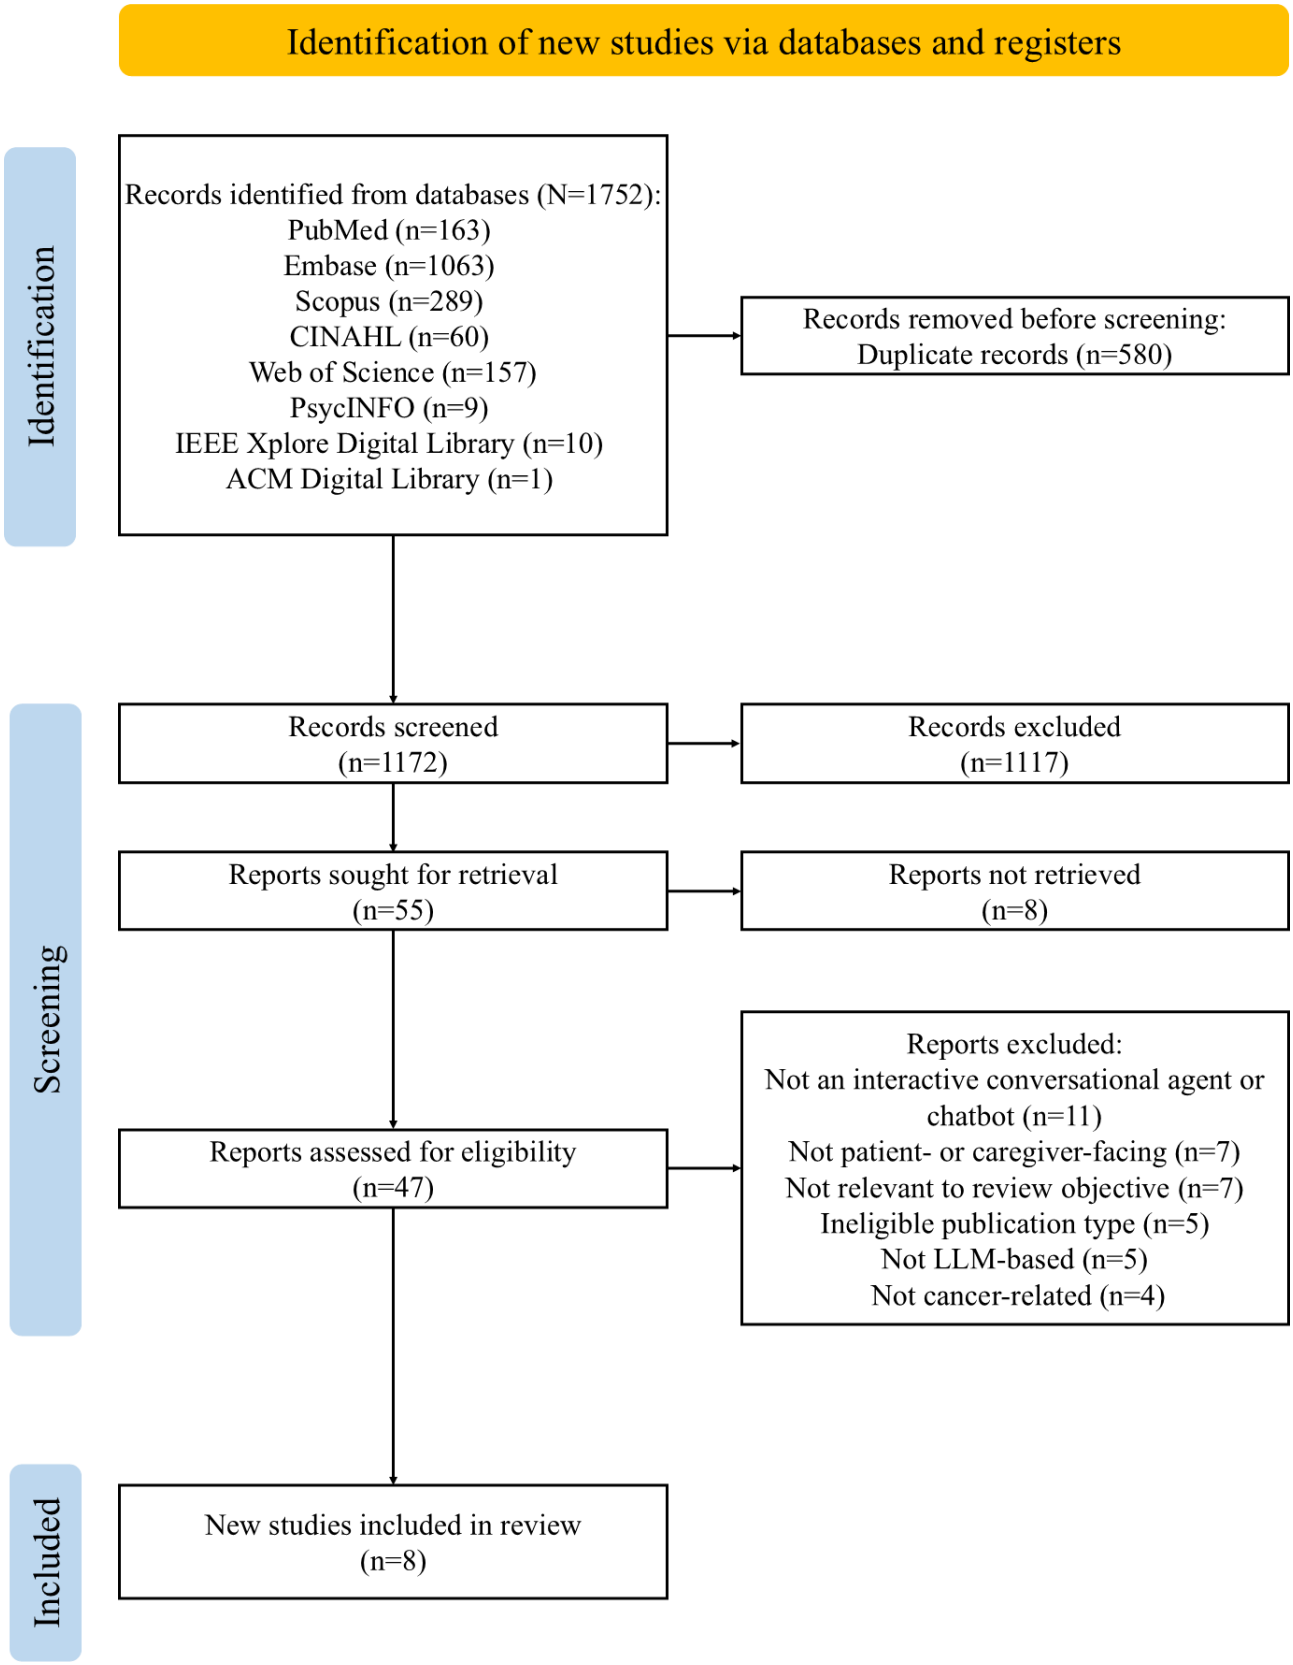
Data extraction was performed independently by 2 researchers using a predefined data extraction form, which was refined after pilot testing on a subset of studies. Data extraction was recorded using an electronic database tool (Notion), with a third researcher (ES) mediating when necessary.

Data extraction items included the following: (1) authors and publication year, (2) study country and setting, (3) study design and type, (4) participant characteristics, (5) primary purpose of the chatbot, (6) type of LLM used and system configuration, (7) evaluation design and key evaluation results, (8) reporting on safety and risk management, and (9) reporting on transparency or reproducibility elements related to the LLM.

The level of reporting on transparency and reproducibility of the LLM-related components was classified according to predefined criteria, adapted from reporting elements specified in TRIPOD-LLM [21]. The level of prompt reporting was assessed based on whether (1) system prompts, (2) user prompts, and (3) specific descriptions of model settings or parameters were provided. Complete reporting was defined as cases where all 3 elements were explicitly described, while partial reporting was defined as cases where only some elements were reported. Cases in which relevant information was not explicitly described were classified as not reported.

RAG was classified as applied when the term was explicitly used in the study or when the study described integrating information from external documents prior to response generation. Additionally, safety risk factors were categorized based on the risk factors described in each study.

The extracted data were organized into tables and diagrams according to study characteristics and key concepts, and the results were presented using descriptive mapping.



Results

Search Results

This review searched a total of 8 databases according to a predefined search protocol. The search and selection process is presented in Figure 1. The initial search identified a total of 1752 documents, including books, conference proceedings, and journal articles. After removing 580 duplicate documents, 1172 documents were included for title and abstract screening.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram showing the study selection process.

Following the title and abstract screening, a total of 1117 documents were excluded, and 55 were selected for full-text review. Excluded documents were categorized based on predefined inclusion and exclusion criteria, with some documents meeting multiple exclusion criteria simultaneously. The specific distribution of exclusion reasons at the title and abstract stage is presented in Multimedia Appendix 3.

During the full-text review stage, 47 of the 55 articles were reviewed, excluding 8 articles with restricted full-text access. These comprised 1 oral abstract, 3 conference abstracts, 2

XSL•FO
RenderX

ePosters, 1 book chapter, and 1 news or views article, none of which met our inclusion criteria. Articles excluded during the full-text review were categorized based on 1 primary exclusion reason. The main exclusion reasons were as follows: not being an interactive chatbot (11 studies; eg, studies generating tailored health education materials using LLMs without conversational interaction, or evaluating the accuracy of single-turn question-answering systems), not primarily targeting patients or caregivers (7 studies), not addressing a cancer-related context (4 studies), not using an LLM (5 studies), publication type not meeting inclusion criteria (5 studies), and insufficient relevance to the study objectives (7 studies).

Ultimately, a total of 8 studies were included in this scoping review. The limited number of included studies reflects that research applying LLM-based interactive chatbots to patients with cancer and caregivers is a relatively recent field of study.

General Description of the Studies

A total of 8 studies were included in this systematic review (Table 1). Two studies were reported in 2024 and 6 in 2025. Countries where studies were conducted included Germany, Japan, South Korea, the United States, Turkey, India, China, and the United Kingdom, with 1 study each from these countries. Publication types comprised 5 journal articles and 3 conference proceedings.

Regarding study design, development studies were the most common (5), followed by clinical evaluation studies (2) and usability evaluation studies (1). Seven studies developed chatbots exclusively for patients with cancer, while 1 study developed a chatbot exclusively for informal caregivers. No included study developed a chatbot for joint use by both patients and caregivers. Three studies specified breast cancer as the cancer type, while the remaining 5 studies did not restrict to a specific cancer type.

Two studies targeted newly diagnosed patients with cancer within 1 year of diagnosis, while 6 studies did not restrict by disease stage or timing of diagnosis. One study included a control group, 2 applied a pre-post design, and 5 did not use a comparison group, indicating varied comparative designs across studies. Overall, the included studies showed heterogeneous characteristics in terms of research design, participant characteristics, and comparison methods.

Types and Design Characteristics of LLM-Based Chatbots

Analysis of the types of LLMs used in the studies showed that ChatGPT 4.0 accounted for the largest share with 5 studies. ChatGPT 3.5, ChatGPT 3.5 Turbo, and Gemini were each used in 1 study. Additionally, some studies used various LLMs such as Gemini, Llama 3.1, Mistral 7B, and PHI 3.5 to perform model comparisons (Table 2).

Five studies applied RAG techniques, while 3 studies did not report on RAG application. Regarding knowledge sources used by chatbots, clinical practice guidelines were the most common source, used in 3 studies. Educational materials, books, and published literature were each used in 1 study. Conversely, 3 studies did not explicitly specify their knowledge sources.

Three studies explicitly used frameworks like LangChain or knowledge graphs for chatbot development, while the remaining 5 did not report on frameworks. Overall, the studies included in this literature review centered on ChatGPT-based models. However, heterogeneity was observed in model composition, with some studies using open-weight models for comparative evaluations. Differences were also noted in the level of reporting regarding knowledge sources and system implementation methods.

XSL•FO
RenderX

Meanwhile, the level of reporting on conversational memory handling was also limited. Only 1 study implemented embedding-based memory retrieval, and 1 reported history-based memory retention. Conversely, the remaining 6 studies did not present any method for maintaining context.

Table . Large language model (LLM)–specific design characteristics of included studies[a,b].

Characteristics	Number of studies

[a]"Not reported" indicates that the item was not explicitly described in the study.

[b]Study [35] evaluated 3 large language models comparatively, and all models assessed are listed.

[c]RAG: retrieval-augmented generation.

Primary Purposes of LLM-Based Chatbots

Analysis of the primary purposes of the developed chatbots revealed 4 categories: emotional support, information provision, enhancing user convenience, and analyzing user experience. Three studies focused on emotional support as their primary purpose, aiming to provide psychological support centered on reducing anxiety, depression, and stress. Three studies focused on information provision as their primary purpose, developing chatbots that provide personalized responses to cancer-related questions and deliver medical information.

Meanwhile, 1 study primarily aimed to support clinical research by automating the collection and organization of patient-reported outcomes (PRO) data. Another study primarily focused on exploring the interaction experience with conversational AI support agents, targeting caregivers as the main subjects.

Overall, the included studies used LLM-based chatbots as tools for information provision or emotional support. Some studies focused on enhancing clinical convenience or understanding user experience and interaction patterns.

Evaluation Approaches and Outcome Domains

Analysis of evaluation methods and domains revealed that the assessment approaches and measured outcome domains varied significantly across studies (Table 3). One study evaluated participants' psychological outcomes using validated measurement tools, while another reported psychological states

XSL•FO
RenderX

using a predefined scoring scale. Additionally, 1 study focused its evaluation on user experience and perceptions.

Four studies evaluated the response performance of LLM-based chatbots, focusing on chatbot response accuracy, completeness, comprehension, consistency, and security or safety. One study focused on chatbot development and did not report separate evaluation results.

The studies included in this literature review were evaluated across diverse domains such as clinical outcomes, response quality, and user experience, revealing heterogeneous characteristics in the evaluation design and outcome domains. However, despite being multiturn interactive systems, no studies were identified that evaluated the continuity of conversation or the interaction process itself.

Table . Evaluation methods and outcome measures used in included studies.

Characteristics	Number of studies
General evaluation outcomes	
Psychological outcomes (validated instruments)	1 [31]
User-reported psychological states (nonvalidated measures)	1 [34]
User experience and perception	1 [36]
LLM[a]-specific evaluation outcomes

Reported Safety Risks and Mitigation Strategies

Analysis of safety risks and mitigation strategies reported in the included studies revealed that the level of safety-related reporting varied across studies (Table 4). Risks related to the reliability of chatbot responses were reported in 4 studies, while risks related to physical and psychological safety were identified in 1 study each. Conversely, 3 studies did not provide specific reports on safety risk factors.

Two studies specified expert intervention as a strategy to mitigate safety risks. Two studies applied an automated escalation system that provided emergency contacts to participants or connected them to external support systems during crisis situations. Additionally, 1 study applied a strategy to exclude models with low performance or potential harm. However, the remaining 3 studies did not report on risk mitigation strategies. While some studies proposed safety management strategies, systematic reporting of safety risk factors and mitigation strategies was limited.

Table . Reported safety risks and mitigation strategies in included studies.

Characteristics	Number of studies
Safety risks	
Response reliability	4 [29,31,34,35]
Psychological safety risk	1 [34]
Physical safety risk	1 [32]

Transparency and Reproducibility of LLM-Specific Components

Analysis of the reporting level for LLM-related components revealed that transparency in prompt design and system configuration varied across studies (Table 5). No study reported prompts in full, while 5 studies reported only partial components. Conversely, 3 studies did not report prompt design at all.

Only 1 study explicitly reported the system prompt as a prompt component, 2 reported the user prompt, and 2 reported model parameters. However, 3 studies did not report specific information about prompt components. Furthermore, only 1 study explicitly referenced LLM-based research reporting guidelines, while the remaining 7 studies made no mention of such guidelines.

Overall, the included studies provided basic information on LLM selection and use, but reporting on reproducibility aspects, such as prompt design and system configuration, was limited. The research landscape across the 5 research questions is summarized in Figure 2.

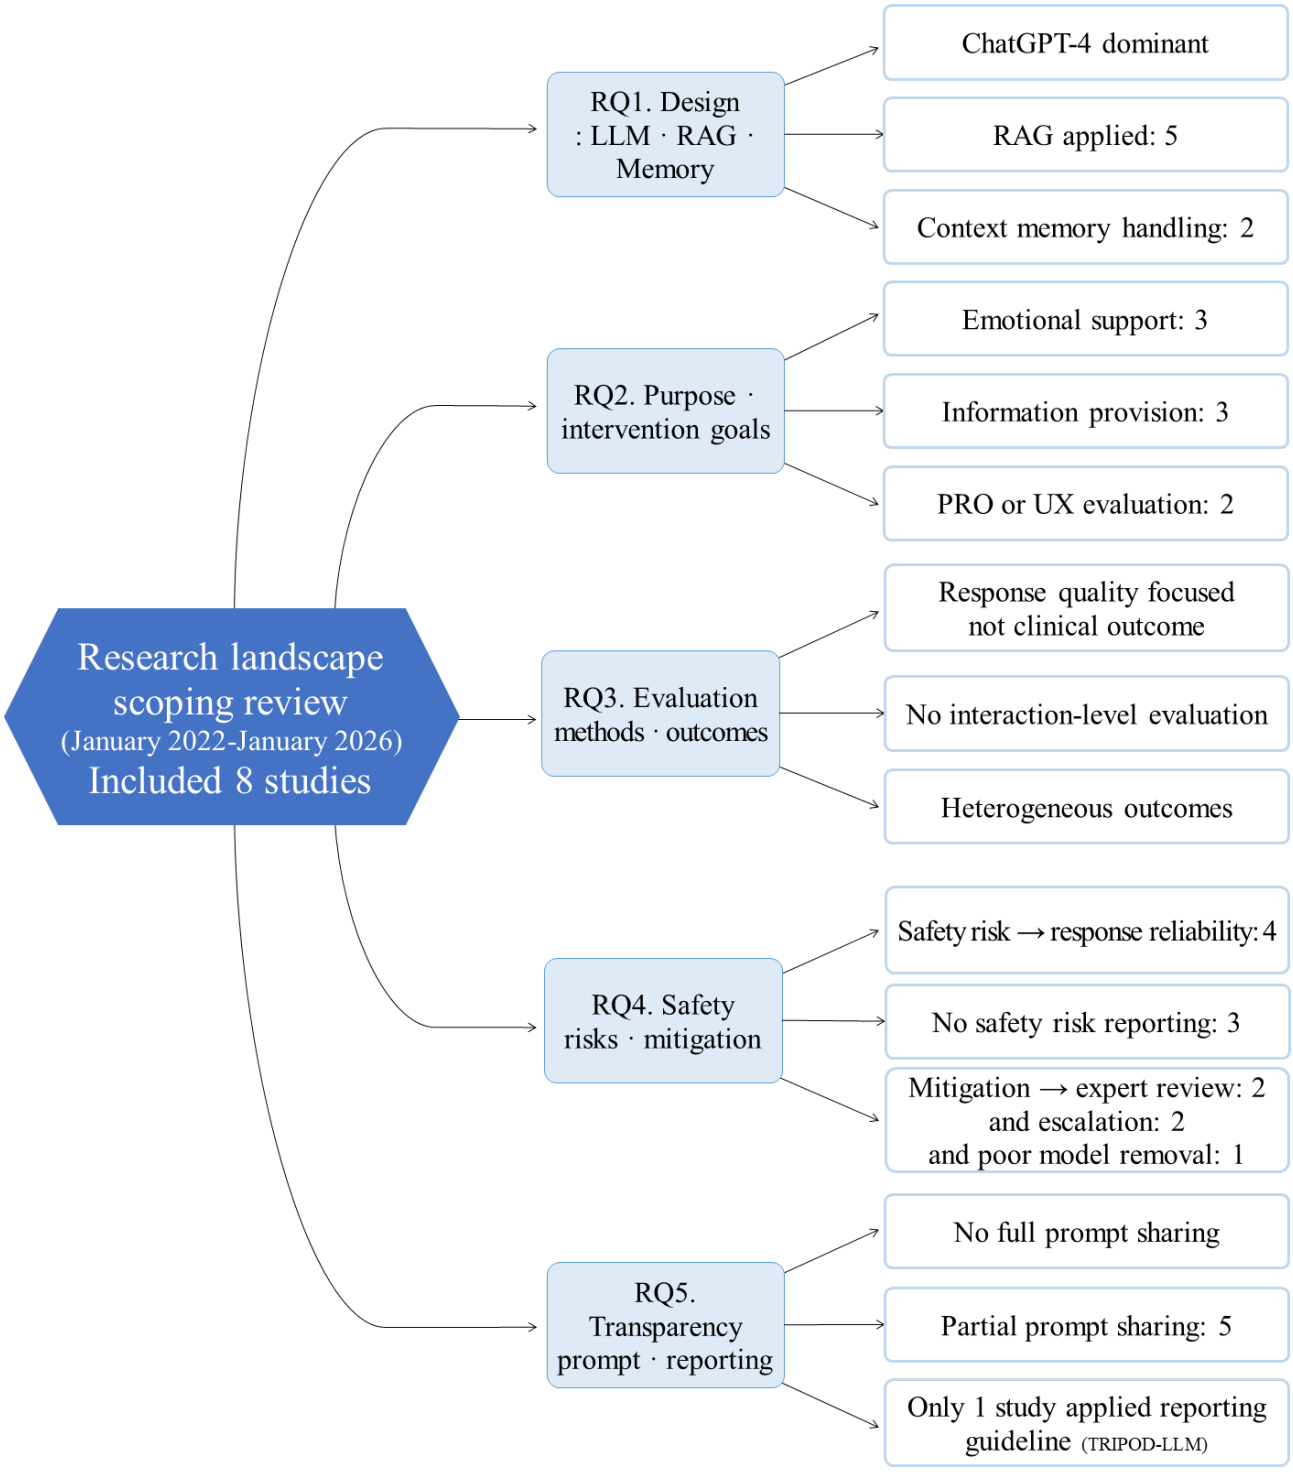

Table . Transparency and reproducibility of large language model (LLM)–specific components.

Characteristics	Number of studies
Prompt reporting completeness	
Complete	0
Partial	5 [29,30,33-35]
Not reported	3 [31,32,36]
Prompt components reported	
System prompt	1 [33]

Discussion

Principal Findings

The most significant finding of this review is the immaturity of the multiturn chatbot field in oncology. Multiturn interactions are often regarded as an inherent and fundamental feature of conversational agents. Nevertheless, studies that could be rigorously classified as genuinely multiturn were markedly limited. This scoping review identified 8 studies, of which only 2 explicitly reported any conversational memory mechanism. Most studies included in this review remained at the stage of system development and prototyping, with limited research applying comparative designs or validating clinical efficacy. While systematic assessments of patient-centered clinical outcomes were relatively scarce, most of the studies focused on response quality and safety verification.

In terms of design, ChatGPT-based models were primarily used, with some studies applying RAG techniques or external

XSL•FO
RenderX

knowledge integration methods. The level of reporting on key design elements—such as knowledge sources, retrieval architecture, model configuration, and prompt composition—varied significantly across studies. Furthermore, reported safety risk factors, mitigation strategies, and transparency of LLM components were inconsistent across studies. Only 1 study explicitly referenced reporting guidelines.

Research on LLM-based oncology multiturn conversational chatbots is rapidly expanding but has not yet reached maturity. Key areas requiring further development include clarity of design architecture, validation of clinical efficacy, safety management strategies, and reporting standardization.

Design and Intervention Characteristics of LLM-Based Oncology Chatbots

Overall, the included studies focused on prototype-level implementations based on commercial LLMs, exhibiting heterogeneity in model selection, knowledge integration strategies, and system design approaches. This design diversity can be interpreted as reflecting the exploratory application phase of the technology [37]. However, such diversity in chatbot design also complicates comparability between studies [20,38].

In oncology, LLM-based chatbots were often developed for emotional support and information provision. Some studies presented automation of collecting and organizing PRO data or exploring user experience and interaction patterns as primary objectives. This aligns with prior research indicating that LLM-based chatbots in oncology are applied for education and patient support [39,40].

Meanwhile, studies specifying a particular cancer type were primarily focused on breast cancer, and several studies targeted patients in the early stages of diagnosis. These patterns suggest that LLM-based chatbot interventions are initially being applied to patient groups with relatively standardized clinical guidelines and high informational and emotional support needs [13,41]. However, this bias toward specific cancer types and disease stages limits generalizability across oncology. Furthermore, despite being premised on multiturn interactions, studies explicitly addressing conversational memory handling were limited.

Most studies identified in this literature review focused on individual response-level performance metrics, such as chatbot response accuracy or completeness. No studies were found that evaluated the multiturn interaction process itself. Multiturn dialogue systems generate responses by considering previous utterances and conversation history. They are reported as a crucial technical element for providing sophisticated information and building psychological rapport by posing follow-up questions in real time [42,43]. Furthermore, the ability to generate consistent responses while maintaining long-term conversational context is presented as a major research challenge for LLM-based conversational systems [18]. Therefore, evaluating interaction-level factors, such as conversational continuity and context retention capability, may also be important considerations.

Evaluation, Safety, and Transparency of LLM-Based Conversational Agents

Included studies tended to focus on response quality and safety verification, with limited comparative designs evaluating clinical efficacy. Furthermore, while some studies mentioned potential psychological risks, safety reporting was limited in a significant number of studies, and specific safety threat factors were not explicitly reported. Additionally, while evaluating the “quality” and “stability” of interactions is crucial for multisession interactive chatbots, reporting on this aspect was also limited.

LLMs are generative models based on probabilistic next-word prediction engines that can produce plausible-looking but factually inconsistent hallucinations [44,45]. Response accuracy varies across studies and models, but reported accuracy levels around 80% still imply the potential for generating inaccurate information [46-48]. Particularly, cancer treatment requires a multidisciplinary approach and complex decision-making. Therefore, the accuracy and reliability of information provided by LLM-based chatbots can significantly impact the decision-making and treatment processes of patients with cancer [24,49,50].

Mitigation strategies to reduce hallucinations and improve accuracy, such as RAG or knowledge graphs that connect LLMs with external evidence sources, have been proposed. At the clinical level, some studies proposed expert prereview as a safety measure [31,34] or introduced escalation mechanisms connecting to external support systems during crisis situations [34]. However, these mitigation strategies were not consistently applied or systematically evaluated across studies, and many studies did not sufficiently describe specific risk management strategies. Therefore, establishing a standardized framework to systematically define and report safety threats in LLM-based conversational chatbots is required.

With respect to transparency, reporting on LLM-related components was generally limited across the included studies, as noted in existing literature [20,51,52]. While some studies partially disclosed prompts, key elements such as system prompts, user prompts, and model parameters were often insufficiently described. Prompt engineering, the process of adjusting LLM responses through the input structure and instruction design, impacts response accuracy [53-56]. Furthermore, since LLMs respond sensitively to prompt structure without revealing their internal reasoning processes, prompt design is a critical variable in determining response appropriateness in medical settings [21,57-59]. Therefore, the failure to clearly report prompt structure and model settings may limit the interpretability and reproducibility of research findings [60].

Notably, only 1 included study explicitly referenced a reporting guideline—specifically, TRIPOD-LLM [21]—underscoring the limited adoption of standardized reporting frameworks in this emerging field. Standardized and transparent reporting is essential for building trust in the use of generative AI models in clinical practice [22]. Reporting guidelines such as TRIPOD-LLM, CHART, and CONSORT-AI have been developed to address this gap [21,22,61]. Future studies on

XSL•FO
RenderX

LLM-based chatbots in oncology should explicitly adhere to these frameworks.

Implications for Future Research and Practice

Future research should report model versions, knowledge update cycles, retrieval strategies, prompt systems, and system pipelines in standardized formats to enhance comparability and reproducibility across studies. For systems designed for multiturn interactions, it is necessary to describe conversational state management and context retention (conversational memory handling) strategies and apply interaction-level evaluation metrics such as dialogue consistency and safety. Furthermore, the applicability across diverse cancer types, disease stages, and user groups (patients and caregivers) should be systematically validated, and comparative designs enabling clinical efficacy assessment should be expanded. Finally, adherence to established reporting guidelines is strongly recommended to promote transparency and reproducibility in future studies.

Limitations

This study has the following limitations. First, the search was restricted to English-language publications in 8 databases, so the possibility of omitting relevant studies cannot be ruled out. Second, due to the rapidly evolving nature of this research field, conference papers were included; however, some studies did not sufficiently report detailed methods and components, limiting interpretation. Third, consistent with the nature of a scoping review, methodological quality assessments of individual studies were not performed, preventing a systematic comparison and evaluation of the evidence levels across the included studies. Fourth, given the rapid pace of LLM research, studies published after the search cutoff (February 2026 for the primary databases and May 2026 for the supplementary AI or computer science databases) may not be captured in this review, and periodic updates are recommended to reflect the latest developments in this field.

Conclusion

This scoping review systematically summarized the overall research landscape of LLM-based multiturn conversational chatbot studies developed for patients with cancer and their informal caregivers. Only 8 studies were included, most of which were recently reported prototype-focused development research, reflecting the emerging nature of this field. Heterogeneity among studies was found in design architecture, evaluation methods, safety management strategies, and the level of transparency. Notably, despite the conversational nature of the included systems, reporting on interaction-level evaluations, such as context retention strategies, was limited.

LLM-based oncology conversational chatbots show potential as promising tools for patients with cancer and caregivers. Genuine multiturn conversational capability should therefore be prioritized in future development. However, safety management and standardization of design and reporting must proceed concurrently. Future research should explicitly identify potential patient safety risks and propose corresponding mitigation strategies. Furthermore, LLM-based chatbot development in oncology should explicitly document prompt design and system configuration in accordance with validated reporting guidelines.

Abstract

Background: Fear of cancer recurrence (FCR) is prevalent among cancer survivors, affecting between 39% and 97% of patients. FCR is associated with impaired concentration, sleep disturbances, decreased quality of life, and increased psychological distress and health care use. To date, the literature lacks a review that summarizes the breadth of psychological interventions available for reducing fear of recurrence.

Objective: This review aims to identify and summarize the evidence on psychological interventions for addressing FCR across all cancers.

Methods: The Joanna Briggs Institute method for scoping reviews guided the processes, and we reported the review following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. We searched 5 databases (CINAHL, PsycInfo, the Cochrane Central Register of Controlled Trials, Embase, and MEDLINE) and 2 gray literature sources (ProQuest Dissertations & Theses Global and the World Health Organization International Clinical Trials Registry). Eligible studies included adults (≥18 years) diagnosed with cancer and evaluated psychological interventions aimed at reducing FCR. Data extraction captured study characteristics, intervention details, outcome effectiveness, and follow-up durations. We synthesized the findings using descriptive summaries and narrative analysis.

Results: Overall, 5131 articles were screened, and 122 were included in this review; 48 (39.3%) involved patients with breast cancer, 47 (38.5%) focused on patients with multiple cancer types; over half of the studies (n=64, 52.5%) were randomized controlled trials. Only 28 (23%) studies explicitly reported the definition of FCR. Eighteen different measurement tools were used. Blended interventions (different combinations of cognitive behavioral therapy, mindfulness, acceptance and commitment therapy, and other strategies) formed the largest intervention category (n=38, 31.1%), followed by cognitive behavioral therapy interventions (n=26, 21.3%) and mindfulness-based interventions (n=24, 19.7%). Of the included studies, 104 (85.2%) demonstrated significant reductions in FCR. Most interventions were delivered face-to-face by disciplinary specialists (n=75, 61.5%), while some were delivered remotely (n=34, 27.9%), with the majority of these delivered via the website (n=18, 52.9%). Follow-up duration ranged from postintervention to 3 years.

Conclusions: FCR has been the focus of an increasing number of studies since 2009, with the majority being randomized controlled trials. Most interventions are delivered face-to-face and rely on trained specialists. Most have had statistically significant results. However, the included studies demonstrated heterogeneity in terms of delivery, duration, and dose, requiring cautious interpretation of intervention effects. Future research should develop consistent guidelines to standardize the definition of FCR, the measurement tools used, and the timing of follow-up assessments. Long-term follow-up data are needed to evaluate the sustained effects.

Introduction

In 1981, Northouse first introduced the concept of fear of cancer recurrence (FCR) to describe the concerns of cancer patients in remission who feared that their cancer might return [1]. FCR is defined as fear, worry, or concern about the possibility of cancer returning [2]. FCR arises when cancer-related cues or bodily sensations are interpreted as signs of threat. These threat appraisals, combined with difficulties managing distress, can lead to patterns of hypervigilance, worry, reassurance seeking, or avoidance [3-5]. In addition, the idea that staying alert prevents recurrence further maintains persistent monitoring and rumination. Ongoing uncertainty about symptoms or the course of illness can amplify anxiety and contribute to the persistence of FCR over time [5,6].

Previous studies report that between 39% and 97% of cancer survivors experience FCR, with 22% to 87% experiencing moderate to high levels of fear [7]. This wide range may be due to heterogeneity in cancer types and survivorship stages, differences in measurement instruments, and variation in the timing of assessment [7]. It is common for cancer survivors to experience short-term or low levels of FCR. In some cases, such fear may be protective by increasing vigilance to bodily symptoms and promoting positive health behaviors, such as attending regular follow-up appointments and maintaining a healthy lifestyle [8]. However, when it becomes persistent and severe, it can interfere with a person's mental health and daily functioning [9,10]. FCR may disrupt concentration, decision-making, sleep, and social functioning [11,12]. It also decreases overall well-being and quality of life and increases psychological distress and resistance to follow-up appointments [13-15]. High levels of FCR are significantly associated with a range of psychological comorbidities, including depression, anxiety, impaired emotional functioning, and insomnia [6]. FCR is linked to frequent checkups and additional examinations [16], and high levels can increase health care use, particularly in primary care [17,18]. FCR may also significantly delay return to work or even lead to premature withdrawal from employment [19]. If untreated, FCR can continue unabated throughout a patient's survival journey [20,21]. In a large cohort study, 44% - 56% of patients continued to report clinical levels of FCR up to 18 months post surgery [22].

To date, only one scoping review has summarized psychological interventions for FCR [23]. However, it was solely focused on cognitive behavioral–based approaches [23]. In our review, we aim to map studies of the psychological interventions designed to reduce FCR in people with cancer, detailing the study characteristics, intervention details, outcome measurement, and follow-up durations to provide an overview of the interventions and highlight evidence gaps. These insights could inform the development of potential strategies to address FCR in specific populations.

Methods

Study Design

The review followed the Joanna Briggs Institute method for scoping reviews [24] and was reported by the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist [25]. We preregistered the scoping review protocol on the Open Science Framework (registration number: 29YA3) [26].

Review Objective

The primary objective of this scoping review is to map and summarize the evidence on the effects of psychological interventions designed to reduce FCR in people with cancer.

The scoping review addressed the following questions:

1. How has FCR been defined?
2. What instruments have been used to measure FCR?
3. What psychological interventions have been investigated to reduce FCR?
4. What are the intervention characteristics (types, setting, duration of intervention content, mode of delivery, personnel involved, and number of sessions)?
5. What is the effect of interventions in reducing FCR?
6. What is the follow-up duration of interventions addressing FCR?

Eligibility Criteria

We used the population/participant-concept-context framework [24] to define eligibility.

- Population: studies focused on FCR in all people who have been histologically and clinically diagnosed with cancer, aged 18 years or older at diagnosis.
- Concept: any type of intervention with a psychological component aiming to reduce FCR. There were no limitations on the intervention's duration, frequency, delivery method, or type of provider.
- Context: interventions provided in any type of setting.

Type of Evidence Sources

We included any quantitative study design that reported data relevant to the research questions, including randomized controlled trials (RCTs), quasi-experimental studies, nonrandomized intervention studies, observational studies, and mixed methods studies with extractable intervention data. Review articles were excluded to avoid data duplication, but the reference lists were screened for relevant studies. We also excluded ongoing trials and protocol papers.

Search Strategy

The search strategy was initially focused on colorectal cancer, but due to an insufficient number of studies, it was broadened to include all people with cancer. The search strategy was developed based on three key concepts: (1) neoplasms, including synonyms such as neoplas*, cancer, carcinom*, malignant*, tumor*, and oncolog*; (2) fear, with related terms including anxiety, worr*, concern, and distress; and (3) recurrence, with associated terms such as relapse, progress*, reappearance, and return. These terms were combined using the Boolean operator "OR" within each concept group and "AND" between the concept groups. However, the "fear" and "recurrence" concepts were combined using a proximity operator (*adj4*) in most databases to ensure co-occurrence within a 4-word context. The research team designed the search strategy in collaboration with

XSL•FO
RenderX

an experienced librarian, and it was adapted for each database. We searched the reference lists of all studies included in the review to identify additional studies.

We searched 5 electronic databases: CINAHL, PsycInfo, the Cochrane Central Register of Controlled Trials (CENTRAL), Embase, and MEDLINE. To capture relevant gray literature, we also searched 2 gray literature sources: ProQuest Dissertations & Theses Global and the World Health Organization International Clinical Trials Registry Platform. These sources were searched from January 1980 to April 2024, given that the concept of FCR was initially raised in the early 1980s [1]. The detailed search strategy and results are provided in Table S1 in Multimedia Appendix 1. We imported the search results from all databases into Covidence [27] and removed duplicates.

Study Selection

Two authors (NL and TOL) screened titles and abstracts independently for assessment against the inclusion criteria. A third author (CW) resolved any disagreements. A flowchart was created to standardize article selection decisions between screeners (Figure S1 in Multimedia Appendix 1). Two independent reviewers (NL and CW) assessed the full texts in detail against the inclusion criteria. Any disagreements between the reviewers were resolved through discussion with a third author (LR). Reasons for exclusion at the full-text stage were recorded and are presented in the PRISMA-ScR flow diagram (see the Results section).

Data Extraction

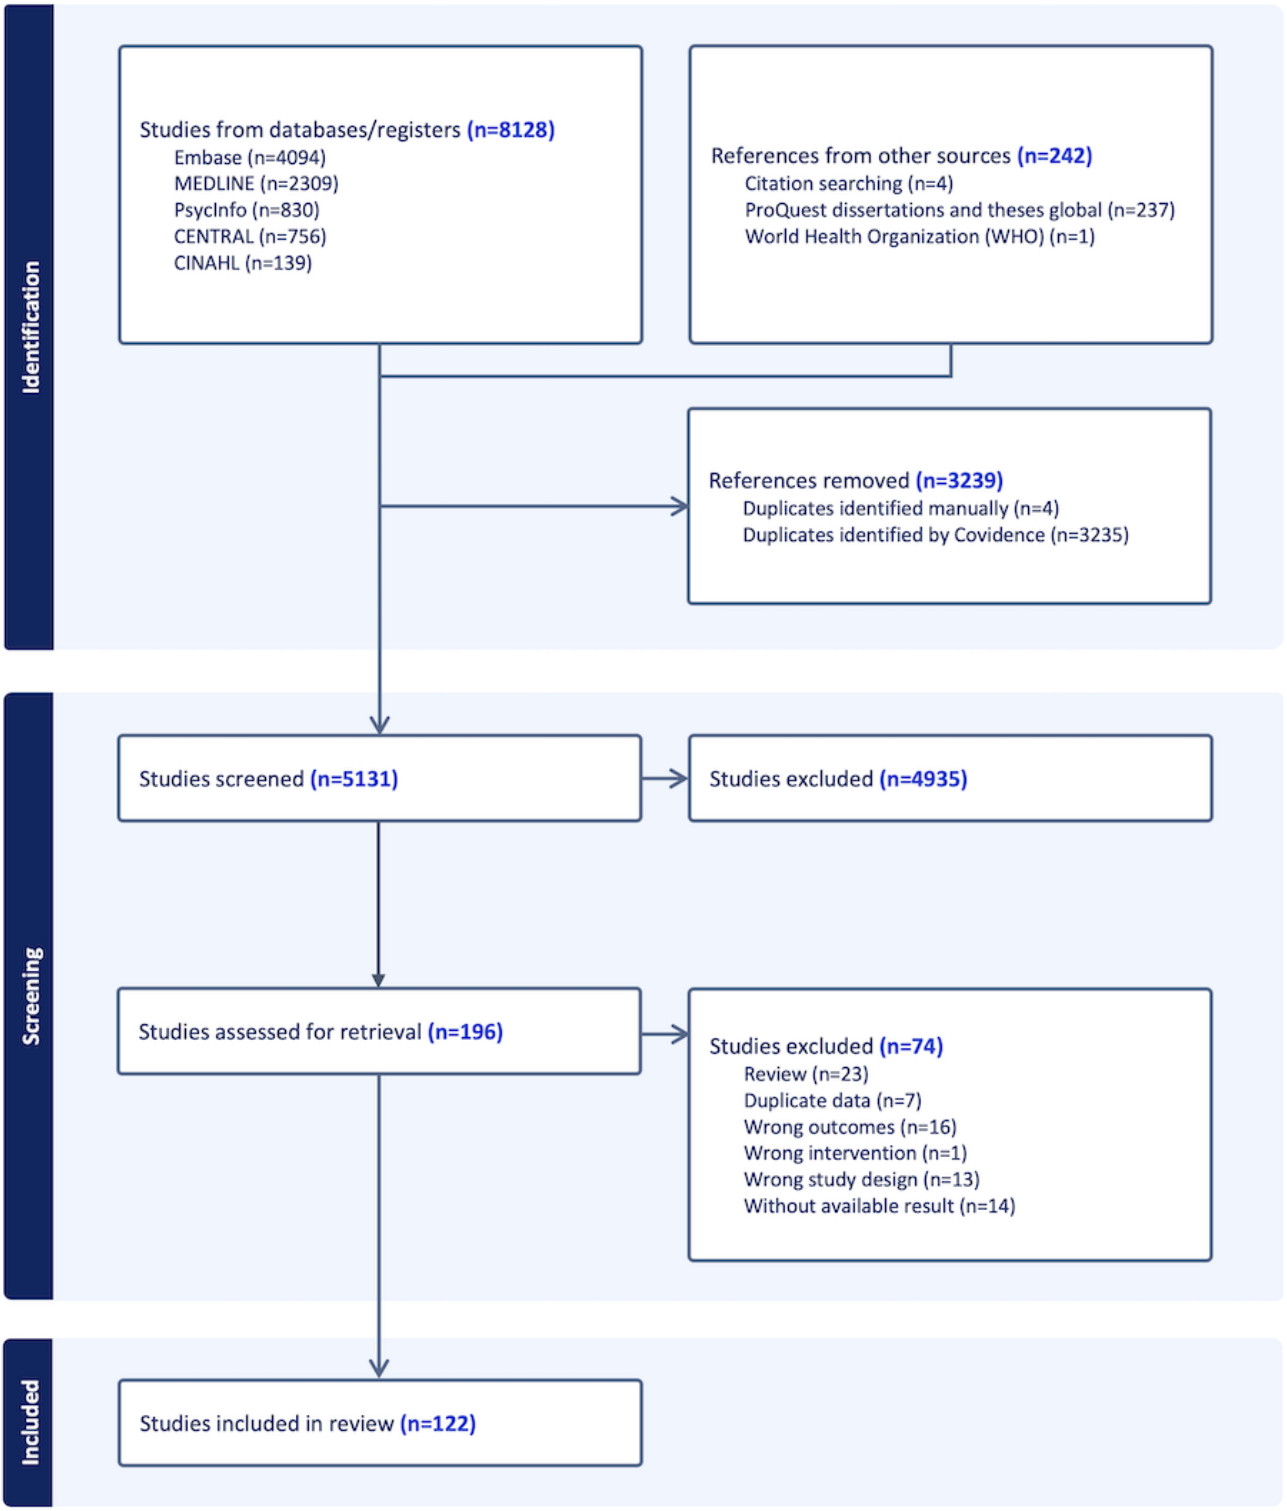
We piloted the data extraction form on the first 5 eligible studies and modified it accordingly. A data dictionary was developed with collective input from the author team to specify all elements of the data extraction form (Table S2 in Multimedia Appendix 1). One reviewer (NL) then extracted the data in Microsoft Excel under the supervision of the research team to ensure adherence to the predefined extraction protocol. The extracted data included:

- General information (author, year of publication, title, journal, country, and study aim);
- Participant characteristics (sample size, age, gender, diagnosis, inclusion criteria, and cancer stage);
- Concept-related information (definition of FCR/progression, study design, intervention timepoint, intervention components, intervention provider, provider qualification, recruitment method, intervention frequency/intervals/duration, definition of control group (if applicable), follow-up timepoints, theoretical framework, outcomes, measurement tool, and result);
- Context (setting and format of delivery);
- Study methodology, key findings, and research gaps.

Data Analysis and Presentation

Given the heterogeneity across included studies, we conducted a descriptive analysis approach to synthesize the findings. Descriptive numerical summaries were presented through tables and figures to map the characteristics of the included studies, and the findings were synthesized narratively [28]. The synthesis was structured around the review questions.

We summarized the characteristics of the identified studies by reporting frequencies and percentages. We also extracted how FCR was defined and which measurement tools were used in each study and grouped these definitions and measures into tables separately. Key intervention content (ie, components, sample sizes, measurement tools, study design, and reported statistical significance) was summarized. To clearly present the diverse intervention approaches for reducing FCR, we classified the interventions according to their theoretical basis (including blended interventions, cognitive behavioral therapy [CBT], mindfulness-based intervention [MBI], acceptance and commitment therapy [ACT], tailored psychoeducational interventions, and others) with categories developed inductively from the included studies. We created a harvest plot to visually present the distribution of interventions across cancer types and study designs.



Results

Overview

We identified 8128 citations through database searches and 242 additional records from gray literature and reference tracking. After removing duplicates, 5131 titles and abstracts were screened, with 4935 excluded. We assessed the full texts of the remaining 196 articles and excluded 74 of them. A total of 122 studies were included in the review (Figure 1).

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) flowchart.

Sixty-five (53.3%) studies were published within the last 5 years (Table 1). The United States accounted for the highest number of studies (n=35, 28.7%). Forty-eight (39.3%) studies focus on breast cancer, followed by 47 (38.5%) studies that included participants with more than one cancer type. The majority of studies (n=64, 52.5%) were RCTs.

Not available	5 (4.1)

[a]Although 122 studies were included, some were conducted in more than one country; therefore, the total geographic region count is 126.

The interventions were categorized according to their theoretical basis (Table 1). Blended interventions (different combinations of CBT, mindfulness, ACT, and other strategies) formed the largest category (n=38, 31.1%), followed by CBT (n=26, 21.3%) and MBIs (n=24, 19.7%). All studies implemented interventions post diagnosis (Table S3 in Multimedia Appendix 1). In 38 (31.1%) studies, researchers did not report the exact clinical timepoint of intervention delivery. Thirty-six (29.5%) trials included "people who had completed or were still undergoing cancer treatment." The remaining 48 (39.3%) targeted "people who were disease-free," with the timing of intervention delivery ranging from 3 months to 15 years following primary cancer treatment. Most interventions were delivered by disciplinary specialists (n=117, 95.9%), with psychologists being the most common providers (n=68, 55.8%).

The Definition of FCR

Only 28 (23%) studies identified which FCR definition they used. Among them, 9 (32.1%) studies used Vickberg's definition [28-36], 18 (64.3%) studies used Lebel et al definition [37-54], and 1 (3.6%) study [55] cited the FCR definition by Herschbach and Dinkel [56]. These three definitions are summarized in Table 2. Vickberg's [57] definition, developed for breast cancer patients, describes FCR as the fear that cancer may return either in the same location or in another part of the body. Lebel et al [2] proposed a definition based on a Delphi consensus process, defining FCR as "fear, worry, or concern relating to the possibility that cancer will come back or progress." Herschbach and Dinkel [56] introduced the concept of fear of progression (FoP), which specifically highlights concerns about disease progression and its associated psychosocial consequences.

Table . Definition of FCR[a].

Author	Definition
Vickberg (2003) [57]	"Fear or concern about the return or progression of the disease in the same organ or other parts of the body."
Lebel et al (2016) [2]	"Fear, worry, or concern relating to the possibility that cancer will come back or progress."
Herschbach and Dinkel (2014) [56]	"Fear of progression (FoP) is defined as the fear and anxiety of patients whose disease will progress or recur with all its social and biological consequences."

[a]FCR: fear of cancer recurrence.

FCR Measurement Tools

Eighteen validated measurement tools were identified (Table S4 in Multimedia Appendix 1). Thirteen (72.2%) were specifically designed to assess FCR/FoP, while the remaining 5 (27.8%) included FCR-related items as part of broader assessments. The Fear of Cancer Recurrence Inventory [58] was the most frequently used tool, appearing in 40 (31.7%) studies. Other commonly used tools included the Concerns About Recurrence Scale [57], used in 20 (15.9%) studies, and the Fear of Cancer Recurrence Inventory-Short Form [59], used in 18 (14.3%) studies.

Intervention Characteristics and Effects

Summary

We summarized author, year, intervention, sample size, measurement tools, statistical significance, and study design (Table 3). The distribution and reported effects of interventions across cancer types and study designs are summarized visually

XSL•FO
RenderX

(Figure 2). Detailed characteristics of statistically significant interventions are outlined (Table S5 in Multimedia Appendix 1).

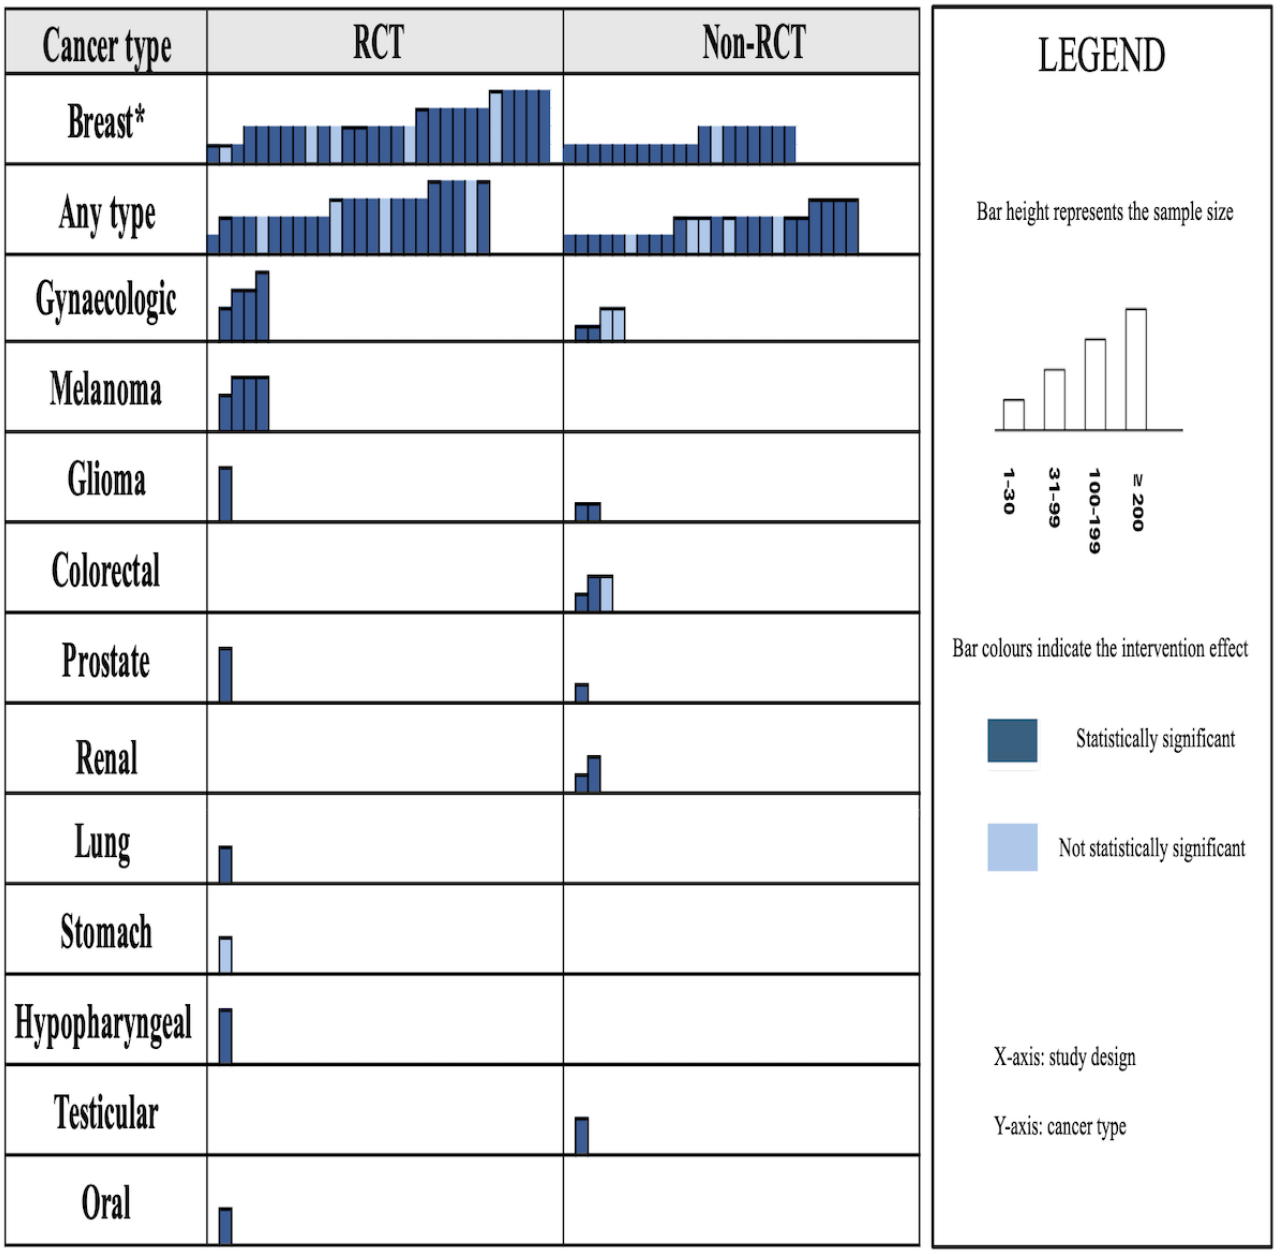
[a]Fear of cancer recurrence (FCR) tools used are as follows—ASC: Assessment of Survivor Concerns; CARQ: Concerns About Recurrence Questionnaire; CARS: Concerns About Recurrence Scale; CWS: Cancer Worry Scale; CWS-6: 6-Item Cancer Worry Scale; FACT: Functional Assessment of Cancer Therapy; FCR-4: Fears of Cancer Recurrence, 4-Item Version; FCR-7: Fears of Cancer Recurrence, 7-Item Version; FCRI: Fear of Cancer Recurrence Inventory; FCRI-SF: Fear of Cancer Recurrence Inventory—Short Form; FCRS: Fear of Cancer Recurrence Scale; FoP-Q: Fear of Progression Questionnaire; FOP-Q-SF: Short-Form Fear of Progression Scale; MAX-PC: Memorial Anxiety Scale for Prostate Cancer; Mini-MAC: Mini-Mental Adjustment to Cancer Scale; PQ-FCR: Personal Questionnaire—Fear of Recurrence; QLACS: Quality of Life in Adult Cancer Survivors Scale; WOC: Worry of Cancer Scale.



[b]"Yes" means that the intervention had a statistically significant mitigating effect on fear of cancer recurrence (FCR); "No" means that the intervention did not have a statistically significant mitigating effect on FCR.

[c]RCT: randomized controlled trial.

[d]N/A: not available.

XSL•FO
RenderX

Figure 2. Harvest plot showing the distribution of interventions by study design and cancer type. Each bar represents one study. Bar colors indicate the intervention effect, and bar height reflects the sample size. “Any type” refers to studies that include more than one type of cancer. Blue bars indicate a statistically significant effect (P<.05) in reducing fear of cancer recurrence; light blue bars indicate no statistically significant effect. Studies are grouped by cancer type (y-axis) and study design (randomized controlled trial [RCT] vs non-RCT; x-axis). * represents one study with missing sample size data. Within each group, studies are ordered from left to right by sample size, starting with the smallest sample size on the left.

Blended Interventions

Thirty-eight (31.1%) studies evaluated the effect of blended interventions [31,32,34,35,37,40,42-44,46,50,53,61-63,67,72,89,91,93,94,107,111,112,114,115,123,132,133,136,137,139-141]. Most of them (n=23, 60.5%) combined CBT with other interventions (eg, mindfulness, ACT, and other strategies). Eighteen (47.4%) studies used a pre-post study design [31,32,34,35,37,42-44,46,63,89,94,107,115,137,139-141]. Fourteen (36.8%) studies were RCTs [40,48-50,53,61,62,67,72,91,111,112,133,153].

The majority of studies (n=33, 86.8%) reported statistically significant effects. Among them, 22 (66.7%) were conducted in person by disciplinary specialists [31,32,34,37,46,48,49,63,67,72,90,91,93,94,107,111,114,133,136,137,140,148], 8 (24.2%) were delivered remotely [40,43,44,47,62,123,132,139], and 3 (9.1%) used a hybrid format, combining both in-person and remote delivery [35,50,112]. These interventions typically followed a weekly format, lasting from 5 to 12 weeks. Individual sessions ranged from 10 minutes to 2 hours. Moreover, the length of the follow-up period varied, with assessments conducted from immediately after the intervention up to 2 years.

CBT

Twenty-six (21.3%) studies evaluated the effect of CBT [30,36,38,39,41,45,51,52,60,82-84,91,92,95,96,105,119,143-145,147,152,154-156].

XSL•FO
RenderX

The majority of the studies (n=16, 61.5%) were RCTs [36,38,52,60,82,83,91,92,95,96,105,117,145,147,152,155], followed by 5 (19.2%) pre-post studies [30,119,143,144,154], 4 (15.4%) mixed methods studies [39,45,51,84], and 1 (3.9%) non-RCT [41].

Twenty-three (88.5%) studies reported statistically significant effects. Among them, 11 (47.8%) were delivered face to face by disciplinary specialists [36,39,45,83,95,96,105,152,154,155,157], while 7 (30.4%) studies used remote delivery methods [30,41,82,117,119,143,147], followed by 5 (21.8%) delivered both in-person and online [38,51,84,144,145]. These interventions typically followed a weekly format, lasting from 1 to 12 weeks. Individual sessions ranged from 10 minutes to 2.5 hours, with follow-up periods spanning from immediately after the intervention to 15 months.

Mindfulness-Based Interventions

Twenty-four (19.7%) studies evaluated the effect of MBIs [29,33,68,69,71,73-78,85,99-104,110,121,125,126,128,146]. Seven (29.2%) studies [29,33,100,102-104,128] used mindfulness-based stress reduction interventions. Six (25%) [73,76,77,110,121,146] applied mindfulness-based cognitive therapy. Four (16.7%) studies [74,75,78,101] evaluated mindfulness-based fitness or movement programs, and 1 (4.2%) study [71] conducted a mindful self-compassion program. Additionally, 6 (25%) studies [68,69,85,99,125,126] incorporated a mix of mindfulness components. Most studies (n=16, 66.7%) were RCTs [29,33,74-78,100-103,121,125,126,128,146], followed by 6 (25%) pre-post studies [68,69,71,85,99,104] and 2 (8.3%) mixed methods studies [73,110].

The majority (n=21, 87.5%) reported statistically significant effects. Disciplinary specialists delivered most effective interventions (n=14, 66.7%) face-to-face, while 7 (33.3%) studies delivered interventions remotely via websites [74,104,125,128], and apps [62,68,69]. The majority of interventions (n=19, 90.5%) involved weekly sessions lasting between 5 and 12 weeks, with each session lasting between 90 minutes and 2.5 hours. All studies measured outcomes immediately post intervention, and the longest follow-up lasted 1 year.

Acceptance and Commitment Therapy

Fifteen (12.3%) studies evaluated the effect of ACT [55,64,65,86-88,98,116,118,124,129-131,134,135]. Among them, 8 (53.3%) studies were RCTs [55,65,86-88,98,118,134], while 7 (46.7%) followed a pre-post design [64,116,124,129-131,135].

Most studies (n=11, 73.3%) reported statistically significant effects. All effective interventions were delivered in person by disciplinary specialists, following a weekly format that ranged from a single session to 8 weeks. Each session lasted between 50 and 120 minutes. Follow-up periods varied widely, from immediately post intervention to up to 8 months.

Tailored Psychoeducational Interventions

Thirteen (10.6%) trials evaluated the effect of tailored psychoeducational interventions. Among them, 5 (38.5%) studies [53,54,108,109,151] evaluated the effect of an intervention named the Managing Cancer and Living Meaningfully intervention. Three (23.1%) studies evaluated the effect of a melanoma care program [79-81]. The majority of studies were RCTs (n=9, 69.2%) [53,54,70,79-81,106,127,151].

Most studies (n=9, 69.2%) reported statistically significant effects. All interventions were delivered by disciplinary specialists, with 8 (88.9%) delivered face-to-face. The duration of effective interventions ranged from 4 to 24 weeks, with individual sessions lasting between 30 minutes and 4 hours. Follow-up periods ranged from immediately post intervention to up to 3 years.

Others

In addition to the widely used interventions described above, 6 (4.9%) studies explored alternative approaches, including writing interventions [66,138], a holistic biopsychosocial intervention [150], a problem-solving intervention [97], an intervention grounded in hope theories [113], and an intervention inspired by broadening and building theories [158]. Among them, 5 (83.3%) studies used a pre-post design [66,97,113,120,150], and 1 used an RCT design [138]. Five (83.3%) reported statistically significant effects and were delivered online by disciplinary specialists. Follow-up periods ranged from immediately post intervention to 4.5 months.

Discussion

Principal Findings

This scoping review is the first to map all psychological intervention strategies for alleviating FCR across cancer types and to identify key gaps in existing evidence. From our review, only about one-fifth of the studies reported the definition of FCR used. Eighteen validated FCR measurement tools were identified. Blended interventions, CBT, and MBIs were the most common approaches, typically delivered face-to-face by disciplinary specialists. Breast cancer populations dominated the evidence base, while other cancer types received limited attention. Most interventions reported statistically significant effects in reducing FCR, although the wide variation in study designs, intervention components, outcome measures, and follow-up durations makes meaningful interpretation difficult.

A clear definition of FCR is critically important, as it underpins the identification of its clinical manifestations, supports accurate diagnosis in clinical settings, and informs the design of targeted interventions that address the specific fears and cognitive patterns associated with cancer recurrence [21,32]. Much of the existing literature treats the definitions of FCR and FoP interchangeably [159,160]. However, Coutts-Bain et al [161] conducted a factor analysis and found that, although FCR and FoP are related, they are structurally distinct psychological constructs. It challenges the previous assumption that the two are the same construct and emphasizes the importance of clearly distinguishing between FCR and FoP in clinical practice and research. Conceptually, FCR is more relevant to cancer survivors

XSL•FO
RenderX

who have completed curative treatment and are in remission, encompassing concerns about the cancer returning after a period of being disease-free. In contrast, individuals with metastatic cancer are less likely to fear recurrence and more likely to experience fear of progression, worrying about the cancer worsening or spreading further due to the ongoing nature of their illness [162]. Consequently, clearly distinguishing between FCR and FoP in clinical practice and research not only facilitates the development of more effective, targeted interventions but also enhances the accuracy of research findings and enables the provision of more tailored psychological support to cancer survivors.

Blended interventions were the most commonly investigated for reducing FCR among cancer survivors, with numerous studies reporting positive outcomes. This finding aligns with another review of 13 studies [163], which also identified that interventions combining CBT and MBI strategies were effective in reducing FCR. In recent years, researchers have proposed that traditional CBT may have limitations in managing FCR, particularly among survivors living with ongoing uncertainty [21,164]. An overemphasis on challenging "irrational" thoughts may leave some people feeling misunderstood or emotionally invalidated, especially when their fears are grounded in real risk rather than cognitive distortion [165]. However, evidence supporting these concerns remains limited. Some scholars regard ACT as a contextual extension of CBT, incorporating core mindfulness-based practices to enhance individuals' awareness and acceptance of their emotions [166]. Similarly, mindfulness techniques are increasingly integrated into traditional CBT. A prime example of this integration is mindfulness-based cognitive therapy, which combines the cognitive restructuring techniques of CBT with mindfulness practices to help individuals break the cycle of negative thinking and reduce the FCR [121].

The diversity in FCR interventions reflects the lack of a universally agreed theoretical foundation and the variety of disciplinary approaches to understanding cancer-related psychological experiences, which creates challenges for their application in clinical practice. Despite growing research on FCR interventions, cancer survivors still rarely receive support for managing FCR outside the research environment [167]. It is therefore important to identify the core effective components across FCR interventions and to examine whether tailored approaches for specific cancer populations offer advantages over more general interventions [168]. Furthermore, for widespread adoption, considerations such as cost-effectiveness and resource requirements will be essential to ensure the feasibility of dissemination [169,170].

The majority of existing FCR interventions were resource-intensive, requiring in-person delivery over multiple sessions by trained specialists. These findings are also supported by a previous review by Pradhan et al [122]. As FCR is a persistent and commonly unmet concern across cancer survivor populations, there is a pressing need for scalable solutions [47,164]. In addition, a recently published consensus statement [165] indicates that approximately 80% of cancer survivors do not require high-intensity therapy, and that lower-intensity approaches, such as self-guided online programs, psychoeducational resources, or brief interventions delivered via SMS text messages or telephone, can reduce FCR [165]. In this context, mobile health interventions offer greater scalability and accessibility with reduced demands on health care resources, making them a promising alternative [171]; text messaging–based programs have shown positive outcomes in the management of mental health disorders [172] and in improving self-management of chronic conditions [173]. However, there remains a lack of mobile health programs in managing FCR.

In this review, the majority of studies (85%) reported statistically significant effects of interventions on FCR. This trend is consistent with evidence from previous systematic reviews and meta-analyses, which also demonstrated small-to-moderate reductions in FCR across specific psychological interventions [164,174]. However, this predominance of positive findings may be partially explained by publication bias, whereby studies with null or negative results are less likely to be published [175]. Researchers and journals often favor significant or "positive" outcomes, which can distort the evidence base and lead to an overestimation of intervention effectiveness [176]. Selective outcome reporting may further contribute to this bias, as authors might emphasize significant results while downplaying or omitting nonsignificant findings [177]. Small sample sizes in some studies may increase the risk of false positives and inflated effect sizes [178]. Collectively, these factors could mislead clinical decision-making and contribute to the adoption of interventions with uncertain or limited effects. In addition, while most interventions reduced FCR, these findings should be interpreted with caution due to the heterogeneity across the included studies. The interventions varied widely in terms of dose, delivery format, sample size, measurement time points, and study design, all of which pose significant challenges for synthesizing the findings. Such variability limits the comparability of studies and makes it difficult to have a specific conclusion regarding the overall effect of interventions for managing FCR. These challenges are inherent to scoping reviews, which aim to map diverse and broad evidence [28,179]. It is necessary to conduct a systematic review with high-quality RCTs to evaluate the effectiveness of different interventions in the future.

Although FCR was recognized as a clinical concern in the 1980s [1], our review found that interventions only began to appear from around 2009. FCR was underrecognized as a distinct psychological construct and was often assessed as part of broader measures of distress, anxiety, or quality of life previously [7]. The lack of validated tools specifically designed to assess FCR also limited early research and hindered the earlier evaluation of intervention outcomes [58]. Over the past two decades, the growing number of cancer survivors has shifted the focus of cancer care from survival alone to long-term psychological well-being, highlighting the need for FCR-specific interventions [2].

Limitations

First, this review used a vote-counting approach to summarize intervention effects because of the heterogeneity across studies. However, this means all studies were weighted equally, regardless of their quality, sample size, or effect size, which

XSL•FO
RenderX

limits our ability to compare effect estimates or assess the clinical meaningfulness of intervention outcomes. In addition, we did not conduct a quality appraisal of the included studies, consistent with the methodological nature of a scoping review. Future research would benefit from high-quality systematic reviews and meta-analyses that incorporate rigorous risk-of-bias assessments and enable quantitative comparisons of the effectiveness of different intervention modalities.

Second, this review was limited to English-language articles or English-language abstracts, and the exclusion of non-English publications may have reduced the completeness and representativeness of the evidence. This restriction may introduce language bias and underrepresent studies conducted in non-English-speaking regions. Nonetheless, our review included studies from 5 continents, indicating some geographic diversity despite the language limitation. Future reviews should consider removing language restrictions to ensure broader inclusion.

Third, this review relied solely on published information and did not seek additional details from study authors, which may have resulted in incomplete reporting of methodological or contextual elements, such as the specific definitions of FCR used. Future studies would benefit from more detailed reporting and from contacting authors when necessary to obtain missing information.

Conclusion and Implications

Our scoping review mapped the full range of psychological intervention strategies aimed at alleviating FCR across cancer types. We identified 122 studies encompassing diverse FCR interventions. FCR has been the focus of an increasing number of studies since 2009, with the majority being RCTs. Most interventions are delivered face-to-face and rely on trained specialists, limiting their scalability and accessibility. Most have had statistically significant results. However, the included studies demonstrated heterogeneity in terms of delivery, duration, and dose, requiring cautious interpretation of intervention effects. Future research should develop consistent guidelines to standardize the definition of FCR, the measurement tools used, and the timing of follow-up assessments, thereby improving comparability across studies and strengthening the evidence base. Long-term follow-up data are needed to evaluate the sustained effects. As most studies have focused on breast cancer survivors, further research is needed to provide evidence for other cancer populations.

Abstract

Background: People surviving breast cancer often face long-term impairments in physical function, significantly impacting their quality of life. In recent years, a variety of technologies have been developed to monitor and assess these functions; however, there is no consolidated synthesis linking specific technologies to targeted functional domains and real-world clinical contexts, limiting comparability and translation into practice.

Objective: This scoping review aimed to systematically explore and map the use of advanced clinic-based technologies for assessing and monitoring key physical functions, such as balance, muscle strength, and range of motion, among individuals surviving breast cancer. The purpose of this review was not only to identify which technologies have been applied but also to clarify how they are being used, the clinical settings, target physical functions, assessment protocols, and types of outcomes measured. It further summarized the current patterns of use to inform and enhance clinical assessment practices.

Methods: A comprehensive literature search was conducted across MEDLINE, Scopus, CINAHL, and Web of Science databases, with no publication date restrictions. Eligible studies included adults with breast cancer assessed using advanced clinic-based technologies to monitor physical function. Screening and selection followed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The data extraction captured study characteristics, participant demographics, technologies applied, and related outcomes. The extracted data were organized in Covidence and synthesized descriptively to map the types of technologies, assessed functional domains, and application settings across studies.

Results: Across the 17 included studies, the participants (N=719; age range between 30 and 75 years) were predominantly female and largely drawn from stage 0 to III breast cancer cohorts; 1 (5.9%) study reported a single male participant, and 2 (11.8%) studies did not specify participant sex. Among the 17 included studies, 11 (64.7%) were published from 2017 onward. Technologies spanned balance platforms (force plates, Technobody-PK 200 WL, Sensory Organization Test; 5/17, 29.4%), isokinetic dynamometry (Biodex systems; 4/17, 23.5%), and range of motion assessment via motion capture (3/17, 17.6%) or digital inclinometers (5/17, 29.4%). Sample sizes per study ranged from 20 to 100 participants (median 43), and follow-up durations varied from 1 session to 6 months.

Conclusions: Advanced clinic-based technologies for assessing balance, muscle strength, and range of motion in breast cancer survivors were identified across the literature, including balance platforms, isokinetic dynamometry, digital inclinometers, and markerless motion capture systems. Considerable heterogeneity in devices, outcome reporting, and study designs limited direct comparison across studies and prevented definitive conclusions about the superiority or clinical readiness of any single technology.

Introduction

Breast cancer remains the most prevalent malignancy among women worldwide, with increasing survival rates due to advances in early detection and treatment [1]. Although breast cancer mortality has declined in recent decades, as survival rates improve, attention has shifted from survival alone to long-term recovery, quality of life, and function, with rehabilitation emerging as a central component of survivorship care [2-4]. Physical function, the ability to perform physical tasks that enable daily activities and participation, is an important factor in cancer survivorship and rehabilitation and is framed within the International Classification of Functioning, Disability, and Health (ICF) [5]. Impairments in physical function after breast cancer treatment are commonly reported and include deficits in balance, muscle strength, and range of motion (ROM) [6-8]. Women undergoing chemotherapy may experience up to a 25% loss in strength and joint dysfunction [8]. Moreover, individuals surviving cancer have highlighted difficulties with balance and walking as the most common functional issues, with prevalence rates of 19% and 24%, respectively [9]. These functional limitations have been associated with poorer health-related quality of life and reduced mobility in survivorship cohorts [10,11]. At the same time, impairments in gait and balance control have been documented as potential contributors to fall risk and reduced independence in everyday life among breast cancer survivors [6]. According to the literature on cancer survivorship, over half of individuals who have undergone cancer treatments encounter physical function impairments [12].

The American Physical Therapy Association (APTA) Oncology Evaluation Database to Guide Effectiveness (EDGE) Task Force has provided evidence-based recommendations for standardized outcome measures in oncology rehabilitation. For balance assessment, the Task Force strongly supports the use of low-cost, performance-based tools such as the Fullerton Advanced Balance Scale, gait speed, Timed Up and Go, Five Times Sit-to-Stand, and the Balance Evaluation Systems Test, all rated as reliable and clinically feasible for cancer survivors [13]. In contrast, computerized balance systems such as force plates and the Sensory Organization Test (SOT) have been less recommended due to limited clinical utility and high cost, despite growing evidence supporting their sensitivity in detecting subtle postural sway and vestibular deficits in individuals with cancer and chemotherapy-induced peripheral neuropathy [14]. For shoulder ROM, the Task Force rated passive goniometry (score 4) as a recommended tool, while for muscle strength, handheld dynamometers (HHDs) (score 3) and manual muscle testing (score 2B) were endorsed as appropriate clinical measures [15]. Although these conventional methods remain the clinical standard, their limited sensitivity and responsiveness underscore the need for more objective, automated technologies capable of quantifying subtle changes in function [16,17].

Furthermore, a variety of technologies such as wearable sensors (accelerometers/pedometers), fitness trackers, smartphone apps, and advanced motion-capture systems are increasingly used to quantify physical function in breast cancer survivorship [18-22], providing objective, high-resolution data [21,22]. However, most reported applications remain in research or specialized settings with limited protocol and outcome standardization [19,22].

Accordingly, this review aims to map and characterize the use of such advanced, clinically based technologies in assessing key physical functions, including balance, muscle strength, and ROM, among individuals surviving breast cancer. For the purposes of this review, “advanced” is defined as instruments that provide automated, objective outputs beyond unaided observation or analogue readouts. “Clinic-based” denotes systems that can be operated in clinical rooms or clinically configured spaces by routine clinical staff with minimal specialist engineering support, for monitoring and assessing physical functions. These terms were selected based on their relevance within the ICF framework and their frequent association with impairment among breast cancer survivors [6,23,24]. By examining how these technologies are currently integrated into clinical practice, this review seeks to identify gaps in the existing literature and highlight areas where further research is needed.

Methods

Search Strategy

A comprehensive literature search was conducted across the MEDLINE, Scopus, CINAHL, and Web of Science databases. The initial search strategy was developed in collaboration with an experienced academic health sciences librarian (Liz Dennett) to ensure methodological rigor and comprehensive coverage. The selection of the search terms was informed by preliminary scoping searches and key indexing terms from prior reviews in oncology rehabilitation and motion analysis. The MEDLINE strategy served as the base and was adapted for syntax variations across databases. The search was conducted in multiple stages, starting with the initial search on February 2, 2024, followed by updates on June 24, 2024. Each search was repeated across the 4 databases to ensure comprehensive coverage of the relevant literature. The final search included combinations of controlled vocabulary, such as MeSH (Medical Subject Headings) terms and free-text terms related to breast cancer, physical function, and measurement technologies. The complete search strategy and related keywords are provided in Multimedia Appendix 1. In addition to peer-reviewed databases, gray-literature searches were limited to PhD dissertations. All identified articles were imported into Covidence software (Covidence Ltd) for screening. Duplicate records were automatically identified and removed by Covidence’s built-in algorithm, followed by manual verification by the reviewers to ensure accuracy.

Inclusion and Exclusion Criteria

Studies were included if they were published in English, had full-text availability online, involved adults diagnosed with breast cancer, and utilized technologies to objectively measure

XSL•FO
RenderX

one or more physical functions (balance, strength, and ROM) as primary or secondary outcomes. No publication date restrictions were applied. All study designs were considered for inclusion, excluding nonoriginal articles such as study protocols, reviews, conference abstracts, books, or editorials. Additionally, studies were excluded if they involved technologies that did not meet the criteria for being both advanced and clinically based. These technologies are intended to directly assess and monitor physical functions in patients, facilitating clinical decision-making and supporting rehabilitation processes. Technologies like Vicon, for instance, were excluded if they were not designed for clinical use. To be effective in clinical settings, technologies must be easily integrable into workflows without requiring complex setups or specialized technical expertise.

Screening and Selection Process

An initial search strategy was developed in collaboration with the academic librarian to capture studies using any technology to assess physical function in adults with breast cancer. During the title and abstract screening process, it became evident that this comprehensive approach would yield several hundred eligible studies, predominantly due to the extensive literature on accelerometers and pedometers, as well as the frequent application of laboratory-based marker-based motion-capture systems. To preserve methodological rigor and avoid redundancy with existing systematic reviews and meta-analyses focused on accelerometer and pedometer studies, while ensuring a clinically actionable synthesis, an additional consultation with the librarian was conducted to refine the eligibility criteria prior to initiating full-text review and data extraction. The inclusion criteria were subsequently refined to prioritize advanced, clinically deployable technologies for point-of-care assessment of 3 core domains of physical functions. As a result, articles that used traditional technologies, such as dynamometers or goniometers, which do not meet the established definition of advanced measurement technology for the purposes of this review; nonclinic–based accelerometers and pedometers; and some lab-based motion capture systems requiring reflective markers, multicamera stereophotogrammetry, calibration routines, and dedicated laboratory infrastructure, were excluded unless the authors explicitly described clinical deployment or adaptation for real-world clinical settings. The study selection process was conducted in several stages following established scoping review methodology. Initially, two reviewers (authors MA and AW) independently screened titles and abstracts of all retrieved references against the eligibility criteria. Discrepancies between the two reviewers at this stage were flagged within Covidence for subsequent resolution. Studies deemed potentially eligible by either reviewer advanced to full-text screening, which was similarly conducted independently by the same two reviewers (MA and AW). Following both screening phases, conflicts were systematically resolved through a structured consensus process. For any study where the two primary reviewers disagreed on inclusion or exclusion, the full text and relevant eligibility criteria were reviewed collaboratively by all three reviewers (MA, AW, and MFP) in a consensus meeting. During these discussions, each reviewer presented their rationale, and discrepancies were resolved through deliberation until unanimous agreement was reached. If consensus could not be achieved through discussion, the third reviewer (MFP) served as the final arbiter. All final inclusion decisions and data extraction were completed through this consensus process, with regular meetings held among the three reviewers to ensure consistency in the interpretation of eligibility criteria and data extraction procedures throughout the review.

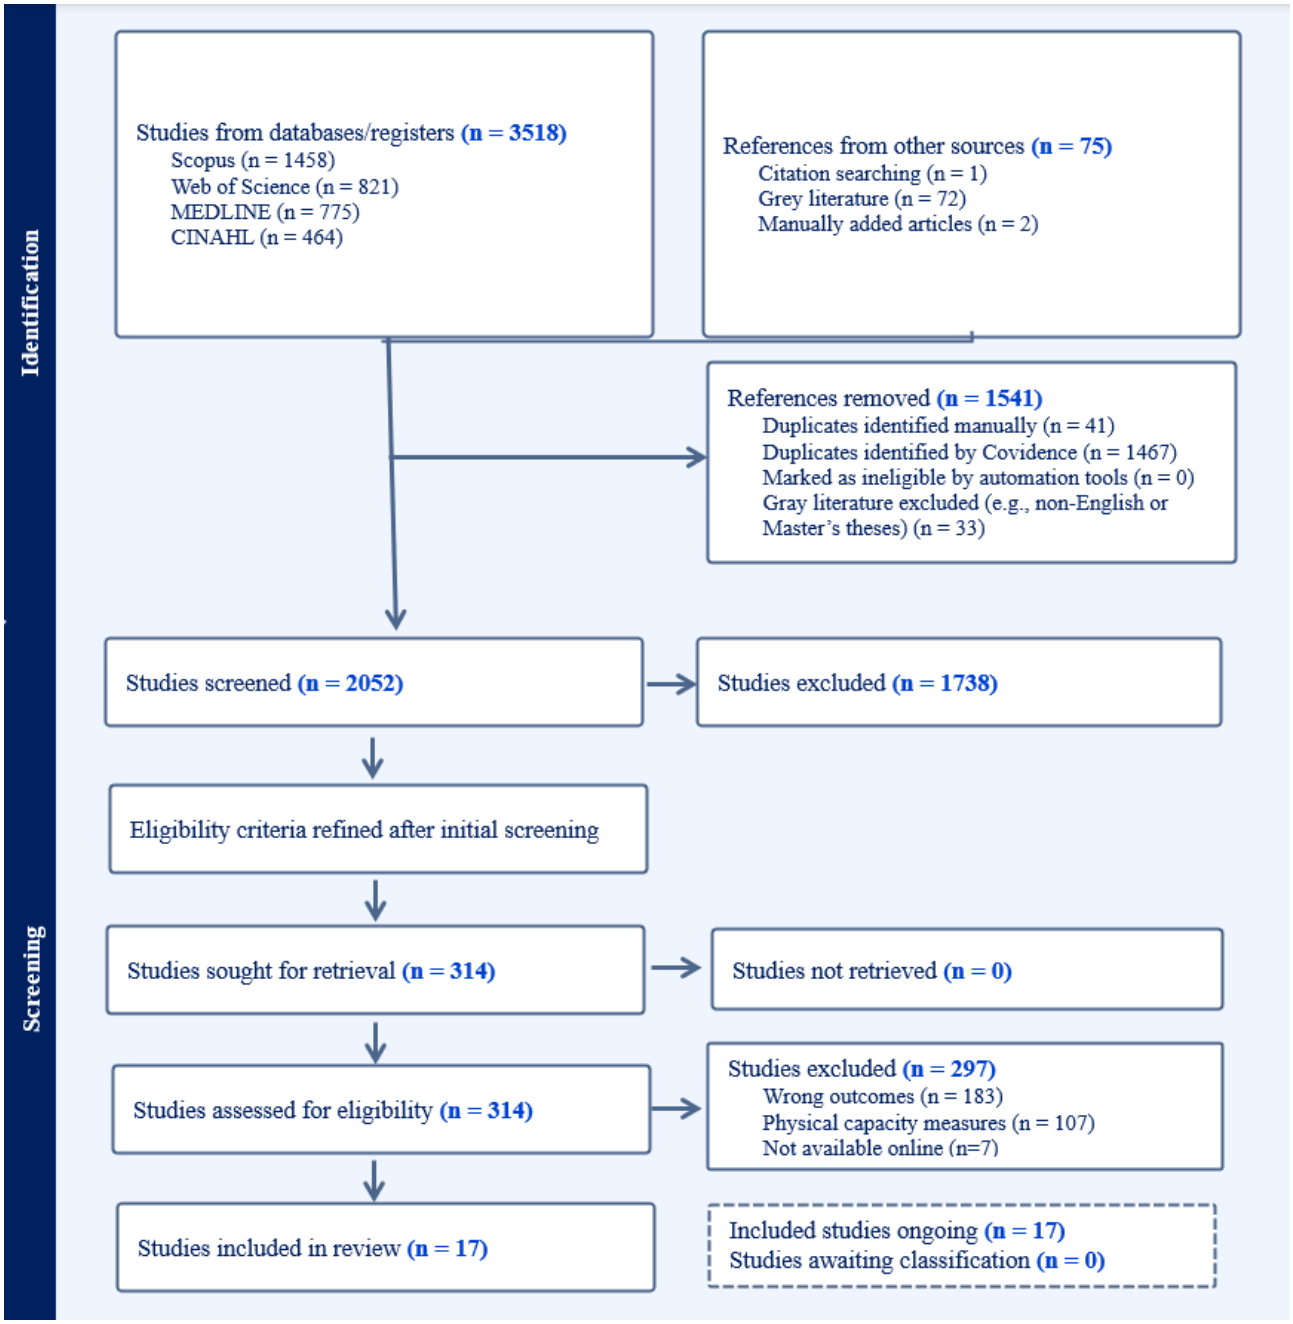
Data Extraction

Data extraction was collaboratively performed by the three reviewers (MA, AW, and MFP). For each included study, details regarding the study title, year of publication, country, aim, and design were recorded. Participant characteristics, including demographic information, inclusion and exclusion criteria, and recruitment methods and settings, were extracted. Information on sample size, cancer treatment details, and the instruments employed, including technological characteristics, was collected. We also recorded methodological features relevant to implementation and key findings reported by the original authors in relation to the use or outcomes of the measurement technology. The extracted data were organized and managed in Covidence for transparency and synthesis.

Data Synthesis

The extracted data from relevant studies were synthesized narratively and summarized in tabular format to provide a comprehensive overview of advanced clinic-based technologies used to monitor and assess functional outcomes in individuals surviving breast cancer. Studies were first categorized by the component of physical function assessed (balance, strength, and ROM) and then organized according to the specific measurement technology employed. For each technology identified, the corresponding data analysis methods used in the original studies were extracted and documented. This synthesis sought to deliver an analysis of the current knowledge and methodologies used to assess the included physical functions. The findings were analyzed to highlight common methodologies, instruments, and outcomes reported in the literature. This process defines how functional outcomes are commonly evaluated in individuals with breast cancer using advanced and clinic-based technologies and identifies potential gaps or inconsistencies in current practices, including variations in measurement protocols, differences in data normalization methods, and the range of technologies applied to assess similar functional outcomes.

Results



Study Identification

Initially, 3593 articles were retrieved from Medline, Scopus, Web of Science, CINAHL, and gray literature. After removing duplicates and nonrelevant gray literature (n=1508), a total of 2052 records were screened for eligibility. Following title and abstract screening, 314 articles were eligible for full-text review. Ultimately, 17 studies, each assigned a unique study ID (ranging from 001 to 017), were included for data extraction. These 17 studies, involving a total of 719 participants, were included in the review. The number of articles and methodologies utilized for reviewing, selecting, and verifying them at each stage of the

XSL•FO
RenderX

process is presented in a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram (Figure 1) [25]. While gray literature, including PhD dissertations, was considered, none met the inclusion criteria. Furthermore, the specific characteristics of the studies included in this study are comprehensively detailed in Table 1, providing an in-depth overview of their methodologies, sample populations, and key findings. Additionally, no formal quality assessment of the studies was conducted as part of this scoping review.

Table 1. Characteristics of the included studies.

ID	Author (s)	Pub. Year	Title	Study setting and design	Sample size and participant characteristics	Physical function	Instruments	Key findings
001	(Bertoli et al) [26]	2023	Mat Pilates improves lower and upper body strength and flexibility in breast cancer survivors undergoing hormone therapy: a randomized controlled trial (HAPiMat study).	Hospital and randomized controlled trial	n=43; stage 0-III; ≥40 years; undergoing hormone therapy; sex not reported	Hip flexor and extensor muscle strength	Biodex Medical system 4 (Shirley)	Biodex assessments showed that the Pilates group significantly improved their lower body strength, with increases in isometric flexor-extensor peak torque and enhanced concentric and eccentric flexor peak torque and mechanical work.
002	(Rao and Pattanshetty) [27]	2022	Effect of myofascial release, stretching, and strengthening on upper torso posture, spinal curvatures, range of motion, strength, shoulder pain and disability, and quality of life in breast cancer survivors.	Hospital and pre - post experimental study	n=22; female, 35-70 years; newly diagnosed; treated with surgery, radiation, chemotherapy, or combination	Shoulder and cervical range of motion	Cervical range of motion was evaluated using a digital inclinometer	Significant improvements were observed for cervical movements.
003	(Højvig et al) [28]	2022	Donor-site morbidity following breast reconstruction with a latissimus dorsi flap - A prospective study.	Hospital and prospective observational study	n=20; female, 32-70 years; undergoing delayed breast reconstruction with latissimus dorsi flap	Shoulder Strength	Biodex System4 Pro-dynamometer	The study revealed that breast reconstruction using the LD[a] flap led to significant decreases in isometric shoulder strength for adduction and extension due to LD muscle removal, supporting its impact on shoulder girdle strength; however, isokinetic strength remained largely unchanged 12 weeks after surgery.
004	(Zabi˙t Özdemir and İyi˙gün) [29]	2022	Is there a difference in balance functions between breast cancer survivor women and healthy women?	Eastern Mediterranean University's Healthy Living Center and A prospective study	n=66; female, 35-70 years; 33 postmastectomy survivors vs 33 healthy controls; no chemo/radiation	Dynamic balance	Computer-based Dynamic Balance Platform (Technobody-PK 200 WL)	No differences were observed between the groups in subparameter dynamic balance measurements, computer-based dynamic balance platform assessments, or Y-Balance Test results.

005	(Wechsler et al) [30]	2022	Persistent cancer-related fatigue predicts static and dynamic balance in women with a history of breast cancer	A breast cancer center at a large urban hospital and cross-sectional study	n=43; female, 30-85 years; postchemotherapy ± radiation; stage I-III	Static and dynamic balance	Force plates (Bertec Corporation model 4060NC)	CRF[b] independently and significantly impairs both static and dynamic balance individuals surviving cancer, leading to compensatory stabilization strategies and highlighting CRF's critical role in increased postural sway and fall risk even years after treatment.
006	(Artese et al) [31]	2021	Effect of functional impact training on body composition, bone mineral density, and strength in breast cancer survivors	Laboratory and randomized controlled trial	n=44; sedentary postmenopausal women, 52-68 years; stage 0-III; ≥3 months postchemotherapy/radiation.	Isokinetic concentric knee extension and flexion	Biodex Medical System 3 (Shirley)	Both groups demonstrated significant improvements over time in lower body strength, specifically in isokinetic knee extension and flexion at all tested speeds. However, after adjusting for baseline differences and time since diagnosis, there were no significant differences in posttraining knee strength measures between the two groups.
007	(Evans et al) [32]	2021	Examination of clinical and laboratory measures of static and dynamic balance in breast cancer survivors	In the Department of Rehabilitation Services at Alamance Regional Medical Center and a cross-sectional study	n=43 (20 breast cancer survivors + 23 controls); female, 40-70 years; stage 0-III; completed chemo/radiation ≤ 5 years	Static balance	SOT[c] was conducted using the NeuroCom SMART Balance Master (Natus Medical, Pleasanton)	NeuroCom SOT equilibrium assessments revealed that individuals surviving breast cancer generally maintained similar postural stability to the healthy control group. However, they showed significantly impaired balance in Conditions 2 and 3, which rely on proprioceptive and vestibular systems for maintaining balance.

008	(Uhm et al) [33]	2020	Usefulness of Kinect sensor-based reachable workspace system for assessing upper extremity dysfunction in breast cancer patients	Konkuk University Medical Center and a cross-sectional study	n=20; age 46-62 years; unilateral breast cancer; sex not specified	Upper extremity active range of motion	The Kinect sensor-based reachable workspace analysis system	The reachable workspace was divided into four shoulder-centered quadrants: upper medial (Q1), lower medial (Q2), upper lateral (Q3), and lower lateral (Q4). The analysis revealed that the upper quadrants (1 and 3) on the affected side had significantly smaller reachable workspace areas compared to the unaffected side, while the lower quadrants showed no differences.
009	(Ribeiro et al) [34]	2019	Three-dimensional scapular kinematics, shoulder outcome measures and quality of life following treatment for breast cancer - a case control study	An outpatient breast cancer surgery (part of a hospital) and case control study	n=42; female, 40-60 years; 21 presurgery vs 21 controls	Shoulder range of motion	Shoulder motion measured by a digital inclinometer	The breast cancer surgery group exhibited reduced range of motion compared to healthy controls.
010	(Monfort et al) [35]	2017	Gait, balance, and patient-reported outcomes during taxane-based chemotherapy in early-stage breast cancer patients	An outpatient oncology clinic setting and longitudinal study	n=33; 32 female, 1 male; 36-59 years; Stage I-3	Static balance	Balance plate (Bertec Corp)	Cumulative exposure to taxane therapy was associated with notable declines in patients' balance, indicating a detrimental effect on their physical functionality.
011	(De Groef et al) [36]	2017	Effect of myofascial techniques for treatment of upper limb dysfunctions in breast cancer survivors: randomized controlled trial	Department of Physical Medicine and Rehabilitation of the University Hospitals Leuven and randomized controlled trial	n=48; female, 38-70 years; primary breast cancer; 23 intervention vs 25 control	Active shoulder range of motion	Inclinometer	The study found no significant differences between the group receiving myofascial therapy combined with physical therapy and the group receiving physical therapy alone in terms of shoulder range of motion.
012	(De Groef et al) [37]	2016	Arm lymphoedema and upper limb impairments in sentinel node-negative breast cancer patients: a one-year follow-up study	Multidisciplinary Breast Centre of University Hospitals Leuven and longitudinal study	n=100; female, 50-70 y	Shoulder range of motion	Gravity inclinometer	One year after the sentinel lymph node biopsy, 30% of patients experienced reduced shoulder range of motion.

013	(Moreira et al) [38]	2015	A Kinect-based system for upper-body function assessment in breast cancer patients	Not specified and an observational study	n=48; female; 24 with lymphedema; age not reported	Upper-body joint range of motion includes shoulder, elbow, and wrist flexion/extension and shoulder abduction/adduction	Kinect-based system	The study validated a Kinect-based system for assessing upper-body function, demonstrating high accuracy in classifying normal vs. impaired function. The system, which uses kinematic data for machine learning classification, shows potential for remote monitoring and early detection of functional impairments during rehabilitation.
014	(Gritsenko et al) [39]	2015	Feasibility of using low-cost motion capture for automated screening of shoulder motion limitation after breast cancer surgery	Academic cancer center oncology clinic and descriptive study	n=20; women, 51-69 years; stage 0-III	Active and passive shoulder range of motion	Motion capture by Kinect	The study found that the low-cost Kinect motion capture system effectively identified moderate to severe shoulder motion impairments in individuals surviving breast cancer, with strong correlations to goniometric measurements for active movements.
015	(Winters-Stone et al) [40]	2011	Identifying factors associated with falls in postmenopausal breast cancer survivors: a multidisciplinary approach	Comprehensive cancer center and case-control plus prospective observation	n=59; female, 49-68 years; stage 0-III	Dynamic balance	The SOT, used in computerized dynamic posturography	Individuals surviving breast cancer had higher fall rates due to vestibular balance deficits from chemotherapy, particularly affecting dynamic balance, while static balance remained similar between fallers and non-fallers.
016	(Harrington et al) [41]	2011	Comparison of shoulder flexibility, strength, and function between breast cancer survivors and healthy participants	The Neuromuscular Research Laboratory and case-control study	n=48; female, 40-60 years; stage 0-III	Active and passive shoulder range of motion	Digital inclinometer	The study found that breast cancer survivors had reduced shoulder range of motion compared to healthy controls, particularly in flexion and external rotation.
017	(Waltman et al) [42]	2003	Testing an intervention for preventing osteoporosis in postmenopausal breast cancer survivors	In participants' homes or at convenient sites and pilot intervention study	n=21; female, 40-65 years; stage I-II	Muscle strength of the knee, hip, and wrist (flexion and extension)	Biodex System 2 multijoint testing	The study found significant improvements in muscle strength for hip flexion, hip extension, and knee flexion over 12 months.

Characteristics of the Included Studies

A review of 17 studies focusing on individuals surviving breast cancer revealed key insights into research locations, designs, timelines, participant stages, and objectives. The United States emerged as the most common location, hosting 7 (41.2%) of the included studies. The remaining research was conducted across a diverse set of countries, including Finland, Turkey, Portugal, Belgium, Brazil, South Korea, India, and Denmark. The review included 5 (29.4%) experimental studies, among which were 3 (17.6%) randomized controlled trials [26,31,36], 1 (5.9%) pretest-posttest experimental study [27], and 1 (5.9%) pilot intervention, [42] and 12 (70.6%) observational studies, including 4/17 (23.5%) cross-sectional studies [30,32,33,38], 3 (17.6%) case-control studies [34,40,41], 2 (11.8%) prospective observational studies [28,29], 2 (11.8%) longitudinal cohort studies [35,37], and 1 (5.9%) descriptive study [39]. The publication timeline indicated a growing interest in this area, with 11 (64.7%) studies published in 2017 or later, while the remaining 6 (35.3%) studies were published between 2003 and 2016 [37-42]. The studies aimed to assess different physical functions, with a particular emphasis on balance, strength, and flexibility related to breast cancer treatments. The objectives of the studies were varied, ranging from evaluating the effectiveness of specific interventions, such as mat Pilates [26] and myofascial techniques [36], to assessing the impact of cancer-related fatigue [30] on balance and postural control. Some studies also investigated the feasibility and usefulness of motion capture technologies for screening and assessing functional impairments [33,38,39].

Furthermore, the studies included in the review were conducted in multiple settings, predominantly within specialized medical facilities. Many studies took place in hospitals or hospital-affiliated centers. Isokinetic dynamometry using Biodex was reported mainly in hospital settings [26,28], with 1 (5.9%) study conducted in a laboratory environment [31]. Digital inclinometers were used across hospitals, rehabilitation services, and outpatient oncology clinics [34,36,37,41]. Kinect-based markerless motion capture (MMC) was implemented within oncology services spanning a medical center and an outpatient oncology clinic [33,38,39]. One (5.9%) study even extended its setting to participants' homes or convenient community sites [42].

In terms of recruitment strategies, many studies enrolled participants through state and hospital cancer registries, clinician referrals, and ongoing treatment facilities within large urban hospitals. Researchers also leveraged community outreach by utilizing social media platforms, distributing flyers in regional cancer hospitals, and engaging with breast cancer support groups. Local media outlets, such as newspapers and radio announcements, were employed to broaden their reach. Some studies relied on word-of-mouth, emails, and telephone contacts.

The studies included in this review primarily focused on individuals surviving breast cancer, with participants aged between 30 and 75 years, and an average age range of 50 to 60 years. Among the 15 (88.2%) studies that reported participant sex, all included only female participants except for 1 (6.7%) study, which included a single male participant [35]. A total of 2 (11.8%) studies did not report any information about participant sex [26,33]. Nine (53%) of the included studies explicitly reported participants' cancer stage; all 9 enrolled individuals with stage 0 to III disease [26,30-32,35,39-42]. Among the 17 studies, 5 (29.4%) studies involved participants undergoing or having recently completed chemotherapy [27,30-32,41], and 1 (5.9%) study specifically enrolled women receiving hormone therapy [26]. Moreover, 1 (5.9%) study focused on surgical reconstruction (latissimus dorsi flap) [28]. Two (11.8%) studies included postmastectomy survivors compared to healthy controls [29,32], and 3 (17.6%) enrolled mixed-treatment cohorts [27,30,40]. In terms of sample sizes, these varied considerably throughout the studies, ranging from as few as 20 participants to as many as 100. People with stage IV cancer and cognitive impairments were generally excluded. Additional exclusion criteria, such as uncontrolled cardiovascular or musculoskeletal conditions, severe neuropathy, or inability to provide informed consent, were applied to ensure participant safety and maintain the validity of assessment results.

Reported Instruments and Key Findings on Physical Function

This scoping review found that most studies assessed physical function using a variety of outcome measures, and ROM was reported in 8 (47.1%) of the included studies [27,33,34,36-39,41]. Balance outcomes were reported in 5 (29.4%) studies [29,30,32,35,40], and muscle strength outcomes were reported in 4 (23.5%) studies [26,28,31,42]. Of these, 3 (17.6%) studies employed motion capture technologies [33,38,39], Kinect-based systems to assess upper extremity kinematics and ROM in individuals surviving breast cancer. Inclinometers were used in 5 (29.4%) studies to further quantify shoulder movements [27,34,36,37,41]. Balance assessments were another key focus: 2 (11.8%) studies employed force plates to measure postural sway in both static and dynamic conditions [30,35], while the SOT was used in another 2 (11.8%) studies to assess balance under varying sensory inputs [32,40]. In addition, 1 (5.9%) prospective study evaluated dynamic balance using a computer-based dynamic balance platform (Technobody PK 200 WL) [29].

Moreover, strength assessments were conducted using different models of the Biodex System (2, 3, 4, and 4 Pro) to evaluate isometric and isokinetic strength in muscle groups, including the shoulder, hip, knee, and wrist [26,28,31,42]. Measurements included isometric strength normalized to body weight, as well as peak torque during isokinetic contractions at varying angles and velocities. Further details on the specific tools and data analysis methods used in each study are provided in Table 2.

XSL•FO
RenderX

Table 2. Overview of technologies and data analysis methods.

Category and technology used	Data analysis method	Author
Strength		
Biodex System 2 multijoint testing	The highest peak torque measure, obtained during 4 repetitions, was recorded in Newton meters and used for data analysis.	Waltman et al [42]
Biodex Medical System 3	The highest peak torque value from the 3 repetitions was recorded for each speed.	Artese et al [31]
Biodex Medical Systems 4	Peak torque and mechanical work, normalized to body mass, were analyzed.	Bertoli et al [26]
Biodex System 4 pro	The data were analyzed by averaging 3 trials of isometric and isokinetic strength (in Nm/kg).	Højvig et al [28]
Digital inclinometer	Active and passive shoulder flexion/extension and external/internal rotation range of motion were measured with 3 trials averaged for data analysis.	Harrington et al [41]; Rao and Pattanshetty [27]; Ribeiro et al [34]
Gravity inclinometer	The analysis assessed the prevalence of impaired shoulder range of motion, defined as an interlimb difference of 15 degrees or more between the affected and unaffected arms. Additionally, it evaluated the number of patients who experienced a decrease in shoulder ROM[a] greater than 15 degrees from their baseline measurements, indicating a significant loss of mobility after treatment or surgery.	De Groef et al [36,37]
Range of motion		
Kinect-based system	The study used a Kinect-based system to capture 3D motion data, extracting features like range of motion, hand height, elbow flexion, and movement acceleration. These were analyzed using machine learning algorithms to classify patients as having normal or impaired upper-body function.	Moreira et al [38]
Automated motion analysis system using Microsoft Kinect	The Microsoft Kinect sensor was used to assess shoulder motion limitations. The technology tracked body landmarks and converted the captured data into joint angles using a custom algorithm.	Gritsenko et al [39]
Microsoft Kinect Sensor	The Microsoft Kinect sensor captured participants' upper extremity motion trajectories during standardized seated arm movements. These data allowed for the reconstruction of each participant's reachable workspace envelope, divided into 4 quadrants relative to the shoulder joint. The reachable surface areas for each quadrant and the total workspace were calculated and then normalized by individual arm length to account for differences among participants.	Uhm et al [33]
Force plate model 4060NC (Bertec Corp) and recorded through Motion Monitor Software (Innsport Training, Inc)	Balance was assessed using a force plate to measure postural sway in the medial-lateral and anterior-posterior planes under both static and dynamic conditions. For static balance evaluation, participants stood still for 30 seconds before and after moderate-intensity exercise. Dynamic balance was measured during the rising phase of an Instrumented Sit-to-Stand test, where participants quickly stood up from a seated position, and sway was recorded throughout this transition.	Wechsler et al [30]
Balance		
Balance plate (Bertec Corp)	Data collected from the CoP[b] included measurements of its location and displacement during standing trials, specifically focusing on the root mean squared excursion in the medial-lateral direction to evaluate postural stability and the risk of falling.	Monfort et al [35]
Technobody-PK 200 WL, a computer-based dynamic balance platform	Participants performed the “Equilibrium Assessment” and “Sleight Assessment” tests on this device, which measured parameters such as anterior/posterior and medial/lateral sleight, balance assessments, number of targets reached, perimeter, and average pace. Each test was repeated 3 times, and the best score was recorded for analysis.	Zabi˙t Özdemi˙r and İyi˙gün [29]
Computerized dynamic posturography with the SOT	Participants' sway responses were recorded under 6 sensory conditions that manipulate visual and somatosensory information.	Winters-Stone et al [40]
NeuroCom SOT[c]	Equilibrium scores from the NeuroCom SOT under 6 conditions varying platform stability and visual input, with and without the serial sevens cognitive task, were analyzed to assess static balance and the impact of cognitive load.	Evans et al [32]

[a]ROM: range of motion.

[b]CoP: center of pressure.

[c]SOT: Sensory Organization Test.

Discussion

Principal Findings

This scoping review mapped 17 studies deploying advanced clinic-based technologies to assess physical function in breast cancer survivors. The review identified technologies used to assess three domains, namely ROM, balance, and muscle strength, and documented variation in instrument type. These technologies were applied in varied clinical environments, primarily hospital-based and outpatient oncology settings, to measure specific aspects of physical function through structured protocols.

The studies used advanced methods to determine how people maintain their balance. These detailed assessments consistently revealed information that simpler, one-time tests often overlook. Studies using advanced balance equipment in clinical settings measured different aspects of postural control and consistently revealed information that simpler, one-time tests often overlook. SOT protocols showed balance problems when proprioceptive and vestibular systems were challenged, even though performance was nearly normal under easier conditions. This suggests that balance deficits in breast cancer survivors depend on the situation rather than affecting all balance tasks equally [32,40]. This pattern supports the clinical value of multi-condition batteries that probe sensory reweighting, rather than relying solely on single-task screens. Force plates quantify quiet-stance stability by deriving center of pressure (CoP) signals and summarizing them with standard sway metrics, typically medial-lateral (ML) and anterior-posterior (AP) excursion (range or root mean square (RMS)), total path length, mean sway velocity, and planar sway area (often a 95% confidence ellipse). These metrics capture both the magnitude (eg, excursion, area) and temporal dynamics (eg, velocity) of postural control. Notably, key ML CoP metrics, including mean velocity, mean amplitude, and RMS displacement, have been linked to higher prospective fall risk [43]. In the included longitudinal study of taxane-based chemotherapy, Monfort et al [35] used a laboratory force plate to track changes in CoP behavior during treatment; cumulative taxane exposure was associated with deteriorations in balance control, reflected by increased sway and concurrent gait alterations (shorter step length, slower walking speed). Complementing this, Wechsler et al [30] showed that cancer-related fatigue independently predicted poorer postural stability on force-plate measurements. Fatigued individuals showed compensatory stabilization strategies and greater body sway in both standing still and moving conditions. Together, these findings suggest that when clinically relevant stressors are present (eg, neurotoxic chemotherapy and fatigue), force-plate CoP metrics could be sensitive to subtle balance changes.

For measuring ROM, the review describes a spectrum of technologies. At one end are digital inclinometers, which are widely accessible but depend on the operator. At the other end are automated MMC systems, which provide less biased 3D assessments and show promising evidence of clinical usefulness. The successful application of MMC for upper extremity ROM assessment in breast cancer survivors was demonstrated across 3 studies in diverse settings, including oncology clinics and outpatient centers. This suggests these technologies have overcome initial feasibility barriers and may be ready for broader clinical implementation [33,38,39]. The strong correlation between Kinect-derived reachable workspace metrics and QuickDASH, a validated and widely used tool for assessing upper extremity disability in breast cancer survivors [44], and the system's ability to detect side-to-side differences in functionally relevant movement zones (overhead reaching) demonstrate practical utility for monitoring recovery [33]. However, there is significant variation in how different studies measure ROM. Studies differ in whether they assess active versus passive motion, which planes or tasks they evaluate, and whether they use absolute measurements versus side-to-side comparisons. This inconsistency makes it difficult to compare studies and develop clear, evidence-based clinical guidelines. Taken together, within the bounds of the included studies, MMC appears to have promising potential for assessing upper-extremity function in breast cancer survivors.

Muscle strength was quantified with isokinetic dynamometry in controlled clinical or laboratory settings [26,28,31,42]. Systems such as the Biodex (models 2-4/4 Pro) are seen as the top choice for testing dynamic muscle strength. They control precise, preset angular velocities and capture full torque-angle-velocity relationships together with work and power outputs. These multidimensional profiles can reveal deficits in force production and velocity-dependent behavior (eg, concentric versus eccentric weakness) that are not apparent from single-value manual grades, and their test-retest reliability in musculoskeletal [45,46]. The trade-off is practical; true isokinetic testing requires dedicated equipment, space, regular calibration, and staff skilled in positioning, stabilization, familiarization, and protocol standardization, all of which limit routine deployment outside well-resourced centers. Given these constraints, many rehabilitation services rely on portable HHDs for strength assessment. Professional guidance from the APTA Oncology EDGE Task Force recognizes HHDs as an appropriate option for cancer populations, provided that clinicians use standardized patient and tester positioning, consistent lever arms, and repeated trials to improve reliability [15].

This scoping review had some limitations. First, the inclusion of solely English-language studies raised the possibility of language bias and the exclusion of relevant work published in other languages. Additionally, the review focused solely on 3 physical functions, potentially overlooking other important aspects of physical function in individuals surviving breast cancer. While multiple databases were searched, some relevant studies may not have been captured if they were published in databases that were not included in the search strategy, which can limit the comprehensiveness of the review. Finally, the variability of the included studies in design, clinical setting, treatment phase, and outcome definitions (eg, active versus passive ROM, task/plane selection, and absolute versus interlimb metrics) precluded quantitative synthesis and limits cross-study comparability. Specifically, individuals with stage IV cancer were typically excluded from most of the included studies to focus on nonmetastatic cases.

Comparison With Prior Work

A recent scoping review by Amarelo et al (2024) [47] examined the application of technological resources in cancer rehabilitation, identifying wearable devices, web-based platforms, mobile health (mHealth) apps, virtual reality, and exergaming as commonly employed tools. Their review emphasized the wide diversity of technologies and underscored the need for further research to assess their long-term effectiveness, cost-efficiency, and successful integration into clinical practice. In contrast, our scoping review narrows the focus to advanced clinic-based technologies specifically used to assess and monitor physical functions, balance, muscle strength, and ROM in individuals surviving breast cancer. By concentrating on this particular population and key physical functions, our review offers a detailed analysis of the clinical applicability, measurement properties, and limitations of these technologies. This focused approach addresses the gap identified by the previous work [47] regarding the need for more targeted research on the integration of technological tools into cancer rehabilitation practices. Moreover, our findings corroborate a previous review that recognizes force plates as effective tools for detecting subtle balance impairments [6] and Biodex systems as the gold standard for muscle strength assessment [48].

Conclusion

This scoping review synthesized current evidence on advanced clinic-based technologies used to assess and monitor 3 key physical functions, namely balance, muscle strength, and ROM, in individuals surviving breast cancer. The review found that balance assessments predominantly utilized force plates and SOT, muscle strength was assessed using various models of the Biodex isokinetic dynamometer, and range of motion was measured using digital inclinometers and MMC systems. These studies were conducted primarily in hospitals and specialized medical facilities, with participant samples spanning various treatment phases and survivorship stages. The review documented considerable heterogeneity in measurement approaches, clinical settings, and reporting practices across the included studies. These findings underline that a diverse toolkit is currently applied to measure physical function in breast cancer survivorship, but that variability in methods limits cross-study comparability. Mapping this landscape can help us prioritize targeted validation and implementation studies and inform the development of pragmatic guidance for selecting feasible, clinically useful technologies in rehabilitation practice.

Abstract

Background: Patients with pediatric cancer often experience reduced physical activity (PA) due to treatment-related fatigue, functional limitations, and lack of structured exercise programs. Digital health solutions, including wearable sensors and augmented reality (AR)-based interventions, may offer new possibilities for monitoring and improving PA in this population.

Objective: This scoping review aims to address existing research gaps by identifying the instruments—both conventional and digital—used to monitor PA in patients with pediatric cancer during treatment. In addition, this study examines PA monitoring methods, identifies the variables collected, and explores the applicability of digital health solutions in facilitating PA engagement among patients with pediatric cancer.

Methods: In accordance with the Joanna Briggs Institute methodology, a systematic search was conducted across 8 scientific databases—ProQuest, Web of Science, EBSCO Complete, Google Scholar, ScienceDirect, Scopus, MEDLINE (PubMed), and Cochrane—on April 18 and 19, 2024. Studies were screened using the Rayyan AI-assisted review tool based on predefined inclusion criteria targeting children aged 7-19 years who were undergoing cancer treatment or were within 2 years posttreatment. Eligible studies included clinical trials and observational studies that examined objective (eg, wearable sensors) and subjective (eg, questionnaires and self-reports) approaches to PA monitoring. Keywords and controlled vocabulary (eg, MeSH [Medical Subject Headings] terms) were identified through a review of relevant literature. Data were extracted systematically to capture study characteristics, intervention types, and outcome measures. Extracted data were charted and synthesized narratively to identify patterns, technological applications, and research gaps in PA monitoring among patients with pediatric cancer.

Results: Twelve studies met the inclusion criteria and employed a range of PA monitoring tools. Digital health solutions, including Actical and Garmin VivoFit 3 devices, were used in 5 studies to assess step counts, gait cycles, and movement intensity. Self-reported measures were identified in 11 studies, most commonly the Activities Scale for Kids and the Pediatric Quality of

XSL•FO
RenderX

Life Inventory-Multidimensional Fatigue Scale, which provided insights into mobility and fatigue. Despite their feasibility, subjective assessments were limited by recall bias and motivational factors. Although digital health solutions—such as wearable sensors, gamification, and mobile applications—showed potential to improve PA adherence, their application remains underutilized, and evidence regarding their integration in pediatric oncology is limited.

Conclusions: Existing objective and subjective methods for monitoring PA provide valuable insights; however, gaps remain in the use of interactive digital health solutions, such as AR-based interventions, for PA monitoring and engagement. Future research should focus on integrating digital tools that not only track PA but also actively engage patients, enhance motivation, and support rehabilitation across both clinical and home settings.

KEYWORDS

pediatric oncology; cancer; physical activity monitoring; augmented reality; digital health solutions; gamification

Introduction

Every year, approximately 400,000 children and adolescents aged 0-19 are diagnosed with cancer worldwide [1]. Advances in childhood cancer treatment have significantly improved survival rates, with more than 80% of patients receiving modern cancer therapy surviving at least 5 years beyond diagnosis, and many achieving full remission [2,3]. However, despite these improvements in medical care, childhood cancer survivors remain at risk of recurrence, secondary malignancies, chronic conditions, and functional impairments [4]. These late effects of cancer and its treatment contribute to early mortality among survivors, making ongoing health management a critical concern [5]. Physical activity (PA) is increasingly recognized as a key component in mitigating the adverse effects of cancer and its treatment [6]. Nevertheless, published data indicate that fewer than 50% of patients with pediatric cancer meet PA guidelines, highlighting a serious challenge in maintaining adequate activity levels [7]. The World Health Organization (WHO) defines PA as any bodily movement produced by skeletal muscles that requires energy expenditure, including activities performed during leisure time, transportation, and daily routines—not just structured exercise [1]. Cancer-related fatigue is a major barrier to PA, contributing to sedentary behavior and reduced mobility [8]. In addition, some patients with pediatric cancer experience physical limitations that affect their ability to perform daily activities, as observed in conditions such as clear cell sarcoma, which often affects the legs, feet, arms, hands, and torso [9]. Given these challenges, implementing interventions to counteract cancer-related physical side effects is a major priority in pediatric oncology. There is growing evidence that PA is not only safe during both the acute treatment phase and survivorship [10] but also effective in reducing cancer treatment–related side effects [11,12]. Encouraging PA in patients with pediatric cancer is therefore essential; however, existing approaches face significant barriers. Currently, hospital-based PA interventions are the most common approach, led by physiotherapists, occupational therapists, and nurses who encourage children to remain active during therapy sessions [13]. However, pediatric oncology rehabilitation services are often underutilized, with few children referred for specialized rehabilitation. Medical professionals have identified a shortage of dedicated pediatric oncology rehabilitation services, while rehabilitation specialists have highlighted the lack of appropriate environments and equipment [14]. These limitations exacerbate challenges related to organizing PA, particularly for patients who experience fatigue and mobility restrictions [7]. To address these gaps, digital technology is emerging as a valuable complement to conventional PA interventions. Technologies such as wearable sensors, augmented reality (AR), and the Internet of Things offer new approaches to engaging patients with pediatric cancer in PA and monitoring their progress. For instance, wearable devices can track step counts, gait cycles, and movement patterns in real time, providing immediate feedback on PA performance [15]. Mobile health (mHealth) apps that incorporate gamification techniques have proven effective in increasing PA by offering interactive challenges and motivational feedback, thereby helping to sustain engagement among patients with pediatric cancer [16,17]. In addition, virtual reality (VR)– and AR-based interactive digital health solutions can create immersive exercise environments, helping to overcome the lack of dedicated health care—particularly rehabilitation—spaces, while providing personalized and engaging PA experiences [18]. These technologies offer scalable, flexible, and patient-centered solutions that could enhance PA participation and adherence in pediatric oncology care [19,20]. Understanding the specific individual needs of patients with pediatric cancer is crucial for developing effective PA interventions that align with their physical capabilities and treatment constraints. This scoping review aimed to address existing research gaps by identifying conventional and digital health instruments used to monitor PA in patients with pediatric cancer during treatment. Furthermore, it examined PA monitoring methods, characterized the variables collected, and explored the potential of digital health solutions to facilitate PA engagement in patients with pediatric cancer.

The research questions guiding this review are as follows:

- What conventional and digital methods are used to monitor PA in children and adolescents with cancer?
- What variables collected by conventional and digital health instruments are used to monitor PA in children and adolescents with cancer?
- What is the applicability of different conventional and digital health instruments for monitoring PA levels in children and adolescents with cancer?
- How are digital health solutions and PA monitoring tools incorporated into interventions aimed at improving PA in children and adolescents with cancer?

XSL•FO
RenderX

In addressing these questions, the authors use the term "variables" specifically to refer to objective measurements, such as step count and gait cycles/minute, distinguishing them from subjective values obtained through self-reported questionnaires. By mapping the available PA monitoring tools and interventions, this review aims to contribute to a more comprehensive understanding of how digital solutions can support PA promotion in patients with pediatric cancer.

Methods

Protocol and Registration

This scoping review was conducted between April and September 2024. The review followed the Joanna Briggs Institute (JBI) methodology for scoping reviews [21,22] and was reported in accordance with PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews; Multimedia Appendix 1) guidelines [23]. The 6-stage framework proposed by Arksey and O'Malley [24] was applied. The protocol was registered with the Center for Open Science [25], and the review was conducted without deviations from the registered protocol.

Eligibility Criteria

Overview

Based on recommendations from the JBI [21,22] and the research questions formulated to refine the focus of the scoping review and develop an effective search strategy, we defined the eligibility criteria according to the Population, Concept, and Context framework [22].

Population: Children and Adolescents With Cancer

- Children and adolescents with cancer during treatment or up to 2 years after treatment. Based on existing studies, this 2-year period—including active treatment and early recovery—is used because it allows researchers to assess how PA supports the restoration of cardiorespiratory fitness and muscle strength while helping to alleviate lingering posttreatment fatigue and physical limitations [26].
- Studies including children and adolescents aged 7-19 years. This age range was selected because it corresponds to the pediatric cancer population. Younger children are generally unable to complete questionnaires or engage in PA independently, while older age groups are typically classified as adults with cancer. Children and adolescents in this age range can effectively engage in self-directed activities and structured exercise programs. Moreover, older adolescents face unique physical and psychological challenges during the transition to adulthood, making their inclusion essential for understanding the impact of PA during and after cancer treatment [6,13].

Concepts: Digital Health Solutions Such as Wearable Sensors, Gamification, and Mobile Apps

- Wearable sensors, AR, and gamification provide new approaches to engaging patients with pediatric cancer in PA while enabling continuous monitoring of their progress [16].
- The incorporation of AR and gamification in pediatric cancer care is justified by their demonstrated effectiveness in enhancing PA levels among children and adolescents [17,18,20].
- Digital health solutions enable objective, data-driven monitoring of PA patterns, allowing health care professionals to tailor interventions and evaluate treatment-related functional outcomes [16,20].

Context: Physical Activity

- PA, as defined by the WHO, encompasses bodily movement that enables individuals to perform daily activities effectively and engage in exercise [13].
- The term "physical activity" includes all forms of bodily movement performed in educational, recreational, home, or community settings, including but not limited to aerobic exercise, resistance training, flexibility, endurance activities, and stretching routines.
- Key parameters for evaluating PA include frequency, intensity, duration, type of activity, and distance covered. In pediatric cancer, assessing a child's engagement in daily PA can provide valuable insights into recovery and health outcomes after treatment.

Selection of Records of Evidence

Individual studies published between 2000 and March 2024 were included. The starting year of 2000 was selected to capture research conducted during the period when digital technologies began to be systematically introduced into health care and rehabilitation, marking the global transition toward digital health strategies and culminating in the WHO's Global Strategy on Digital Health 2020-2025 [27]. The selection of records for this review was guided by predefined inclusion and exclusion criteria to ensure a comprehensive and relevant assessment of digital technologies for monitoring PA in patients with pediatric cancer. Inclusion and exclusion criteria were defined according to the Population, Concept, and Context framework (Textbox 1).

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

1. Inclusion criteria

- Population: children and adolescents diagnosed with cancer
- Concept: digital health solutions related to physical activity (eg, augmented reality, gamification, digital tools, digital environments)
- Context: physical activity outcomes
- Setting: supervised clinical environment
- Study type: original studies with any design or data type (quantitative and qualitative)
- Publication status: published in a peer-reviewed journal
- Publication language: English
- Full-text available
- Included keywords: cancer, pediatric, oncology, exercise, monitoring, physical activity, fitness, movement, digital technologies, augmented reality, gamification, digital tools, digital environment.

2. Exclusion criteria

- Population: children and adolescents more than 2 years after cancer treatment
- The study does not include patients aged 7-19
- Concept: digital technologies not related to physical activity (eg, for health management)
- Context: nonphysical activity outcomes or monitoring; specific physical fitness measures
- Setting: nonclinical
- Study type: other study types (eg, protocols, narrative reviews, or systematic reviews)
- Publication status: published without peer review, dissertations, books, conference papers, letters, or editorials
- Publication language: written in a language other than English
- Full-text not available
- Excluded keywords: drug, in vitro, animal, mice, mouse, animals, bacteria, murine, rat, fish, canine, rodents, transgenic, rodent, piglets, rabbits
- Mental health outcomes are excluded unless they are mentioned in combination with a physical activity outcome.
- Duplicate data: if studies provide overlapping datasets or are part of the same project without additional insights, they should be excluded to avoid repetition.

Information Sources and Search Strategy

A comprehensive search was conducted in ProQuest, Web of Science, EBSCO Complete, Google Scholar, ScienceDirect, Scopus, MEDLINE (PubMed), and Cochrane on April 18-19, 2024. The search strategy (Multimedia Appendix 2) combined keywords and controlled vocabulary (eg, MeSH [Medical Subject Headings] terms) related to pediatric cancer, digital technologies, PA, and outcome measurement, using Boolean operators. The final search strategy was adapted for each database. Only articles published in English were included, and gray literature was excluded. Following the database searches, all records were imported into the Rayyan AI-assisted review tool, after which the study selection process was conducted in 3 phases. First, titles and abstracts were screened, followed by full-text review to identify articles relevant to the research questions of this scoping review. In the final phase, a data extraction template was created within the Rayyan AI-assisted review tool to facilitate the systematic collection of key information from the selected articles. Given the anticipated volume of articles, all 11 coauthors participated in the selection process at each stage, with each article independently reviewed by 2 team members (AK and DB). If the Rayyan AI-assisted review tool identified a conflict regarding inclusion or exclusion, a third reviewer (GS) resolved it. Data extraction was performed independently and cross-checked to enhance accuracy. In addition, the team met regularly online to address any issues arising during the article selection phases.

Data Charting Process

Extracted data from the reviewed articles were categorized and analyzed using a structured set of variables. Key elements of the analysis included the paper ID, first author (name and surname), journal name, and article title, providing a bibliographic foundation for the review. To contextualize the research geographically and demographically, the country of the study, study aim, and participant information (number, sex, age, diagnosis, comorbidities, treatment status, and setting) were documented. In addition, details regarding participants' diagnosis and treatment were recorded to further clarify the clinical context. The methodology of each study was assessed, including study type (eg, cross-sectional, longitudinal), applied methods (PA monitoring instruments, questionnaires, proxy reports, digital technologies), specific tools used for monitoring, and study outcomes (objectives, data type, inclusion or empowerment, intervention effectiveness, and potential effects

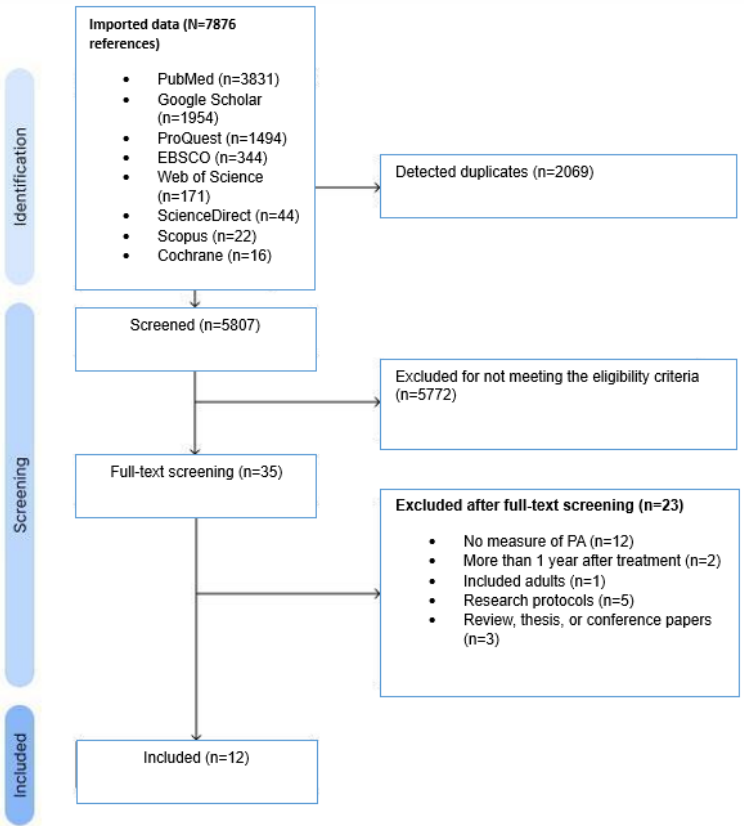
XSL•FO
RenderX

of monitoring methods on activity levels). In this review, the treatment period was defined as the active treatment phase, extending up to 2 years posttreatment.

Data Synthesis and Analyses

Following the final stages of the 6-stage framework for scoping reviews proposed by Arksey and O'Malley [24], data synthesis was conducted after identifying, selecting, and charting the relevant studies. Extracted information was first organized in a structured Excel (Microsoft Corporation) matrix, enabling systematic comparison across studies. The synthesis process involved 2 main phases:

- Descriptive numerical summary, where studies were grouped by publication year, country, cancer type, participant age, treatment phase, study design, and type of PA intervention or monitoring technology. Frequency counts and distributions were used to illustrate research trends and methodological characteristics.
- Qualitative thematic synthesis, where data related to intervention characteristics, PA measurement methods, feasibility, and outcomes were coded inductively by 2 reviewers (AK and DB). Codes were iteratively compared and refined through discussion among all coauthors until consensus was reached. Emerging categories were then grouped into overarching themes, including (1) feasibility and adherence of PA monitoring, (2) barriers and facilitators to engagement, and (3) identification of digital and exercise-based interventions.



This structure enabled the systematic identification of recurring patterns, differences, and knowledge gaps across studies. Results were synthesized narratively and organized in tables to highlight key themes, relationships, and interconnections among the examined variables.

Results

Selection of Records of Evidence

Our search identified a total of 7876 records across 8 electronic databases. Of these, 2069 duplicates were removed, leaving 5807 records eligible for screening, which indicates the feasibility of our search strategy. Following the initial screening based on eligibility criteria, 5772 records were excluded, and 35 were sought for retrieval. Of these 35 records, 23 were excluded because they did not include a measure of PA, the research was conducted more than 2 years after treatment, the sample included adults, or the records were research protocols, reviews, theses, or conference papers. A total of 12 publications met all eligibility criteria and were included in this scoping review. The source and selection of evidence are presented in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the literature search and study selection process.

Characteristics of Included Studies

The characteristics of the 12 selected studies included in this review are summarized in Table 1. The studies encompassed various research designs, including 4 (33%) randomized controlled trials [28-31], 1 (8%) quasi-randomized trial [32], 4 (33%) cross-sectional studies [33-36], 1 (8%) multicenter cohort study [37], 1 (8%) pilot study [15], and 1 (8%) prospective

XSL•FO
RenderX

observational study [38]. The included studies investigated PA levels, motor performance, and quality of life among children and adolescents diagnosed with cancer, both during and after treatment. Studies were conducted in Germany [16,27,33,37], the Netherlands [15,29,30,33], the United States [37,38], Hong Kong [36], and South Korea [32]. The interventions employed objective PA monitoring tools, such as accelerometers (Actical, Move 3, Step Watch 3, Garmin vívofit 3) and subjective self-report measures, including the Activities Scale for Kids (ASK), Pediatric Quality of Life Inventory (PedsQL)-Multidimensional Fatigue Scale, and other health-related quality-of-life instruments. Across the 12 studies, a total of 1083 participants (ages 3-20 years) were assessed, with sample sizes ranging from 25 to 482. Most participants had leukemia (acute lymphoblastic leukemia or acute myeloid leukemia) or lymphoma (non-Hodgkin lymphoma or Hodgkin), while others had solid tumors (eg, bone tumors, brain tumors, neuro-oncology cases). Some studies included mixed cancer diagnoses without specific classification. Two studies examined participants posttreatment [32,35], whereas the remaining 10 focused on patients undergoing active treatment or within the first year after completion. For example, Kang et al [32] investigated a mobile game–based healthy lifestyle program for childhood cancer survivors in South Korea, while Stössel et al [35] compared PA behaviors before, during, and after cancer treatment in Germany.

PA Monitoring Methods and Obtained Variables in Patients With Pediatric Cancer

Both objective and self-reported methods were used to assess PA levels, motor performance, and fatigue in children and adolescents with cancer. Across the included studies, these 2 approaches complemented each other, providing quantitative and subjective perspectives on PA behavior and its relationship to treatment-related fatigue and recovery. Objective PA monitoring was employed in 5 studies [28,30,33,34,38], using accelerometers such as Actical, Move 3, Step Watch 3, and Garmin vívofit 3. van Dijk-Lokkart et al [30] used Actical accelerometers with a required wear time of at least 500 minutes/day to measure PA levels in children undergoing or recently completing cancer treatment. Similarly, Gaser et al [28] utilized the Move 3 accelerometer alongside motor performance tests to examine PA in patients with leukemia and lymphoma. Withycombe et al [38] used the Garmin vívofit 3 over a 4-day period to track step counts and correlate them with symptom reports. This illustrates that objective PA monitoring focused primarily on step counts and time spent in different intensity zones (light, moderate, and vigorous), reflecting a general shift toward using wearable accelerometers as a feasible and noninvasive method for tracking daily movement patterns during and after cancer treatment. In addition, subjective self-reported PA assessment methods were applied in 7 studies [28,30,33-37]. For example, the ASK, which includes 30 items across 7 subdomains (personal care, dressing, other skills, locomotion, play, standing up, and movement), and the PedsQL-Multidimensional Fatigue Scale were used. Gaser et al [28] combined ASK with motor performance testing to evaluate functional abilities such as mobility and locomotion, balance and coordination, strength and endurance, as well as fatigue and energy levels. Mack et al [37] employed caregiver-reported measures to assess mobility, pain interference, and fatigue, incorporating surveys that evaluated children's ability to perform daily tasks, their experience of pain, and levels of physical exhaustion. Götte et al [34] assessed

XSL•FO
RenderX

fatigue using the PedsQL-Multidimensional Fatigue Scale, which captures general, sleep-related, and cognitive fatigue. Additional self-report instruments, such as the Child Health Utility 9D used by Stössel et al [35], were applied to assess health-related quality of life, while structured questionnaires like the Pediatric Outcomes Data Collection Instrument, used by Braam et al [33], provided insights into mobility and participation in PAs. These self-reported instruments captured complementary domains—mobility, participation, fatigue, and quality of life—allowing researchers to contextualize accelerometer-derived data with patient-perceived outcomes and daily functional capacity. The integration of objective and self-reported measures provided a comprehensive understanding of patients' functional status across different stages of cancer care. For comparison, while some studies focused on the active treatment phase, others, such as Kang et al [32] and Stössel et al [35], specifically examined PA behaviors in posttreatment survivors. Kang et al [32] investigated the effects of a mobile game–based healthy lifestyle program on PA levels, sedentary behavior, and overall quality of life in childhood cancer survivors in South Korea. Stössel et al [35] analyzed PA behaviors before, during, and after cancer treatment, focusing on changes in daily activity levels, mobility patterns, and engagement in sports or recreational activities. Both studies provided valuable insights into long-term functional outcomes, highlighting the impact of cancer treatment on sustained PA and overall well-being in survivors. This comparison between active treatment and posttreatment groups revealed common patterns: patients typically exhibited reduced PA levels during therapy, with gradual improvement during recovery, although many survivors continued to experience limitations in endurance and persistent fatigue. In the included studies, PA monitoring primarily focused on assessing overall activity levels using accelerometers to calculate step counts and estimate time spent in light, moderate, and vigorous activity. None of the studies conducted detailed activity recognition beyond basic actions such as walking, running, or sitting, nor did they employ multisensor systems for body motion analysis or fatigue detection. More sophisticated approaches—such as recognizing complex daily activities, detecting nuanced movement patterns, or assessing early signs of fatigue—were absent, highlighting an important gap for future research.

Applicability of PA Monitoring Instruments in Pediatric Oncology

Overall, the studies included in this review demonstrated that PA monitoring instruments were feasible for use with patients with pediatric cancer. Feasibility was largely determined by patient adherence and device usability, both of which were reported as satisfactory in most studies. Withycombe et al [38] utilized the Garmin vívofit 3, worn on the wrist for 4 consecutive days, to measure step counts and activity patterns, observing that wearable technology effectively tracked PA, although results varied according to treatment stage and location (eg, fewer steps during hospitalization). van Dijk-Lokkart et al [30] reported good compliance with accelerometer-based PA monitoring using Actical accelerometers worn on the hip for at least 500 minutes/day over a 1-week period. Gaser et al [28] employed the Move 3 accelerometer, also positioned on the hip, with a minimum required wear time of 5 days. Some studies imposed restrictions on PA measurement, such as excluding nonambulatory patients or requiring a minimum number of valid wear days for data inclusion [34,37]. While feasibility and compliance rates were generally acceptable, the studies also highlighted important contextual and individual barriers affecting the accuracy and consistency of PA monitoring in this population. Mack et al [37] found that fatigue, treatment side effects, and hospitalization influenced step counts and overall compliance. Braam et al [29] identified psychological factors, including lack of motivation and fear of overexertion, as key barriers to PA engagement. Lam et al [36] cited time constraints and limited access to PA resources as additional challenges for participants. Despite these barriers, authors suggested that self-monitoring through wearable devices served as a motivational tool, encouraging participants to maintain PA levels. These findings suggest that while device-based PA monitoring is technically and behaviorally feasible, its effectiveness depends on addressing both physical and psychosocial barriers that influence patient participation during cancer treatment and recovery.

Interventions for Improving PA in Pediatric Oncology

PA interventions varied across the 12 selected studies, incorporating individualized exercise programs, supervised training, and digital health tools to enhance and monitor PA levels. Intervention durations ranged from 4 weeks to 12 months, depending on study design and patient condition. Most studies reported retention rates above 80% and adherence rates ranging from 70% to 95%, indicating strong engagement with the interventions [28-30,32]. For example, Braam et al [29] reported a 92% adherence rate to supervised PA sessions, which included aerobic training, resistance exercises, and motor performance activities 2-3 times/week at moderate-to-high intensity. Similarly, Kang et al [32] reported a 90% program completion rate and high user engagement metrics (eg, daily log-ins and activity tracking) with a mobile game–based lifestyle program for childhood cancer survivors, encouraging daily movement. van Dijk-Lokkart et al [30] implemented individually tailored programs with varying intensity and duration based on the child's physical condition, reporting over 85% adherence in most participants. Gaser et al [28] also employed individualized exercise protocols for patients with leukemia and lymphoma, focusing on moderate-intensity exercises, and reported a 100% retention rate and 88% session completion. Across these interventions, personalization of exercise type, frequency, and duration emerged as a key determinant of both adherence and safety, reinforcing the importance of individualized approaches in pediatric oncology rehabilitation.

Table 2 (also see Multimedia Appendix 3) summarizes the PA monitoring methods, variables, applicability, and interventions across the studies in pediatric oncology, providing detailed information on the tools and strategies used to assess and promote PA in this population. A summary addressing each research question, accompanied by easily interpretable tables, is presented in Multimedia Appendix 4, offering an overview of how the selected studies address the research questions.

XSL•FO
RenderX

Table 2. Summary of PA[a] monitoring methods, variables, applicability, and interventions in pediatric oncology.

Reference	1. What methods are used for PA monitoring in patients with pediatric cancer?	2. What variables are collected to monitor PA in patients with pediatric cancer?	3. What is the applicability of different instruments to facilitate the PA level (monitoring) in patients with pediatric cancer?	4. What interventions are used to improve PA in patients with pediatric cancer research?
Gaser et al [28]	• The Move 3 accelerometer (movisens GmbH) • Self-reported questionnaire	• Step count, amplitude of moderate-to-vigorous PA, body position, and wear time	• Participants wore the device on the right hip during the daytime and removed the device during nighttime sleep. • Records of ≥4 days of ≥8 hours/day of wear time were included. • The younger participants (n=5, ages 4-7 years) felt more disturbed by the sensor on the hip. As a result, all of them refused the measurement. Because of the accelerometer's algorithm, the PA could be calculated only for those participants aged over 7 years.	N/A[b]
Gaser et al [31]	• The Move 3 accelerometer (movisens GmbH) • Self-reported questionnaire	• Step count	• Participants wore the device on the right hip during the daytime and removed the device during nighttime sleep. • Records of ≥4 days of ≥8 hours/day of wear time were included. • Reasons for invalid measurements were the lack of compliance and unscheduled inpatient hospitalizations.	Exercise program–specific strength training combined with a standard care exercise program (2-3 exercise sessions/week).
Braam et al [33]	• Actical accelerometer (B series; Philips Respironics Actical MiniMitter) • Self-reported questionnaires	• Counts/minute; the acceleration signal is summed over a specific time interval (epoch). A 15-second epoch was used in the study.	• The activity monitor was attached to an elastic waist belt and worn on the left hip during daytime at waking hours (between 6:00 AM and 11:59 PM) for 4 consecutive days (Wednesday-Saturday). The device was removed while bathing. • When the device was worn for less than 500 minutes/day, the measurement was considered invalid. • The memory capacity of the accelerometer did not allow assessment of PA by 15-second epoch for 7 days; therefore, 4 days were used. Missing data on 3 days within the measurement week remain a limitation.	N/A
Götte et al [34]	• Step Watch 3 sealed uniaxial Activity Monitor (Orthocare Innovations) • Self-reported questionnaire	• The volume of activity/day (gross counts/day) and intensity of activity (gross counts/minute)	• The device was attached to the ankle with an elastic strap. • Participants wore the activity monitor for 7 consecutive days from the morning after waking up to bedtime. • Days with <8 hours of wear time were excluded. • The study concluded that objective measures should be preferentially used for the assessment of PA in children and adolescents with cancer to ensure accurate and reliable data. Self-reports can complement objective measures by capturing activities or sports that are not reflected in step counts, as well as individuals' expectations and attitudes toward exercise.	N/A

Withycombe et al [38]	• The Garmin vívofit 3 accelerometer • Self-reported questionnaire	• Step count	• Participants wore an accelerometer for 7 days. Data were included if available for at least 4 days during a defined 7-day period. • Eligible days included a minimum of 10 hours of wear time between 6 AM and 10 PM. • Step monitoring may serve as an objective indicator for overall symptom count, fatigue, PA, and physical function.	N/A
Rehorst-Kleinlugtenbelt et al [15]	• The Actical (Philips Respironics, Mini Mitter Co, Inc)	• Step count • Counts/minute • 15-second epoch	• The device was fastened to an elastic waist belt strap and worn on the right hip. A minimum wearing time of 8 hours/day was required, with a minimum of 4 valid days a week. • Parents or participants maintained a "wearing time" activity diary. • The study found that accelerometry is suitable for the objective assessment of PA in children with childhood cancer during their treatment. The data gave a presentation of their PA behavior during the day. Accelerometers provide an objective assessment of PA and can be used in different kinds of patients.	N/A
Mack et al [37]	• Self-reported questionnaire • Caregiver proxy report	• PROMIS[c] assessments of the child's physical function (mobility) and symptoms, including pain interference, fatigue, depressive symptoms, anxiety, and psychological stress; 5 response categories. Each question's recall period is the past 7 days.	• Our findings suggest that proxy reporting is influenced by the proxy's personal experience of symptoms and function as well as the child's experience. • Caregivers tended to overestimate symptoms and underestimate function relative to children themselves.	N/A
van Dijk-Lokkart et al [30]	• Actical accelerometer (B series; Philips Respironics Actical MiniMitter) • Self-reported questionnaire • Caregiver proxy report	• Counts/minute, 15-second epoch	• The accelerometer was worn on the hip during daytime at waking hours (between 6:00 AM and 11:59 PM) on 4 consecutive days (Wednesday-Saturday), at least 500 minutes/day over a 1-week period. • Although the PedsQL-MFS[d] has acceptable psychometric properties, including content validity, internal consistency, and responsiveness, there are inconsistent reports regarding known group validity in pediatric cancer.	Cardiorespiratory and muscle strength training twice a week for 12 weeks at a physical therapy sports center near the child's home.
Lam et al [36]	• Self-reported questionnaires		• N/A	N/A

	• Actical accelerometer (B series; Philips Respironics Actical MiniMitter) • Self-reported questionnaires • Caregiver proxy report		• The accelerometer was attached to an elastic waist belt and worn on the left hip during waking hours (6:00 AM to 11:59 PM). Participants wore the device for 4 consecutive days (Wednesday-Saturday). After the monitoring period, the accelerometers were returned to the research team by postal mail. Compliance with accelerometer use was low during the final study measurement week. Nonuse was primarily attributed to discomfort associated with wearing the device on a hip-mounted belt, with complaints reported particularly by girls and children who were overweight.	The 12-week intervention comprised 24 individual physical exercise sessions, consisting of two 45-minute exercise sessions/week conducted at a local physical therapy practice, and one 60-minute psychosocial training session every 2 weeks delivered to the child at the treating pediatric oncology hospital.

[a]PA: physical activity.

[b]N/A: not applicable.

[c]PROMIS: Patient-Reported Outcome Measurement Information System.

[d]PedsQL-MFS: Pediatric Quality of Life Inventory-Multidimensional Fatigue Scale.

In addition to traditional exercise and supervised rehabilitation programs, several studies integrated digital components to enhance monitoring capabilities and sustain motivation beyond clinical settings. Digital health interventions, such as Kang et al's [32] mobile game–based program, wearable step-count monitoring [15,38], and other digital tracking tools, were used across multiple studies to assess PA levels and support motivation in patients with pediatric cancer. These programs were implemented in diverse settings, including hospitals [29,38], physical therapy centers [29,30], and home-based contexts [15,32], with supervision provided by physiotherapists, pediatric oncology specialists, or through digital applications. The inclusion of gamified and interactive elements was particularly effective in maintaining engagement among children and adolescents, consistent with evidence that motivation and enjoyment play critical roles in sustaining PA behavior during and after cancer treatment. Despite challenges such as fatigue and other treatment-related side effects, studies consistently reported that structured PA programs—including those incorporating digital elements—were associated with improved adherence and participation [30,32,38]. These digital and traditional interventions targeted a range of physical and psychosocial outcomes, with variations in duration and intensity influencing their overall effectiveness. PA intervention durations varied across studies examining effects on physical functioning [29,30,38], fitness [29,31], fatigue [30,37], quality of life [32,36], and psychological well-being [29,37]. For example, Kang et al [32] evaluated a mobile game–based intervention, which increased daily activity, improved health behaviors, and enhanced self-reported well-being. van Dijk-Lokkart et al [30] implemented a structured PA program that reduced fatigue and improved functional capacity over time. Rehorst-Kleinlugtenbelt et al [15] examined a structured physical exercise intervention delivered in both hospital and home settings, which led to increased PA levels and better adherence to exercise programs over time. By contrast, Braam et al [29] examined a structured exercise intervention delivered in a hospital and at a local physical therapy practice, which showed no significant beneficial effects on physical outcomes.

Discussion

Principal Findings

This scoping review identified various PA assessment instruments, including digital solutions, used to monitor PA in patients with pediatric cancer. Self-reported questionnaires remain the most frequently used instruments due to their accessibility and cost-effectiveness [28-30,32-39]. While these instruments provide valuable insights from the patient's perspective, their reliability is limited by recall bias and motivational factors, making them inherently subjective. Although widely utilized, self-reported questionnaires have been increasingly complemented by accelerometry, which provides empirical, quantifiable measurements of PA [38,39]. Self-reported surveys are often favored because they are inexpensive, easy to administer, and adaptable to different age groups, making them feasible even in larger study settings. Self-reported questionnaires also provide important patient-centered insights by capturing subjective experiences such as fatigue, pain interference, and broader quality-of-life outcomes (eg, Götte et al [34], Mack et al [37], Stössel et al [35], Braam et al [33]). However, their accuracy is limited by recall bias, motivational influences, and social desirability, which may distort reported activity levels. While self-reported surveys offer valuable perspectives on how children and adolescents perceive their PA and related symptoms, they are less reliable for accurately quantifying activity levels. This underscores the importance of complementing self-reported surveys with objective monitoring tools to achieve a more comprehensive assessment of PA in pediatric cancer.

XSL•FO
RenderX

Self-reported questionnaires remain widely used due to their low cost, ease of administration, and ability to capture subjective patient experiences that objective measures may not assess. These instruments are also feasible for large-scale studies and adaptable to different age groups. However, subjective methods are prone to bias, social desirability, and motivational influences, which can affect the accuracy of data outcomes. In summary, self-reported questionnaires demonstrate lower reliability in quantifying PA levels compared with objective instruments such as accelerometers.

Accelerometer-based approaches provided objective data such as step counts, wear-time compliance, and time spent at different activity intensity levels (eg, Actical in van Dijk-Lokkart et al [30], Garmin vívofit 3 in Withycombe et al [38], Move 3 in Gaser et al [28]). In some studies, accelerometry was combined with motor performance testing to assess balance, coordination, strength, and endurance [28]. Other studies extended the focus to participation in recreational or social activities, linking activity patterns to broader dimensions of daily life [33,34]. Overall, accelerometers appear to be practical and feasible tools for objectively monitoring PA in patients with pediatric cancer. Accelerometers provide reliable, quantifiable data and are generally well-tolerated by participants; however, their usefulness is limited by the need for compliance, inability to capture complex or context-specific activities, and the lack of standardized protocols across studies. When used alongside complementary instruments, accelerometers can be a valuable component of PA monitoring in both research and clinical practice. Despite growing interest in interventions using digital tools, this review found that only 1 study employed a mobile game–based approach for PA tracking in patients with pediatric cancer [32], which also functioned as a mobile engagement tool. In this study, children participated in a serious game requiring completion of 26 quests, including 7 subelements (nutrition, exercise, hygiene, interpersonal relationships, stress management, meaning of life, and health responsibility), to promote a healthy lifestyle [32]. This review demonstrated the potential of digital solutions to integrate PA monitoring with the promotion of healthy lifestyle habits during cancer treatment in clinical settings. The selected studies also highlighted the limited research outcomes available to date. While digital tools may be feasible and applicable, their broader implementation in pediatric oncology remains largely unexplored.

The integration of PA monitoring with patient engagement strategies for behavior change, such as gamification and AR, holds promise for enhancing both data accuracy and patient motivation [18,32]. This highlights a research gap where interactive digital solutions could play a pivotal role in optimizing PA interventions for patients with pediatric cancer. While prior studies have extensively examined the effectiveness of digital technology in promoting PA [15,31,32,38], only a few have explored how PA monitoring itself can facilitate PA participation and adherence [30,32,38]. Although most studies relied on accelerometers and questionnaires, a gap remains regarding the use of AR and gamification specifically for PA monitoring in pediatric oncology. Studies employed a variety of methods to promote PA in children and adolescents with cancer, including self-reported questionnaires, wearable accelerometers, and digital game–based tools. Self-reported questionnaires, such as the ASK used by Gaser et al [28] and the PedsQL-Multidimensional Fatigue Scale applied by Götte et al [34], Mack et al [37], and others [33,36], captured subjective experiences of mobility, fatigue, pain, and quality of life, providing valuable patient-centered insights, though they are limited by recall bias and motivational factors. Wearable devices, including Actical accelerometers in van Dijk-Lokkart et al [30], Move 3 in Gaser et al [28], and Garmin vívofit 3 in Withycombe et al [38], offered objective, continuous measures of step counts, activity intensity, and motor performance, enhancing accuracy and enabling longitudinal monitoring, but they may fail to capture complex or context-specific activities and depend on participant compliance. Digital interventions, such as Kang et al's [32] mobile game–based program, combined PA tracking with engagement and health education, supporting adherence and motivation; however, evidence remains limited, and these tools are largely unvalidated. Hybrid approaches integrating subjective and objective measures, as applied in several studies [32,38], show promise for providing a multidimensional understanding of PA and potentially improving adherence, though they require greater resources and supervision. Overall, these findings highlight the need to further explore innovative interventions that implement digital tools designed to be both engaging and user-friendly for patients with pediatric cancer. For instance, AR-based interactive games have been proposed as a promising approach, as they may enable real-time monitoring and provide personalized support for daily PA. Such technologies have the potential to offer health care professionals accurate information about a patient's daily activity level and enhance motivation to remain active during different treatment stages. Further research is required to evaluate the impact of digital tools on physical and mental health outcomes in patients with pediatric cancer, while also addressing the limitations of current methods highlighted in this review.

Implication for Practice

This review underscores the need for a standardized approach to PA monitoring in patients with pediatric cancer, as current practices are heterogeneous and often lack consistency. While innovative digital solutions, such as AR and gamification, may offer promising approaches to enhance motivation and adherence to PA interventions, their applicability and effectiveness in pediatric oncology remain largely unexplored and require further investigation.

Additionally, this review highlighted the need for a standardized approach to PA monitoring in patients with pediatric cancer. The diversity of accelerometers [28-34,38] and self-report questionnaires [28-38] underscores the necessity for unified guidelines to ensure consistency in data collection and interpretation. Developing standardized guidelines for PA assessment would enhance comparability across studies and support the integration of digital monitoring solutions into clinical practice.

Limitations

This review has several limitations. It included only articles published in English, which may have resulted in the exclusion of relevant research published in other languages. Additionally,

XSL•FO
RenderX

the focus on children and adolescents aged 7-19 years who were undergoing treatment or within 2 years posttreatment may have limited insights into long-term PA outcomes beyond this period. Furthermore, heterogeneity in study designs, PA measurement tools, and intervention methodologies posed challenges for direct comparisons. The aim of this review was not to evaluate the validity or reliability of the selected instruments but to map the available measurement methods and digital solutions used to monitor PA in patients with pediatric cancer. The limited adoption of interactive digital solutions highlights a critical research gap, underscoring the need for further studies to evaluate their feasibility, appropriateness, and long-term impact on PA engagement in this population.

Future Directions

Our findings indicate that future research should focus on exploring how PA monitoring can actively facilitate PA participation in patients with pediatric cancer. While numerous studies have examined PA monitoring tools, only a few have assessed their impact on promoting PA. Further investigation is also needed into the use of AR-based interventions and gamification for PA monitoring in pediatric cancer. Among the 12 included studies, none involved an AR-based intervention, and the only digital engagement tool identified was a gamified mobile game by Kang et al [32]. AR represents an unexplored but promising area for future research in pediatric oncology rehabilitation. Interactive digital interventions have the potential to both measure and enhance PA engagement by providing real-time feedback and motivation [18]. Evaluating patient acceptance, clinical integration, and long-term adherence to such technologies will be crucial to optimizing their effectiveness. Furthermore, the absence of standardized PA monitoring protocols highlights the need for unified guidelines for digital monitoring solutions tailored to patients with pediatric cancer. Establishing consistent assessment criteria would improve comparability across studies and facilitate the integration of digital monitoring solutions into routine clinical practice.

Conclusions

Despite the growing need to monitor and promote PA in patients with pediatric cancer, opportunities for interactive and engaging PA monitoring remain limited. The findings of this scoping review indicate an emerging body of literature on digital health technologies, including wearable sensors such as accelerometers, mHealth apps, and gamification, which are being explored for PA assessment and engagement. Future research should further investigate the purpose, scope, and integration of digital health technologies to facilitate interactive and personalized approaches for effectively monitoring and enhancing PA in both clinical and home-based settings for patients with pediatric cancer.

Acknowledgments

We extend our gratitude to the Riga Stradins University librarian and all collaborators involved for their support in making this research possible. The authors declare the use of generative artificial intelligence in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy) (2025), proofreading and editing were delegated to the generative artificial intelligence ChatGPT (OpenAI, GPT-5) under full human supervision. Responsibility for the final manuscript lies entirely with the authors. Generative artificial intelligence tools are not listed as authors and do not bear responsibility for the outcomes.

Funding

This project was funded by the Internal RSU and External RSU with the LSPA Consolidation Grant “Monitoring of physical activity habits of pediatric oncology patients using a digital approach with augmented reality-based interactive game elements” (RSU/LSPA-PA-2024/1-0002).

Abstract

The Internet of Things (IoT) is transforming various industries, including health care. IoT-based systems are increasingly prevalent in consumer health applications, while intelligent or smart devices equipped with sophisticated sensors are gaining recognition for their potential to improve clinical care practice and decision-making. Cancer care is a particularly promising area for IoT applications, enabling real-time and personalized interventions. However, empirical research on the effects of IoT in this field is limited due to the complexities inherent in cancer as a dynamic disease and the paucity of IoT-generated data available for research. This presents an opportunity to apply mathematical modeling to understand the effects of IoT under various scenarios. These analytical and "in silico" mathematical approaches are instrumental with limited data. Such models support the analysis of treatment uncertainty and patient response while balancing patient preferences, clinical outcomes, and system-level constraints. Grounded in mathematical oncology and health informatics, this paper proposes a conceptual framework that integrates real-time IoT data as dynamic inputs into adaptive mathematical models to simulate cancer dynamics. By exploring applications across multiple levels of analysis, the study demonstrates how IoT-enhanced mathematical models could inform implementation and optimize oncology services, addressing a critical gap in current research.

Introduction and Motivation

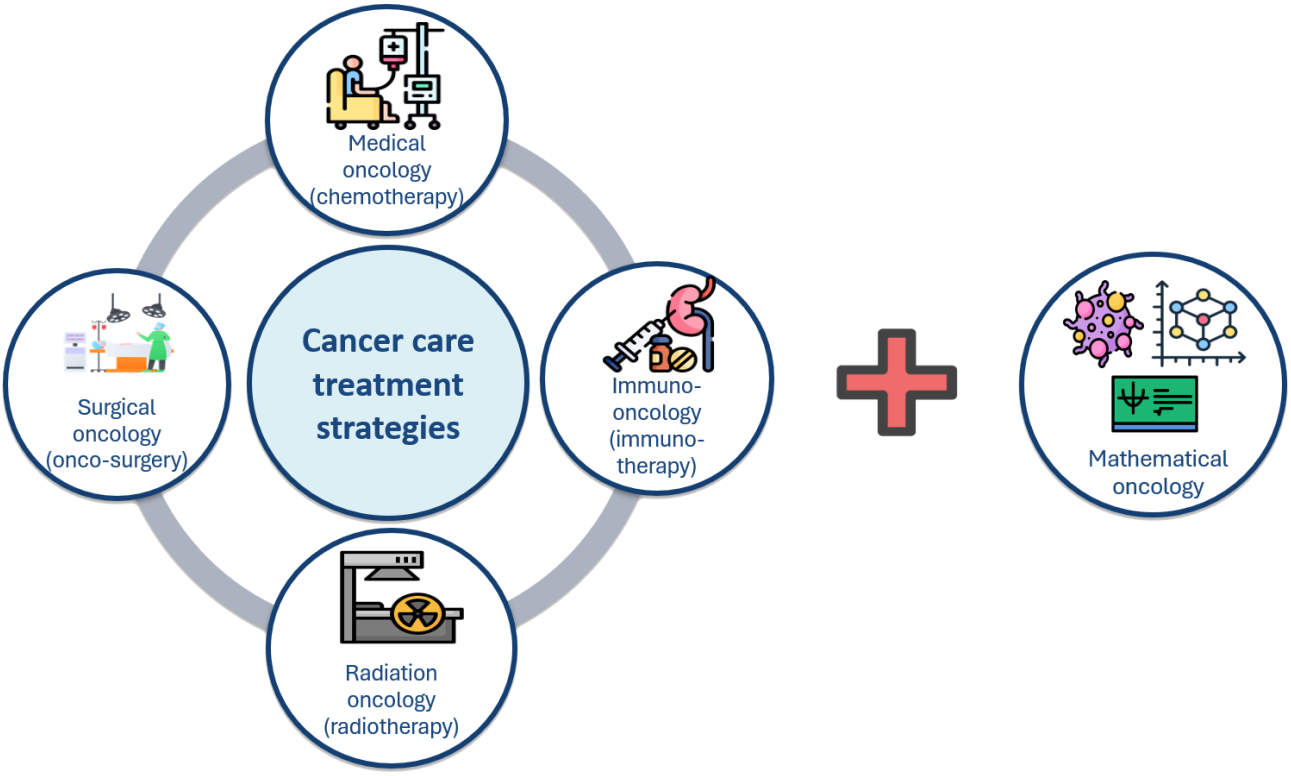
The Internet of Things (IoT) represents a paradigm shift in technological advancement, enabling interconnected, intelligent, and responsive systems through continuous data collection, communication, and analysis. As a key driver of Industry 4.0, IoT facilitates the convergence of information technology and operational technology by interconnecting physical objects in internet-aware environments. Its rapid adoption across industries, governments, and society underscores its value in enabling interoperable, data-driven services beyond traditional machine-to-machine communication [1].

In health care, numerous IoT applications have been proposed to support care delivery, access, and patient safety [2-9]. However, despite growing interest, few studies empirically evaluate or mathematically model the effects of IoT interventions, particularly in cancer care. While mathematical oncology and IoT-based cancer care systems have mainly evolved in parallel, research that unifies these approaches remains limited. Integrating IoT with mathematical oncology offers an opportunity to link mechanistic disease dynamics with real-time, patient-specific data, enabling more adaptive and patient-centered cancer care.

The primary goal of this work is to investigate how integrating IoT technologies with mathematical oncology can enhance the modeling, analysis, and optimization of cancer care through real-time, data-driven, and adaptive approaches to improve treatment efficacy and patient outcomes. This study specifically builds on an established melanoma immunotherapy model [10] to develop a conceptual framework that integrates real-time IoT data into adaptive mathematical models of cancer dynamics and behavior. This framework extends treatment strategies and supports business process modeling by embedding IoT-enabled devices within business process modeling elements—tasks, events, activities, and resources—allowing continuous monitoring and evaluation of cancer conditions and characteristics in IoT-enabled care systems.

The paper is organized as follows. The *Overview and Literature* section reviews cancer, common treatment strategies, and existing mathematical models, highlighting their limitations. The *Case Study* section on immunotherapy for melanoma presents a conceptual framework for adaptive cancer care modeling using real-time IoT data as dynamic parameter inputs.

XSL•FO
RenderX



The *Innovative Modeling Approach* section examines IoT-based health care applications in cancer care and integrates IoT with business process management to develop an end-to-end cancer care model. The *Implementation and Challenges* section discusses operational and security considerations for IoT-enabled cancer care systems. The paper concludes with key findings and directions for future research.

Overview and Literature

Cancer and Treatment Strategies

Oncology is the medical discipline dedicated to the prevention, diagnosis, and treatment of cancer. Cancer results from genetic mutations that disrupt normal cellular regulation, leading to uncontrolled proliferation, tumor formation, tissue invasion, and potential metastasis [11]. Four primary clinical treatment modalities are widely used: onco-surgery, chemotherapy, radiotherapy, and immunotherapy, which are often applied individually or in combination, as illustrated in Figure 1.

Figure 1. Cancer care treatment strategies and mathematical oncology.

Mathematical oncology is an interdisciplinary field that applies mathematical methods to study cancer dynamics and treatment outcomes, traditionally focusing on the responses of normal and cancerous cells to therapeutic inputs [6,12-16]. These models emphasize biological and physiological parameters—such as cell growth rates, population dynamics, invasion, and progression—to predict tumor growth, treatment response, and metastasis, thereby informing clinical decision-making.

With the rapid advancement of IoT in health care, integrating smart, connected devices into patient care enhances the practical relevance of these models. IoT-enabled mathematical modeling leverages real-time data from connected sensors to support adaptive, data-driven oncological practices beyond traditional mathematical oncology.

Mathematical Modeling of Cancer Treatment

Overview

Cancer has a substantial global impact, with treatment outcomes varying widely due to pronounced patient and tumor heterogeneity, which complicates the prediction of disease progression. Cancer arises from genetic alterations driven by inherited predispositions, environmental exposures such as radiation and chemical carcinogens, and viral agents (deoxyribonucleic acid or ribonucleic acid viruses), leading to dysregulated cell cycles through oncogene activation and inactivation of tumor suppressors [17,18]. Mathematical oncology offers quantitative frameworks to improve prediction and support more effective treatment strategies.

A wide range of mathematical models has been developed to characterize tumor growth, treatment dynamics, and control mechanisms, particularly for chemotherapy, radiotherapy, and immunotherapy, though onco-surgery remains largely unaddressed. Growing evidence supports the use of mathematical modeling in cancer treatment, as patient-specific responses and tumor size dynamics challenge population-level, “one-size-fits-all” approaches [12,13,18-20]. Models of untreated tumor growth include linear, exponential, logistic, and sigmoidal forms such as Bertalanffy and Gompertz functions [20,21], while additional formulations describe immune-tumor

XSL•FO
RenderX

interactions under immunotherapy, chemotherapy, and vaccine-based treatments [4,22].

Radiotherapy or Radiation Oncology

Liu and Yang [23] examined the dynamical behavior of normal cells under periodic radiation using mathematical models, deriving conditions for the persistence or extinction of normal and irradiated cells. Belostotski et al [13] proposed a Lotka-Volterra–based competition model capturing interactions between healthy and cancer cells under radiotherapy, incorporating multiple radiation control mechanisms, including "harvesting-type" control, which has been shown to produce spill-over effects on healthy cells that can be quantified to refine treatment strategies [13,19]. Weerasinghe et al [24] highlighted the importance of quantitative models in studying cancer cell plasticity, using them to inform therapeutic design and optimization across tumor progression stages such as avascular and vascular growth, angiogenesis, invasion, and metastasis within the tumor microenvironment.

Chemotherapy or Medical Oncology

Isaeva et al [16] use differential equation–based chemotherapy models to examine interactions among tumor, healthy, and immune cells, linking theoretical analysis with empirical evidence. Similarly, Song et al [10] propose a model that incorporates three cell populations and drug concentration to study immune-mediated tumor control and the side effects of chemotherapy on both tumor and effector cells. The dynamics of tumor and immune cell populations under chemotherapy are described by the following model [10]:

with initial conditions:

.N(0)=N0>0, L(0)=L0>0, T(0)=T0>0, and u(0)=u0>0

The variables $T(t)$ and $N(t)$ represent the population sizes of cancer cells and Natural Killer *NK* cells, respectively, at any given time t; $L(t)$ for the cytotoxic tumor cell (CTL) population; and $\mu(t)$ for the amount of drug at the tumor site. The parameters in equation (1), along with their descriptions, are as depicted in Table 1.

Table . Description of the parameters in equation (1).

Parameter	Description	Parameter	Description
	Growth rate of NK[a] cells	β_1	CTL[b] death rate
	Inverse of NK cells capacity	β_2	Rate of CTL-induced tumor death
c	Growth rate of tumor	ν	Influx of drug
d	Inverse of tumor capacity	ω	Drug decay rate
r	Activation rate of CTLs	k_N, k_L	Immune cells killed by drug[c]
μ	CTL death rate	k_T	Tumor cell killed by drug[c]
α_1	NK cell death rate	—[d]	—
α_2	Tumor death rate of NK	—	—

[a]NK: natural killer cell.

[b]CTL: cytotoxic tumor cell.

[c]Note that the 3 different response coefficients are denoted by k_N, k_L, and k_T because chemotherapy affects all 3 cell populations and the model assumes side effects on both tumor and effector cells [10].

[d]Not applicable.

Immunotherapy or Immuno-Oncology

In immunotherapy, the effect of vaccine therapy is considered a parametric perturbation of the model commonly used in chemotherapy, in which simulations show that the efficiency of vaccine therapy depends on tumor size, the condition of the immune system, and the response of the organism to vaccination. The goal of immunotherapy is to enhance the antitumor resistance of an organism and improve the immune system's condition [12]. There are 3 known main categories of immunotherapy: immune response modifiers (cytokines), monoclonal antibodies, and vaccines. Such immune response modifiers as interleukin-2 (IL-2), interferon-α (IFN-α), and tumor necrosis-α are widely used in cancer immunotherapy [10,12,23]. The system of equations alluded to in [10] for tumor-immune dynamics is based on the presence of treatment components consisting of 5 populations: tumor cells (T), cytotoxic tumor cell population (L), cytokine IL-2 population (I_2), chemotherapeutic drug (C), and IFN-α population (I).

(2)dTdt=−aTln (bTa)−c(I) TL−MT(I2)(1−e−C)T

(3)dLdt=d+eLI2−fL−ML(I2)(1−e−C)L

(4)dI2dt=VI2(t)+gTT+l−jLI2−kTI2

(5)dCdt=VC(t)−pC

(6)dIdt=VI(t)−qI

The tumor growth is described by Gompertzian law (the first term in equation 1). The destruction of tumor cells by *CTL* is presented by the second term in equation (1) in which the destruction rate is proportional to the number of tumor cells and *CTL* cell populations. In equation (3), d characterizes the steady inflow of *CTL* into the tumor site. The second and third terms in equation (2) describe CTL proliferation in response to IL-2 action and *CTL* death rate. In equations (3-5), ($I = I_2$, C, I)

XSL•FO
RenderX

describes the external influxes of IL-2, a chemotherapeutic drug, and IFN-α, respectively. Since therapy is assigned to a certain schedule, these influxes are taken to be time-dependent. IL-2 production in equation (3) is described by hyperbola (the second term), which allows us to consider a limitation in the stimulation of the immune system by the growing tumor. At small T (ie, $T <=$), the growth rate is nearly linear in tumor size, while for big tumor (ie, $T>>$), it tends to a maximum constant value g. The parameter influences the IL-2 production rate. The smaller the value of , the quicker the IL-2 production rate achieves its maximum value g.

Radiotherapy and Mathematical Oncology

Belostotski and Freedman [19] introduced a mathematical model for radiotherapy treatment strategy based on the Lotka-Volterra competition system, which was later extended by Liu and Yang [23]. The model assumes that cancerous and healthy cells coexist within the same region of the organism and that radiation preferentially eliminates cancer cells while exposing healthy cells to lower doses. Radiotherapy is thus modeled as a harvesting-type control mechanism that regulates the rate of change in both cancer and healthy cell populations, as discussed in Multimedia Appendix 1.

Limitations of Mathematical Models

While mathematical models offer valuable frameworks for understanding cancer dynamics, several challenges limit their direct clinical applicability. Ghaffari et al [12] highlight a key gap between theoretical mathematical oncology and clinical practice, largely due to the limited availability of high-quality, patient-specific clinical data required for robust model validation. Song et al [10] similarly note that difficulties in accurately predicting treatment outcomes hinder practical implementation. Additional challenges include patient-level variability in parameter estimation, scarcity of comprehensive clinical datasets, reliance on simplifying assumptions that may not capture complex biological behaviors, and the difficulty of modeling treatment resistance. As noted by Yin et al [20], these factors introduce significant uncertainty into clinical use. In particular, critical parameters often derived from in vitro or in vivo experiments are difficult or impossible to measure directly, necessitating indirect estimation and inferential approaches. Collectively, these limitations constrain the routine clinical deployment of mathematical cancer models [25].

The study of complex IoT interventions in cancer care is constrained by the limited availability of IoT data, heterogeneity in care processes and interventions, and the intrinsic variability of cancer characteristics. Despite these challenges, mathematical models stand to benefit substantially from IoT integration, while modeling and simulation within IoT environments offer opportunities to mitigate many existing limitations. Incorporating additional data sources, such as nanotechnology-enabled sensing, and enabling real-time adaptation to diverse data streams can enhance predictive accuracy and clinical relevance. Although it has been suggested that the complete eradication of cancer cells is unattainable regardless of treatment type or timing [21], emerging evidence indicates that wireless sensor networks and IoT technologies can significantly improve treatment personalization and effectiveness, as demonstrated in our prior work [7]. Addressing data-related barriers—particularly IoT data governance, interoperability, quality, privacy, and security across the data lifecycle—is, therefore, essential for effective integration.

Overall, Yin et al [20] provide a comprehensive overview of mathematical models for tumor dynamics in cancer treatment, including empirical models of therapeutic effects, as well as algebraic, partial differential, stochastic, and deterministic formulations such as game-theoretic and integral-differential approaches. Building on this foundation, the models discussed in the preceding section—ranging from ordinary differential equations and tumor heterogeneity frameworks to biologically integrated tumor process models—inform the adaptation of these mathematical approaches to an IoT-enabled treatment context. This adaptation aims to strengthen computational and simulation capabilities, addressing the limitations of purely analytical models, as discussed in the following section.

Patient and Clinician Adoption of IoT Interventions in Cancer Care

The adoption of the proposed approach in cancer care requires a supportive environment for change, including adequate resources and process redesign. Key resources include human, physical, network, and information assets, with patients and clinicians central to implementation and evaluation. Patient adoption is likely to be influenced by concerns about data privacy and security; targeted education, transparent data governance, user-centered design, and ongoing support can enhance trust, engagement, and adherence. Clinician adoption, on the other hand, depends on early involvement in system design to ensure alignment with clinical workflows and usability requirements. Although workload and technical complexity may pose barriers, the potential to streamline workflows, improve task integration, and optimize resource utilization can support clinician acceptance and sustained use.

The IoT intervention is intended to serve as a mathematical control mechanism in which IoT-aware parameters actively modify the system dynamics of the mathematical models. While the tumor-immune interaction equations are adapted from established mathematical oncology models, the proposed IoT-enhanced immunotherapy framework introduces a fundamental shift by enabling IoT-driven parameter adaptation. Unlike traditional IL-2 tumor-immune models that assume static or population-averaged parameters, the IoT-enhanced formulation incorporates time-varying, patient-specific parameter modulation informed by continuous physiological and biomarker sensing. This enables dynamic responses to toxicity, treatment tolerance, and disease progression, improving predictive stability and clinical relevance. The additional term introduced in the revised equations represents an IoT-driven feedback mechanism that adaptively modulates immune dynamics based on real-time patient data, extending classical fixed-parameter models into responsive, patient-specific systems. This formulation explicitly illustrates and justifies the role of IoT-driven modifications, as discussed in subsequent sections.

Case Study (Immunotherapy for Melanoma)

Overview

In demonstrating the impact of IoT integration in cancer care services, this study presents a case study based on an adapted immunotherapy mathematical model (equations 2-6) introduced in the *Overview of Cancer and Treatment Approaches* section. Immunotherapy was selected because such models are widely applied in melanoma treatment and leverage immune system stimulation to target cancer cells. Compared to other treatment modalities, immunotherapy requires continuous monitoring and dynamic management to mitigate adverse effects, making IoT-enabled devices particularly valuable for real-time patient monitoring and adaptive, data-driven care.

Background

Melanoma patients often receive immunotherapy, which includes treatments with cytokines and immune checkpoint inhibitors. In this treatment option, the continuous monitoring and precise control of drug administration can significantly enhance the efficacy of such treatment therapies through the interfacing and integrating smart and intelligent connected devices.

IoT Integration

1. Enabled (wearable) sensors: Patients wear IoT-enabled devices that monitor physiological parameters indicative of immune responses, such as body temperature, heart rate, and biomarker levels in sweat or blood.
2. Embedded (implantable) devices: Smart connected sensors are implanted near the tumor site to continuously measure tumor size and local immune markers directly.

This demonstrates the IoT integration for cancer treatment, which allows the enabled and embedded sensors and devices to be deployed in cancer care services by forming autonomous wireless ad hoc networks that interact with patients to collect information from patients and their environments. Through these ad hoc networks, the sensor nodes collaborate to perform the required task or tasks, such as processing, transmission, and aggregation of data from various sources, which are used to determine the nature of the illness by those in the circle of care to determine the nature of treatments and diagnoses to offer. As observed, data and information from sensors are transmitted or routed from various patient sites within the network to the data center through cloud services, facilitating the exchange of data and information from patient locations to the main hospital data center.

During implementation, various components are integrated to ensure the functioning of IoT-based systems or environments. Although these elements are broadly grouped at the component level, together they form an IoT-based component ecosystem. In practice, modeling an IoT-enhanced immunotherapy system for melanoma requires the integration, interconnectivity, and coordination of multiple components, including device, communication criteria, access technologies, communication network, data management, and application layers. Each component serves a distinct role in enabling effective operation and service delivery within the system.

The communication network component enables data sharing and traffic transmission from the point of observation to the data management platform and onward to various system applications. It operates through the access technologies component and supports communication across the network using routing protocols, different topologies and architectures, transmission channels, geographical locations, wireless sensor networks, wireless access points, and internet connectivity from the internet service provider, while ensuring security and encryption.

Therefore, adopting an appropriate routing strategy in wireless sensor networks is essential to balance optimality and efficiency while maintaining computation and communication performance [26]. This is especially important as health care resources become more interconnected and the number of sensor motes continues to grow. These motes collect sensory data by measuring, monitoring, and recording physical conditions in the health care environment and are connected through the internet to a central network infrastructure that enables data transmission and exchange, ultimately improving operational processes and service delivery.

Proposed IoT-Enhanced Mathematical Framework

Mathematical model adaptation: The existing model equations can be adapted by introducing terms (ie, new variables) representing data inputs from IoT devices and adjusting treatment protocols based on real-time data.

The IoT-enhanced equations are derived from the baseline model by introducing IoT-driven input functions that adapt system dynamics in real time. For each added IoT function parameter, we provide corresponding biological and computational rationales to justify its inclusion in the mathematical framework.

Formula 1. Formula for tumor cell dynamics (T)

$$dTdt=-aTln\,(bTa)-c(I)\,TL-MT(I2)(1-e-C)T+ST(t)$$

As shown in Formula 1, $S_T(t)$ represents the real-time tumor size adjustment based on data from the implantable or embedded sensors for its effects on immunotherapy.

- Biological rationale: Tumor burden evolves heterogeneously and may change rapidly in response to immunotherapy. Implantable or embedded sensors (eg, tumor microenvironment probes, imaging-derived biomarkers) can provide near-real-time indicators of tumor growth, hypoxia, or metabolic activity that are not captured by fixed growth or killing rates.
- Computational rationale: The term $S_T(t)$ introduces a corrective adjustment to tumor dynamics based on observed tumor-state deviations. Computationally, this term allows the tumor growth trajectory to be continuously recalibrated using sensor-derived feedback, improving model responsiveness and reducing reliance on static growth assumptions.

Formula 2. Formula for CTL dynamics (L):

$$dLdt=d+eLI2-fL-ML(I2)(1-e-C)L+SL(t)$$

XSL•FO
RenderX

As shown in Formula 2, $S_T(t)$ represents the CTL modulation influenced by wearable sensor data for its effects on immunotherapy.

- Biological rationale: CTL activity is sensitive to systemic stress, fatigue, and immune suppression, which can be indirectly inferred from wearable sensor data such as heart rate variability, temperature, or activity levels. These physiological signals correlate with immune competence and treatment tolerance.
- Computational rationale: The term $S_T(t)$ enables time-varying modulation of CTL population dynamics in response to the patient's state. This prevents the unrealistic persistence of immune efficacy under adverse conditions and allows the model to reflect immune exhaustion or recovery observed clinically.

Formula 3. Formula for IL-2 Dynamics (I_2):

$$dI2dt=VI2(t)+gTT+l-jLI2-kTI2+SI2(t)$$

As shown in Formula 3, SI2(t) represents an adjustment in IL-2 based on continuous biomarker monitoring for its effects on immunotherapy that is, a function of a sensor-derived toxicity or inflammation signal $z(t)$.

To illustrate the qualitative effect of IoT integration on immunotherapy dynamics, we introduce a normalized sensor-derived control signal $z(t) \in [0,1]$ representing a composite patient toxicity and immune-activation index. This signal, computed from continuously monitored physiological and biomarker data (eg, body temperature, heart rate variability, oxygen saturation, and inflammation-related markers), drives the IoT feedback term SI2(t;z(t)) in the IL-2 dynamics. The term SI2(t;z(t)) enables real-time, patient-specific modulation of immune response, transforming the model from a static, open-loop formulation into an adaptive, feedback-driven system. This enhances predictive stability and clinical plausibility by reflecting treatment adjustments informed by continuous monitoring rather than fixed schedules.

- Biological rationale: IL-2 levels are tightly linked to immune activation and toxicity, with excessive IL-2 associated with severe adverse effects. Continuous biomarker monitoring (eg, cytokine levels, inflammatory markers) provides early signals of immune overactivation or suppression.
- Computational rationale: The IoT-driven SI2(t) acts as an adaptive feedback mechanism that adjusts IL-2 dynamics in real time. This allows the model to represent dose adjustment, treatment delay, or attenuation strategies triggered by early biomarker changes, improving stability and clinical plausibility.

Formula 4. Formula for drug dynamics (C):

$$dCdt=VC(t)-pC+SC(t)$$

As shown in Formula 4, $S_C(t)$ represents the chemotherapeutic drug infusion rates controlled by IoT devices to maintain optimal drug levels for its effects on immunotherapy.

- Biological rationale: Chemotherapeutic and immunotherapeutic drug infusion rates are increasingly controlled by smart pumps and IoT-enabled delivery systems that respond to patient-specific tolerance and toxicity signals.
- Computational rationale: The term $S_C(t)$ converts drug administration from a predefined input into a sensor-driven control variable. This enables dynamic regulation of drug concentration to maintain therapeutic efficacy while minimizing toxicity, reflecting real-world adaptive dosing practices.

Formula 5. Formula for IFN-α dynamics (I):

$$dIdt=VI(t)-qI+SI(t)$$

As shown in Formula 5, $S_I(t)$ represents the IFN-α level adjustments based on sensor data for its effects on immunotherapy.

- Biological rationale: IFN-α plays a central role in immune activation but is also associated with systemic side effects. Sensor-derived indicators such as fever, fatigue, and inflammatory response provide indirect measures of IFN-α activity and tolerance.
- Computational rationale: The IoT term $S_I(t)$ allows IFN-α dynamics to be adaptively adjusted based on patient response, preventing sustained overactivation and enabling more realistic immune regulation within the model.

Implementation

- *Real-time data processing*: IoT devices transmit data to a central system where they are processed in real time. The system uses algorithms to predict and adjust the influx rates (VI2(t), VC(t), VI(t)) and introduces corrections (ST(t), SL(t), SI2(t), SC(t) and SI(t)) based on the patient's current state and treatment response.
- *Feedback system*: The treatment regimen is adjusted dynamically, allowing for personalized therapy schedules that optimize immune response and tumor suppression based on continuous feedback.

Conclusion

Integrating IoT in immunotherapy allows for dynamic, personalized treatment adjustments that can potentially lead to better patient outcomes by ensuring optimal drug levels and immune responses at all times. This approach leverages the power of real-time data to make informed decisions on the complex dynamics of cancer treatment.

Definitions of Parameters

The mathematical modeling of oncology treatment pathways and real-time patient monitoring relies on a specialized set of variables, which are categorized into biological parameters, IoT input functions, and time-dependent external influxes

1. Biological parameters:
   - Tumor growth parameters (a and b): They reflect the natural growth rate and carrying capacity of the tumor.
   - Immune response modifiers ($c(I)$, $M_T(I_2)$, and $M_L(I_2)$): They depend on the specific immune response elicited by different cytokines or drugs.

XSL•FO
RenderX

- Drug effectiveness (e^{-c}): It represents the effectiveness of the chemotherapeutic drug, typically modeled as an exponential decay.
- *CTL* dynamics (*d*, *e*, and *f*): They represent the rate of *CTL* inflow to the tumor, *CTL* proliferation rate, and death rate, respectively.
- Production and decay rates (*g*, *j*, *k*, *p*, and *q*): They control the dynamics of *IL-2*, *CTL*, and drug concentrations.
- I: It affects the production rate of IL-2 by the tumor.

2. IoT input function parameters:
   - Sensor data adjustments (ST(t), SL(t), SI2(t), SC(t), and SI(t)): They are model functions that adjust parameters based on real-time data from IoT devices.
3. External influxes:
   - Time-dependent influxes (VI2(t), VC(t), VI(t)): They define how external treatments are administered over time.

Innovative Modeling Approach to Cancer Care Through IoT

Overview

Cancer research is increasingly moving toward intelligent, IoT-enabled health care delivery for cancer care [1,5-7,22]. Integrating IoT technologies with mathematical modeling enhances the precision of treatment dynamics by enabling the adaptive control of therapy parameters and patient-specific responses. This convergence gives rise to a mathematically modeled IoT-based cancer care system that embeds control mechanisms, parameters, and behaviors within IoT-driven clinical workflows.

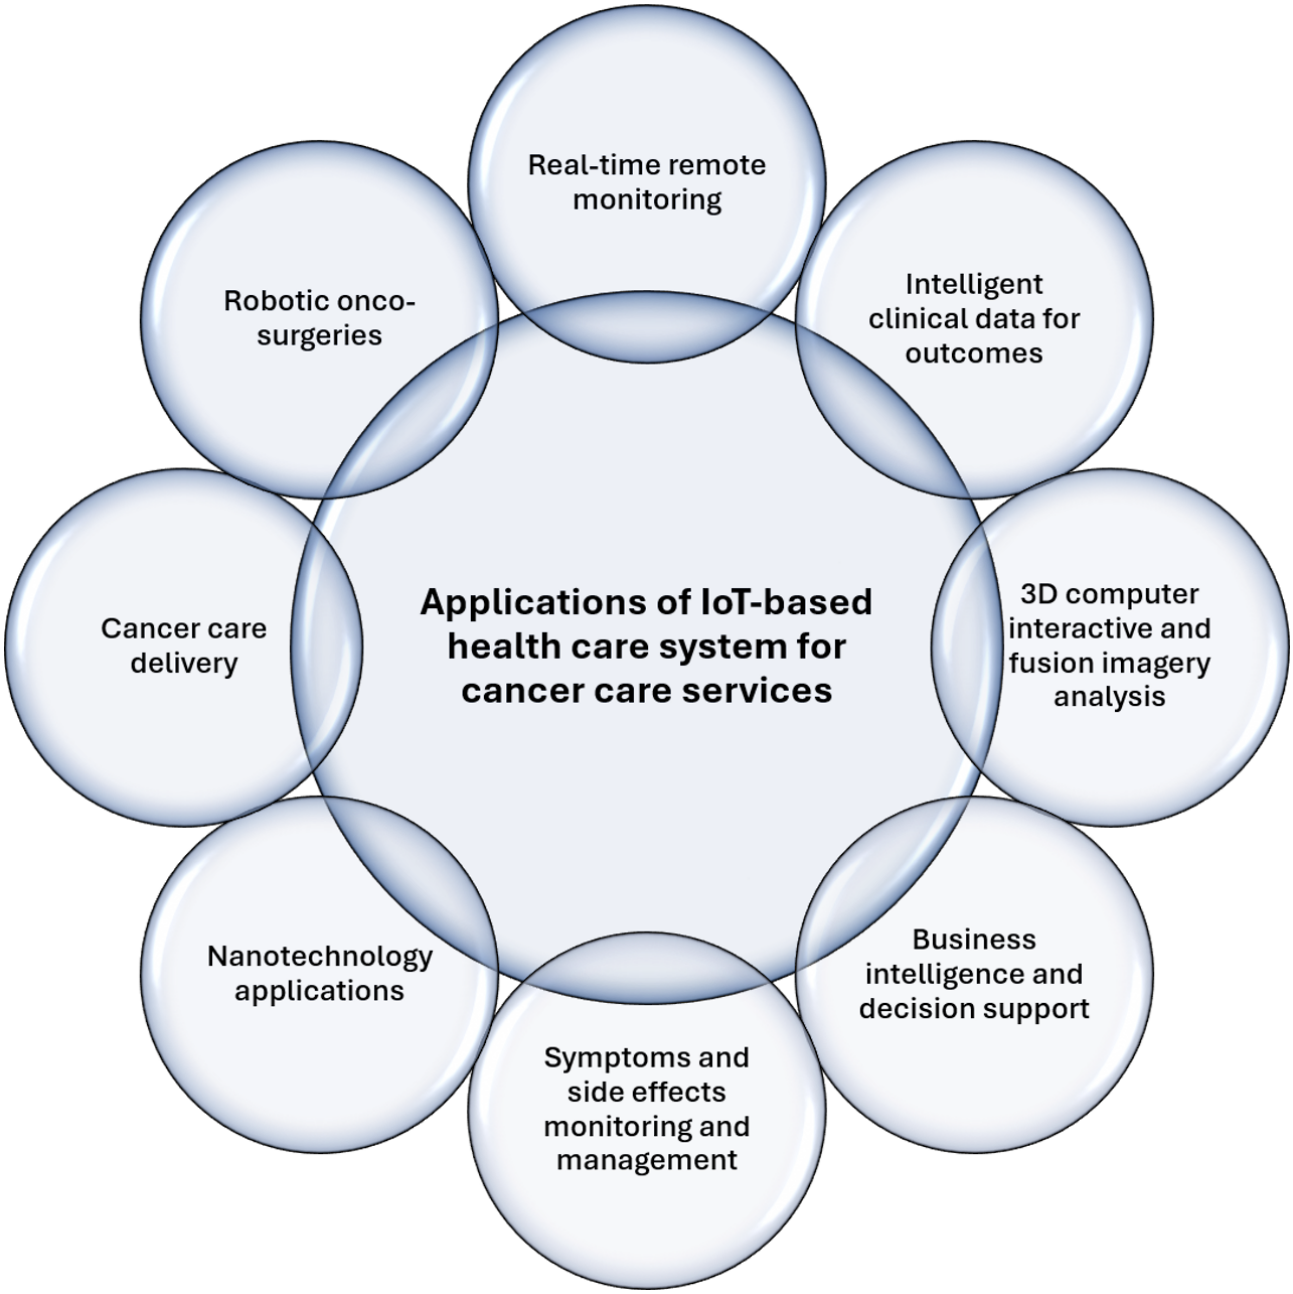
Simulation and computational approaches can effectively bridge the gap between the theoretical frameworks of mathematical oncology and clinical practice. Central to these models are mathematical equations, especially differential equations, which quantify the behaviors and relationships within biological systems [12,16,17]. These models use specific biological parameters, such as growth rates or drug responses, enabling the simulation of diverse scenarios. Real-time data integration allows for further dynamic adjustments to parameters in response to individual-level factors or conditions. Overall, the responsiveness and dynamism of computational and simulation-enhanced mathematical models support the rapid validation of IoT-enabled cancer treatment effects under different scenarios.

The complex modeling required to validate the effects of IoT-enabled cancer treatment underscores the need for approaches that are both responsive and informed by underlying mechanisms. These models transcend the limitations of data reliance typical of population-level statistical methods, including some computational machine-learning techniques. Instead, they use mathematical models that clarify dynamic causal mechanisms between individuals, supplemented by the best available data, thereby enhancing predictive accuracy for personalized medicine.

In oncology, mathematical modeling approaches such as agent-based models and cellular automata are increasingly used [12]. These models are pivotal in understanding the biological complexities of cancer and developing effective therapies. When considering the application and implementation of IoT technologies, methods such as process simulation and digital models offer another dimension through which mathematical oncology can inform and optimize health system operations. These approaches provide advanced computational techniques to enhance the efficiency and effectiveness of service delivery and overall management within health care systems, ensuring a comprehensive and integrated approach to both individual patient care and broader health system settings.

By integrating IoT and related technologies, we can address many challenges, such as resistance and assumptions, that have hindered the effectiveness of various models in clinical trials and routine patient care. This integration enhances personalized approaches, helping to pinpoint the most effective treatment options and therapeutic regimens. Additionally, the use of advanced sensors, such as nanodevices implanted in patients, allows for the real-time monitoring of cancer's nature and progression. Coupled with intelligent medical image analysis and the application of 3D computer-interactive technologies in virtual reality, augmented reality, and mixed reality contexts, these innovations offer significant potential to improve cancer treatment and the patient's health care experience more effectively and efficiently [3].

Data sharing in health care environments, particularly with IoT-generated big data, presents a challenge due to the diversity of smart connected sensors, objects, devices, data, services, and other supporting applications resulting from the real-time flow and volume of data between systems. The adoption of health care standards and protocols for data interoperability, such as Health Level 7 connectivity, Digital Imaging and Communications in Medicine, and Fast Healthcare Interoperability Resources, may be critical to facilitating appropriately scaled and seamless data exchange between systems. In contrast, conformance to privacy and security standards and policies, in addition to these technical standards, can help protect highly sensitive personal health information from privacy risks and incidents.



Applications of IoT-Based Health Care System for Cancer Care

Overview

Mathematical biological parameters describing cancer growth, cell populations, invasion, and progression are integrated into IoT-based cancer care services to enhance the design, simulation, and deployment of integrated health care solutions. The convergence of IoT and related technologies enables novel, data-driven approaches to cancer care. Figure 2 illustrates key IoT-based health care applications for cancer care.

XSL•FO
RenderX

Figure 2. Applications of Internet of Things (IoT)–based health care system for cancer care.

Real-Time and Remote Monitoring

IoT devices are seamlessly integrated with cancer treatment protocols to enable real-time and remote monitoring of patients, including the capture and exchange of vital signs, patient-reported measures, activity, and biometric data across various geographical locations, enabled by IoT-connected technologies.

Intelligent Clinical Data for Outcomes

Integrating IoT-related technologies into cancer care facilitates a significant shift from traditional to digital health care. The electronic health record is anticipated to help manage this data stream, characterized by an expanded volume and variety of quality data for routine use in value-based learning health systems. These capabilities, not offered by IoT modeling approaches alone, support comprehensive patient management, including communication, monitoring, alerting, diagnosis, prognosis, and treatment. However, streams of personal data collected from IoT-connected devices carry ethical implications. Ethical guidelines and regulations for cancer patient data must be established to safeguard patient data against hacking, compromise, misuse, misdiagnosis, unauthorized access, attacks, and breaches, while improving transparency and accountability.

3D Computer Interactive and Fusion Imagery Analysis

Intelligent medical image analysis using 3D computer interactive and fusion imagery technologies will significantly improve cancer treatment, especially in personalized health care experiences, making treatment more effective and efficient.

Business Intelligence and Decision Support

IoT-based cancer care provides a framework for analyzing patient data from IoT-enabled devices through business

XSL•FO
RenderX

analytics. This assists health care providers and clinical researchers in converting data streams about patients' health conditions into actionable insights and evidence-based decision-making at all levels.

Symptoms and Side Effects Monitoring and Management

Systemic cancer treatment may lead to significant side effects and complications such as allergies, side effects, and other adverse effects. Current mathematical modeling approaches do not account for these variances, but IoT platforms provide an interface to collect data from various devices and analyze them to detect anomalies. This capability is essential for rapid diagnosis and treatment adjustments, thereby effectively improving the quality of life of patients with cancer by managing these issues.

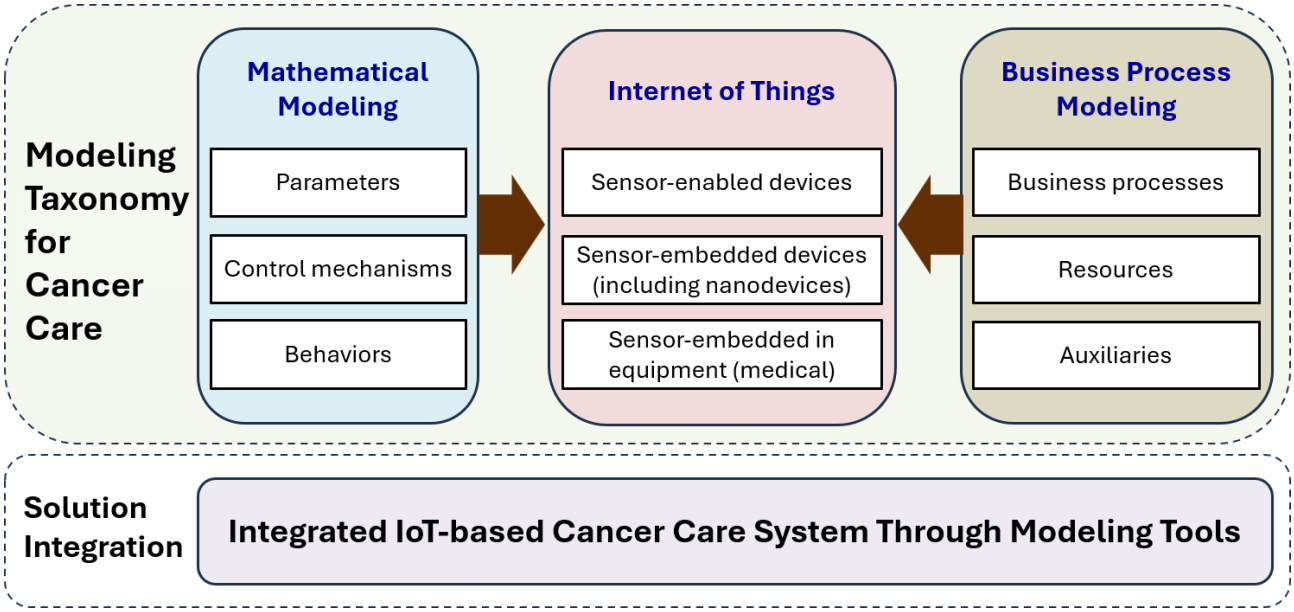
Nanotechnology Applications

The integration of IoT with nanotechnology (such as nanomaterials, nanodevices, nanostructures, nanoparticles, nanoprocessors, and nanonetworks) and communication engineering has led to the development of the Internet of Nano-Things and the Internet of Bio-Nano Things. These platforms facilitate interconnectivity, automation, and data exchange by embedding biosensors and computing nanodevices in biological systems, thereby enhancing cancer treatment through precise monitoring and targeted therapy delivery.

Cancer Care Delivery

Integrating IoT technologies with oncological treatment strategies changes how cancer care is administered by providing more responsive, personalized, and accessible treatment experiences that promote patient survival and quality of life. IoT devices, including smart sensors, enable the continuous monitoring of cancer evolution, optimizing treatment plans, and minimizing exposure of healthy tissues to harmful effects. In addition, IoT collaborative delivery models facilitate real-time communication and coordination among health care providers and empower patients by providing access to their health data for shared decision-making.

Robotic Onco-Surgeries



Integrating IoT with surgical robotics enables precise onco-surgical procedures by supporting high-accuracy, time-intensive interventions under continuous monitoring. IoT-enabled robots, augmented with embedded artificial intelligence, enhance surgical precision in targeting and excising locoregional tumors, including lymphadenectomy, while preserving healthy tissue within clinical margins. Real-time IoT monitoring during and after surgery supports patient stability, surgical condition awareness, and coordinated management of drains and tubes, thereby improving patient safety and postoperative recovery.

Integrated IoT-Based Cancer Care System Through Modeling Tools

Cancer care services stand to benefit substantially from IoT-enabled technologies; however, as IoT technologies enable more personalized oncology treatment strategies, mathematical frameworks must evolve to incorporate the advancements made possible by IoT. Mathematical oncology provides the foundation for IoT-adapted models that support drug delivery optimization, predictive patient monitoring, treatment scheduling, and interpretation of complex sensor-generated data streams. This integration ensures that IoT applications in oncology are clinically relevant and operationally feasible.

With continued advances, integrating IoT, mathematical modeling, and complementary analytical tools supports more automated and adaptive cancer care services, informing workflow redesign, clinical decision support, and improved care delivery. Figure 3 illustrates the taxonomy and interrelationships of cancer care modeling approaches examined in this study and future work, showing how IoT-enabled devices are embedded within business process modeling artifacts—tasks, events, activities, and resources—to enable the continuous monitoring of cancer conditions and characteristics.

Figure 3. Taxonomy of Modeling tools of an integrated Internet of Things (IoT)–based cancer care system.

XSL•FO
RenderX

Business process management (BPM) tools are widely used in health care due to their service-oriented nature [27,28]. In cancer care, BPM provides a structured approach to evaluate IoT-enabled services, tasks, and workflows, while IoT enhances efficiency and service delivery. BPM modeling helps identify redundancies, inefficiencies, and gaps in current processes, guiding the design of improved or future processes or workflows that better support the circle of care. It also informs optimal resource allocation and effective IoT interventions to optimize processes and improve patient outcomes. IoT-enabled BPM enables real-time monitoring and analysis of patient conditions and treatment responses using on-body, in-body, and off-body devices, supporting proactive and adaptive care.

Incorporating IoT into health care systems for cancer care services, especially radiotherapy, has been revolutionizing. A recent report by Chen et al [2] suggests that radiotherapy has evolved as a frontier discipline in cancer care services, driven by innovative advancements in artificial intelligence, which extend human intelligence. This has resulted in the widespread implementation of “intelligent radiotherapy," encompassing various tools, namely, big data, deep learning, extended reality, digital twin, radionics, and the IoT. Recognizing that target contouring and treatment planning are at the heart of the entire radiotherapy process, it becomes clear that there is considerable potential for improvement in this area. Radiation oncologists can begin to enhance the radiotherapy process with intelligent radiotherapy that facilitates automation and intelligence, especially through business process modeling. This demonstrates that when evaluating effects, we cannot overlook the significance of IoT and related digital technologies in the modern health care system landscape.

All these applications and technologies, through smart and intelligent devices and equipment, are adopted and adapted to underpin smart cancer care service delivery, which supports the conclusion that cancer treatment under a combination of multiple treatment strategies will yield better outcomes. This extends even to the use of the mathematical treatment strategies or model-based approaches. Drawing from the assertion by Ghaffari et al [12] that “the field of mathematical oncology is somewhat disconnected from the clinical practice of oncology,” we cannot apply mathematical modeling with only traditional oncology treatments in mind; instead, we must adapt to model the complex interventions that are enhanced by technological advancements.

Implementation and Challenges

It is essential to address the technological, regulatory, operational, and security challenges associated with implementing IoT-enabled cancer care systems within the proposed modeling framework. Mathematical and business process simulations offer a practical means or mechanism to translate or operationalize compliance, security, interoperability, and reliability requirements into testable parameters, enabling their evaluation before system deployment.

From a business process perspective, cancer-care workflows (eg, monitoring, alert generation, clinical decision, and intervention) can be modeled using discrete-event or business process model and notation-based simulations in which network latency, data loss, authentication delays, interoperability failures, or device downtime are injected as stochastic disturbances. These perturbations propagate through the workflow as delayed alerts, missed detections, or increased clinician response times, allowing the system to quantify process-level degradation such as time-to-intervention, queue buildup, or alarm fatigue under varying operational conditions.

From a mathematical modeling perspective, these process-level delays can be directly coupled to treatment-response models (eg, tumor-immune interaction models). For example, latency in vital-sign transmission or intermittent sensor dropout can be represented as delayed or incomplete feedback signals, leading to mistimed dose adjustments or prolonged exposure during adverse events. Simulation enables the quantification of the resulting clinical impact, such as reduced dose intensity, increased toxicity risk, or diminished therapeutic response.

Together, this integrated simulation framework functions as a predeployment environment, enabling the identification of critical thresholds—such as maximum allowable latency, minimum data completeness, or minimum sampling rates under low-power constraints—beyond which safety or efficacy is compromised. These findings can be translated into evidence-based design requirements that guide decisions on edge analytics, redundancy, interoperability standards, and security architectures, thereby influencing the performance of IoT-enabled devices and sensors.

Discussion and Future Work

This research proposes an integrated framework that combines mathematical modeling and IoT-based interventions to enhance cancer care delivery. Drawing on concepts from mathematical oncology, the study explores selected models to examine treatment dynamics while acknowledging the broader landscape of existing cancer models and their associated limitations. These limitations—particularly data scarcity, uncertainty, and system complexity—motivate the incorporation of IoT technologies to balance the trade-offs among patient preferences, clinical outcomes, and health care system constraints. An adaptive, innovative IoT-enabled modeling approach has been developed and demonstrated through a melanoma immunotherapy case study, highlighting the potential of real-time sensing and adaptive decision support. Data interoperability is identified as a key challenge, necessitating the use of health care data standards and secure protocols to enable real-time data exchange while preserving privacy and security.

Future research will advance this work along two complementary directions: mathematical modeling and business process modeling. From a mathematical perspective, future studies will incorporate additional parameters and empirically derived patient data to refine and validate treatment-response models. From a business process perspective, IoT-enabled cancer-care workflows will be simulated to assess performance, scalability, and regulatory compliance across different levels of oncology service delivery.

XSL•FO
RenderX

The integration of these perspectives offers a pathway toward digitally transformed cancer care, enabling the systematic evaluation of both clinical and operational capabilities across the continuum of care—from screening and diagnosis to treatment administration, rehabilitation, and follow-up. Thus, this disrupts current health care practices by replacing traditional health care with a frontier of digital health care. Methodologically, this will involve structured business process modeling using BPMN 2.0 (by means of mathematical modeling of cancer care services), application of the BPM lifecycle to transition from as-is to to-be care pathways, and simulation of IoT-enabled future-state models. Together, mathematical and process-based simulations provide a rigorous foundation for improving care quality, supporting decision-making, and guiding the evolution of IoT-enabled cancer care systems.

Abstract

Cancer diagnosis depends on data from radiology, digital pathology, molecular profiling, laboratory testing, and longitudinal clinical records. AI performs well in selected tasks, but most systems remain narrow and disconnected from the iterative reasoning required in oncology. This Viewpoint defines an AI agent as a feedback-driven system that maintains task state, selects among governed tools, observes results, and revises its plan under explicit safety constraints. This definition separates agents from multimodal foundation models, retrieval-augmented generation, and fixed workflow automation. We organize the discussion across multimodal data collection, preprocessing, fusion and representation learning, and diagnostic decision support. We distinguished agent-level evidence, component- or infrastructure-level evidence, and prospective propositions throughout. Clinical translation will require resilient failure handling, guideline version control, prospective evaluation, computational and workflow feasibility, and clinician authority over final decisions. The near-term opportunity is therefore transparent and traceable clinical decision support rather than autonomous cancer diagnosis.

(JMIR Cancer 2026;12:e103545) doi:10.2196/103545

KEYWORDS

artificial intelligence agent; multimodal oncology diagnosis; clinical decision support; large language model; human–artificial intelligence collaboration; diagnostic workflow

Introduction

Cancer remains a leading cause of morbidity and mortality. Global Cancer Observatory (GLOBOCAN) 2022 estimated that there were nearly 20 million new cancer cases and 9.7 million cancer-related deaths worldwide in that year [1]. Treatment delays are associated with higher mortality across several cancer indications [2]. Timely diagnostic pathways are therefore important, but they must also account for genomic, histopathological, microenvironmental, and temporal heterogeneity [3].

Modern oncology diagnosis is intrinsically multimodal. Clinicians combine imaging, pathology, laboratory results, molecular assays, and longitudinal electronic records, often across separate specialties and information systems. This fragmentation creates cognitive and coordination burdens that motivate integrated workflows [4,5]. Task-specific AI has advanced lesion detection, pathology classification, molecular modeling, and risk prediction [4,6-8]. However, most deployed or evaluated models address a single bounded input-output task rather than the full diagnostic process.

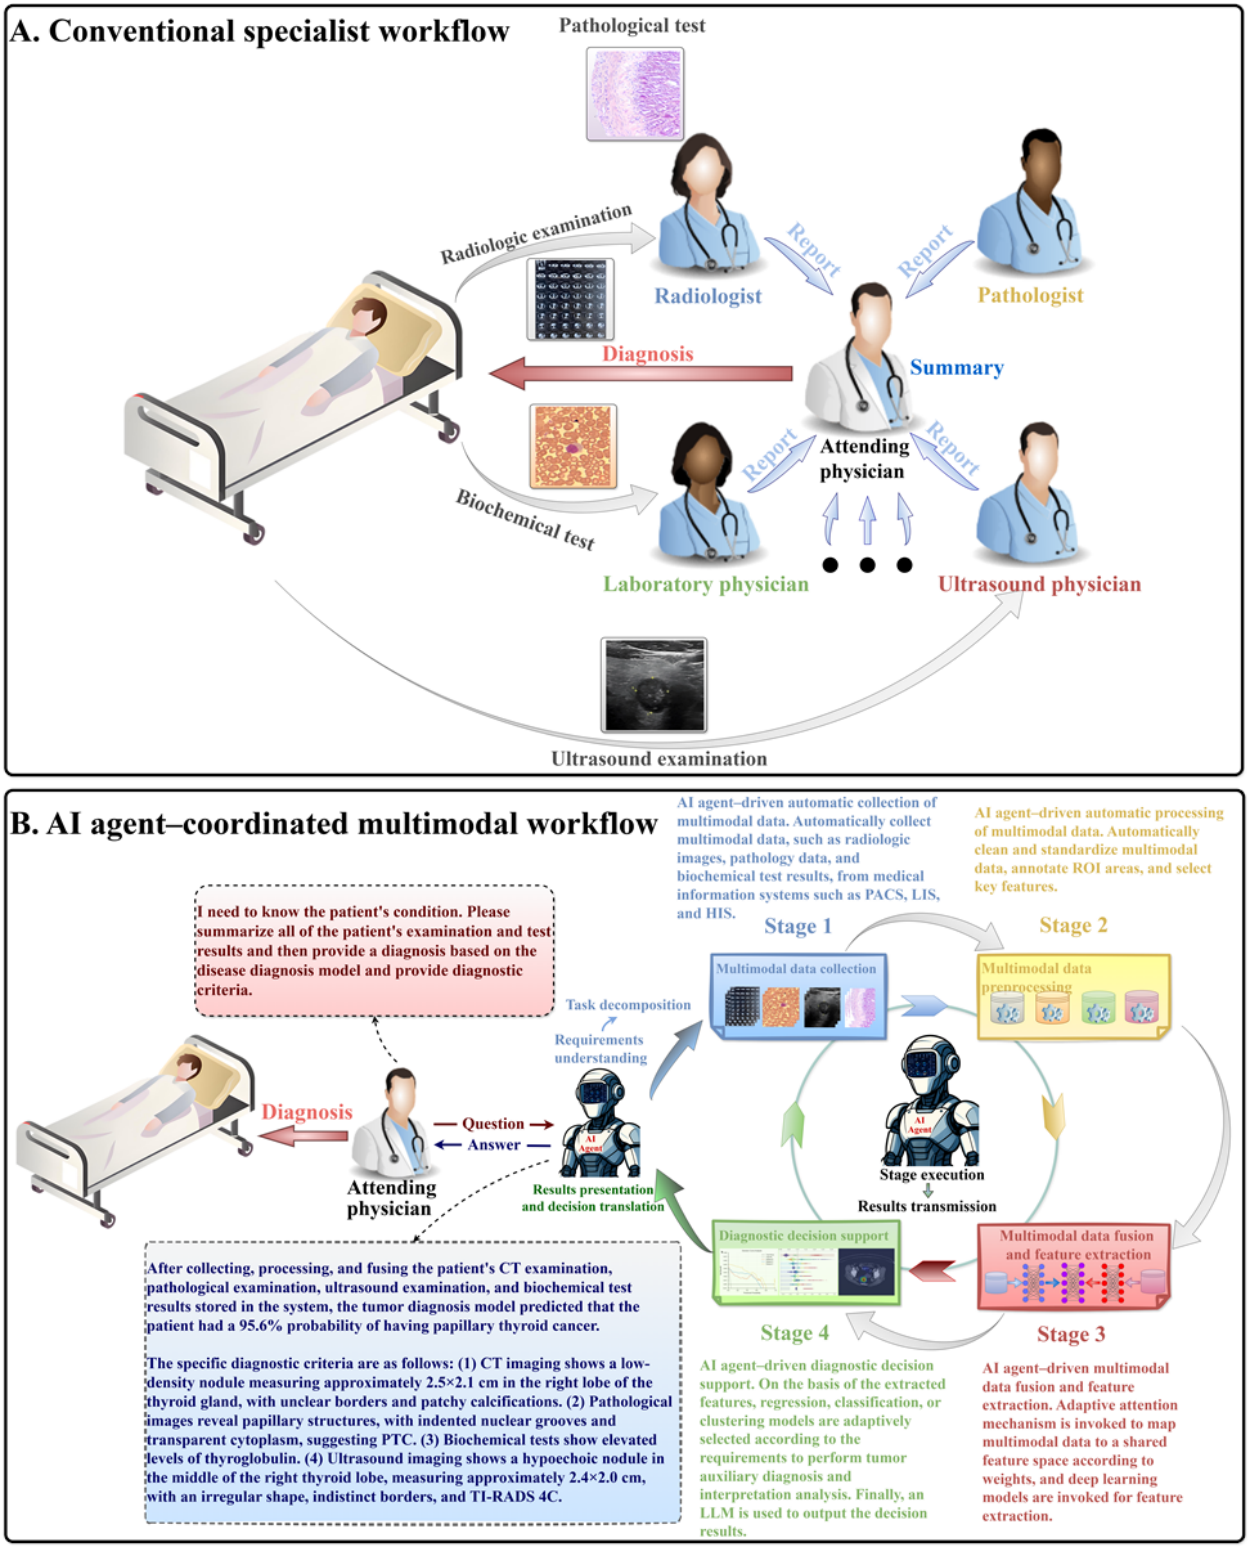
XSL•FO
RenderX

Large language models (LLMs), multimodal foundation models, and tool-use frameworks create a technical basis for coordinating these tasks [9,10]. However, a model that accepts several modalities is not automatically an agent. Similarly, retrieval-augmented generation (RAG) adds external evidence to generation, and fixed workflow orchestration links predetermined modules, but neither property alone establishes runtime planning or feedback-driven control.

This Viewpoint examines AI agents as auditable orchestration layers for multimodal oncology diagnostics. We organized the field around 4 connected stages: data collection, preprocessing, multimodal fusion and representation learning, and diagnostic decision support. Our central position is deliberately bounded: agentic orchestration may improve coordination and auditability, but clinical benefit and safety remain deployment-specific questions.

From Task-Specific AI to Agentic Oncology Diagnostics

We used an operational definition of agentic behavior. In a conventional fixed pipeline, an output is generated through a predetermined composition, $y=f_n(...f_1(x))$, and the sequence of functions does not change at runtime. An AI agent instead maintains a state s_t and selects an action $a_t = \pi(g, s_t, A_t)$ from an allowed tool set A_t. For a clinical goal g, it observes each tool's result and updates its state before choosing the next action. The practical distinction therefore lies in conditional planning, tool selection, observation, and revision within a governed loop.



Four adjacent concepts should remain separate. A multimodal foundation model supplies reusable representations or generation across data types. RAG retrieves external sources to ground an answer. Fixed workflow orchestration executes a prescribed sequence of services. A feedback-driven AI agent can change the sequence, request missing evidence, retry or switch tools, abstain, and escalate to a clinician according to the evolving state. Long-term memory is optional and should be limited to an authorized, versioned, patient-specific or institutional state rather than treated as an unrestricted capability.

First, Figure 1 contrasts a conventional specialist synthesis with an agent-coordinated 4-stage workflow. Second, Figure 2 operationalizes the agentic layer as a plan-act-observe-update-check loop. Act coordinates the 4 stages in Figure 1B; update records state and provenance; and check evaluates evidence sufficiency, cross-modal consistency, and whether further action remains within the authorized scope. If these criteria are met, the synthesis proceeds to clinician review. Remediable gaps return the workflow to planning; gaps that cannot be supplemented trigger clinician escalation. The agent-coordinated elements in both figures are prospective design propositions and not validated clinical systems or performance claims.

We applied 3 evidence labels throughout this Viewpoint. Agent-level evidence evaluates a complete loop that plans, uses tools, and produces an integrated output, as in the external oncology evaluation by Ferber et al [11]. Component or infrastructure evidence evaluates a model, retrieval method, data pipeline, or governance mechanism that an agent could invoke [12]. Prospective propositions describe plausible clinical workflows that still require system-level and prospective validation. This hierarchy prevents strong component performance from being misread as proof of a clinically validated agent.

Figure 2. Feedback-driven orchestration and evidence-adequacy control for an AI agent in multimodal oncology diagnostics. The control architecture links plan, act, observe, update, and check. Act invokes governed tools across the 4 task stages shown in Figure 1B. Update appends each tool result to the current state and provenance log. Check evaluates whether evidence is sufficient and consistent across modalities and whether further action remains within the authorized scope. If these criteria are met, the synthesis proceeds to clinician review. Remediable gaps return the workflow to planning, whereas gaps that cannot be supplemented trigger clinician escalation.

Multimodal Data Collection

The first stage is the governed assembly of patient-specific evidence. Relevant data may be distributed across a hospital information system (HIS), laboratory information system (LIS), picture archiving and communication system (PACS), electronic medical record (EMR), pathology archives, and genomic platforms. These systems differ in format, ontology, temporal granularity, and access control.

Component-level infrastructure studies show that integration must be engineered. A single-center oncology data supply chain linked clinical, genomic, and imaging data for more than 170,000 patients across 11 cancer types and more than 800 features per case [13]. Its extract-transform-load (ETL), natural language processing (NLP), and quality control procedures support the feasibility of a data layer but not the validation of an agent. Standards such as Health Level Seven Fast Healthcare Interoperability Resources (HL7 FHIR) and Digital Imaging and Communications in Medicine (DICOM) can reduce site-specific translation [14]. Local mapping and governance nevertheless remain necessary.

An agent could use secure interfaces to identify, retrieve, and temporally align data for a specific diagnostic question. It could connect a new scan to prior pathology, biomarker trajectories, sequencing results, and notes [9,15]. Unstructured text and patient-reported or wearable data may add context in selected settings [16]. Each input should carry its source, acquisition and update times, missingness status, and freshness threshold. Contradictory or stale records should trigger clarification rather than silent fusion. Once evidence is assembled, the next risk is whether every modality is technically fit for analysis.

Multimodal Data Preprocessing

Multimodal preprocessing converts heterogeneous inputs into representations that downstream tools can use. Imaging varies by scanner and acquisition protocol. Digital pathology depends on tissue preparation, staining, and slide digitization [6]. Laboratory and genomic data may be incomplete or generated on different platforms, while clinical text often contains duplication and institution-specific shorthand.

A fixed workflow applies the same preprocessing sequence. An agentic workflow could select modality-specific tools according to file type, quality, and clinical purpose. It might invoke imaging quality control and segmentation or pathology stain normalization, tiling, tissue filtering, and feature extraction. Pathology foundation models provide reusable component representations [17,18], while self-supervised medical imaging models illustrate robustness and data-efficiency strategies [19]. Attribution tools such as gradient-weighted class activation mapping can support region-level inspection, although an attribution map is not itself a clinical explanation [20].

Every action should be recorded with the input source, time stamp, parser or model version, quality control result, and review status. If optical character recognition or parsing fails, the system should not fabricate a normalized record. It should retry within a bounded policy, switch to a validated alternate parser, return a partial result with an explicit missingness flag, or request human review. This provenance-aware preprocessing creates the conditions for fusion without concealing upstream uncertainty.

XSL•FO
RenderX

Multimodal Fusion and Representation Learning

Fusion is not the mere presence of multiple data types. Imaging describes macroscopic phenotype, pathology reveals tissue architecture, molecular assays characterize biological drivers, and longitudinal records provide clinical context. Multimodal models can combine these views for characterization and risk estimation [7], but many assume that all modalities are harmonized and simultaneously available.

At the molecular level, machine learning can integrate complementary omics layers and prioritize regulatory interactions. Omidi combined RNA sequencing and microRNA sequencing profiles from 2 public cohorts [21]. The analysis included 78 adrenocortical carcinoma samples from The Cancer Genome Atlas adrenocortical carcinoma (TCGA-ACC) and 250 normal adrenal samples from the Genotype-Tissue Expression (GTEx) project, reconstructing condition-specific competing endogenous RNA networks. Random forest models performed best for predicting microRNA-messenger RNA associations, and predicted interactions were cross-referenced with TargetScan and miRTarBase. This study is an in silico systems biology module that an agent could invoke. Batch effects, cohort imbalance, cross-cohort heterogeneity, and the absence of independent or experimental validation prevent these findings from being interpreted as validation of a multimodal agent.

An agent could select a fusion strategy according to the clinical question, available modalities, and uncertainty. If pathology and imaging are available while genomic testing is pending, it could use a modality-robust model, mark molecular evidence as unavailable, and revise the synthesis later. Explainable multimodal real-world models have identified patient-level marker contributions in large cohorts and undergone independent validation [22]. These results support component-level representation and explanation but not autonomous clinical orchestration. Fusion outputs must therefore pass an evidence-adequacy check before decision support. The evidence-adequacy gate and its return-or-escalate logic are shown in Figure 2.

Diagnostic Decision Support

The final stage translates analyzed evidence into a structured, reviewable diagnostic summary. The purpose is not autonomous diagnosis or treatment selection. It is to state the supported findings, unresolved conflicts, missing evidence, uncertainty, and provenance in a form that clinicians can audit.

A recent feasibility study evaluated Gemini 2.5 Pro (Alphabet Inc) and ChatGPT 4o (OpenAI) on 80 Turkish-language prostate-specific membrane antigen positron emission tomography–computed tomography (PSMA PET-CT) reports [23]. The prompts incorporated the American Joint Committee on Cancer (AJCC) staging, the Chemohormonal Therapy Versus Androgen Ablation Randomized Trial for Extensive Disease (CHAARTED) criteria, and few-shot examples. The models assigned T, N, and M categories and disease volume classes, with overall task accuracies of 93.8% and 91.3%, respectively. Errors clustered around equivocal findings and different interpretive thresholds, including overstaging of ambiguous lesions. The single-center design, 1 expert reference standard, and exploratory sample of 80 reports limit generalizability. The study supports an LLM-based report-to-staging component that requires expert oversight; it does not validate a complete AI agent.

Other component studies illustrate evaluable end points. Multimodal oncology chatbots have been tested on image-containing clinical cases [24]. Explanation types can alter physician trust and diagnostic performance [25]. On the contrary, fabricated details can induce hallucinated clinical elaboration despite simple mitigation attempts [26]. Agent evaluation should therefore include tool selection, evidence citation, contradiction handling, safe refusal, calibration, workflow burden, and final conclusion quality rather than fluency alone.

In practice, an agent might prepare a multidisciplinary team (MDT) case by linking a suspicious lung lesion to pathology, molecular markers, smoking history, and prior imaging. It could rank competing diagnoses, identify a missing confirmatory test, and provide an evidence-linked summary. Proposed MDT assistance and randomized source-attribution studies support case preparation and verifiable retrieval as useful components [27,28]. Clinicians must retain authority over the final judgment, with explicit responsibility assigned across users, institutions, and manufacturers [29].

Challenges and Future Directions

Limits of the Current Evidence

The evidence base remains uneven. Most cited studies validate models, infrastructure, or simulated workflows rather than prospectively deployed agentic systems. The following implementation requirements should therefore be read as a translational agenda and not as established clinical effectiveness.

Data Quality and Interoperability

Interoperability does not guarantee semantic correctness. A deployable system must map local fields to versioned ontologies, record lineage and freshness, and quantify missingness. It must also test performance across scanners, laboratories, institutions, demographic groups, and unavailable-modality patterns [13,14,19]. External validation and subgroup analysis remain necessary because an agent can amplify errors introduced by any upstream component.

Operational Resilience and Graceful Degradation

Real-time MDT use requires an explicit latency budget for retrieval, preprocessing, inference, and rendering. Institutions may precompute stable features, use asynchronous tasks, or choose smaller local models when the expected benefit does not justify the delay. Time-outs should activate circuit breakers rather than indefinite retries. A parser or API failure should trigger a typed error and one of the following governed responses: a bounded retry, use of a validated alternate tool, a partial-result flag, or abstention with human escalation. The audit record should preserve the failed attempt and the fallback

XSL•FO
RenderX

path. This fallback logic corresponds to the supplementation and clinician-escalation branches in Figure 2.

Knowledge Life Cycle and Guideline Synchronization

Oncology guidelines and drug knowledge change frequently. Retrieval stores should preserve source dates, jurisdiction, guideline version, and effective period. Updates require staged ingestion, regression tests against reference cases, comparison with the previous version, canary deployment, and rollback criteria. A response should identify the version used and warn when local policy conflicts with an external guideline. This reduces, but cannot eliminate, legacy hallucinations.

Evaluation and Clinical Integration

Evaluation should follow the clinical workflow and the evidence label. Component metrics include extraction accuracy, calibration, source verifiability, latency, throughput, and failure rate. Agent-level evaluation additionally requires plan appropriateness, tool-use accuracy, recovery from failed steps, contradiction resolution, abstention, clinician workload, and patient safety end points [11,24-28]. Prospective studies should compare the full human-agent workflow with current practice and not only the agent with a static model.

Governance, Cost, and Institutional Adoption

Deployment also depends on computing cost, local infrastructure, cybersecurity, procurement, workflow fit, regulatory status, reimbursement, and institutional adoption. Trustworthy AI principles require fairness, traceability, usability, robustness, and explainability [12]. Precision oncology governance should add access control, deidentification, audit logging, incident response, continuous monitoring, model and knowledge base change control, and explicit accountability [29,30]. These controls are prerequisites for a clinical service and not evidence that the service improves outcomes.

Table 1 summarizes the current evidence supporting AI agents in oncology diagnostics and the limitations that constrain their interpretation and clinical use.

XSL•FO
RenderX

Table 1. Evidence supporting and delimiting AI agents in oncology diagnostics.

Evidence domains	Study design or setting	Main empirical finding	Agentic relevance and boundary
Agent-level oncology decision support	External evaluation on 20 realistic multimodal oncology cases [11]	Reported 87.5% correct tool use, 91% correct clinical conclusions, and 75.5% accurate guideline citation	Agent-level evidence from simulated cases; a useful benchmark but not prospective clinical validation
Real-world multimodal infrastructure	Single-center data supply chain covering >170,000 patients, 11 cancer types, and >800 features per case [13]	Integrated clinical, genomic, and imaging data with extract-transform-load, natural language processing, quality control, and continuously updated records	Infrastructure evidence; supports a callable data layer but does not evaluate agent planning or clinical benefit
Multimodal oncology chatbot benchmarking	Case-based evaluation of multimodal chatbots on 79 image-containing oncology cases [24]	Demonstrated that image-text oncology reasoning can be measured with case-level accuracy	Component evidence; a chatbot benchmark does not establish workflow orchestration or safety
Large language model–assisted prostate cancer staging from unstructured imaging reports	Single-center feasibility study of 80 Turkish-language prostate-specific membrane antigen positron emission tomography–computed tomography reports with embedded American Joint Committee on Cancer and Chemohormonal Therapy Versus Androgen Ablation Randomized Trial for Extensive Disease criteria and few-shot prompting [23]	Overall task accuracy was 93.8% for Gemini 2.5 Pro and 91.3% for ChatGPT 4o; errors clustered around equivocal findings	Component evidence; supports a report-to-staging module requiring expert oversight and not a complete agent
Machine learning integration of molecular regulatory networks	In silico integration of 78 The Cancer Genome Atlas adrenocortical carcinoma tumors and 250 normal adrenal samples from the Genotype-Tissue Expression project using RNA and microRNA sequencing [21]	Random forest best predicted microRNA-messenger RNA associations; predictions were cross-referenced with TargetScan and miRTarBase.	Specialized analytic module; cohort imbalance, batch effects, and the absence of independent or experimental validation limit inference
Tumor MDT[a] workflow	Workflow-focused proposal for AI assistance in tumor MDTs [27]	Identified opportunities for case preparation, synthesis of unstructured data, and rationale capture	Prospective workflow proposition; final decisions remain clinician led and require comparative evaluation
Source-attributed uro-oncology decision support	Randomized reader evaluation of a retrieval-augmented uro-oncology chatbot [28]	Improved recommendation correctness, source attribution, and source verifiability compared with a general chatbot	Component evidence; supports governed retrieval and verifiable sources and not full agent autonomy
Explainable multimodal real-world oncology AI	Multimodal model in 15,726 patients across 38 solid cancer types with external validation in 3288 patients with lung cancer [22]	Estimated patient-level marker contributions and prognostic interactions	Model-level evidence; supports reusable prediction and explanation tools with external validity boundaries
Hallucination and safety	Multimodel simulation of adversarial hallucination during clinical decision support [26]	Fabricated details induced false elaboration despite simple mitigation prompts	Safety evidence supporting contradiction checks, retrieval constraints, abstention, and human escalation
Interoperability	Clinical interoperability analysis across the AI data life cycle [14]	Emphasized standardized information exchange for data entry, processing, sharing, replication, and analytics	Infrastructure evidence; local semantic mapping and provenance remain necessary
Governance, liability, and implementation	Consensus trustworthy AI guidance, liability analysis, and precision oncology implementation review [12,29,30]	Identified requirements for fairness, traceability, usability, robustness, explainability, responsibility, safety, governance, cost, and harmonization	Cross-cutting requirements; governance controls enable evaluation but are not evidence of clinical effectiveness

[a]MDT: multidisciplinary team.

Conclusions

AI agents should be understood as auditable, feedback-driven orchestration systems rather than as another name for multimodal models or RAG. Oncology-specific studies now support selected agent-level, component-level, and infrastructure capabilities, including tool use, report-to-staging, multimodal modeling, and source attribution. However, these findings do not establish the safety or benefit of autonomous diagnosis. The defensible near-term goal is a resilient human-agent workflow that exposes provenance, uncertainty, failures, guideline versions, and escalation decisions. Prospective comparison with current clinical practice is required before broader implementation claims are justified.

Abstract

Background: Tele-oncology addresses geographic barriers to cancer care, but implementation challenges persist in rural settings. AI-enhanced predictive analytics offer opportunities for optimizing deployment through personalized, data-driven strategies; however, evidence in rural tele-oncology contexts remains limited, and critical equity considerations remain underexamined.

Objective: This scoping review aimed to map evidence on AI-enhanced predictive analytics in tele-oncology implementation, with particular attention to rural and underserved populations, to identify research gaps and inform implementation science priorities.

Methods: We searched 5 databases (PubMed, Embase, CINAHL, Web of Science, and IEEE Xplore) using 4 concept domains (tele-oncology, rural implementation barriers, AI or predictive analytics, implementation science) from January 2015 through November 2025. Two independent reviewers screened 330 unique records (title or abstract; Cohen κ=0.78), with the principal investigator resolving conflicts. Of 138 full-text reviews (κ=0.82), 4 studies met inclusion criteria. Data extraction captured study characteristics, AI applications, implementation factors, and outcomes. We used narrative thematic analysis to map findings into three themes: (1) the current tele-oncology implementation landscape in rural and underserved settings, (2) potential AI applications addressing implementation challenges, and (3) implementation considerations for AI systems themselves.

Results: Four included studies (1 pilot feasibility study, 1 proof-of-concept validation study, 1 cross-sectional predictive study, and 1 platform development study; published 2019 - 2025) demonstrated limited evidence at the intersection of AI, tele-oncology, and rural health equity. Patient characteristics predicted telehealth modality preferences with 86.2% accuracy, revealing that male patients exhibited 66% increased odds of video selection versus female patients (*P*=.004), and urban residents showed 101% increased odds compared to rural counterparts (*P*<.001). Liu et al demonstrated that disadvantaged populations engaged with AI-generated health literacy content 2.52-fold more frequently than nondisadvantaged counterparts. However, all 4 studies documented substantial implementation barriers (patient, provider, organizational, and system levels) persisting despite technological sophistication. Organizational threshold effects, where remote monitoring interventions succeeded with adequate provider capacity but failed under resource constraints—suggest that algorithmic innovations cannot overcome structural limitations in rural facilities. No studies explicitly examined algorithmic bias, cross-population validation, or potential harms in rural contexts. Geographic concentration in high-resource countries (United States n=2, Greece n=1, and Singapore n=1) and limited oncology-specific focus underscore structural gaps in knowledge generation for underserved populations.

Conclusions: Current evidence remains insufficient to support definitive practice recommendations. The observed evidence gap may reflect broader structural inequities in knowledge generation: populations with the greatest implementation challenges appear to remain substantially underrepresented in AI and digital health literature. Future research should prioritize comparative effectiveness studies in authentic rural contexts with implementation science outcomes, equity-centered cross-population validation, specification of translation mechanisms linking AI predictions to implementation strategies, health economic analyses, and mechanistic research on sociotechnical integration factors, ensuring technological innovation reduces rather than perpetuates disparities in cancer care.

KEYWORDS

artificial intelligence; predictive analytics; tele-oncology; telemedicine; rural health; implementation science; health equity; scoping review

Introduction

Terminology and Key Definitions

To ensure clarity and consistency throughout this review, we define key terms as follows: we use telehealth as the broader umbrella term encompassing all remote health care delivery using telecommunications technology, including both clinical services (telemedicine) and nonclinical services (tele-education, administrative videoconferencing) [1]. Telemedicine refers specifically to remote clinical services involving diagnosis, treatment, and patient monitoring [1,2]. Tele-oncology denotes the application of telehealth or telemedicine specifically to cancer care delivery, encompassing video consultations for diagnosis and treatment planning, remote symptom monitoring, virtual tumor boards, telephonic follow-up care, and hub-and-spoke models connecting rural facilities with specialized cancer centers [3,4]. AI-enhanced predictive analytics encompasses computational approaches, including supervised machine learning (random forests and gradient boosting), natural language processing, ensemble methods, and deep learning techniques that analyze data to forecast future outcomes, identify patterns, or generate predictions to inform clinical or operational decision-making [5]. Rural is defined broadly to include populations in geographically isolated areas with limited health care access, consistent with heterogeneous definitions across included studies, recognizing that rural classifications vary by country and health care system [6]. Implementation refers to the process of translating evidence-based interventions into routine practice, encompassing activities related to adoption, integration, sustainability, and scale-up of tele-oncology services within health care delivery systems [7].

Tele-oncology has emerged as a critical strategy for expanding access to cancer care, particularly for individuals facing geographic, socioeconomic, or infrastructure-related barriers to traditional in-person services [8,9]. Following rapid implementation during the COVID-19 pandemic [10], tele-oncology has demonstrated feasibility across varied settings and patient populations [4,8,10]. However, substantial implementation challenges persist, including gaps in technological literacy among patients, limitations in broadband infrastructure in rural areas, complexities in workflow integration, barriers to device access, and constraints on health care system resources [11,12].

These implementation barriers disproportionately affect rural and underserved populations, potentially exacerbating existing cancer care disparities [13,14]. Patients with cancer living in rural areas experience lower survival rates and later-stage diagnoses compared to their urban counterparts [15], driven partly by limited access to oncology services, multidisciplinary care teams, and clinical trials [16]. While tele-oncology theoretically addresses geographic access barriers, populations with the greatest potential to benefit from telehealth often demonstrate the lowest usage rates [17]. This implementation gap reflects complex, multilevel barriers spanning individual patient factors (technological literacy, device access, and digital confidence), health care system characteristics (infrastructure capacity, workflow integration, and provider comfort with telehealth), and contextual elements (broadband availability, reimbursement policies, and organizational support) [1,14,18].

Recent advancements in artificial intelligence and predictive analytics present opportunities for addressing these implementation challenges through more personalized, data-driven approaches to tele-oncology deployment [19]. Emerging evidence from adjacent health care domains demonstrates that AI-enhanced systems can accurately predict the preferences of patients for different telehealth modalities based on demographic and clinical characteristics [20], identify individuals at high risk for implementation barriers before they manifest clinically [21], optimize resource allocation by forecasting demand and prioritizing high-need populations [22], and enable remote symptom monitoring with predictive capabilities for early complication detection [23]. These applications suggest potential translational pathways for enhancing tele-oncology implementation, though direct evidence specifically addressing AI applications in rural tele-oncology contexts remains limited.

The integration of AI-enhanced predictive analytics with implementation science frameworks offers a promising approach for optimizing tele-oncology delivery [19,24]. Implementation science provides systematic methods for translating evidence-based interventions into routine practice, with established frameworks for assessing barriers, designing implementation strategies, and evaluating outcomes [7,25]. Recent theoretical work has articulated how AI applications could specifically address implementation science challenges related to speed, sustainability, equity, generalizability, contextual assessment, and causal inference [18,19]. However, the successful translation of AI technologies into clinical practice requires careful attention to implementation considerations, including stakeholder engagement, workflow integration, technical infrastructure requirements, validation across diverse populations, and proactive monitoring for unintended consequences [24].

This scoping review systematically examines current applications of AI-enhanced predictive analytics and digital health technologies across oncology care delivery, with particular attention to implementation considerations relevant for rural and underserved populations. Given the nascent and heterogeneous nature of research at this intersection, we used a scoping review methodology to map existing evidence, identify research gaps, and synthesize findings to inform a suggested research agenda [26,27]. Our specific objectives were to: (1) characterize current applications of AI and predictive analytics in telehealth and digital oncology care; (2) examine empirical evidence on implementation factors, barriers, and facilitators;

XSL•FO
RenderX

and (3) identify critical research gaps and future directions for optimizing tele-oncology implementation in rural contexts.

Methods

This scoping review followed established methodological frameworks [26] and adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines (Checklist 1) [28] and PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Literature Search Extension) guidelines (Checklist 2) [29] reporting guidelines. Complete adherence documentation is provided in (PRISMA-ScR checklist) and Multimedia Appendix 1 (full search strategy). No published protocol was developed, consistent with exploratory scoping review methodology. The review was not prospectively registered.

Studies were included if they addressed: (1) tele-oncology implementation across any setting, (2) rural health care barriers or implementation strategies relevant to underserved populations, and (3) AI or machine learning applications in health care delivery with transferable insights for oncology. Consistent with Joanna Briggs Institute methodological standards for scoping reviews, which are designed to synthesize primary empirical evidence, systematic reviews, and scoping reviews were excluded from the eligible study designs [26,27]. Where relevant secondary reviews were identified during screening, specifically Aziz et al [30] and Anderson et al [31], these were retained and referenced in the “Discussion” section to contextualize primary study findings within the broader evidence landscape, consistent with accepted practice in scoping review reporting.

Publications were restricted to English-language, peer-reviewed literature from January 2015 through November 2025, capturing recent AI developments and postpandemic tele-oncology expansion. Complete inclusion or exclusion criteria, along with operational definitions, examples, and rationale, are detailed in Multimedia Appendix 2.

We searched 5 databases selected for disciplinary breadth: PubMed or MEDLINE (biomedical literature), Embase (pharmaceutical and European coverage), CINAHL (nursing and allied health), Web of Science (multidisciplinary sciences and implementation research), and IEEE Xplore (computer science and AI technical literature). The search strategy, developed in consultation with a health sciences librarian, integrated 4 concept domains using controlled vocabulary (MeSH, Emtree, and CINAHL headings) and free-text keywords: (1) tele-oncology or telehealth in cancer care, (2) rural health care and implementation barriers, (3) AI and predictive analytics, and (4) implementation science. These domains were combined using Boolean logic to optimize sensitivity while maintaining specificity.

An initial search was completed on April 9, 2025. Following reviewer feedback indicating limited evidence, the search strategy was comprehensively revised and rerun from inception (January 2015) through November 2025, using broader search terms across all 5 databases (Multimedia Appendix 1). Supplemental strategies included backward citation chasing of included articles and forward citation tracking of seminal papers.

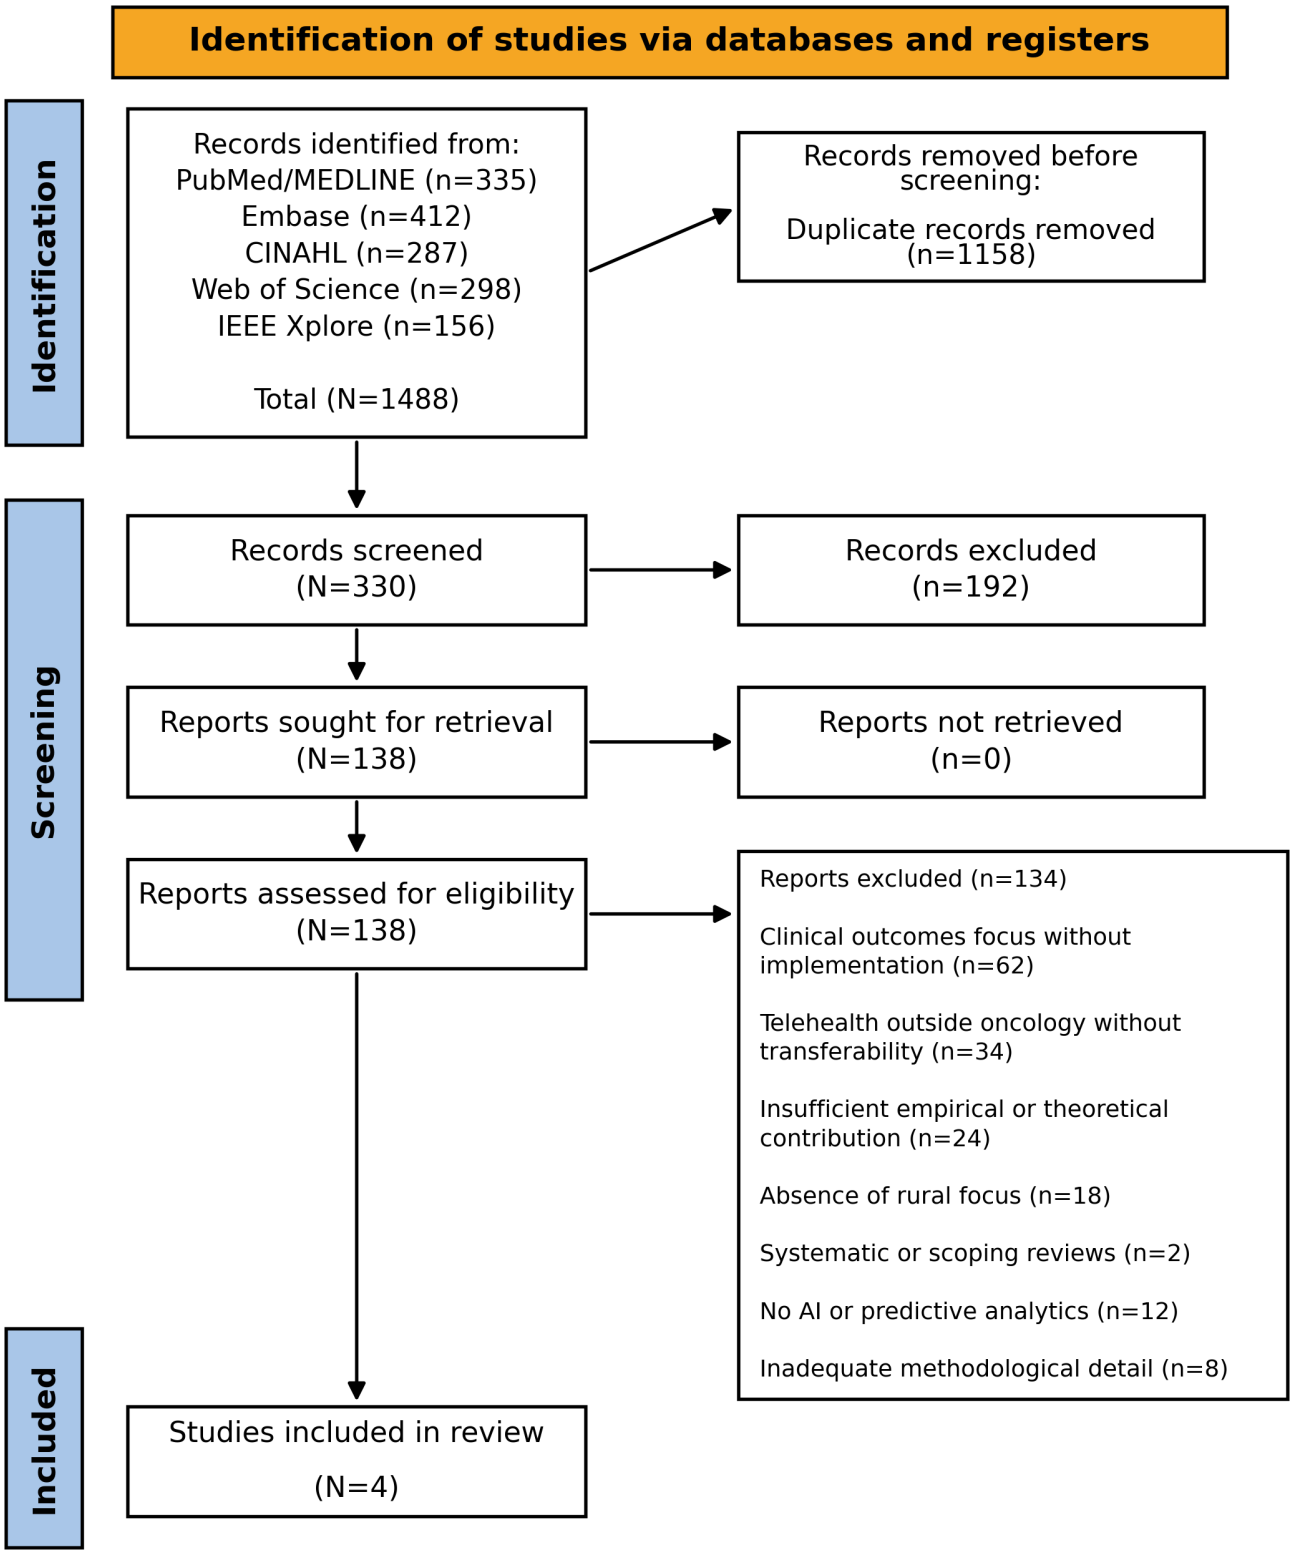
Following duplicate removal via Covidence systematic review software (Veritas Health Innovation), 330 unique records underwent title or abstract screening by 2 independent reviewers (RZ and MS). The principal investigator (PI) (LH) served as the arbiter for conflicts. Calibration exercises on pilot samples demonstrated substantial interrater agreement (Cohen κ=0.78 for title or abstract screening, κ=0.82 for full-text review). Of the 330 records screened, 138 proceeded to full-text review. The same 2 independent reviewers conducted the full-text assessment and data extraction, with the PI resolving any disagreements. Full-text assessment excluded 130 studies primarily for the following reasons: clinical outcomes focus without implementation considerations (n=62, 47.7%), telehealth outside oncology without transferability (n=34, 26.2%), insufficient empirical or theoretical contribution (n=24, 18.5%), absence of rural/barrier focus (n=18, 13.8%), no AI or predictive analytics application (n=12, 9.2%), or inadequate methodological detail (n=8, 6.2%). Four studies met all inclusion criteria. Detailed screening procedures, interrater agreement calculations, and reasons for key exclusions are documented in Multimedia Appendix 2.

Data extraction used a standardized form to capture: study characteristics (design, setting, and population), tele-oncology implementation details (modality, clinical application), AI or predictive analytics applications (techniques, prediction targets, and performance metrics), implementation factors (barriers, facilitators, and strategies), and outcomes (implementation, clinical, and process measures). The extraction form, which was developed iteratively through pilot testing and team discussions, is provided in Multimedia Appendix 3.

Synthesis used narrative thematic analysis, which was appropriate for heterogeneous evidence that precluded meta-analysis. Following a modified framework synthesis, we organized findings into 3 prespecified themes aligned with the review objectives: (1) the current tele-oncology implementation landscape in rural and underserved settings, (2) potential AI-powered predictive analytics applications addressing implementation challenges, and (3) implementation considerations for AI systems themselves. Two independent reviewers (RZ and MS) coded the extracted data, with the principal investigator resolving disagreements and developing subthemes inductively through iterative discussion and consensus. Formal quality appraisal was not conducted, consistent with scoping review methodology [27]. As articulated in foundational frameworks, scoping reviews prioritize evidence mapping and gap identification over intervention effectiveness synthesis, which is the purview of systematic reviews requiring quality assessment.

Results

The systematic search yielded 330 unique records; 138 underwent full-text review, resulting in 4 included studies (Figure 1). This limited evidence base reflects the nascent intersection of AI-powered predictive analytics, tele-oncology implementation, and rural health equity—domains that have



XSL•FO
RenderX

evolved largely in parallel rather than through integrated inquiry. The included studies comprised 2 pilot feasibility studies [32,33], 1 cross-sectional predictive study [34], and 1 platform development study [35], published between 2019 and 2025. Geographic concentration in high-resource settings (United States n=2, Greece n=1, and Singapore n=1) and limited oncology-specific focus underscore structural gaps in evidence generation for underserved populations.

Table 1 presents study characteristics, including methodological approaches, populations, AI applications, and key limitations. Table 2 synthesizes implementation barriers across multilevel ecological domains. Table 3 maps AI-powered predictive analytics applications to specific tele-oncology implementation challenges, articulating translational pathways from current evidence to future research priorities. Figure 2 presents an evidence gap map illustrating the distribution of current evidence across AI application domains, implementation science dimensions, and equity and validation considerations.

Table . Characteristics of included studies (N=4).

Study	Design	Setting or population	AI[a] or analytics application	Key implementation findings	Limitations
Daly et al [32], 2020	Single-arm pilot feasibility study	Academic cancer center regional site; n=100 high-risk patients initiating antineoplastic therapy	ML[b] risk stratification model identifying high-risk patients for preventable acute care; daily PRO[c] symptom surveillance with alert generation	29% enrollment rate; 56% daily response rate sustained 6 months; 93% generated severe alerts; 4 patient archetypes identified; 22% vs 39% acute care use (enrolled vs nonenrolled); provider volume threshold effects	No control group; single-site; resource-intensive (3 FTE[d] for 100 patients); cost-effectiveness unknown
Mammas et al [33], 2022	Proof-of-concept validation study	Peripheral Greece (rural); n=40 patients with breast cancer (32 malignant, 8 benign)	AI-assisted remote multidisciplinary tumor boards integrating teleradiology, telepathology, telecytology with algorithmic interpretation	Mean accuracy: 94.1% surgical planning (95% CI: 85% - 99%), 96.8% chemotherapy, 96.7% hormonal therapy; addresses rural subspecialty access barrier	Small sample; breast cancer only; single health care system; generalizability unclear
Khairat et al [34], 2019	Cross-sectional predictive analytics	Academic medical center; n=1403 virtual urgent care encounters; 44% rural	Multinomial logistic regression predicting patient preferences for mHealth vs telemedicine based on demographics and chief concern	Sex (P=.004) and geographic setting (P<.001) significantly predicted modality choice; 86.2% prediction accuracy; rural patients 50% less likely to choose video; high satisfaction both modalities (91.1%, 89%)	Single-site; limited demographic diversity; selection bias (self-selected virtual care users)
Liu et al [35], 2025	Platform development and pilot study	This block should read single-site US (Emory University); n=40 (20 colorectal cancer patients + 20 caregivers); 55% disadvantaged (income ≤250% Federal Poverty Level, Medicaid, or uninsured)	Generative AI (ChatGPT, Pictory) creating accessible health literacy content at 6th-grade reading level with multimedia	8-week pilot: disadvantaged participants logged in 2.52 × more than nondisadvantaged; 3.98/5 satisfaction; addresses health literacy barrier disproportionately affecting rural or underserved	Short duration; small sample; single cancer type; generative AI accuracy or reliability concerns

Table . Multilevel implementation barriers identified across the included studies (N=4).

Level	Barrier category	Specific barriers (studies reporting)
Patient	Technological access	Device ownership gaps [33,34]; broadband connectivity limitations, especially in rural areas [33,34]; inadequate infrastructure supporting telehealth access [33]
Patient	Digital literacy	Technological skill deficits [32,34,35]; low digital confidence or self-efficacy [33-35]; platform navigation difficulties [32,34]
Patient	Health literacy	Inability to interpret health information without support [35]; limited understanding of symptom significance [32,35]; educational barriers limiting self-management [35]
Patient	Psychosocial	Cancer-related distress limiting engagement [32]; preference for in-person care [33]; privacy/security concerns about data sharing [34]
Provider	Workflow integration	EMR[b] integration complexities [32,33]; disrupted clinical workflows [32,34]; time requirements for reviewing AI-generated outputs [32,34]
Provider	Algorithmic trust	Algorithmic opacity hindering understanding [34]; uncertainty about appropriate reliance on predictive recommendations [32,34]
Provider	Clinical concerns	Medicolegal uncertainty regarding AI-supported care decisions [32]; inability to perform physical examination remotely [33]; care fragmentation concerns [32]
Provider	Training or support	Insufficient AI literacy among clinicians [32]; inadequate technical support infrastructure [32,34]; limited training on platform use [34]
Organizational	Technical infrastructure	EMR interoperability challenges [32-34]; data standardization deficits [34]; cybersecurity requirements [33]
Organizational	Human resources	Dedicated monitoring team requirements [32]; technical support staffing needs [32,34]; competing clinical priorities limiting engagement [32]
Organizational	Financial	High startup costs [32,34]; uncertain return on investment [32,34]; reimbursement ambiguities [34]; ongoing maintenance costs [32](
Organizational	Organizational culture	Resistance to change in clinical practice [32]; inadequate leadership support for tele-oncology implementation [32,34]; misaligned organizational incentives [34]
System	Infrastructure	Rural broadband inadequacies [33,34]; digital divide persistence in underserved regions [33,35]; geographic infrastructure limitations [33]
System	Regulatory or policy	Licensure barriers across state/national borders [32,34]; reimbursement policy limitations constraining sustainability [34]; data privacy or HIPAA[c] compliance requirements [32]
System	Validation or standards	Lack of standardized validation frameworks for AI[a] systems [32-34]; algorithmic bias in training data [34,35]

Table . Translational pathways: mapping AI-powered predictive analytics to tele-oncology implementation challenges.

Implementation challenge	AI[a] or predictive analytics application	Current evidence base	Research priorities
Low telehealth used among rural or underserved populations despite geographic barriers	Predictive models identifying patient subgroups likely to engage with specific telehealth modalities; personalized platform matching based on demographic and clinical characteristics; algorithmically informed outreach strategies	Khairat et al [34]: 86.2% accuracy predicting mHealth versus telemedicine preference based on sex, geographic setting, and chief concern; urban residents showed 101% increased odds of video selection vs rural (P<.001)	Validate modality prediction models in rural tele-oncology settings; develop actionable implementation protocols translating predictions into targeted outreach; examine sustainability of personalized matching approaches
Preventable acute care use during cancer treatment due to undetected symptom escalation	Risk stratification models identifying high-risk patients; real-time symptom surveillance with predictive escalation alerts; machine learning identifying patients at risk for acute care events	Daly et al [32]: ML[b] risk stratification model targeting high-risk quartile; 93% of enrolled patients generated severe symptom alerts; preliminary data suggested 22% acute care usage vs 39% in nonenrolled high-risk controls	Conduct RCTs[c] comparing AI-enhanced vs standard symptom monitoring; optimize alert threshold sensitivity or specificity; determine cost-effectiveness in rural cancer centers; validate across cancer types; examine long-term sustainability
Lack of subspecialty oncology expertise in rural facilities for multidisciplinary treatment planning	AI-assisted virtual tumor boards integrating imaging or pathology interpretation with algorithmic decision support; remote access to tumor board expertise via AI-augmented consultations	Mammas et al [33]: AI-assisted remote tumor boards achieved 94.1% accuracy for surgical planning (95% CI: 85% - 99%), 96.8% for chemotherapy recommendations, and 96.7% for hormonal therapy decisions in breast cancer cases (n=40)	Expand validation to multiple cancer types beyond breast cancer; validate across diverse health care systems and geographic regions; examine implementation feasibility in US rural cancer centers with limited technical infrastructure
Health literacy barriers limiting self-management capacity, disproportionately affecting rural/underserved populations	Generative AI creating personalized, accessible educational content tailored to individual literacy level, language preferences, and learning modality; AI-generated multimedia for symptom management and treatment adherence	Liu et al [35]: Generative AI platform creating 6th-grade reading level content with multimedia enhancement; disadvantaged participants (income <$50,000 or education ≤ high school) demonstrated 2.52-fold higher engagement compared to nondisadvantaged counterparts	Validate generative AI accuracy and reliability in oncology contexts; test across cancer types and treatment modalities; examine long-term outcomes on self-management and treatment adherence; assess equity in content generation
Inadequate resources for proactive identification and outreach to patients experiencing implementation barriers	Predictive models identifying patients at elevated risk for technology access barriers, digital literacy deficits, and other implementation obstacles using SDOH[d] data; automated risk flagging enabling targeted interventions	Theoretical frameworks emphasized [32,34] but no empirical validation in tele-oncology contexts	Develop and validate barrier prediction models integrating SDOH data; design targeted intervention protocols addressing identified barriers; test implementation in rural cancer centers; examine cost-effectiveness
Workflow integration challenges and provider resistance limiting adoption of tele-oncology platforms	AI-assisted clinical decision support reducing cognitive burden; automated clinical documentation generating summaries from encounters; intelligent prioritization of high-risk patients; systems learning from provider feedback to improve usability	Frameworks emphasize sociotechnical integration [32,34] with emphasis on perceived usefulness and ease of use, but limited empirical testing of specific AI features addressing workflow pain points	Develop AI tools targeting specific workflow pain points identified through provider ethnography; conduct rigorous usability testing; measure time savings and clinician satisfaction; examine adoption and fidelity in rural settings
Algorithmic bias in AI systems potentially exacerbating existing health disparities in rural cancer care	Fairness-aware machine learning approaches; bias detection algorithms monitoring performance across demographic groups; continuous equity monitoring of disparate impact; diverse training data representation; transparent performance reporting disaggregated by population	Theoretical emphasis on equity monitoring [32,34] but minimal empirical application in tele-oncology	Develop equity-focused validation frameworks requiring intersectional analyses; mandate diverse, representative training datasets; implement real-time disparities monitoring; publish disaggregated performance metrics by race, ethnicity, SES[f], geographic location; establish accountability mechanisms

Figure 2. Evidence gap map [32-35]. ML: machine learning; NLP: natural language processing.

Khairat et al [34] demonstrated that patient characteristics predict telehealth modality preferences with sufficient accuracy (86.2%) to inform personalized implementation strategies. Analyzing 1403 virtual care encounters, multinomial logistic regression revealed sex (P=.004) and geographic setting (P<.001) as primary determinants: male patients exhibited 66% increased odds of video telemedicine selection versus female patients, while urban residents showed 101% increased odds compared to their rural counterparts. Chief medical concern independently predicted modality choice (P<.001), with privacy-sensitive conditions (eg, urinary tract infections and gynecological complaints) associating with telephone preference and visual assessments (eg, dermatological concerns and conjunctivitis) predicting video selection. High satisfaction persisted across modalities (91.1% mobile health and 89% telemedicine), suggesting that offering choice and algorithmically matching patients to appropriate platforms enhances acceptability without compromising outcomes.

These findings illuminate how predictive analytics can address the implementation paradox, wherein individuals experiencing the greatest geographic barriers demonstrate the lowest telehealth usage. By identifying patient subgroups likely to engage with specific modalities, health care systems can proactively tailor outreach, technology support, and platform recommendations—moving beyond one-size-fits-all implementation toward precision approaches responsive to intersecting social determinants.

Three studies examined AI applications in oncology remote monitoring, revealing feasibility alongside persistent implementation challenges. Daly et al [32] integrated machine learning risk stratification with digital symptom surveillance for 100 high-risk patients initiating antineoplastic therapy. The predictive model prospectively identified patients at elevated risk for preventable acute care usage, enabling targeted enrollment. Daily patient-reported outcome assessments achieved a 56% sustained response rate over 6 months, with 93% of enrolled patients generating severe symptom alerts requiring clinical intervention. Qualitative analysis identified 4 patient engagement archetypes—Promise Keeper, Data Tracker, Unengaged, and Overwhelmed—each characterized by distinct motivational drivers and implementation needs, underscoring heterogeneity in technology acceptance even among self-selected participants.

Preliminary acute care data suggested a potential benefit (22% usage among enrolled patients vs 39% among nonenrolled high-risk controls), though the absence of a randomized design precludes causal inference. Critical implementation barriers emerged: providers with low patient volumes perceived information overload and care fragmentation, while those with adequate panel penetration valued the intervention, suggesting threshold effects for workflow integration. Organizational requirements—dedicated nursing team (2 registered nurses and 1 nurse practitioner for 100 patients), custom electronic medical record (EMR) integration, and 12-hour daily coverage—raise scalability concerns for rural facilities with constrained resources.

Mammas et al [33] demonstrated the technical feasibility of AI-assisted remote multidisciplinary tumor boards for breast cancer in peripheral Greece, achieving mean accuracy of 94.1% for surgical planning, 96.8% for chemotherapy, and 96.7% for hormonal therapy (95% CI 85%–99% for all 3 estimates), across 40 cases. This model addresses a fundamental rural implementation barrier—the absence of local subspecialty expertise—by leveraging AI to augment telehealth consultations. However, generalizability beyond breast cancer and validation in diverse health care contexts remain unexplored.

Liu et al [35] used generative AI to create accessible health literacy content for colorectal cancer self-management, targeting disadvantaged populations at a single US academic medical center. The platform automatically generated 6th-grade reading level materials with multimedia enhancement. Disadvantaged participants (defined as income ≤250% of the Federal Poverty Level, Medicaid enrollment, or uninsured status) demonstrated 2.52-fold higher platform engagement than nondisadvantaged counterparts, suggesting particular value for populations

XSL•FO
RenderX

experiencing compounding socioeconomic marginalization. This application illustrates how AI can address specific implementation barriers, such as inadequate health literacy, that disproportionately constrain rural and underserved community engagement with tele-oncology.

Cross-study synthesis reveals fundamental evidence gaps. No included studies directly examined AI-powered predictive analytics for identifying or mitigating tele-oncology implementation barriers in rural settings—the core focus of this review. Validation of predictive models across diverse populations, health care systems, and geographic contexts remains limited, with most studies conducted in single academic medical centers serving nonrepresentative populations. Translation of AI predictions into actionable implementation strategies has received minimal empirical examination. Cost-effectiveness analyses comparing AI-enhanced approaches versus standard approaches were notably absent. Longitudinal research examining sustainability, adaptation, and the impact on disparities beyond pilot phases would strengthen the evidence for scaling.

Table 2 synthesizes implementation barriers across patient, provider, organizational, and system levels. Patient-level barriers encompassed technological literacy deficits, device access limitations, broadband connectivity constraints, and digital confidence gaps—challenges disproportionately affecting older adults, individuals from lower socioeconomic populations, and people living in rural communities. Provider barriers included workflow integration complexities, algorithmic opacity concerns, time requirements for reviewing AI-generated outputs, and medicolegal uncertainty regarding appropriate reliance on algorithmic recommendations. Organizational barriers spanned technical infrastructure (EMR integration and data interoperability), staffing resources (dedicated monitoring teams and technical support), and financial sustainability (startup costs, ongoing maintenance, and reimbursement uncertainties). System-level barriers encompassed broadband infrastructure inadequacies in rural areas, regulatory ambiguities, data privacy requirements, and the absence of standardized validation frameworks.

Figure 3 illustrates the relative prominence of each barrier category within each included study, highlighting areas where challenges to implementation challenges were most extensively documented.

Figure 3. Barrier heat map [32-35]. AI: artificial intelligence.

RenderX

stakeholder buy-in, and sustained organizational commitment beyond pilot funding. The evidence suggests that AI implementation success depends less on technological sophistication per se than on systematic attention to sociotechnical integration—aligning AI capabilities with clinical workflows, organizational contexts, and patient needs through iterative, stakeholder-engaged development and deployment processes.

Discussion

Principal Findings

This scoping review sought to (1) characterize current applications of AI and predictive analytics in telehealth and digital oncology care; (2) examine empirical evidence on implementation factors, barriers, and facilitators; and (3) identify research gaps and future directions for optimizing tele-oncology implementation in rural contexts. Across all 3 objectives, the overarching finding is one of substantial evidence scarcity. Of 330 unique records screened, only 4 primary studies [32-35] met inclusion criteria, none of which directly tested the integration of AI-enhanced predictive analytics within a rural tele-oncology implementation context. The included studies offered selective proof-of-concept across discrete AI applications (modality preference prediction, remote symptom monitoring, AI-assisted multidisciplinary tumor boards, and generative health literacy tools): yet each was conducted in a well-resourced or academic setting, with limited applicability to the rural contexts that are the focus of this review. Multilevel implementation barriers were consistently documented across all 4 studies, and no study examined algorithmic bias, cross-population validation, or equity-related harms. These findings suggest that the field remains at an early, exploratory stage, and that current evidence is insufficient to support practice recommendations or policy guidance for rural tele-oncology implementation.

Technical Feasibility and the Gap to Implementation Readiness

The included studies collectively suggest that AI-based tools may, under specific conditions, address discrete implementation challenges in oncology care delivery. Khairat et al [34] found that patient demographic and clinical characteristics were sufficiently predictive of telehealth modality preference to potentially inform personalized outreach strategies, a finding with plausible relevance for rural populations, who exhibit lower rates of video-based telehealth adoption in the broader literature [14,17]. Daly et al [32] demonstrated the operational feasibility of machine learning risk stratification integrated with digital symptom surveillance, with preliminary signals suggesting reduced acute care use among enrolled patients, though the absence of a control group precludes causal inference. Mammas et al [33] reported the technical accuracy of AI-assisted remote tumor boards for breast cancer management in rural Greece, offering a possible model for extending subspecialty access to geographically isolated facilities [15,16]. Liu et al [35] showed that generative AI can produce health literacy materials that may engage socioeconomically disadvantaged populations more effectively than standard content, though this finding was observed in a single cancer type in Singapore, and its generalizability to rural Western contexts warrants caution.

However, this provisional feasibility evidence coexists with documented implementation fragility. Daly et al [32] observed organizational threshold effects, whereby the remote monitoring intervention functioned adequately when provider panel penetration was sufficient, but generated information overload and care fragmentation concerns under lower-volume conditions—conditions more representative of rural cancer facilities [14]. The intervention's staffing requirements raise additional scalability questions for resource-constrained settings [32]. These tensions are echoed in the broader contextual literature. Aziz et al [30], synthesizing 11 studies of AI-driven remote patient monitoring in oncology, concluded that available evidence remains insufficient to establish superiority over traditional care delivery, identifying consistent barriers including technical infrastructure requirements, gaps in literacy among patients and providers, and workflow integration complexities. The fact that this conclusion emerged from studies largely conducted in well-resourced academic environments further underscores the depth of the evidence gap for rural contexts. Anderson et al [31] noted that only 26% of the telehealth predictive analytics studies they reviewed focused on predictive systems, with a notable absence of resource optimization models applicable to rural or underresourced implementation contexts. This suggests that the orientation of existing research may be poorly matched to the implementation challenges that rural settings face [18,19,31].

Persistence of Multilevel Implementation Barriers

A consistent pattern across the primary studies and contextual review literature is that implementation barriers operate simultaneously across patient, provider, organizational, and system levels, and that technological sophistication does not, in itself, resolve barriers operating at other levels [7,14,18]. At the patient level, device access limitations, broadband connectivity gaps, digital literacy deficits, and health literacy constraints appear to intersect in compounding ways, with particular salience for older adults, individuals with lower incomes, and people living in geographically isolated areas [13,14,17]. Khairat et al [34] found that people living in rural areas were significantly less likely to select video-based telehealth even when it was available, suggesting that geographic context independently shapes technology engagement beyond questions of mere access. At the provider level, algorithmic opacity (clinicians' difficulty in interpreting and appropriately acting on AI-generated outputs) emerges as a recurrent concern across studies [32,34], and is identified by Aziz et al [30] as a barrier to adoption of AI-enhanced monitoring across multiple health care systems. Reddy [24] similarly argues that translating AI tools into clinical practice requires governance structures and workflow integration processes that most current deployment efforts have not adequately addressed.

Organizational and system-level barriers may be especially consequential for rural settings. The dedicated staffing, EMR integration, and sustained technical support required by the Daly et al [32] intervention represent structural prerequisites that are unlikely to be available in many rural facilities [14,15].

XSL•FO
RenderX

Anderson et al [31] noted the absence of resource optimization models in the telehealth analytics literature, suggesting that the field has yet to systematically engage with how AI tools might be deployed sustainably under resource constraints. At the system level, rural broadband inadequacies, cross-border licensure ambiguities, and reimbursement policy limitations add further layers of complexity compounding facility-level constraints and potentially limiting the transferability of findings from academic settings [13,14,19].

Equity Considerations and Gaps in the Evidence Base

A notable gap across all 4 primary studies is the absence of equity-centered analysis. None of the included studies explicitly examined algorithmic bias, conducted cross-population validation of AI system performance across racial, socioeconomic, or geographic subgroups, or assessed potential harms associated with AI deployment in underserved populations. This gap is particularly concerning given documented evidence that AI systems trained predominantly on data from majority or well-resourced populations may perform differentially—and potentially harmfully—when applied to underrepresented communities [5,18,19]. Individuals with cancer living in rural and lower-income areas, who are already subject to compounding health care disadvantages, including later-stage diagnoses and poorer survival outcomes [15,16], may be disproportionately exposed to such risks.

Aziz et al [30] explicitly identified insufficient attention to equity impacts as a limitation of the AI-enhanced remote monitoring literature, observing that reviewed studies rarely examined whether benefits were distributed equitably across patient subgroups or whether the implementation burden fell disproportionately on already-disadvantaged populations. Anderson et al [31] similarly found that the vast majority of telehealth predictive analytics studies were conducted in single academic medical centers serving nonrepresentative populations, with minimal rural implementation focus and no systematic reporting of outcomes disaggregated by socioeconomic or demographic characteristics. Taken together, these observations suggest that populations with the greatest potential need for equitable tele-oncology implementation may be systematically underrepresented in the research base intended to inform it [5,17,18].

The implications of this gap extend beyond research design. Maw et al [18] argue that achieving equitable AI implementation in health care likely requires pragmatic implementation science approaches that explicitly center population diversity, contextual adaptation, and community engagement—an orientation that appears largely absent from the current evidence base. Trinkley et al [19] further caution that AI applications in implementation science carry the risk of perpetuating or amplifying existing disparities if equity considerations are not prospectively embedded in system design, validation protocols, and ongoing monitoring frameworks. Without deliberate attention to whose data informs AI models and whose outcomes are measured, there is a meaningful risk that AI-enhanced tele-oncology tools could widen rather than narrow existing cancer care disparities for rural and underserved populations [5,18,19].

Implications for Future Research

Table 4 summarizes the identified research priorities, mapped to the gap type, supporting evidence, and ratings of urgency, feasibility, and equity relevance.

XSL•FO
RenderX

Table . Research priorities matrix.

Research priority	Gao type	Primary evidence (this review)	Contextual support	Urgency	Near-term feasibility	Equity relevance
Comparative effectiveness studies measuring implementation outcomes (adoption, fidelity, penetration, and sustainability) in authentic rural health care settings, with longitudinal follow-up beyond initial pilot phases	Methodological gap	Daly et al [32], Mammas et al [33]	[7,25,26]	High	Low	High
Cross-population validation of AI[a] systems, with performance disaggregated by rural versus urban status, race or ethnicity, socioeconomic position, and digital literacy level	Equity or validation gap	All 4 studies (absent in each)	Aziz et al [30], Anderson et al [31]	High	Medium	High
Research specifying translation mechanisms linking AI predictions to actionable implementation strategies, examining how predictions are acted upon by clinicians and organizations	Implementation science gap	Khairat et al [34], Daly et al [32]	Trinkley et al [19]; [7,19,24]	High	Medium	Medium
Health economic analyzes comparing AI-enhanced versus standard implementation approaches in rural settings, informing infrastructure investment, workforce, and reimbursement decisions	Economic evidence gap	Daly et al [32], Khairat et al [34]	Absent from current literature	Medium	Medium	Medium
Qualitative and mixed methods research on sociotechnical integration in resource-constrained settings, and development or testing of implementation science–informed governance frameworks	Mechanistic or governance gap	Daly et al [32]	Reddy [24]; [12,24]	Medium	High	Medium

[a]AI: artificial intelligence.

The gaps identified through this review point to several interrelated priorities for future investigation. Perhaps most foundationally, the field would benefit from comparative effectiveness studies conducted in authentic rural health care settings (rather than academic medical centers) that measure implementation science outcomes, including adoption, fidelity,

XSL•FO
RenderX

penetration, and sustainability, alongside clinical end points [7,25,26]. Scoping reviews such as this one can identify where evidence is absent, but only prospectively designed trials and implementation studies can determine whether AI-enhanced approaches offer meaningful advantages over standard care under realistic rural conditions. Longitudinal designs capable of capturing sustainability beyond initial pilot phases are likely necessary, given that existing feasibility studies were of limited duration and scope and cannot speak to whether observed benefits persist once dedicated research support is withdrawn [32,33].

Cross-population validation of AI systems represents a further priority of considerable urgency, with performance reporting disaggregated by rural versus urban status, race and ethnicity, socioeconomic position, and digital literacy level. Both Aziz et al [30] and Anderson et al [31] identify this as largely unaddressed in current literature, and the absence of such validation means that the equity implications of deploying existing AI tools in rural oncology contexts remain genuinely unknown. Relatedly, research that specifies the translation mechanisms linking AI predictions to actionable implementation strategies would address a theoretical gap articulated by Trinkley et al [19] but not yet empirically examined in rural oncology contexts. Understanding not just whether AI can predict an outcome, but how those predictions are acted upon by clinicians and organizations, and under what contextual conditions, is essential for implementation science to move beyond feasibility demonstration [7,19,24].

Health economic analyses comparing AI-enhanced and standard implementation approaches in rural settings are notably absent from the current evidence base [32,34], yet they are likely to be important for policy decisions regarding infrastructure investment, workforce development, and reimbursement, ultimately determining whether AI-enhanced tele-oncology becomes accessible to rural populations at scale. Finally, qualitative and mixed-methods research examining sociotechnical integration in resource-constrained settings would provide mechanistic insight into the organizational and cultural factors enabling or constraining implementation success—insight that quantitative approaches alone cannot offer [12,24]. Reddy [24] argues that implementation science-informed governance frameworks are a prerequisite for responsible AI deployment in health care; developing and testing such frameworks in rural oncology contexts represents a meaningful and tractable research contribution.

Limitations

Several limitations of this review should be considered when interpreting its findings. The small number of included primary studies (n=4), their heterogeneous designs, and their concentration in single academic or high-resource sites preclude comparative synthesis and limit generalizability. Geographic concentration in the United States, Greece, and Singapore means that findings may not reflect implementation contexts in low-income and middle-income countries or in rural settings with more severe infrastructure limitations. The English-language restriction may have introduced systematic bias by excluding relevant non-Anglophone literature. Formal quality appraisal was not conducted, consistent with scoping review methodology [26,27], which means the internal validity of individual study findings remains unassessed. The rapid pace of AI development also means that applications currently under development or reported in gray literature may not yet be captured in the peer-reviewed evidence base, and implementation-focused research characteristically lags behind technology development [19,24]. Finally, while Aziz et al [30] and Anderson et al [31] are used as contextual evidence throughout this discussion, their conclusions are themselves subject to the limitations of the primary studies they synthesized, including heterogeneous quality and limited rural-specific analysis.

Conclusions

This scoping review suggests that the potential of AI-enhanced predictive analytics to improve tele-oncology implementation in rural and underserved settings, while theoretically plausible, remains empirically underdeveloped. The 4 included primary studies offer isolated proof-of-concept evidence but collectively illustrate a pattern in which technological capability may outpace implementation readiness, and in which the structural constraints most characteristic of rural settings receive comparatively limited research attention. The broader contextual literature reinforces this assessment: Aziz et al [30] found that AI-enhanced remote monitoring in oncology has not yet demonstrated clear superiority over standard care, and Anderson et al [31] observed that predictive analytics research in telehealth has largely not addressed the resource optimization and implementation science questions most relevant to populations in underserved areas.

The systematic underrepresentation of rural, low-income, and racially diverse populations in AI and digital health research is not merely an empirical gap—it may reflect and perpetuate structural inequities in knowledge production that have downstream consequences for health equity [5,18]. Deploying AI tools with unexamined performance characteristics in contexts where patients already experience compounding disadvantages carries meaningful risks that the field has not yet adequately engaged with [15,16,19]. Reddy [24] and Trinkley et al [19] both suggest that responsible AI implementation in healthcare requires equity monitoring, community engagement, and governance frameworks that remain underdeveloped in current practice. Until such frameworks are established and empirically validated in rural oncology contexts, the risk that AI-enhanced tele-oncology reproduces rather than reduces existing disparities warrants serious consideration.

Advancing this field equitably will likely require a reorientation of the research agenda toward community-engaged, implementation science-informed study designs conducted in authentic rural contexts, with explicit attention to equity, sustainability, and population diversity [7,18,25,26]. Rural communities should ideally participate as collaborators in the design and governance of AI tools intended to serve them, ensuring that research questions are grounded in authentic implementation challenges [18,19]. Funding priorities, editorial standards, and implementation science frameworks that incentivize disaggregated outcome reporting, long-term

XSL•FO
RenderX

sustainability research, and equity-centered validation may support this reorientation [5,7,26]. Only through such an approach can the theoretical promise of AI-enhanced tele-oncology be meaningfully evaluated and responsibly translated for the populations who may stand to benefit most.

Acknowledgments

The authors declare the use of generative artificial intelligence (AI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to generative AI tools under full human supervision: structuring and formatting data extraction tables, including organizing extracted study characteristics, implementation barriers, and translational pathway content into standardized tabular formats. All AI-assisted outputs were critically reviewed, verified against source materials, and revised by the authors. Generative AI was not used for literature searching, screening, data interpretation, or the drawing of conclusions. The views expressed in this publication are those of the authors and do not reflect the position or policy of the Department of Veterans Affairs, United States government, State of Texas, or other organizations with which authors may be affiliated.

Funding

This scoping review received no specific grant from any public, commercial, or not-for-profit funding agency. Institutional support was provided through startup fund resources affiliated with the authors' institution. The authors received no direct financial compensation for the conduct of this research or preparation of this manuscript.

Data Availability

All data supporting this scoping review are available in the manuscript and supplementary files (PRISMA-ScR checklist, complete search strategies, inclusion/exclusion criteria, and data extraction form). Screening decisions and extracted data are available from the corresponding author upon reasonable request. All included articles are publicly available through their respective publishers as cited in the References. No primary data were collected; all data were extracted from published literature.

Authors' Contributions

LH conceived and designed the scoping review, developed the protocol, led the systematic search strategy across all 7 databases, performed data extraction and synthesis, conducted the thematic analysis, drafted the manuscript, and served as the principal investigator responsible for resolving screening conflicts. MM contributed to the conceptualization of the review framework, provided methodological guidance on implementation science frameworks, and critically revised the manuscript for important intellectual content. BE contributed to the conceptualization and design of the review, provided expert input on implementation science and health equity considerations, and critically revised the manuscript. RZ conducted independent title/abstract and full-text screening, performed data extraction, assisted with the expanded database searches following peer review, and contributed to drafting and revising manuscript sections and supplementary materials. MS conducted independent title/abstract and full-text screening, performed data extraction, contributed to the expanded search and supplementary materials development, and assisted with drafting and revising manuscript sections. GJ provided expert oversight on tele-oncology and rural health content, contributed to the interpretation of findings, and critically revised the manuscript for important intellectual content. All authors reviewed and approved the final manuscript.

Abstract

Background: Adolescents and young adults with cancer have distinct developmental and psychosocial needs that require care models bridging pediatric and adult oncology systems. While survival outcomes have improved, there is growing recognition of the need to strengthen coordinated care, psychosocial support, and survivorship services. In Ontario, regional and community-based cancer programs play a central role in delivering accessible care and are well-positioned to support adolescents and young adults closer to home. However, variation in infrastructure, workforce capacity, and system-level coordination influences how developmentally appropriate oncology care is implemented. Existing literature has focused on tertiary and specialty centers, highlighting the need to leverage and strengthen regional systems, providers, and community resources to support high-quality adolescent and young adult cancer care.

Objective: This study aimed to explore how structural barriers and supports shape the experiences of adolescents and young adults with cancer, their caregivers, and health care providers (HCPs) in accessing and navigating regional cancer care in Ontario.

Methods: An exploratory qualitative study was conducted between July 2024 and March 2025, guided by Bronfenbrenner's Ecological Systems Theory and a social constructionist orientation. Semistructured interviews were conducted with 14 participants (adolescents and young adults, caregivers, and HCPs) in Southwestern Ontario. Participants were recruited through purposive sampling. Data were analyzed using reflexive thematic analysis. Trustworthiness and rigor were strengthened through reflexive team discussions and audit trail documentation.

Results: A total of 2 adolescents and young adults, 6 caregivers, and 6 HCPs were interviewed. Youth were in their early 20s and represented different cancer diagnoses. Most caregivers (n=5) were mothers, and HCPs had 2-20 years of experience. Six key themes were generated: (1) structural gaps in coordinated care, (2) reliance on individual champions, (3) developmental and environmental misalignment, (4) barriers to youth engagement and autonomy, (5) gaps in psychosocial, palliative, and survivorship support, and (6) local system enablers. Participants described fragmented care poorly suited to adolescents' and young adults' needs. Care environments often defaulted to child- or adult-oriented models, limiting autonomy and engagement. Psychosocial, palliative, and survivorship supports were unevenly available, particularly during transitions off treatment. Despite these challenges, local satellite clinics and community organizations reduced travel burden, fostered continuity, and provided long-term emotional and financial support.

Conclusions: Adolescent and young adult cancer care in regional settings is delivered within evolving systems adapting to youth's developmental and psychosocial needs. Our findings suggest that targeted investments in workforce development, coordinated communication structures, and age-appropriate care models can further enhance regional capacity to support adolescents

XSL•FO
RenderX

and young adults across the cancer trajectory. By shifting from reliance on informal solutions toward more structured, team-based approaches, regional programs can build resilient, youth-responsive systems that promote high-quality, equitable adolescent and young adult cancer care.

Introduction

Adolescents and Young Adults With Cancer: Challenges Within Care

Adolescents and young adults with cancer represent a distinct population whose needs have historically been overlooked within pediatric and adult oncology systems [1]. While overall cancer survival has improved, adolescents and young adults continue to experience slower gains and face persistent inequities in access, supportive care, and survivorship services [1]. Cohort and qualitative studies published over the past several years indicate that these inequities persist despite increased recognition of adolescent and young adult–specific needs, with ongoing gaps in psychosocial support, care coordination, and survivorship planning across cancer systems [2-4]. In Ontario, policy efforts have sought to promote developmentally appropriate care, yet regional and community settings often lack the infrastructure and resources to deliver it [5]. Within this context, adolescents and young adults continue to encounter challenges that extend beyond medical treatment.

Cancer diagnosis during adolescence and young adulthood presents unique challenges extending beyond medical treatment to encompass educational, social, and developmental disruptions [6,7]. Globally, adolescents and young adults with cancer experience structural misalignment between health care systems designed for children or adults and the developmental needs of youth in transition [6,8]. Unlike younger children who rely on parental advocacy or adults who navigate systems independently, adolescents and young adults are in a distinct developmental stage characterized by emerging autonomy, identity formation, and increasing self-determination [9]. However, health care structures are often inadequately designed to recognize this developmental stage, creating what literature has described as a dual disadvantage where youth experience gaps in both pediatric and adult care systems [10]. Despite growing evidence documenting high psychosocial distress, disrupted life trajectories, and unmet developmental needs among adolescents and young adults with cancer, much of this literature remains concentrated in tertiary or specialty care contexts, offering limited insight into how these challenges are navigated within regional and community-based systems [11-14].

Systemic Barriers Beyond Clinical Care

The structural inadequacy extends beyond clinical care into broader systems surrounding adolescent and young adult cancer treatment. Educational institutions face challenges accommodating youth with fluctuating health needs, employers demonstrate limited understanding of cancer's long-term impacts, and social support systems frequently default to child-focused or adult-oriented models that inadequately address adolescent developmental needs [3]. The convergence of these structural barriers creates cumulative disadvantages that may persist beyond treatment completion, impacting educational achievement, career development, and psychosocial outcomes [15-17]. Within the Canadian health care context, accessible care delivery is a core mandate for Ontario's community hospitals [18,19]; yet, achieving equitable access to cancer services between community and tertiary oncology centers remains an ongoing challenge, particularly for adolescents and young adults [12].

An Ecological Systems Lens

Bronfenbrenner's Ecological Systems Theory provides a framework for examining how systemic barriers operate across multiple levels to constrain adolescent and young adult cancer care delivery [9]. At the exosystem level, institutional policies, funding structures, and professional training deficits establish structural conditions that either facilitate or constrain quality care delivery. Research applying this framework has documented how institutional constraints, including unclear mandates, underresourced settings, and workforce limitations, compromise the system's capacity to address youth-specific needs [2,20]. Despite efforts to decentralize tertiary care pediatric oncology services through initiatives such as the Pediatric Oncology Group of Ontario (POGO) and its satellite clinics, substantial community-based inequities in adolescent and young adult care persist. While some satellite sites provide essential follow-up and supportive care for younger patients, adolescents and young adults older than 18 years or those requiring specialized interventions must access tertiary centers for diagnosis, treatment initiation, and subspecialist consultation [16,21]. For youth navigating developmental transition characterized by increasing autonomy, identity formation, and life planning, these structural care disruptions may be particularly destabilizing [22]. This theoretical lens guided our examination of system-level conditions, policies, organizational processes, and service structures, rather than focusing solely on individual experience.

Theoretical Underpinning

A social constructionist epistemological orientation and relativist ontological stance shaped the study, recognizing that participants' accounts reflect socially situated interpretations of their interactions with health systems. By incorporating perspectives from youth, caregivers, and health care providers (HCPs), the design enabled an integrative view of the

XSL•FO
RenderX

organizational and structural dynamics influencing adolescent and young adult cancer care.

Resource Constraints in Community Hospitals

In community health care settings, these systemic challenges are amplified by infrastructure limitations and resource constraints. Community hospitals are mandated to deliver outpatient and supportive care; however, many lack the necessary infrastructure, staffing, and specialized services to provide comprehensive, developmentally appropriate adolescent and young adult oncology care [16,23,24]. Consequently, youth and their families in smaller communities require travel, often repeatedly, to tertiary centers for diagnosis, treatment, and acute care management [21,25]. These care disruptions create substantial logistical, financial, and emotional burdens, particularly for families with limited socioeconomic resources, single-parent households, newcomers to Canada, and those with reduced informal support networks [3].

Community hospitals typically operate with limited oncology-specific resources, creating challenges for clinical teams who must adapt adult or pediatric protocols for adolescent and young adult patients without specialized training or institutional support [8]. Care providers often lack training in adolescent and young adult oncology, with limited guidance on managing complex psychosocial issues or coordinating with tertiary care teams [2,20]. Systemic limitations often necessitate reliance on informal champions, typically nurses or allied health professionals, who also function as care coordinators in the absence of more structured support. While their contributions are essential, this reliance on individual practitioners highlights deeper systemic vulnerabilities, including insufficient interdisciplinary teams, the absence of contingency planning, and inadequate infrastructure to support workforce sustainability. High provider turnover, burnout, and service discontinuity represent recurring challenges, particularly in settings where care delivery depends on limited personnel [8,12]. Community hospitals serving adolescents and young adults frequently lack resources, training, and capacity to deliver developmentally appropriate care [7,26]. Youth perspectives are often marginalized in these settings, where reliance on parental involvement in care inadequately addresses developmental needs for autonomy and self-advocacy within an adolescent and young adult population [17].

Knowledge Gaps in Community-Based Adolescent and Young Adult Oncology

Much of the existing research has examined travel burdens and navigation barriers in tertiary and adult oncology settings, leaving the experiences of adolescents and young adults and their families in community settings comparatively underexplored [26,27]. Care providers in these contexts face considerable challenges in addressing service gaps and supporting youth through complex medical and psychosocial transitions [8,20]. Understanding how systemic barriers operate across multiple ecological levels in community contexts is essential for developing interventions that address the underlying causes of care fragmentation.

Study Objectives

To explore how structural barriers and supports shape the experiences of adolescents and young adults with cancer, their families, and HCPs in accessing and navigating regional cancer care.

Methods

Study Design

We used an exploratory qualitative design informed by Bronfenbrenner's Ecological Systems Theory [9]. This design was chosen to help investigate and understand adolescents and young adults', caregivers', and HCPs' experiences with oncology care within the complex health care systems. The study is reported in accordance with the Consolidated Criteria for Reporting Qualitative Research.

Sampling and Recruitment

Recruitment took place between July 2024 and March 2025. Purposive sampling was used to recruit participants who represented diverse social contexts, including variation in gender identity, family composition, and neighborhood socioeconomic background. Eligibility criteria for youth included (1) diagnosis of cancer between January 2018 and December 2024, (2) age 15-18 years at time of diagnosis, (3) residence in Southwestern Ontario and receipt of care through the pediatric oncology satellite clinic, (4) completion of treatment and at least 3 months in remission prior to interview, (5) adequate communicative and cognitive ability to participate, and (6) fluency in English. Youth currently on active treatment, recently diagnosed (<3 months), or identified by clinicians as being at risk of psychological harm from participation were excluded. Parents or caregivers of eligible youth were invited to participate, with English fluency as the only inclusion criterion. HCPs were recruited using the same approach, with study information distributed through community hospital networks and professional contacts, and interested individuals contacting the research team directly. Eligible HCPs included physicians, nurses, social workers, and child life specialists with direct clinical responsibilities in adolescent and young adult cancer care within regional hospitals or POGO satellite clinics. Eligibility was confirmed during initial contact through brief screening questions aligned with the study's inclusion criteria prior to scheduling interviews. Data analysis was conducted with all participants as a whole rather than as 3 separate groups (adolescents and young adults, caregivers, and HCPs), as each group had fewer than the required 8 participants. Data saturation was met when no new data yielded new insights.

Data Collection

Recruitment materials (information sheet and poster) were distributed through the POGO satellite clinic in Southwestern Ontario and via closed social media networks, including ChildCan and POGO. Interested individuals responded by contacting the research team directly using the contact information provided on the study materials. This recruitment approach supported purposive sampling by enabling the identification of participants with direct experience of adolescent and young adult cancer care within community hospital settings,

XSL•FO
RenderX

including youth, caregivers, and HCPs involved in care delivery. Semistructured interviews were conducted individually by JT or MM based on participants' expressed availability. Two youth who were interviewed were young adults and preferred to be interviewed independently without their caregiver. Microsoft Teams meeting invites were emailed to participants for access to the meeting; contact information was provided if any technical difficulties arose. Verbal consent for study participation and audio recording was obtained during the meeting prior to proceeding with the interview. Consent was treated as an ongoing process, and participants were reminded that they could decline to answer questions or withdraw from the interview at any time without consequence. Interviews were audio recorded on Microsoft Teams and lasted 45-90 minutes, after which they were transcribed and verified for accuracy prior to analysis. Additional procedural details are available in the published protocol [28].

Youth interviews focused on their daily lives and routine, along with their transition throughout treatment. Caregiver interviews revolved around the emotional impact of navigating the health care system and experiences with caregiving. HCP interviews focused on care delivery, navigating systemic barriers, and recommendations for care. See Multimedia Appendices 1 and 2 for interview guides.

Data Analysis

Analysis followed Braun and Clarke's [29] 6-phase reflexive thematic analysis, which supported the identification of recurring patterns while attending to the contextual meanings expressed by participants. Transcripts were deidentified and managed in NVivo (version 15; Lumivero) to help organize and manage codes and find patterns for theme development. The Bronfenbrenner's Ecological System framework was used to help with data analysis and theme development to structure themes around adolescent and young adult oncology care within the complex and multifaceted layers of the health care system [9].

In Phase 1, team members individually reviewed transcripts (JT, MM, and BG) to identify features related to systemic processes, access pathways, and coordination challenges. In Phase 2, data were coded with attention to organizational and structural dynamics, rather than individual coping or emotional responses. Initial codes were inductively developed through iterative engagement with the data, involving the application and refinement of descriptive labels to meaningful text segments and constant comparison across transcripts. For example, segments describing repeated travel to tertiary centers due to unavailable local services were initially coded as "care fragmentation" and later integrated into a broader theme reflecting systemic discontinuity in regional adolescent and young adult cancer care. In Phases 3-5 (theme generation, review, and refinement), codes were iteratively developed into potential themes and reviewed across youth, caregiver, and HCP accounts to ensure coherence and depth at the system level. As part of this process, data from youth, caregivers, and HCPs were examined both within and across participant groups to identify areas of convergence, complementarity, and divergence in experiences of regional adolescent and young adult cancer care. The final phase synthesized themes into a thematic structure that reflects how system organization, developmental alignment, and community-level conditions influence adolescent and young adult cancer care experiences. Both inductive and deductive reasoning informed analysis, drawing on existing adolescent and young adult oncology models to refine interpretation.

Early coding differentiated between individual experiences and system-level processes. Through team discussion, codes related to travel burden, delayed communication, and unavailable services were grouped as structural issues rather than individual concerns, reflecting their shared system-level origins. Themes were retained based on their presence across youth, caregiver, and HCPs' accounts, rather than their frequency within a single group, to support relevance across roles and settings. Divergent cases were examined to refine themes and ensure the findings reflected variation in regional adolescent and young adult cancer care experiences rather than a single dominant perspective. Any disagreements were discussed until a consensus was reached. Regular team debriefings supported critical reflection on emerging patterns and facilitated discussions across the diverse participant groups, including youth, caregivers, and HCPs.

Ethical Considerations

This study received ethical clearance from the Windsor Regional Hospital Research Ethics Board (REB 24-477) and the University of Windsor Research Ethics Board (REB 24-027). All participants were English-speaking and resided or worked in the Windsor-Essex region. Informed consent was received prior to proceeding with the interview and audio recording. Both interviewers, a registered pediatric nurse and a research assistant trained in qualitative interviews, are trained in detecting signs of distress and pausing interviews if needed. Mental health resources were also provided to participants during interviews. Interviews were then transcribed verbatim by trained research assistants, deidentified, and stored on a secure computer. Participants were then given an electronic gift card via email.

Rigor and Reflexivity

To strengthen the rigor and trustworthiness of our findings, we used several strategies, including methodological alignment, role-based triangulation, maintaining an audit trail, and ongoing reflexive practice. Three research team members (JT, MM, and BG), each with qualitative research experience, collaboratively led the coding and thematic development, bringing complementary perspectives to the analysis. We systematically recorded analytic decisions and individual reflections in an audit trail, revisiting these notes and consulting with the research team to ensure interpretations remained closely tied to the data. To enhance credibility and transferability, the research team documented and discussed key analytic decisions throughout the analysis. Throughout the study, we remained reflexive by journaling and openly examining how our disciplinary training and varying clinical involvement in adolescent and young adult oncology shaped our analytic lens and helped mitigate potential biases. This reflexive process helped us foreground participant voices and mitigate the influence of preexisting assumptions.

Results

Participant Characteristics

A total of 16 participants signed up for the study, but 2 did not meet the eligibility criteria. As a result, 14 participants were interviewed, including 2 youth, 6 caregivers, and 6 HCPs. Among the caregivers, the majority (5/6) were mothers, with 1 father. Youth participants were in their early 20s and represented different cancer diagnoses. HCPs included professionals with varied roles, such as child life specialist, family support liaison, pediatrician, pharmacist, and registered nurses. There was a range of 2 to >20 years of experience in adolescent and young adult oncology among HCPs. Full demographic details are provided in Table 1.

Overview of Themes

Thematic Summary

Analysis generated 6 interconnected themes that illuminate how structural barriers operate across ecological system levels to constrain adolescent and young adult cancer care. These themes demonstrate the complex relationship between individual experiences and systemic deficiencies that characterize regional adolescent and young adult oncology. These themes are (1) structural gaps in coordinated and equitable oncology care; (2) overreliance on individual champions in an underresourced system; (3) developmental and environmental misalignment in youth cancer care; (4) barriers to youth engagement, autonomy, and voice; (5) gaps in psychosocial, palliative, and survivorship supports; and (6) system enablers that support youth and families. Findings reflect converging and contrasting perspectives across youth, caregivers, and HCPs, highlighting shared challenges as well as role-specific experiences within regional adolescent and young adult cancer care.

Structural Gaps in Coordinated and Equitable Oncology Care

HCPs consistently mentioned fragmented communication and uneven care quality between tertiary and regional centers as key barriers to coordinated adolescent and young adult oncology care. Despite the need for youth-centered care, participants described a disconnect across sites, leaving both HCPs and caregivers underinformed and youth vulnerable to suboptimal care.

Structural gaps in coordinated and equitable oncology care were described as multifaceted and interconnected. Across participant groups, these gaps encompassed fragmented communication between tertiary and regional centers, uneven access to clinical expertise and oncology-trained personnel, and limited availability of medications and treatment protocols in community settings. Communication breakdowns included inconsistent written documentation, delayed information sharing, and limited direct access to tertiary specialists, leaving regional teams and families to bridge gaps informally. Together, these structural deficiencies undermined continuity, timely decision-making, and eroded confidence in the coordination of care across settings, particularly within regional follow-up and shared care pathways, even as confidence in tertiary oncology expertise remained high. One regional HCP articulated this disconnection vividly:

> *[The youths] don't tell me anything. They will go to their tertiary care centre and then divulge all this information to their oncologist, but that sometimes doesn't get back to me.* [HCP01]

These communication gaps hindered the delivery of timely and responsive care, placing added pressure on families who were left to navigate disconnected systems on their own. Providers described encountering patients during follow-up appointments without access to critical discharge information, leading to delays and uncertainty:

> *Patients come back for follow-up, and it is not in the discharge doctor's note. I don't know what I am supposed to do. Patients have to wait until we figure it out ... there are a lot of barriers there and parents get upset.* [HCP04]

Rather than functioning as part of an integrated care system, regional teams were often left reactive, informed only when issues arose:

> *There's room for improvement in terms of more consistent check-ins and streamlined communication between the care teams in [tertiary center] and [regional center]. Communication usually occurs only when there's an issue.* [HCP06]

These accounts illustrate how fragmented communication extended beyond interpersonal exchanges to include gaps in written discharge documentation, delayed information transfer, and limited direct communication channels between regional providers and tertiary oncology teams. While adolescents and young adults and families continued to seek and trust tertiary oncologist expertise, confidence in the system's ability to function as a coordinated whole was diminished, especially during transitions and regional follow-up.

Beyond communication, participants described structural gaps related to limited clinical expertise and staffing capacity in regional settings, which constrained the ability to deliver consistent, oncology-informed care. Parents, particularly those with clinical backgrounds, described regional teams as underresourced and underprepared for the demands of pediatric oncology:

> *We need trained, more educated nurses who know what they're doing with respect to oncology pediatric patients ... if there was none on the floor, they had to call the adult oncology nurse to come.* [P06]

From the provider perspective, limited caseloads and infrastructure posed ongoing challenges to maintaining expertise:

> *You want experts in the field who are seeing this daily. So, if you can't support that with volume ... the care is watered down.* [HCP06]

Structural inequities were also evident in access to medications and treatment protocols, with families encountering limitations to locally available therapies and inconsistent access to chemotherapy regimens. These constraints often required families to travel to tertiary centers or accept suboptimal symptom management in regional settings. One parent described the frustration of discovering that their regional center would not carry a nausea medication that had been effective for their child:

> *There was a medication which they figured out for my son's nausea [but] our cancer center does not have it ... they will not carry it or even order it for you.* [P06]

Others described having to travel to a tertiary treatment center to access specific chemotherapy not available at the local satellite clinic:

> *He could get some [chemo] here at the satellite clinic, but there were certain kinds that ... he'd have to travel*

XSL•FO
RenderX

> *to [tertiary treatment center] for the day and then come back.* [P05]

Continuity of care was frequently sustained through the consistent engagement and relationship-building efforts of individual providers. Their ongoing presence created stability for families within care pathways that were not always seamlessly connected, highlighting that relational continuity often compensated for, rather than resolved, underlying structural fragmentation, and underscoring opportunities to strengthen system-level structures that can better support this work.

Overreliance on Individual Champions in an Underresourced System

Youth cancer care in smaller cities was often sustained by a few dedicated champions, who served as the relational and procedural anchors in the absence of coordinated infrastructure. These longstanding relationships became vital for families navigating a complex and emotionally charged care journey. Nurses who had followed youth through multiple treatment cycles were often seen as irreplaceable. One parent reflected on the central role of a trusted nurse:

> *[The nurse] is someone who is crucial for [the cancer care in the city] ... [she] was a very big part in like, I guess the good part of the cancer diagnosis ... Built a relationship with [youth] as well, so that was a familiar face.* [P04]

Similarly, a provider described the unique role of a long-serving staff member who became the "pillar" of the clinic:

> *I will say that our [satellite] clinic is fantastic in terms of our recent lead staff, who had just retired. I think she was ... the pillar of the clinic. And so, I can definitely appreciate her longitudinal relationships with these children, and you know that consistency and comfort that she brought to the clinic.* [HCP06]

Another provider described the relational disconnect that arose when covering for a colleague on leave:

> *They trust the [healthcare provider] very much, and I have a harder time bonding with that family. I always try really hard to get the parents to open up about how they're feeling.* [HCP04]

While the relational model provided meaningful continuity of care, it placed considerable strain on those stepping into these "individual champion" roles temporarily. Relief staff were expected to handle not only complex clinical tasks such as port access and chemotherapy preparation, but also to meet the relational expectations usually fulfilled by familiar providers. The same provider further reflected on this challenge, noting, "when it's not that primary person, it is difficult and very nerve-wracking for me" (HCP04), highlighting the implicit comparison to a trusted key team member. Participants described how high parental expectations and the lack of team-based backup intensified provider stress:

> *Parents were constantly hovering and commenting, 'will the staff be able to do it like [nurse] does?' ... and I was stressed. There are not enough people who are confident with ports ... I did not have a backup.* [HCP05]

This fragility in having trusting relationships when receiving regional cancer care was not limited to nursing. Other HCPs also reported similar vulnerabilities due to understaffing and role overload. In contrast to tertiary centers, which had designated personnel for oncology services, regional providers often worked in isolation across multiple service areas:

> *Tertiary center has two [healthcare providers of the same role] just dedicated to oncology. I am doing all of these alone ... How do we make it so that it's not just one person?* [HCP05]

While these individual efforts were essential to maintaining continuity, they also underscored the extent to which the care experience relied on personal relationships rather than systemic design. Familiarity with a trusted provider was a powerful buffer against an environment that otherwise felt disjointed from the needs of youth. Without systemic structures in place to ensure developmental responsiveness, care often defaulted to rigid categories (ie, child or adult) that failed to reflect the developmental realities of adolescents and young adults. This disconnect surfaced not only in staffing and coordination but also in the broader environments where care and recovery unfolded.

Developmental and Environmental Misalignment in Youth Cancer Care

Youth, parents, and providers consistently described both regional and tertiary cancer care environments as misaligned with the developmental and psychosocial needs of adolescents and young adults. Designed mainly for children or adults, current systems often leave adolescents and young adults without appropriate spaces or supports, reinforcing feelings of isolation, exclusion, and disempowerment. Many participants described health care environments that were either child-centric or adult-oriented, with no age-appropriate options in between. A provider noted, "We have a pediatric or an adult cancer ward. But what about the young adults?" (HCP05). This forced placement into inappropriate programs often made adolescents and young adults feel out of place and visibly different. One parent recalled the discomfort of being placed in an adult support group:

> *They had registered us for the adult [cosmetic] program ... and so we were in a room full of women ... and my daughter felt very uncomfortable.* [P02]

Beyond issues of age-appropriateness, participants also pointed to systemic limitations in accommodating youth under immunosuppressive protocols. One youth described the social isolation of being physically present but barred from meaningful interaction:

> *Even when I did go back, I wasn't allowed to go around people. I was just able to see them from a distance.* [Y01]

Even when youth were physically present, the surrounding structures seldom provided space for independent voice, reflection, or choice, deepening their sense of invisibility within the system.

XSL•FO
RenderX

This disconnect within exosystems extended beyond health care into education systems as well, where youth and families encountered similar structural gaps in communication and developmental support. For some, physical inaccessibility in school environments compounded the recovery process and emotional toll:

> *Her mobility was hugely restricted ... and I found that the school was not very understanding ... didn't provide extra time ... loaded her up with heavy textbooks.* [P02]

Educational disruption and poor reintegration into school activities were among the most frequently raised concerns. Youth described being met with apathy or misunderstanding from teachers, contributing to a sense of abandonment at a time when support was most needed:

> *It'd be nice just for [teachers] to be a little more supportive, not just kind of shun you or shove you off.* [Y01]

Parents echoed these frustrations, noting the absence of structured communication between hospital-based care and educational institutions. In their view, the lack of coordinated roles and clear processes left families to navigate these transitions on their own:

> *It would be nice to have more collaboration between the contact person at the hospital and the schools ... There wasn't really a process or a system of support in place that I found was really adequate.* [P06]

Even when educational support was available, it was often not tailored to the developmental stage of older youth. As one provider explained, volunteer tutoring programs, while well-intentioned, frequently fell short of meeting the academic needs of senior high school students:

> *We have a volunteer tutoring program ... but for kids that are in grades 11 and 12... It's very difficult to find someone to help who is qualified.* [HCP02]

Youth also described the emotional burden of having to repeatedly explain their cancer history to peers and teachers, an experience that underscored the lack of systemic communication mechanisms:

> *It would be nice if the school knew [so] I didn't have to restate everything and relive all the things that happened.* [Y01]

These mismatches between care environments and developmental needs not only left youth feeling out of place in schools and hospitals but also reinforced patterns of exclusion that limited their ability to participate meaningfully in their own care.

Barriers to Youth Engagement, Autonomy, and Voice

As mentioned earlier, adolescence is a crucial period for developing autonomy and identity. Yet, youth, parents, and providers described barriers to engaging adolescents and young adults as active participants in their care. Young people often felt sidelined by the need for constant parental presence in a hospital setting and health care systems that lacked the structure to center the youth voices in decision-making. The most immediate barrier was the structural absence of private, youth-directed spaces in clinical settings. Providers noted that youth rarely had opportunities to speak independently, as parents were nearly always present during appointments:

> *When they're in the clinic or admitted to the hospital, there is always a parent present. They don't have any time or opportunity to express themselves without a parent listening.* [HCP01]

Even when youth were physically present, the surrounding environment often lacked opportunities for independent voice, reflection, or choice, which may have contributed to a sense of invisibility within the system. In these situations, clinicians observed that parents often took the lead in communication, sometimes speaking on behalf of the youth.

> *You know, it was ... trying to ask them if they had any questions ... kind of engage them in their care versus their parents ... [instead] I get the parents' answer.* [HCP05]

These missed opportunities for confidential conversations with clinicians were seen as limiting not only for youth but also for providers trying to build rapport:

> *[Private spaces or time alone with youths] would be better at helping them open up ... but parents are always there with the kids* [HCP02]

The consequences of these missed youth-provider interpersonal interactions were twofold. First, youth often disengaged entirely, either due to discomfort or lack of perceived agency:

> *With the youth and adolescent population, I struggle ... I feel like I don't necessarily always have the time to explore all the underlying issues ... It's more superficial.* [HCP06]

Second, parents often became the sole conduit for emotional disclosures, an arrangement that left providers relying on second-hand reports to assess psychosocial needs. One provider noted:

> *The biggest issue is that [youth] don't talk about their feelings; parents will usually reach out to me.* [HCP02]

This not only limited the ability to engage youth authentically but also risked reinforcing dependency at a time when adolescents are developmentally primed to begin asserting independence and autonomy. Providers emphasized the importance of structured, developmentally appropriate approaches to foster youth voice and participation:

> *As they're trying to navigate adolescence and personal identity ... young adult transition clinics would be quite important ... they need to build that trust before being able to actually open up.* [HCP06]

Some pointed to peer-facilitated spaces as promising platforms for agency and shared learning:

> *There needs to be a peer-on-peer family group ... having a facilitator could ensure accuracy and support.* [HCP04]

XSL•FO
RenderX

Yet even when youth sought to engage, the absence of integrated psychosocial, palliative, and survivorship supports left many of their broader needs unmet.

Gaps in Psychosocial, Palliative, and Survivorship Supports

The psychosocial aspects of youth cancer care, especially mental health, end-of-life support, and survivorship systems, were described as fragmented, underresourced, and overlooked. Although essential for long-term well-being, these supports are often less developed and less available than medical services. Mental health emerged as a particular area of concern. Parents described the cumulative emotional trauma usually experienced by their children and families and lamented the lack of proactive mental health resources or referrals.

> *There's a lot of trauma. And for no sort of mental health support to be recommended for you to get referrals, no one coming in to talk about it, that is very concerning ... Not just for the child, but for parents, caregivers, and siblings too.* [P06]

Access to services was also marked by inequities. Providers and parents pointed to long waitlists for youth counseling and the financial barriers to accessing private care. One provider and one parent noted:

> *I don't really think that [mental health] support is widely accessible. There are long waitlists for accessing mental health services, and going private depends on whether they have the money or benefits.* [HCP02]

> *I think if there was counselling later that was offered, that wasn't a cost or whatever ... She definitely does have some PTSD [post-traumatic stress disorder] ... and OHIP [Ontario Health Insurance Plan] should cover counselling for critical conditions.* [P05]

For many, the systemic gaps in support became particularly stark during the survivorship and transition periods for the youth. Parents and HCPs both noted that psychosocial support tended to decrease once treatment ended:

> *You're 17, and everything is organized. At 18, you're expected to navigate it all on your own ... Youth transition clinics would be quite important. Smaller cities would definitely benefit from that.* [HCP06]

> *It almost seems like there needs to be a period of transition into adult care ... not just jump from a tertiary children's centre to the adult oncology.* [P03]

This abrupt transition was especially difficult for youth experiencing developmental vulnerability:

> *The transition wasn't gradual; it was sudden. It was becoming stressful for me because he didn't belong there. He belongs around more fun things. Not the adult cancer centre.* [P02]

Equally concerning were the significant gaps in palliative care and bereavement support. Families reported being left to navigate end-of-life planning and grief without structured guidance or psychological care:

> *Try to imagine planning a funeral and a birthday party three days apart ... There is absolutely nothing there [to support a family member after death]... You are so alone.* [P02]

Even when community programs existed, they were often underfunded or unavailable to many:

> *The grief program for kids through CMHA [Canadian Mental Health Association] has no additional funding ... It's purely [based] on fundraising.* [P06]

The challenge of finding trauma-informed therapy was ongoing and deeply taxing for some parents.

> *All the trauma he went through and all the nightmares. Thank God, we took him for therapy ... but it was not easy to find.* [P02]

While many families faced challenging moments in the cancer journey without adequate psychosocial or palliative support systems, their experiences also revealed what mattered when care felt responsive. Participants highlighted local, community-based, and satellite-driven supports that eased the burdens of treatment and recovery.

> *The [satellite] clinic was very helpful ... for blood work or the chemo he could get here instead of us having to travel to [tertiary treatment center].* [P04]

> *It was really good to be close to home, because I could go home and rest after ... And [nurse name] was just always there ... It wasn't some new person every time. It made it feel like people cared, like I wasn't just a number.* [Y01]

These were not incidental benefits but crucial system enablers that, when present, enhanced access, continuity, and emotional well-being for youth and their families.

System Enablers That Support Youth and Families

While participants acknowledged systemic gaps in cancer care, they also highlighted key supports that eased the burden for youth and families. Local satellite clinics, financial assistance, and community-based resources provided critical support. Access to nearby care reduced travel strain, though participants emphasized that proximity must be matched by adequate staffing and resources to ensure safe, high-quality care.

> *It would be nice to have more care closer to home, provided we could, if we had the resources to do it safely and the necessary support staff. We are a satellite center, and we must acknowledge that we are not the primary one, but it would be nice.* [HCP05]

Youth also voiced a desire for greater local capacity, envisioning a future where advanced therapies, like stem cell transplants, might eventually be delivered in regional settings.

> *More local treatment on a grander scale, more options locally to do more treatment here, even so far as like the stem cell transplants.* [Y02]

Alongside local access, financial and transportation support were key. For many families, unexpected levels of financial assistance, offered through local charities and hospital

XSL•FO
RenderX

partnerships, helped offset the high costs of treatment, travel, and time away from work. As one parent shared: "I was very surprised by how much financial support there really is" (P03). Providers also noted that these systemic supports extended beyond the treatment period, with some organizations offering educational bursaries to youth survivors pursuing postsecondary education: "[Community organization] gives bursaries for postsecondary students." (HCP01).

The long-term engagement model offered by community organizations like ChildCan and Fight Like Mason was especially valued [30]. These groups were not seen as peripheral supports, but as integral components in the care ecosystem, offering emotional, logistical, and financial assistance that extended well beyond hospital walls. Youth and families described these relationships as enduring, often continuing for years after active treatment had ended. One provider noted: "Even ten years later, [survivors] can apply for a bursary" (HCP02). This long-term community support was especially valuable in smaller cities, where formal survivorship and mental health services were limited. Community organizations provided a sense of continuity and connection when formal systems withdrew, ensuring that families did not feel abandoned at the end of treatment.

These accounts highlight the importance of flexible, locally embedded supports that bridge gaps in formal care. While satellite clinics, financial aid, and community organizations may not replace the comprehensive health care infrastructure of tertiary centers, they serve as crucial scaffolding, helping youth and families stay connected, supported, and hopeful throughout and beyond the cancer care journey.

Discussion

Principal Findings

This study explored how adolescents and young adults with cancer, their caregivers, and HCPs experienced regional cancer care in Ontario, and identified key barriers to developmental alignment, care coordination, and equitable access within these systems. Our findings reveal structural gaps that create challenges for delivering equitable care to adolescents and young adults with cancer. Communication between tertiary and regional centers is inconsistent, leaving families to rely on individual champions rather than reliable systems. Fragmented communication had implications beyond information exchange, shaping relationships, trust, and continuity of care. Inadequate or delayed discharge documentation limited direct communication channels, and inconsistent access to oncology specialists left regional providers uncertain about care plans and families unsure whom to rely on for guidance. These gaps shifted the burden of coordination onto caregivers and strained therapeutic relationships, particularly for nurses who were expected to provide continuity without access to complete or timely information. From a nursing perspective, such breakdowns undermine relational care by constraining providers' ability to anticipate needs, follow through on care plans, and build confidence with youth and families. These findings highlight the need for more formalized, standardized communication processes between tertiary and regional teams to support continuity, accountability, and relationship-centered care in adolescent and young adult oncology. Care environments often default to binary pediatric or adult models, with adolescent and young adult autonomy and psychosocial needs frequently unaddressed. Gaps in mental health, palliative care, and survivorship services were also evident throughout the care journey, reflecting broader misalignments within existing systems. In this context, families described drawing on local supports and community organizations outside of the formal care system. Our findings point to an opportunity to better align existing communication processes with the needs of adolescent and young adult oncology care across institutional boundaries, drawing on structured handover approaches already used in other areas of health care.

In regional settings, individual providers often took on responsibilities beyond their formal roles to deliver adolescent and young adult cancer care. While this is consistent with rural oncology research indicating that committed professionals sustain care continuity [8,31], our findings suggest that more systematic infrastructure could help strengthen these efforts. This pattern may reflect broader challenges, including infrastructure gaps, insufficient system-level guidance, and limited provider education in developmentally appropriate adolescent and young adult care [8,32]. Reliance on key individuals rather than a sustainable infrastructure means that a single provider's departure can disrupt service continuity and erode trust among patients and families [33,34]. While countries like the United Kingdom and Australia have made strides toward centralized adolescent and young adult care frameworks, implementation remains inconsistent across many jurisdictions, including Canada, leaving individual champions to fill systematic gaps [8,20]. This has implications for workforce sustainability and system resilience, as documented challenges arise when providers operate beyond their scope without adequate support [35-38]. Our findings suggest that while individual champions remain important and should be celebrated, there is significant potential to evolve toward well-resourced, team-based models that ensure more consistent, equitable adolescent and young adult cancer care [6,20]. These dedicated efforts could be enhanced through more systematic support to improve adolescent and young adult care quality and access across regional settings.

Another key insight from our study is the mismatch between existing care models and the developmental realities of adolescents and young adults. Pediatric care often centers on parental involvement, which can delay the development of independence, while adult care assumes emotional and cognitive maturity that many adolescents and young adults are still developing [2,4,39]. Such gaps contribute to disengagement and disruptions in care continuity. The misalignment is further complicated when adolescents and young adults are treated in spaces that do not foster trust or reflect their evolving identities [12,15]. Without youth-appropriate space and support, many are reluctant to raise sensitive issues or participate fully in care decisions [10]. These gaps extend beyond clinical care into important life domains, with our participants describing educational interruptions, limited attention to fertility, and a lack of structured support for work reintegration. These patterns

XSL•FO
RenderX

echo the BRIGHTLIGHT cohort findings of high psychosocial distress among adolescents and young adults due to ineffective communication and insufficient age-appropriate guidance [17], highlighting the need for developmentally relevant supports in sexuality, education, and career planning often overlooked in adult oncology settings [32].

Psychosocial, palliative, and survivorship care remains inconsistently delivered in cancer care settings despite growing awareness of their importance [17,26]. Our findings demonstrate that regional variation in care quality and access creates equity barriers even in publicly funded systems like Canada [27,40,41]. Extending this work, our study also highlights how these gaps are experienced within regional and community-based settings, where limited mental health infrastructure and workforce shortages further constrain access to counselling, bereavement, and trauma-informed care, and our study participants described feeling abandoned during care transitions and struggling with unresolved trauma and grief without access to counselling or bereavement support [20,31,38]. These gaps were particularly significant in rural areas, where mental health infrastructure and workforce shortages were limited [12,25,31]. Psychosocial supports are often overlooked as biomedical treatment takes priority over emotional recovery and life-stage reintegration, partly because of gaps in integrating trauma-informed psychosocial care due to inadequate funding and lack of structural support [10,32]. As a result, families are left to navigate fragmented supports independently, adding emotional strain and worsening inequities.

Strengths and Limitations

This study is limited by its focus on 1 region (Southwest Ontario), which may affect transferability to other health care contexts. A key strength of this study lies in the integration of perspectives across youth, caregivers, and HCPs, enabling examination of converging and contrasting accounts of regional adolescent and young adult cancer care. This sample is predominantly White, which may affect generalization to other populations. While purposive sampling was used to ensure variation across key social characteristics, such as age, socioeconomic background, and geographical location, it may not fully capture diversity across other rural and urban regions in Canada. Although the study included 2 adolescents and young adults with different diagnoses, the sample size is limited, which may be due to the study's specificity and inclusion criteria. This may not reflect the perspectives of youth with other oncology diagnoses or those entirely disengaged from cancer care, such as those lost to follow-up or experiencing ongoing structural exclusion. Due to resource constraints, only parents or caregivers with English fluency were included within the study, which can limit the diversity of this sample.

Comparison With Prior Work

Much of the existing literature has focused on broad national or international perspectives, including the Institute of Medicine workshop summary [10] and the *Canadian Partnership Against Cancer's Adolescents and Young Adults with Cancer: A Reference Report* [12]. Our study offers a regional perspective on how these systemic issues manifest in day-to-day cancer care delivery. While large-scale cohort investigations such as BRIGHTLIGHT emphasize psychosocial outcomes [17] and qualitative studies of advanced disease foreground existential concerns [11], our analysis focuses on how structural barriers and developmental misalignments are experienced within a smaller, underserved Canadian region. This regional perspective complements existing models-of-care reviews [20,32] by illustrating how resource limitations and workforce reliance shape the care landscape in ways not fully captured in national or tertiary-level studies.

Recommendations for Further Research

Future research should explore findings across broader geographic contexts, including interprovincial comparisons of adolescent and young adult oncology models, and examine how structural determinants, such as income, Indigeneity, and gender, may intersect with access to cancer care and subsequent outcomes. Mixed method studies integrating patient-reported outcomes, service use data, and system-level indicators could also deepen understanding of how developmental misalignment and fragmentation affect quality, equity, and survivorship trajectories. Longitudinal research is needed to assess the effectiveness of targeted system interventions, such as youth navigation roles or regional adolescent and young adult coordinators.

Implications for Policy and Practice

To advance equity and quality in adolescent and young adult oncology, policy and practice may benefit from prioritizing care models that reflect young people's developmental contexts, including age-appropriate education, counseling, and clinical environments that support autonomy. Although models such as age-specific care settings and coordinated transition services have shown promise, their implementation has been uneven and often limited to well-resourced settings [6,20]. Sustained improvements will likely require investment in cross-institutional coordination, provider training, and supportive policies, with examples showing that dedicated funding and leadership can drive progress [8,20].

Within this study, nurses were consistently identified as central to supporting adolescents and young adults, often taking on coordinating and advocacy roles despite limited formal recognition or specialized training. These findings suggest opportunities for strengthening nursing contributions in adolescent and young adult care, such as (1) integrating developmental psychology into nursing education, (2) establishing advanced practice adolescent and young adult care coordinator roles, (3) fostering youth-friendly care environments, (4) incorporating trauma-informed approaches to address mental health needs, and (5) developing adolescent and young adult–specific interventions through nursing-led research. Advancing these areas will require institutional support, including dedicated funding, protected coordination time, and recognition of nursing expertise, to move from informal efforts toward more structured, developmentally responsive systems of care.

Conclusion

Adolescents and young adults with cancer receiving care in regional settings often face services that are fragmented, not

XSL•FO
RenderX

fully aligned with developmental needs, and unevenly supported across systems. Families described depending on the efforts of individual clinicians, particularly nurses, to bridge service gaps, while psychosocial, palliative, and survivorship supports were less consistently available. Local clinics and community organizations played an important role in providing accessible and ongoing support, particularly close to home. These findings suggest a need to transition from individually driven solutions to more reliable, coordinated, and developmentally responsive models of adolescent and young adult cancer care that integrate equity, sustainability, and youth voice.

Acknowledgments

We are deeply grateful to the youth, caregivers, and health care providers who participated in this study for their time, trust, and willingness to share their experiences. We also thank Melissa Miljanovski, Brianna Grandi, Bayan Nasra, and Adelia Scofield for their contributions to data transcription and cleaning, and Joanne Ta for preparing the manuscript for submission and for proofreading.

Data Availability

The datasets generated during or analyzed during this study are available from the corresponding author on reasonable request.

Funding

This study was funded by Windsor Cancer Centre Foundation through the WE-SPARK Health Institute Igniting Discovery Grant.

Authors' Contributions

JT was responsible for conceptualization, methodology, investigation, formal analysis, data curation, project administration, funding acquisition, and drafting the original manuscript. MJ contributed to conceptualization and methodology and assisted with manuscript review and editing. TY contributed to conceptualization. JCK contributed to conceptualization, methodology, and investigation, conducted formal analysis, and assisted with manuscript review and editing.

Abstract

Background: Breast cancer and its treatment can negatively affect women's quality of life (QoL), including physical, psychological, and social well-being. Digital health interventions have been increasingly used to provide supportive care, but their effectiveness on QoL and related psychosocial outcomes remains unclear.

Objective: This review aimed to evaluate the effectiveness of digital health interventions on QoL in women with breast cancer and to assess their effects on anxiety, depression, and self-efficacy.

Methods: This systematic review was registered in PROSPERO (CRD420250578307) and conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement. PsycINFO, Web of Science, Scopus, LILACS, and SciELO were searched in September 2025. Eligible studies were randomized controlled trials (RCTs) or controlled quasi-experimental studies with preintervention and postintervention assessments that evaluated digital health interventions in women with breast cancer during or up to 1 year after active treatment and reported QoL outcomes. Two reviewers independently screened all records (interrater agreement >90%) and extracted data using a standardized template, with independent verification by a second reviewer. Risk of bias was assessed using the Cochrane Risk of Bias tool (RoB 2) for RCTs and the Risk of Bias in Non-randomized Studies of Interventions (ROBINS-I) tool for the quasi-experimental study; findings were synthesized narratively following the Synthesis Without Meta-analysis (SWiM) guideline.

Results: A total of 408 records were identified, and 15 studies were included: 14 RCTs and 1 quasi-experimental study. Sample sizes ranged from 35 to 394 participants. Ten studies evaluated internet-based approaches such as websites or apps; 3 used text messaging (eg, WhatsApp [WhatsApp LLC] or WeChat [Tencent Technology, Shenzhen Company Limited]), 1 used virtual reality, and 1 used an email listserve. The direction of effect favored the digital intervention for QoL in 8 of the 15 studies. Self-efficacy was assessed in 5 studies and favored the intervention in only 1, with the effect not maintained at follow-up. Anxiety, depression, or emotional distress were assessed in 13 studies, with a favorable direction of effect in 5. Retention rates ranged from 68.6% to 100%. Among the 14 RCTs, 3 were judged at high overall risk of bias, and 11 raised some concerns; none was at low risk. The quasi-experimental study had a serious overall risk of bias. Certainty of evidence was low for QoL and emotional outcomes and very low for self-efficacy.

Conclusions: Digital health interventions may provide modest, short-term improvements in some dimensions of QoL in women with breast cancer. Favorable effects appeared more often in interventions with active therapeutic components or professional support; however, this pattern was based on indirect comparisons across heterogeneous studies. Effects on self-efficacy and mental health were inconsistent, and acceptability was insufficiently evaluated. Although promising, current evidence does not support strong or generalizable conclusions.

Introduction

The World Health Organization (WHO) identifies breast cancer as one of the leading public health challenges globally and the most prevalent malignancy in both high-income and low- and middle-income countries [1]. According to estimates from the Global Cancer Observatory, more than 2 million cases of breast cancer were recorded worldwide in 2022, with an age-standardized rate of 46.8 per 100,000 women [2]. In addition, projections indicate that global breast cancer cases

XSL•FO
RenderX

will increase by 38% by 2050, and annual deaths from this disease will rise by 68% [3].

Women with breast cancer undergoing oncological treatment experience a range of physical, psychological, and social consequences [4,5]. Fatigue, pain, lymphedema, sexual dysfunction, and sleep disturbances are frequently reported as physical sequelae of breast cancer [6-8]. Psychological consequences such as anxiety, depression, and fear of cancer recurrence have also been demonstrated, with negative impacts on health and quality of life (QoL) [9,10]. In this context, psycho-oncological interventions have shown efficacy in improving coping capacity, enhancing self-efficacy skills, and reducing stress and emotional distress [11-13].

In light of the foregoing, digital health—defined by WHO [14] as the "field of knowledge and practice associated with the development and use of digital technologies to improve health, encompassing other uses of digital technologies for health such as the Internet of Things, advanced computing, big-data analytics, artificial intelligence, including machine learning and robotics"—emerges as a platform through which diverse interventions can be deployed. Before the COVID-19 pandemic, digital health had not been widely incorporated into standard oncological care worldwide [15]; however, its use has increased substantially in recent years. Systematic reviews have examined the impact of digital health among patients with cancer, revealing that digital interventions—such as informational websites including patient narratives, mindfulness intervention apps, physical activity programs, virtual reality (VR) for pain management, and videoconferencing—produce significantly positive outcomes in patient-reported symptoms, fatigue and pain levels, health-related QoL, functional capacity, and depression levels compared with care delivered without such tools [16-18].

AI and other advanced digital technologies are increasingly being applied across the breast cancer care continuum, including screening, diagnostic support, risk stratification, treatment planning, symptom monitoring, and survivorship support [19]. However, this review focuses specifically on digital health interventions directed at supportive care and psychosocial outcomes rather than diagnostic or treatment-decision technologies.

Given the growing use of digital health interventions in oncology, and the heterogeneity in the available findings, this systematic review aimed to evaluate the effectiveness of digital health interventions on QoL in women with breast cancer, and to assess their effects on self-efficacy and mental health outcomes.

Methods

Overview

This systematic review was registered in PROSPERO (CRD420250578307) [20] and its protocol was previously published [21]. It was performed in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [22] and following the Population, Intervention, Comparison, Outcomes, and Context (PICOC) [23]. This review addressed the following question (PICOC): in women with breast cancer during active treatment or up to 1 year after completion of active treatment (Population), do digital health interventions (Intervention), compared with usual care, standard treatment, or a waitlist (Comparator), improve QoL and, secondarily, self-efficacy, anxiety, and depression (Outcomes), and eligible interventions were primarily directed at women with breast cancer, irrespective of geographic location or care setting (Context)?

The following amendments to the registered protocol, made during the conduct of the review, are reported in accordance with PRISMA 2020 (item 24c) as detailed in Checklist 1. First, it is specified that the study designs correspond to both randomized and nonrandomized studies (randomized controlled trials [RCTs] and controlled quasi-experimental studies with preintervention and postintervention assessments). Second, Scopus was searched instead of MEDLINE, representing a deviation from the registered protocol; this was complemented by hand-searching the reference lists of the included studies. Third, risk of bias was assessed according to study design, using the revised Cochrane Risk of Bias tool (RoB 2) [24] for RCTs and the Risk of Bias in Non-randomized Studies of Interventions (ROBINS-I) tool [25] for the quasi-experimental study, in accordance with the amended protocol. Fourth, the certainty of the randomized evidence was rated using the GRADE (Grading of Recommendations Assessment, Development and Evaluation) approach [26,27], an assessment not specified in the protocol, to inform confidence in the findings. Fifth, eligibility was restricted to women from diagnosis through active treatment and up to 1 year after completion of active treatment; studies of long-term survivors (more than 1 year after completing active treatment) were excluded, a temporal restriction of the population that was not specified in the registered protocol. In addition, references were managed in Rayyan [28] (Rayyan Systems Inc; rather than the registered Mendeley) and PsycINFO was searched through the ProQuest platform (ProQuest LLC; rather than EBSCOhost); these operational changes did not affect the eligibility criteria or the synthesis.

Search Strategy

The search was conducted in September 2025 using PsycINFO (ProQuest), Web of Science, Scopus, LILACS, and SciELO. Database-specific free-text terms were adapted to the syntax and indexing fields of each database. The complete search strategies are provided in Multimedia Appendix 1. All articles retrieved from the databases were exported to Rayyan software for screening [28]. The auto-resolve function was used, and any records with less than 95% similarity were manually reviewed by the lead researcher (RZ-T).

Title and abstract screening were conducted independently and in duplicate by 2 reviewers (RZ-T and MB); articles that did not meet the criteria were removed, and those with insufficient information to make a decision were carried forward to the full-text screening stage.

The full text of all potentially eligible records was likewise assessed independently and in duplicate by the same 2 reviewers. Interrater agreement was high (>90%) [29], and any

XSL•FO
RenderX

disagreements were resolved through discussion or, when needed, with a third reviewer (EHE).

Eligibility Criteria

Overview

In this review, digital health interventions were defined as the use of digital technologies—such as computers, mobile devices, wearables, and the internet—to deliver or support health-related information, services, or care. Because this is not a uniform category, interventions were interpreted according to their function: informational patient portals or websites, moderated peer-support forums, symptom monitoring and remote tracking, telerehabilitation, digitally delivered psychological therapy (eg, cognitive behavioral therapy [CBT] or mindfulness), and VR.

Inclusion Criteria

The inclusion criteria were as follows:

1. Articles in English, Spanish, or Portuguese.
2. Studies (papers or theses in databases) with research designs: RCTs and controlled quasi-experimental studies with preintervention and postintervention assessments.
3. Women with breast cancer, from diagnosis through active treatment and up to 1 year after completion of active treatment.
4. Digital interventions had to deliver or support a health-related component through a digital device or platform and report at least one dimension of health-related QoL as an outcome (eg, mindfulness, exercise, and self-efficacy activities).
5. Outcomes must include any dimension of health-related QoL (eg, physical, social, psychological, and symptom dimensions).
6. Studies must provide details about the study design, sample, and intervention components that allow the analysis to be carried out.

Exclusion Criteria

The exclusion criteria were as follows:

1. Nonempirical studies (eg, theoretical or conceptual articles)
2. Reviews, editorials, letters, expert opinions, protocols, or preprints
3. Studies focusing on long-term survivors (more than 1 year after completing active treatment), patients in palliative or end-of-life care, or male patients.

Data Extraction

Data were extracted by the lead author (RZ-T) using a Microsoft Excel template designed to collect details about each digital health intervention and were independently verified by a second reviewer (MB) for all included studies, with any discrepancies resolved by consensus. The data included (1) study characteristics (country, design, sample size, target population, recruitment setting, objective, and methods), (2) primary outcomes of the digital health intervention (mean change and effect size, if applicable), and (3) secondary outcomes of the digital health intervention (mean change and effect size, if applicable).

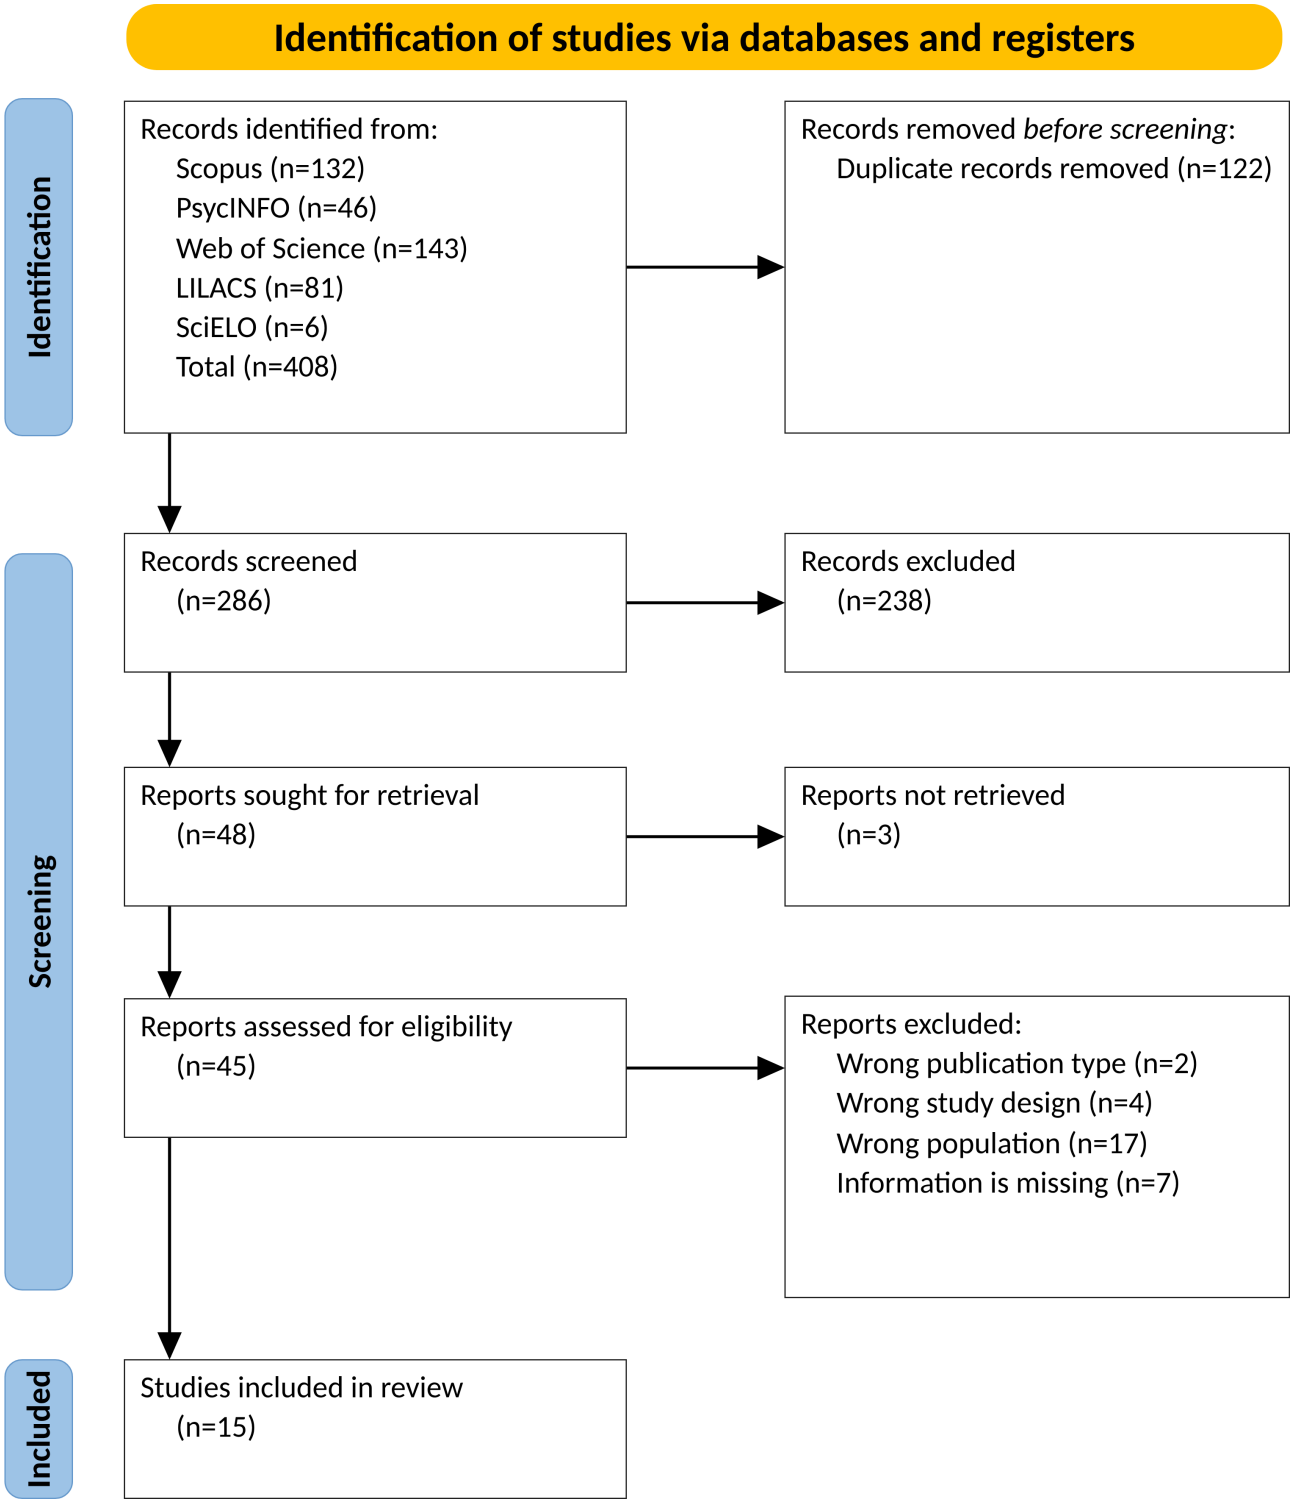
Quality Assessment

The risk of bias of each included study was assessed according to its design. RCTs were assessed using the revised Cochrane RoB 2 tool for randomized trials [24], which evaluates 5 domains—the randomization process, deviations from the intended interventions, missing outcome data, measurement of the outcome, and selection of the reported result—through signaling questions, yielding a domain-level judgment and an overall judgment of “low risk,” “some concerns,” or “high risk.” The nonrandomized quasi-experimental study was evaluated using the ROBINS-I tool [25], as specified in the amended protocol. ROBINS-I assesses bias due to confounding, selection of participants, classification of interventions, deviations from intended interventions, missing data, measurement of outcomes, and selection of the reported result. Each study was assessed independently by 2 reviewers (RZ-T and MB), and disagreements were resolved by consensus or with a third reviewer (EHE).

Data Synthesis

Meta-analysis was not undertaken because the included studies showed substantial clinical and methodological heterogeneity in intervention type and content, comparator conditions, outcome constructs and measurement instruments, and assessment time points. In addition, comparable numerical effect estimates and measures of precision were not consistently reported across studies. Therefore, the findings were synthesized narratively in accordance with the Synthesis Without Meta-analysis (SWiM) reporting guideline [30] and Cochrane guidance for synthesizing findings using methods other than meta-analysis [31]. Studies were grouped according to the outcome domain—QoL (primary) and, secondarily, self-efficacy, anxiety, and depression—and, within each domain, by intervention function (informational portals or websites, moderated peer-support forums, symptom monitoring, telerehabilitation, digitally delivered psychological therapy, and VR), level of human support (guided vs unguided), and length of follow-up. The direction of effect was determined primarily from between-group comparisons at the principal postintervention assessment reported in each study. Findings were classified as favoring the digital intervention, favoring the comparator, or showing no clear direction of effect. Statistical significance was reported when available but was not used as the sole criterion for determining the direction of effect. The certainty of the evidence for each outcome was rated using the GRADE approach [26,27]. The quasi-experimental study was included in the narrative synthesis but was not incorporated into the GRADE certainty assessments.

Results



Study Selection

A total of 408 records were identified from 5 databases and uploaded to Rayyan. After removal of 122 duplicate records, 286 records underwent title and abstract screening, of which 238 were excluded. Forty-eight reports were sought for retrieval; 3 could not be retrieved, and 45 full-text reports were assessed for eligibility. Thirty reports were excluded: 2 because of publication type, 4 because of study design, 17 because of population, and 7 because insufficient information was available

XSL•FO
RenderX

to confirm eligibility. Fifteen studies met the eligibility criteria and were included in the review [32-46]. The study selection process is presented in Figure 1, and study-specific reasons for full-text exclusion are provided in Multimedia Appendix 2.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram for new systematic reviews, which included searches of databases and registers only.

Study Characteristics

Table 1 includes a summary of the participant characteristics of the included studies. The 15 included studies [32-46] had a sample size ranging from 35 to 394, with studies being conducted in China (4/15, 26.7%) [35-37,46], Australia (3/15, 20%) [34,38,43], the United States (2/15, 13.3%) [32,41], and Turkey (2/15, 13.3%) [39,44], and one study each in Finland [33], Japan [42], Brazil [40], and Singapore (1/15, 6.7% each) [45], and were published between 2010 and 2025. Participants were adult women, with mean ages 43.6 (SD 5.0) to 63.9 (SD 7.8) years. In terms of research methodology, 14 studies were RCTs [32-45], and 1 was a quasi-experimental study with pre- and postintervention assessments [46].

Treatment Conditions

A total of 10 (66.7%) studies primarily evaluated internet-based interventions, including websites or mobile apps for patients with breast cancer [33-35,40-46]. One of these studies combined an application with tailored SMS support [46]. The remaining 3 (20%) studies used SMS text messages through different apps such as SMS, WeChat, WhatsApp, or others [36,38,39]. One study used head-mounted VR glasses [37], and one study used an email listserve [32].

The intervention methods included 6 (40%) studies that used psychological intervention strategies as the core component, including online peer support programs [32], mindfulness [36], stress reduction techniques through VR [37], and an online CBT-based psychosocial program [43], along with 2 studies focused on self-efficacy [35,45]. Regarding educational strategies, they were primarily included in 2 (13.3%) studies, providing cancer-related information, symptom management education, and emotional support [34,44]. Two studies worked with empowerment strategies [33,38] (13.3%), 2 studies involved remote symptom monitoring [41,42], and 3 studies focused on physical exercises [39,40,46]. The duration of these interventions ranged from 29 days to 12 months, depending on the study. The professionals involved in these interventions were nurses, psychologists, doctors (physicians or oncologists), physiotherapists, among others. Table 2 summarizes the intervention characteristics of the included studies.

XSL•FO
RenderX

Table . Summary of study characteristics.

Author and year	Intervention group	Contents	Control group	Intervention duration (data collection points)	Instrument of measurement	Results
Salzer et al (2010) [32]	Unmoderated, closed internet listserve (peer-to-peer group)	• Support and emotional experiences shared by participants without professional structure	Review of information on a cancer-related website	12 months (baseline, 4 months, and 12 months)	• FACT-B[a] • SESES-C[b] • HSCL-25[c] • IES[d] • POMS[e] • HHI[f] • MOS-SSS[g]	• No significant differences in QoL[h], self-efficacy, hope, cancer-specific stress, and social support between groups • Psychological distress and mood improved in CG[i]
Ryhänen et al (2013) [33]	Internet-based breast cancer patient pathway portal	• Education program which includes flow chart diagram of the patient pathway during breast cancer treatment, from diagnosis through surgery, chemotherapy, and follow-up	Usual care	9 months (baseline, surgery, after surgery, meeting with oncologist, before and after chemotherapy, before and after radiotherapy, and 12 months postdiagnosis)	• QoL Scale Breast Cancer[j] • STAI[k] • Own questionnaire of side effects	• No significant differences in QoL, anxiety, or side effects between groups. • Anxiety decreased in both groups
White et al (2018) [34]	"Information for Me" website	• Information resources on diagnosis, surgery, chemotherapy, radiotherapy, and survivorship, emotional responses, and support services	Usual care	6 months (baseline, 3 months, and 6 months)	• FACT-B • HADS[l] • SCNS-BC[m]	• General QoL showed an improvement in the IG[n] than the CG at 3 months, but not at 6 months • No significant differences between groups in anxiety, depression, QoL specific, and unmet needs
Zhu et al (2018) [35]	Breast cancer e-Support app	• Learning, discussion, ask-the-expert, and personal stories forums moderated by health care professionals	Usual care	3 months (baseline, 3 months, and 6 months follow-up)	• FACT-B • SICPA[o] • HADS • MDASI[p] • MSPSS[q]	• At 3 months, QoL, self-efficacy, and social support improved in IG • At 6 months, no significant differences were observed between the groups

XSL•FO
RenderX

Author and year	Intervention group	Contents	Control group	Intervention duration (data collection points)	Instrument of measurement	Results
Wang et al (2022) [36]	Internet-delivered mindfulness-based cancer recovery program delivered through WeChat	• Mindfulness techniques including body scan, mindful breathing, self-compassion, integrating mindfulness into daily life, materials, and audios provided	Usual care with health education on managing cancer symptoms, therapy side effects, diet, and exercise	1 month (baseline, postintervention, and 1-month follow-up)	• FACT-B • MDASI	• Significant improvements in QoL and symptom burden in the IG compared to the CG. Emotional distress decreased only at postintervention, but not at 1 month follow-up
Zhang et al (2022) [37]	VR-CALM[r] virtual reality–based psychotherapy intervention for symptom management	• Psychological support (symptom management, self, relationships, meaning, spirituality, and future hope)	Usual care	3 months (baseline and 3 months)	• FACT-B • DT[s] • SAS[t] • SDS[u] • CARS[v] • PFS[w] • PSQI[x]	• QoL, distress, anxiety, depression, fatigue, and sleep outcomes favored the VR-CALM group after the intervention
Singleton et al (2023) [38]	EMPOWER-SMS text messages delivered	• Physical activity, healthy diet, social and emotional well-being, endocrine therapy adherence, and side-effects management	Usual care plus 1 welcome SMS and 1 follow-up interview reminder SMS	6 months (baseline and 6 months)	• EORTC QLQ-C30[y] or EORTC QLQ-BR23[z] • SEMCD[aa] • DASS-21[ab] • GPAQ[ac] • Own self-reported endocrine therapy adherence • BIPQ[ad] • BMI	• No clear between-group differences were observed for QoL, self-efficacy, depression, anxiety, stress, physical activity, BMI, or body composition. Therapy adherence improved in IG
Bahçaci et al (2024) [39]	Tele-rehabilitation-based relaxation exercises delivered via WhatsApp	• Jacobson's progressive relaxation focusing on muscle relaxation with breathing exercises	Relaxation exercise brochure	1.5 months (baseline and 1.5 months)	• EORTC QLQ-C30 • BPI[ae] • HADS • FIS[af] • FACT-Cog[ag] • PSQI	• IG showed a significant improvement in QoL (symptom scale), depression, anxiety, sleep quality, and cognitive function. Fatigue and pain decreased in IG
de Aviz et al (2024) [40]	Asynchronous telerehabilitation via messaging app	• Exercise videos focusing on shoulder mobility, strength, and aerobic activity	Usual care	1.5 months (baseline, day 15, and 1.5 months)	• FACT-G[ah] • FACIT-F[ai] • VAS[aj]	• QoL showed significant enhancement in IG • Fatigue and pain were significantly reduced in the IG

XSL•FO
RenderX

Author and year	Intervention group	Contents	Control group	Intervention duration (data collection points)	Instrument of measurement	Results
Graetz et al (2024) [41]	Mobile app	• App: symptom and medication adherence monitoring, with weekly symptom reporting and alerts to the oncology team • App and feedback weekly tailored text messages	Usual care	6 months (baseline and 12 months)	• SF-12[ak] • PROMIS SEMS[al] • FACT-ES[am] • CPPPA[an] • Own self-reported adherence therapy	• QoL, self-efficacy, and symptom burden with no significant differences between groups • App and feedback group showed decreases in total and high-cost health care encounters and office visits
Okuyama et al (2024) [42]	ePRO monitoring app	• PRO-CTCAE symptoms (insomnia, joint pain, headache, anxiety, and hot flashes) plus daily status/medication; staff followed up as needed	Usual care	3 months (baseline and 3 months)	• FACT-B/B-TOI[ao] • EORTC QLQ-CO-MU26[ap] • PRO-CTCAE	• No significant differences in QoL and communication between health providers • High ePRO response maintained to week 10
Rigg et al (2024) [43]	Finding My Way-Advanced: self-directed online CBT-based program (website)	• Managing fear of progression, emotional distress, and physical symptoms with role functioning and social support	Usual care	1.5 months (baseline and 1.5 months)	• QLQ-C30 • DASS-21 • FOP[aq] • SCNS - Short Form • PTSD Symptom Scale-Self Report[ar] • SCNS	• QoL and role functioning, cancer-specific distress, and fear of progression showed improvements in the IG • Mental QoL, general distress, and social functioning deteriorated in the IG vs CG
Salman Saraç et al (2024) [44]	"Breast Cancer Surgery Information Guide" informative mobile app	• Surgery, treatment, and recovery information. It contained videos, text, and reminders	Routine clinic care/training only; no app	1 month (baseline and 3 weeks after surgery)	• FACT-G • HAD-A only anxiety • NCCN-DT-PL[as]	• QoL showed no significant differences between groups. Anxiety and distress showed significant reduction in IG
Pang et al (2025) [45]	iCareBreast mobile app	• Perioperative care guidance, breast cancer education, psychological support, and social support	Usual care with educational pamphlets	29 days around surgery; measures at T0, T1, T2 (baseline, 2 weeks post surgery, and 2.5 months follow-up)		

XSL•FO
RenderX

Author and year	Intervention group	Contents	Control group	Intervention duration (data collection points)	Instrument of measurement	Results
					• EORTC QLQ-BR23 • GSES[at] • HADS • MFSI[au] • Own Perioperative Care Satisfaction Scale.	• No clear between-group differences were observed for QoL, self-efficacy, anxiety, depression, and fatigue at follow-up. Satisfaction was higher in the IG at the final assessment, but the between-group difference was not statistically significant
Geng et al (2024) [46]	"Breast Care" app combined with tailored SMS-based physical activity support	• Physical activity intervention based on social cognitive theory, self-efficacy theory, and the theory of planned behavior, with personalized goals, self-monitoring, feedback, tailored messages, and support	Usual care plus printed educational material, face-to-face health education during chemotherapy visits	3 months (baseline and postintervention assessment at 3 months)	• FACT-B • HADS; IPAQ-SF[av]	• At 3 months, QoL and anxiety favored the IG, mainly because outcomes deteriorated in the CG; no significant within-group improvement was observed in the IG

Primary Outcome

The reviewed articles all delivered interventions that had the goal, either primary or secondary, of improving QoL, consistent with the inclusion criteria. All included studies assessed QoL as either a primary or secondary outcome, in accordance with the eligibility criteria. The studies used both breast cancer–specific and generic validated QoL instruments. FACT instruments were used in 9 (60%) studies [32,34-37,40,42,44,46], European Organisation for Research and Treatment of Cancer Quality of Questionnaire–Core 30 (EORTC QLQ-C30) or European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire–Breast Cancer Module 23 (EORTC QLQ-BR23) instruments in 4 (26.7%) studies [38,39,43,45], the Quality-of-Life Instrument–Breast Cancer Patient Version in 1 study [33], and the Short Form 12-Item Health Survey (SF-12) in 1 study [41]. Where studies used multiple QoL-related instruments, classification was based on the measure covering the broadest range of QoL dimensions; therefore, the single-domain FACT-Cog [39] and FACT-ES [41] subscales were excluded from the FACT tally to avoid double-counting. Following the SWiM approach, findings were summarized by the direction of effect rather than by statistical significance alone. Seven [34-37,39,40,43] of the 14 RCTs [32-45] showed a favorable direction of effect, whereas the remaining RCTs showed no clear between-group benefit or mixed findings [32,33,38,41,42,44,45]. The controlled quasi-experimental study also favored the intervention group, although this primarily reflected less deterioration relative to the control group rather than a clear within-group improvement [46]. Favorable effects appeared more frequently among interventions containing active therapeutic, behavioral, or rehabilitation components. However, because intervention formats, populations, and comparators differed substantially, this pattern should be regarded as exploratory rather than evidence of a moderating effect. Overall, the randomized evidence suggested a possible short-term benefit for QoL, with low certainty.

Other Outcomes: Self-Efficacy

Self-efficacy was assessed in 5 [32,35,38,41,45] out of the 15 (33.3%) studies [32-46] using different validated instruments. In this regard, general self-efficacy was measured using the General Self-Efficacy Scale (GSES) in 1 study [45]; cancer-specific self-efficacy was measured in 2 studies through the Stanford Emotional Self-Efficacy Scale – Cancer (SESES-C) [32] and the Stanford Inventory of Cancer Patient Adjustment (SICPA) [35]; self-efficacy for symptom management was assessed with the Patient-Reported Outcomes Measurement Information System (PROMIS) Self-Efficacy for Managing Symptoms (SEMS) [41] and the Self-Efficacy for Managing Chronic Disease Scale (SEMCD) in another study [38]. These tools were designed to assess participants' confidence in managing various aspects of their health, such as fatigue, emotional distress, and treatment-related challenges. Regarding effectiveness, the direction of effect favored the intervention in only 1 of the 5 trials. In that study, the professionally moderated Breast Cancer e-Support intervention improved cancer-related

XSL•FO
RenderX

self-efficacy at 3 months, but the effect was not maintained at 6 months [35]. The remaining studies showed no clear between-group benefit. The certainty of evidence for self-efficacy was very low (Multimedia Appendix 3).

Anxiety, Depression, and Emotional Distress

Anxiety was assessed in 11 (73.3%) out of the total selected studies [33-35,37-39,42-46] and was most commonly measured with the HADS-A, used in 6 studies [34,35,39,44-46]. Additionally, the Self-Rating Anxiety Scale (SAS) was used in 1 study [37], the Depression Anxiety and Stress Scale (DASS-21) in 2 studies [38,43], the State-Trait Anxiety Inventory in 1 study [33], and the anxiety item of the Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events in 1 study [42]. Depression, on the other hand, was assessed in 8 (53.3%) studies [34,35,37-39,43,45,46], using the HADS-D in 5 studies [34,35,39,45,46], the DASS-21 [38,43], and the SDS in 1 study [37]. Emotional distress was assessed in 6 (40%) studies using the Profile of Mood States (POMS) and Hopkins Symptom Checklist-25 (HSCL-25) [32], the MD Anderson Symptom Inventory [36], the Distress Thermometer [37,44], and the stress subscale of the DASS-21 [38,43]. The direction of effect favored the intervention in 5 [36,37,39,44,46] of 13 studies [32-39,42-46]. Four of the 12 RCTs favored the intervention, whereas the remaining RCTs showed no clear benefit, effects favoring the comparator, or mixed findings. In the quasi-experimental study, anxiety favored the intervention group at 3 months, although no clear within-group reduction was observed and depression did not differ between groups [46]. Overall, the findings were heterogeneous and generally limited to short-term follow-up. The certainty of the randomized evidence was low.

Acceptability

Regarding acceptability, only 4 studies reported information on this [38,43-45]. Two studies reported good acceptability among participants in the intervention groups [38,43]. Satisfaction was assessed in 2 studies [44,45]; however, one found no statistically significant between-group difference in perioperative care satisfaction [45]. Because acceptability and satisfaction were inconsistently defined and measured, no overall conclusion regarding intervention acceptability could be established.

Retention Rate

Regarding attrition, the lowest retention rate was 68.6% [43], whereas the highest rate was 100% [46].

Quality Appraisal

The RoB 2 assessment included only the 14 RCTs and is presented in Figure 2. No trial was considered to be at low overall risk of bias. Three trials were judged to be at high overall risk of bias, mainly because of missing outcome data [34,39,43], including a pilot trial with a 34% loss to follow-up and differences between those who completed the study and those who did not [43]. The remaining 11 trials raised some concerns. Concerns were identified regarding outcome measurement because the main outcomes were subjective and self-reported by participants who were aware of their allocation to the intervention, and this knowledge could have influenced their reports. Across domains, most studies showed an adequate randomization process (D1), with allocation concealment unclear in a few; deviations from the intended interventions (D2) were generally limited but unblinded; missing outcome data (D3) was the main driver of high risk, with insufficient retention or incomplete handling of attrition in several trials; and selection of the reported result (D5) raised few concerns, while outcome measurement (D4) was limited throughout by self-reported, participant-aware assessment.

The quasi-experimental study was assessed separately using ROBINS-I and was judged to have a serious overall risk of bias [46]. The main concerns arose from the nonconcurrent sequential allocation of the control and intervention groups, the absence of statistical adjustment for potential confounding, and the measurement of subjective self-reported outcomes in participants who were aware of their intervention assignment. Risk was judged to be low for intervention classification and missing data, moderate for participant selection, deviations from intended interventions, and selection of the reported result, and serious for confounding and outcome measurement.

XSL•FO
RenderX

Figure 2. Risk of bias of the randomized controlled trials (RoB 2) [32-45].

Certainty of the Evidence

The certainty of the evidence was rated for each outcome using the GRADE approach [26,27]. Starting from high certainty, the evidence was downgraded for risk of bias and inconsistency across studies. No randomized trial was judged to be at low overall risk of bias, and 3 were at high risk. Certainty was low for QoL and for anxiety, depression, and emotional distress, and very low for self-efficacy, for which the evidence base was small and the instruments were heterogeneous. These ratings indicate that the short-term benefits observed should be interpreted with caution. Further details on the certainty assessments are provided in Multimedia Appendix 3.

Discussion

General Overview

Considering the advancement of digital health interventions in their various forms, it is essential to conduct critical reviews of the existing evidence, focusing on studies with high-quality scientific designs. This systematic review aimed to analyze the published research on digital health interventions in women with breast cancer and critically evaluate the effectiveness of these interventions. Specifically, it assessed the effects of digital health interventions on QoL and other psychological and behavioral variables, such as self-efficacy, anxiety, and depression.

Principal Findings

QoL

With respect to QoL—the primary outcome of this review—the direction of effect favored the intervention in 8 [34-37,39,40,43,46] of the 15 studies [32-46], although the certainty of this evidence was low. Positive results were observed primarily in interventions such as digitally delivered mindfulness [36], VR-assisted psychotherapy [37] or via a website [43], telerehabilitation or guided relaxation [39,40], and a tailored mobile health (mHealth) physical activity intervention grounded in social cognitive theory (SCT), self-efficacy theory, and the theory of planned behavior (TPB) [46]. These interventions incorporated active therapeutic or behavioral components and, in most cases, some degree of professional guidance or personalized support. However, in the quasi-experimental study, total QoL did not significantly improve within the intervention group, and the between-group difference mainly reflected deterioration in the control group during chemotherapy, suggesting a relative preservation of QoL rather than a clear improvement attributable to the intervention; therefore, these findings should be interpreted cautiously given the nonrandomized design and serious overall risk of bias [46]. By contrast, passive interventions generally showed no clear between-group differences in QoL, with the exception of those incorporating health care team support through alert-triggered calls or professional moderation [35]. This trend has been corroborated by recent meta-analyses of digital interventions, which demonstrate that clinician-led support yields superior outcomes compared to stand-alone passive interventions [47-49].

Furthermore, improvements in QoL were primarily short-term. Follow-up beyond 6 months was uncommon, although 3 studies included assessments at or around 12 months [32,33,41], a duration generally recommended as a baseline for assessing the durability of effects and avoiding the overestimation of results [50,51]. This lack of longitudinal data, compounded by the complexity of the oncological process, where symptoms arising from both the cancer and its treatments converge, alongside factors such as digital fatigue due to the loss of the "novelty effect," the absence of continuous human interaction, and the limited integration of digital interventions into long-term daily routines, calls into question the long-term clinical relevance of these interventions [52-54]. These observations suggest that sustaining benefits beyond the initial intensive phase may require ongoing human support or periodic reinforcement rather than one-off, self-guided exposure. However, given the low certainty of the current evidence and the absence of trials directly comparing such strategies, the optimal format, intensity, and timing of reinforcement remain undetermined and should be examined in future research before specific recommendations can be made.

Self-Efficacy

Across the selected studies, few effects were reported. Only one article showed, among its results, improvements in self-efficacy through the use of a supportive mobile app, which were observed particularly at 3 months of using said application; however, such effects were not maintained over time, with no significant improvements at the 6-month assessment [35]. In all the other interventions conducted, those that incorporated SMS delivery [38], an unmoderated peer listserve via email [32], mobile apps for symptom monitoring [41], and perioperative support [45], no differences between groups were evidenced. The foregoing, according to recent literature [55,56], could originate in the conception of the intervention design, since self-efficacy, in accordance with SCT, is sustained by mastery experiences, gradual achievements, and continuous feedback [57]; therefore, the limited active support of the intervention may affect the confidence acquired by patients, which could ultimately explain both the null effects and, at the same time, their limited persistence over time.

Anxiety, Depression, and Emotional Distress

Of the total number of articles, 13 evaluated anxiety, depression, or emotional distress, yielding mixed results [32-39,42-46]; the direction of effect favored the intervention in a minority of them (5/13) [36,37,39,44,46], and the certainty of this evidence was low. In this regard, interventions that incorporated telerehabilitation based on relaxation exercises delivered through messaging apps [39] and psychotherapy via VR [37] showed significant reductions in anxiety, depression, or distress; while mindfulness delivered by messaging generated initial changes in emotional distress; however, the results did not persist at the 1-month follow-up [36]. Favorable effects on anxiety or distress were also observed with an informative mobile app [44] and a theory-based tailored mHealth physical activity intervention [46]; however, in the latter study, anxiety did not significantly decrease within the intervention group, and no between-group difference was observed for depression. By contrast, informational or self-guided interventions delivered via the internet or a website [33-35], empowerment message delivery [38], symptom monitoring [42], and perioperative support [45] did not show differences compared with the control group, while psychological distress and mood favored the control group in one study [32] and another study reported poorer outcomes in the intervention group [43], although its small sample size limits conclusions regarding efficacy.

The foregoing could be explained by the degree of immersion and interactivity of the digital tool used, insofar as psychotherapy via VR provides a multisensory stimulus that could be capable of interrupting the anxiety cycle [58]. In this sense, these findings are consistent with previous evidence [59], as well as with relaxation videos grounded in Mayer's modality

XSL•FO
RenderX

principle [60], whereby the induction of calm through videos replaces the cognitive load associated with reading with an immersive experience that facilitates emotional regulation. In contrast, informational and monitoring platforms may be insufficient to address the affective component, while, as observed in the mindfulness intervention, one-directional support via messaging yields benefits that are not maintained in the long term, because digital mental health depends on proactive human support [61,62]. Across outcomes, the level of human support emerged as a key interpretive axis: guided interventions—those embedding professional facilitation or interaction—were more consistently associated with favorable effects than unguided, self-directed formats, in line with evidence that human guidance enhances the impact of digital health interventions [63,64].

Strengths and Limitations

The main strength of this study lies in the predominance of RCTs, which represented 14 [32-45] of the 15 included studies [32-46], together with the inclusion of one eligible controlled quasi-experimental study in accordance with the predefined eligibility criteria. The inclusion of articles in English, Spanish, and Portuguese also expanded the knowledge base. The findings allow for a systematization of the current state of the art regarding the implementation of different types of digital health tools used to support women with breast cancer and their effects compared with standard care. Furthermore, this review underscores the need for the development of more rigorous randomized trials with greater statistical power in breast cancer populations throughout the entire oncological process.

Despite the contributions of this review, several limitations must be acknowledged. First, there was substantial heterogeneity in the measurement tools used to assess outcomes, which generated discrepancies in how QoL and other psychological variables were operationalized. Additionally, there was wide variability in the types of digital health interventions used, including mobile apps, text messaging, web-based platforms, and even VR devices. This variability extended to the technological formats, content, duration, level of human support, and timing of the interventions, limiting direct comparison across studies and reducing the ability to draw generalizable conclusions. Risk of bias was also a concern; no RCT was judged to be at low overall risk, and 3 trials were judged to be at high risk, primarily because of missing outcome data. The remaining trials raised some concerns, including concerns related to subjective, self-reported outcomes assessed by participants who were aware of their intervention assignment. The quasi-experimental study was judged to have a serious overall risk of bias and was therefore interpreted cautiously.

Finally, the search did not include MEDLINE or a systematic search of clinical trial registries or gray literature, which may have limited the retrieval of relevant or unpublished studies. Furthermore, the comparison between guided and unguided interventions was exploratory and based on indirect comparisons rather than a formal subgroup analysis.

Conclusion

Digital health interventions for women with breast cancer may provide partial and mostly short-term benefits in some domains of health-related QoL and emotional well-being. Favorable effects were more frequently observed in interventions containing active therapeutic components or professional support; however, this pattern was based on indirect comparisons across heterogeneous studies. Nevertheless, several caveats temper these findings. Acceptability was formally assessed in only a few studies, so it cannot yet be considered established; effects on self-efficacy and on anxiety, depression, and emotional distress were limited and inconsistent, and were generally not maintained over time. Moreover, the certainty of the evidence was low to very low because of concerns regarding risk of bias and inconsistency across studies. Taken together, these findings should be interpreted with caution: digital health interventions are a promising adjunct in this population, but current evidence does not yet support strong or generalizable conclusions. Future research should prioritize methodologically rigorous, adequately powered trials with longer follow-up, standardized outcomes, and attention to adherence and the role of human support.

Acknowledgments

Abstract

Background: Oral medications are commonly used in the treatment of breast cancer (BC), despite high rates of nonadherence. As adherence is fundamental for optimal treatment, finding ways to effectively improve it is important. Artificial intelligence (AI) is being widely applied to health care.

Objective: This review aims to offer an overview of the contribution of AI to medication nonadherence among patients with BC, suggesting future research directions, and highlighting existing gaps.

Methods: Four databases (PubMed, Embase, Scopus, and Web of Science) were searched. Studies were eligible if they used AI to predict, monitor, or support medication adherence in patients with BC, were published in English, and had full text available. Reviews, conference abstracts, editorials, and studies with mixed samples were excluded. This review was conducted following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines and was registered in PROSPERO (International Prospective Register of Systematic Reviews) database (CRD42024587020). The risk of bias was evaluated using the PROBAST (Prediction Model Risk of Bias Assessment Tool) and the Downs and Black's methodological quality scale.

Results: Ten studies were included in this review. Most of them (k=9) focused on developing machine learning models to predict medication nonadherence. These studies used a range of techniques, including logistic regression, artificial neural networks, and random forests. Model performance varied widely, with area under the receiver operating characteristic curve values ranging from 0.61 to 1.00. Predictors of nonadherence were clustered into 4 groups: clinical, disease, and treatment-related factors (eg, side effects and comorbidities); behavioral factors (eg, prior nonadherence); psychosocial factors (eg, quality of life and self-efficacy); and sociodemographic factors (eg, age and income). The only intervention study identified evaluated an AI-based chatbot and reported promising results, showing a 20% increase in adherence among participants who engaged with its reminder feature. All included studies were at high risk of bias, mainly due to the absence of model calibration or insufficient reporting, and their findings should therefore be interpreted with caution. A further limitation was the lack of attention to implementation: predictive accuracy alone is insufficient, and future work must also address actionability, safety, and cost-effectiveness to enable real clinical use. Progress in this area will require coordinated efforts among researchers, developers, clinicians, and policymakers to support the responsible development and implementation of these tools into routine care.

Conclusions: To our knowledge, this is the first systematic review of AI applications specifically targeting medication adherence in BC. It focuses on both predictive and interventional studies, mapping current AI applications within this specific clinical context. The findings highlight gaps in the implementation phase and emphasize the need for future research integrating a coordinated, multidisciplinary approach involving researchers, AI specialists, policymakers, and health care teams.

Trial Registration: PROSPERO CRD42024587020; https://www.crd.york.ac.uk/PROSPERO/view/CRD420251123188

Introduction

The use of oral antineoplastic agents has rapidly increased in cancer management over the last few decades, improving overall survival rates and offering the convenience of self-administered treatment [1-3]. While oral agents can enhance cancer care by giving patients greater autonomy and control over their treatment, they also demand active participation, adding complexity to an already demanding routine. Following a cancer diagnosis, patients must manage frequent hospital visits, lifestyle adjustments such as following a healthy diet and staying physically active, and now also adhering rigorously to an oral medication regimen, introducing an additional layer of responsibility [4,5]. Often, this occurs at a time when patients are psychologically and physically drained, having to deal with fear, worries, anxiety, and treatment side effects, all of which contribute to reduced quality of life [6] and further complicate the challenge of optimal medication adherence.

Medication adherence refers to the extent to which patients take their medications as prescribed by the health care provider, including the correct timing, frequency, and dosage [7]. The phenomenon of nonadherence is common across different patient populations, with estimates suggesting that approximately 50% of adult patients fail to achieve optimal adherence [8,9].

Adherence among patients with breast cancer (BC) has been reported to range from 33.3% to 88.6%, with an average decrease of 25% from the first to the fifth year of treatment [10]. Although these estimates span a wide range, they highlight that nonadherence is a significant concern in this clinical population. This is particularly alarming given its association with higher mortality rates, poorer clinical outcomes, and increased health care costs [11,12].

A wide range of factors may influence patients' medication-taking behaviors and contribute to nonadherence, including clinical factors (related to the disease and its treatment), psychosocial and behavioral aspects, sociodemographic characteristics (eg, age, geographic area, and income), and health care system factors (eg, the quality of the patient-provider relationship) [9,13]. Among these factors, commonly reported influences on treatment adherence in patients with BC include the presence of side effects associated with oral antineoplastic agents (eg, joint pain, hot flushes, depression, and weight gain), patients' perceptions of the necessity of treatment or concerns about it, poor quality of the patient-provider relationship, and a lack of social, practical, or emotional support [13]. This overview highlights that adherence is a complex phenomenon, influenced by a diverse set of interrelated and multifaceted factors.

Given the scale of the problem and its negative consequences, improving adherence is essential. However, the various interventions proposed so far have shown only limited effectiveness, and the need for innovative solutions to predict and support medication adherence is still pressing [5,14-17]. Artificial intelligence (AI)–driven technologies, considering their significant advancements and efficiency across various domains [18,19], have the potential to play a key role in bridging this gap.

AI is an umbrella term commonly used to refer to those technologies that simulate complex human skills such as learning, creativity, decision-making, and problem-solving [20-22]. AI can be further characterized into subsets such as machine learning (ML), natural language processing (NLP), and generative artificial intelligence (GenAI) [20].

ML refers to a class of algorithms that are trained on data to automatically learn and improve their performance over time. These algorithms are typically easy to interpret, perform effectively on small to medium-sized datasets, and require relatively short implementation times. Deep learning (DL), a subset of ML, provides more advanced capacities to handle large and complex datasets. However, DL models typically require greater computational resources and involve longer training times due to their multilayered and complex architectures. Moreover, these models are more challenging to interpret compared to traditional ML approaches. Despite these constraints, DL has demonstrated notable results in tasks such as image recognition, cancer subtype classification, and clinical decision-making [23,24]. A particularly relevant application of ML and DL is predictive modeling, a process in which computational analyses are used to generate predictions about the occurrence of specific events or outcomes. ML-powered predictive models have been used in medicine and health care with promising results in areas such as clinical decision-making, disease progression prediction, and the identification of high-risk patients for early intervention [25].

NLP comprises a set of techniques used to process, understand, and sometimes generate human language [20]. NLP models are widely used in health care for tasks involving the processing of speech or text, such as sentiment analysis, screening of electronic health records, computer-aided diagnosis, and support for clinical decision-making [20,26,27].

GenAI is a subset of AI that leverages ML models and NLP techniques to generate content in various formats, such as text, speech, and images. Conversational agents (also known as chatbots) are a widely adopted application of GenAI, leveraging ML and NLP to engage in dialogue, answer questions, provide suggestions, and perform a variety of tasks. In the health care domain, they have been used to deliver patient education, support treatment and monitoring, promote medication adherence, facilitate behavior change interventions, and assist in diagnosis [20,28].

Given its significant impact across various health care domains, such as screening, diagnostics, symptom management, personalized risk prediction, clinical decision-making, and patient engagement [29-32], AI may also represent a promising tool for addressing medication adherence in patients with BC. In this context, AI can contribute to 2 distinct yet interconnected aspects of the problem. First, it may directly support patients in sustaining adequate adherence, for example, when embedded in tools such as chatbots or eHealth platforms that can provide information, reminders, and tailored interventions. Second, AI can analyze large and complex datasets more efficiently than traditional statistical approaches [33], enabling the development of predictive models that identify patients at higher risk of nonadherence who may require timely, targeted support.

XSL•FO
RenderX

Although this second contribution does not act directly on patients' behavior, it remains highly relevant. Many health care systems operate under significant resource constraints, making it unrealistic to provide adherence-supporting interventions to all patients with BC. Prioritizing those most likely to benefit is therefore crucial. Thus, this systematic review aims to offer a comprehensive overview of AI-based approaches used to address medication nonadherence among patients with BC, either by predicting the risk of nonadherence or by monitoring and directly supporting adherence. To our knowledge, this is the first systematic review covering the wide range of AI capabilities addressing nonadherence in this population. Furthermore, the review offers suggestions for future research directions, highlighting open challenges and ethical considerations.

Methods

Study Design

This systematic review was conducted following the PRISMA (Preferred Reporting Items for Systematic Literature Reviews and Meta - Analysis) guidelines [34]. The PRISMA checklist is presented in Checklist 1. This review was registered in the PROSPERO (International Prospective Register of Systematic Reviews; CRD42024587020) after conducting the initial database search. A protocol for the review was not prepared.

A meta-analysis was not performed due to substantial heterogeneity, specifically a high degree of clinical and methodological diversity across studies, including differences in study design, AI techniques, and in the operationalization and measurement of medication adherence. All these factors made the statistical pooling inappropriate and potentially misleading.

Search Strategy

Overview

A search strategy was developed and reported in accordance with the PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses literature search extension) guidelines [35]. The search was conducted by 2 authors (MP and VV) in the following databases: Scopus (Elsevier), PubMed (National Library of Medicine), Embase (Elsevier), and Web of Science Core Collection (Clarivate). No language, publication date, or other search restrictions were applied.

The keywords revolved around three core review terms: (1) adherence, (2) BC, and (3) AI (see Multimedia Appendix 1 for the complete search strategy). Studies published until February 4, 2026, were captured.

Inclusion and Exclusion Criteria

Studies were considered eligible when (1) they reported on any AI technology (eg, ML, DL, NLP, and GenAI) being used to predict, monitor, or support oral medication adherence, (2) they involved a patient with BC sample, (3) the paper was written in English, and (4) the full text was available online. Reviews, conference abstracts, and editorials were excluded. Additionally, studies with mixed populations where it was impossible to separate the results of patients with BC were excluded.

Screening

The screening was organized in Rayyan software: a web and mobile tool for reviews [36], which was also used to identify and remove duplicate records before screening. Both title or abstract and full-text screening were conducted by 2 researchers (MP and VV) in "blind mode" (ie, researchers were unaware of each other's decisions). After the initial screening (title or abstract), MP and VV read the full text of the retrieved papers that met the inclusion criteria to confirm their relevance. Discrepancies in the judgments during both title or abstract and full-text screening were sent to a third author (IC), and disagreements were settled by discussion until reaching a consensus.

Data Extraction and Summary

Data were extracted using a shared, standardized table developed jointly by MP and VV at the outset of the review, which was applied consistently across all studies. For each included paper, relevant characteristics and results were extracted and inserted into the spreadsheet. The extracted data were authors, title, year of publication, country, study design, aim, sample size, AI subtypes and algorithms, adherence measure, and results.

For studies describing the development of ML predictive models, information on predictors, model performance metrics, and types of validation was also extracted. Performance was summarized using discrimination measures, including the area under the receiver operating characteristic curve (AUC), F_1-score, concordance index (C-index), and accuracy.

In this paper, because the 2 types of evidence differ substantially, separate Results and Discussion sections were developed to present findings from studies describing the development of ML predictive models and from the single intervention study identified.

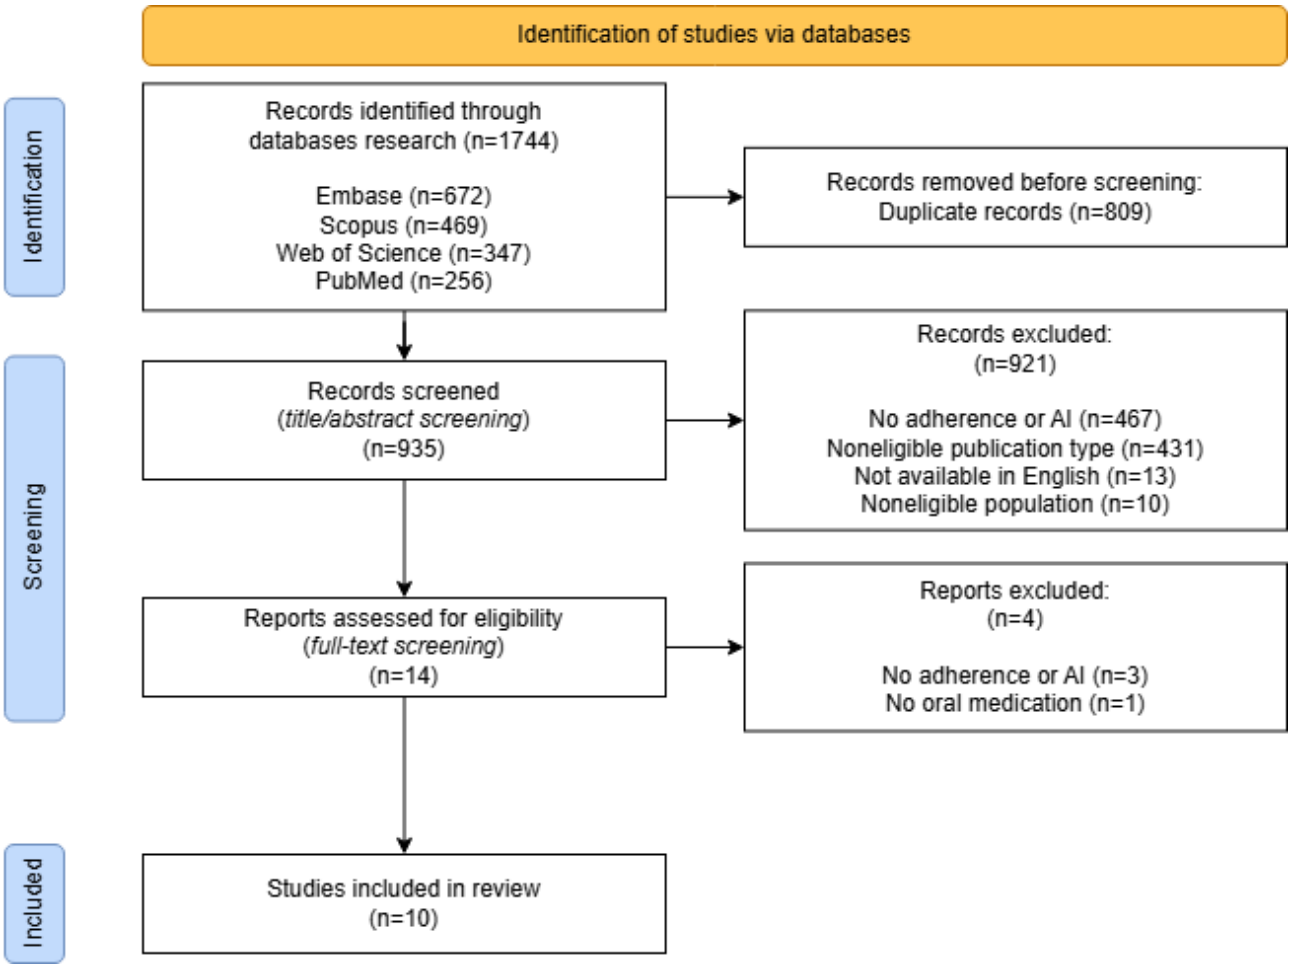
The data were extracted by 2 authors (MP and VV) and checked by 2 researchers (IC and CM). Formal interrater agreement was not assessed.

Risk of Bias Assessment

For studies describing the development of ML predictive models, the risk of bias was assessed using the PROBAST (Prediction Model Risk of Bias Assessment Tool) [37]. PROBAST evaluates the risk of bias in predictive modeling studies through 20 signaling questions distributed across 4 domains: participants, predictors, outcome, and analysis. In addition, it assesses concerns regarding the applicability of the predictive models in the domains of participants, predictors, and outcome.

Conversely, the risk of bias in the study describing the implementation of an intervention to support patients with BC was evaluated with Downs and Black's methodological quality scale [38]. This scale comprises 27 items and provides a score on 5 different methodological quality dimensions: reporting bias, external validity, internal validity, confounding - selection bias, and statistical power.

XSL•FO
RenderX



The risk of bias assessment was conducted by 2 authors (MP and VV), and disagreements were resolved by discussion until reaching a consensus.

Results

Summary of Study Characteristics

The search returned a total of 1744 papers. After duplicate removal and screening of titles and abstracts, 14 studies were considered eligible. After screening the full text, 10 of them met our inclusion criteria (see Figure 1 for a detailed flowchart of the screening process).

Figure 1. PRISMA flowchart illustrating the selection of studies included in this review. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

The included studies were published between 2019 and 2025. Most of them were conducted in the United States (k=5) and Europe (France: k=3; Italy: k=1), with 1 study carried out in Taiwan. Both early-stage BC stages (k=5) and metastatic patients (k=2) were represented in different studies, and 3 studies did not report patients' cancer stages. The sample sizes of the studies ranged from 18 to 229,695.

Adherence was measured using administrative health data or medical records (k=4), self-report measures (k=3), and medication event monitoring systems (k=3).

A total of 9 of the included studies described the development of ML predictive models (7 retrospective cohort studies, 1 prospective study, and 1 randomized controlled trial protocol), while only 1 prospective study described the implementation of an AI-powered intervention to support oral medication adherence.

The key characteristics of the included studies are summarized in Table 1, while Table 2 provides an overview of the AI-based predictive models and adherence support intervention.

XSL•FO
RenderX

Table . Key characteristics of the included studies, including author, year, title, country, design, study aim, sample size, and adherence measures.

Author	Year	Title	Country	Design	Aim	Sample size	Adherence measure
Balazard et al [39]	2023	Adjuvant endocrine therapy uptake, toxicity, quality of life, and prediction of early discontinuation.	France	Retrospective cohort study	To develop a prediction model of early ET[a] discontinuation.	BC[b], stage I-III (descriptive analyses, n=6488; model development, n=5282; training set, n=4225; validation set, n=1057)	Patients' self-declarations recorded in electronic case report forms.
Chaix et al [40]	2019	When chatbots meet patients: one-year prospective study of conversations between patients with breast cancer and a chatbot.	France	Prospective study	To evaluate 1 year of conversations between patients with BC and a chatbot.	BC, stage N/A[c] (n=958; adherence measurement, n=33)	Answers to the chatbot's reminder messages were used to measure adherence rates.
Kaur et al [41]	2025	A computational framework for longitudinal medication adherence prediction in breast cancer survivors: a social cognitive theory based approach.	United States	Retrospective cohort study	To predict daily and weekly adherence by integrating static and dynamic factors.	BC, stage I-III (n=32)	Medication event monitoring system.
Kaur et al [42]	2021	Theory-guided randomized neural networks for decoding medication-taking behavior.	United States	Retrospective cohort study	To predict daily medication-taking behavior over 3 time points (baseline, 4 months, and 8 months).	BC, stage I-III (n=32)	Medication event monitoring system.
Kuo et al [43]	2022	Using data mining technology to predict medication-taking behaviour in women with breast cancer: a retrospective study.	Taiwan	Retrospective cohort study	To predict long-term AHT[d] adherence and persistence.	BC, stage n.a. (n=385)	Clinical registry and medical records (MPR[e]>80%).
Masiero et al [44]	2023	A machine learning model to predict patients' adherence behavior and a decision support system for patients with metastatic breast cancer: protocol for a randomized controlled trial. Table . Summary of AI[a]-based predictive models and adherence-support interventions, detailing technologies and algorithms used, predictors, performance metrics, validation approaches, intervention features, and main results. Higher values of AUC[b], accuracy, and C-index[c] indicate better predictive performance.

Author	Year	AI technologies/algorithms	Predictors	Performance metrics	Validation	Intervention	Results
Balazard et al [39]	2023	ML[d]/L2-penalized Cox regression, gradient boosted trees with a Cox partial likelihood	Discontinuation of ET[e], QoL[f], physical functioning, role functioning, social functioning, emotional functioning, cognitive functioning scores, mastectomy and radiotherapy, fatigue, pain, dyspnea, insomnia, systemic therapy side effects, breast symptoms, and arm symptoms.	C-index (0.60 - 0.64).	Internal (nested cross-validation and held-out validation set)	N/A[g].	Patients who have already discontinued an ET after primary treatment were more likely to discontinue ET definitively; higher QoL, physical functioning, role functioning, social functioning, emotional functioning, cognitive functioning scores, and receiving mastectomy and radiotherapy were associated with lower rates of early ET discontinuation; fatigue, pain, dyspnea, insomnia, systemic therapy side effects, breast symptoms, and arm symptoms were associated with a higher rate of early ET discontinuation.
Chaix et al [40]	2019	ML/N/A	N/A.	N/A.	N/A	A chatbot that interacts with users by simulating a human conversation through text was designed to empower patients and answer their questions with personalized insights.	The overall satisfaction was 93.95% (900/958). The average compliance of patients using the medication reminder feature improved by more than 20%.
Kaur et al [41]	2025	DL[h]/long short-term memory, feed-forward neural networks, SHAP[i]	Medication-taking behavioral patterns, symptom burden, perceived susceptibility, decision regret, and medication-taking self-efficacy.	Accuracy (87.25; 76.04), precision (92.04; 75.83), recall (93.15; 85.8), and specificity (77.5; 72.3).	Internal (nested cross-validation)	N/A.	The models showed strong predictive performance, outperforming traditional ML models across all evaluated performance metrics in the daily model, and in terms of accuracy, recall, and specificity in the weekly model.

Author	Year	AI technologies/algorithms	Predictors	Performance metrics	Validation	Intervention	Results
Rattsev et al [45]	2024	ML/Cox proportional hazards, random survival forest, penalized Cox proportional hazards, gradient boosted models, and SHAP	Genetic markers, disease stage, sleep disturbance, anxiety, depression, previous taxane therapy, fatigue, age, self-reported adherence, endocrine symptoms, physical function, BMI, and joint pain.	Mean AUC (0.57 - 0.66), integrated Brier score, time-dependent AUC, sensitivity, specificity, and positive predictive values.	Internal (cross-validation)	N/A.	The results indicated that integrating genomic and longitudinal features enhances the model's predictive performance, thereby potentially facilitating the identification of patients at risk of early discontinuation.
Rinder et al [46]	2024	DL/gated-recurrent unit network, feed-forward neural network, and SHAP	Age (>70 y), past nonadherence, taking more than 1 treatment in the previous 3 months, and low income were predictors of nonpersistence. The predictors of nonadherence were similar, adding age (<50 y) and irregular intervals in treatment purchases.	AUC (0.71 - 0.73).	Internal (held-out validation set)	N/A.	The model was able to estimate the risk of nonpersistence and nonadherence among French female patients with localized BC and identified that some factors (age, past behavior, and number of treatments) may be associated with the risk of nonpersistence and nonadherence.
Yerrapragada et al [47]	2021	ML/logistic regression, boosted logistic regression, random forest, feed-forward neural network models	Patient features (55 y or older at treatment start, receiving care in the South, being a surviving spouse), pretreatment procedures (lymphatic nuclear medicine, radiation oncology, arterial surgery, microbiology, and imaging) or therapy (β-blockers, antidepressants, and stimulants), and baseline comorbid diagnoses (upper respiratory disease, breathing abnormality, dorsopathy, neurotic disorders, cerebrovascular disease, abdominal pain, and genital disorders).	AUC (0.61 - 0.64), F_1-score (0.59 - 0.62), sensitivity, and specificity.	Internal (cross-validation)	N/A.	All models had poor predictive accuracy. Logistic regression (AUC=0.64) was interpreted with 94% sensitivity (95% CI 89 to 92) and 0.31 specificity (95% CI 29 to 33). The model accurately classified adherence (negative predictive value 89%) but failed in discriminating nonadherence (positive predictive value 48%).

Predictive Models

Most of the included studies (n=9) described the development of ML predictive models [39,41-48]. By feeding ML algorithms with diverse types of patient data, these models aim to offer predictions about which patients are more likely to become nonadherent or to face issues related to medication-taking along their care journey.

Only 2 studies [39,45] developed regression models, using a numerical outcome of interest: the time from treatment initiation to discontinuation. All other studies focused on classification models, defining adherence as a categorical variable and aiming to predict which patients may experience difficulties with medication adherence.

Overall, the performance metrics (ie, AUC, C-index, F_1-score, and accuracy) ranged from poor to excellent (see Table 3 for a summary of the model performance, excluding post hoc analyses).

Several diverse ML algorithms were implemented. Balazard et al [39] evaluated the performance of 2 complementary ML models: L2-penalized Cox regression and gradient boosted trees with a Cox partial likelihood. The models showed similar performance with C-indexes ranging from 0.60 to 0.64. They were first validated internally using nested cross-validation on the training set, and the best-performing model was then evaluated on the held-out validation set.

Yerrapragada et al [47] trained and evaluated 4 models: logistic regression, boosted logistic regression, random forest, and feed-forward neural network. The models were internally validated using 10-fold cross-validation and showed poor performance with AUC ranging from 0.61 to 0.64 and F_1-scores ranging from 0.59 to 0.62 [49]. The authors then applied a post hoc balancing technique, the synthetic minority oversampling technique; the evaluation after the refitting showed an improvement in the performance of the random forest model (AUC 0.93, F_1-score 0.78) and the feed-forward neural network model (AUC 0.79, F_1-score 0.71).

Kuo et al [43] developed an ensemble learning scheme by applying 3 ML models: multiple logistic regression, decision trees, and artificial neural networks. All models demonstrated high performance, with AUC values ranging from 0.90 to 1.00 and accuracy between 92.29% and 96.37%. However, the authors did not specify whether any validation method was applied to the models.

Kaur et al [42] designed a randomized neural network and compared its prediction performance (overall accuracy and individual accuracy) with that of a traditional neural network. The randomized neural network model outperformed the traditional one, achieving high accuracy levels (>0.92) both overall and at the individual level. Although the paper did not report any internal or external validation, the authors indicated their intention to perform leave-one-subject-out cross-validation to properly evaluate the developed model.

The same research group subsequently developed other DL models combining long short-term memory and feed-forward neural networks [41]. Specifically, they built a daily model to predict patients' medication-taking behavior for the following day and a weekly model to predict adherence over the following week. When compared with traditional ML approaches (ie, random forest, support vector machine, XGBoost [Extreme Gradient Boosting], and logistic regression), the proposed models demonstrated superior performance. For the daily and weekly models, respectively, accuracy reached 87.25 and 76.04, precision 92.04 and 75.83, recall 93.15 and 85.8, and specificity 77.5 and 72.3. With regard to internal validation, the study adopted a nested 5-fold cross-validation approach. In addition, the contribution of individual predictors was examined using SHAP (Shapley Additive Explanations) values.

Rinder et al [46] developed a DL predictive model by combining a recurrent neural network and a feed-forward neural network. The model demonstrated satisfactory predictive performance, with an AUC of 0.71 for persistence and 0.73 for adherence. Internal validation was performed using a 60:20:20 train-validation-test split. Once again, SHAP values were analyzed to gain insights into the specific factors' contributions to the model's outcomes.

Masiero et al [44] developed ML predictive models currently undergoing evaluation in a randomized controlled trial involving patients with metastatic BC. The predictive models were developed by applying NLP techniques to an electronic health

XSL•FO
RenderX

record dataset, and they will be further optimized by feeding newly collected data during the randomized controlled trial. The models' predictive performance was evaluated with several metrics (AUC, precision, recall, sensitivity, specificity, κ, and positive and negative predictive values), but the results of the evaluation are not reported. The predictive models use Shapley values for interpretability, allowing the evaluation of how much each specific risk factor contributes to the given prediction.

Yuan et al [48] developed a 2-tier DL ensemble to predict daily adherence. At tier 1, long short-term memory models and tree-based regressors (ie, random forest, XGBoost, and LightGBM [light gradient boosting machine]) were trained. At tier 2, the outputs of these models were integrated using an optimized soft-voting strategy. The resulting multimodal model predicted adherence more accurately than single-modality models, achieving a balanced accuracy of 0.84 and an F_1-score of 0.88. The model was validated using leave-one-participant-out cross-validation, and its predictors were interpreted using SHAP analysis.

Finally, Rattsev et al [45] developed a survival ML model to predict time-to-discontinuation of aromatase inhibitors. The predictive framework was based on 4 survival ML algorithms: Cox proportional hazards, random survival forest, penalized Cox proportional hazards, and gradient boosted models. The results indicated that incorporating genetic markers and follow-up data improved model performance; however, overall discrimination remained modest, with a mean time-dependent AUC of 0.65 and AUC values of 0.71 and 0.67 at 6 and 12 months, respectively. As in the previous studies, SHAP values were used to examine the relative importance of individual features.

Predictors of Nonadherence

The studies describing the development of predictive models using ML identified several predictors of nonadherence. These can be categorized into four groups: (1) clinical, disease-, and treatment-related factors; (2) behavioral factors; (3) psychosocial factors; and (4) sociodemographic factors.

Among clinical, disease-related, and treatment-related factors, the presence of side effects or symptoms [39,41,45,48], complex drug regimens [46,47], comorbidities [47], and low BMI [43] were identified as predictors of nonadherence. Likewise, an increase in BMI was associated with decreased risk of discontinuation [45]. In addition, prior taxane therapy was associated with a higher risk of discontinuation, whereas specific genetic markers and more advanced disease stages were associated with a lower risk [45]. Contradictory results were identified regarding some treatment-related variables. One study found that a history of pretreatment radiotherapy or diagnostic imaging procedures was associated with higher nonadherence [47], whereas another study reported that a recent mastectomy or radiotherapy was associated with increased adherence [39].

Behavioral factors associated with nonadherence included a history of previous nonadherence [39,46], a longer time since treatment initiation, and longer durations of treatment discontinuation episodes [43]. In line with these findings, higher levels of self-reported adherence were associated with a lower risk of discontinuation [45]. Moreover, recent medication-taking patterns were also relevant: adherence on the previous days or during the preceding weeks, as well as consistently taking the medication at the same time each day over the course of a week, was predictive of subsequent adherence [41,45,48].

Psychosocial factors associated with higher adherence included better quality of life [39,42], improved physical, role, social, emotional, and cognitive functioning [39], and greater social support Yuan et al [48]. Moreover, patients' knowledge, attitudes toward medicines [42], self-efficacy in managing medication [41,42], perceived susceptibility to cancer recurrence, and decision regret were identified as predictors of medication-taking behavior [41]. In contrast, baseline depression and sleep disturbance [45], as well as self-reported sadness [48], were associated with a higher predicted risk of nonadherence. Findings regarding anxiety were inconsistent: Rattsev et al [45] reported that higher baseline anxiety was associated with a lower risk of discontinuation, whereas Yuan et al [48] found that higher anxiety was associated with an increased risk of nonadherence.

Finally, among sociodemographic factors, age was the most commonly reported predictor of adherence. Nonadherence was found to be more prevalent among patients at the extremes of the age spectrum, affecting both younger (age <50 y) [43,46] and older individuals (age >65-70 y) [43,45-47]. In addition, lower income [46], being a surviving spouse, and receiving treatment in certain geographic areas [47] were also associated with nonadherence.

Intervention Supporting Medication Adherence

Only one of the included studies described the implementation of an intervention that specifically aimed at supporting adherence by patients with BC to oral medication [40]. The authors developed an ML-based chatbot that provides personalized information via text and supports treatment management. Patients found the chatbot helpful and supportive (with an overall satisfaction rate of 93.95%) and engaged with it frequently. One of its features was a reminder function that patients could easily activate. Although 958 patients participated in the study, only 33 (3.44%) activated the reminder function for a sufficient duration to allow adherence analysis. The authors reported that these patients showed a significant increase in adherence, with a 20% increase in compliance (P=.04) among those who used the reminder function.

Risk of Bias

A summary of the risk of bias and applicability assessment is presented in Table 4.

XSL•FO
RenderX

Table . Risk of bias assessment of the included prediction models using the PROBAST[a].

[a]PROBAST: Prediction Model Risk of Bias Assessment Tool.

[b]RoB: Risk of Bias.

All included studies reporting on ML predictive models demonstrated a high overall risk of bias. This classification followed the PROBAST assessment criteria, according to which a high risk in any single domain results in an overall high-risk rating. In this case, the overall high-risk classification was driven by the fact that all studies showed a high risk of bias in the analysis domain. This domain includes the assessment of analytical methods and statistical considerations, as inaccuracies in applying these components may lead to bias. Specifically, the included studies do not meet the prerequisites for a comprehensive evaluation of model performance, as they do not report calibration plots or tables, nor do they assess calibration using standard methods such as the Hosmer-Lemeshow test. According to PROBAST, both discrimination and calibration must be reported when assessing a predictive model. Discrimination reflects how well a model distinguishes between cases, but without calibration, the predicted probabilities may be unreliable, potentially resulting in inappropriate clinical decisions [37,50]. Rattsev et al [45] represent an exception, as they assessed model calibration using the Integrated Brier Score. Nevertheless, this study was also judged to be at high risk of bias in the analysis domain, given the low number of events per variable, which increases the risk of overfitting.

Other studies raised applicability concerns. It is important to clarify that the applicability section of PROBAST does not refer to the general applicability of the models, but rather to their relevance to the review question defined before conducting the PROBAST assessment [37]. In this case, the review question underlying the assessment concerns ML predictive models developed to predict adherence to oral medication in patients with BC. The models developed by Masiero et al [44] raised concerns in the outcome domain, as they do not directly predict adherence. Instead, they focus on two outcomes that are reportedly associated with adherence and are used to infer potential adherence issues: (1) short- and long-term side effects, and (2) physical status and comorbid conditions. A total of 6 additional studies raised concerns in the predictors domain [39,41,43,45,46,48]. All of these included some form of prior medication-taking behavior as a predictor in their models. However, by definition, such variables are not available at the start of treatment. This raises applicability concerns if the model is intended to be used at treatment initiation, as its predictions would rely heavily on predictors that are not yet available.

Finally, it is important to note that several specific items, and consequently some domains, were rated as “unclear” due to insufficient reporting of relevant information.

The methodological quality of the only included study describing an intervention to support medication adherence [40] was assessed using Downs and Black’s methodological quality scale [38], as PROBAST is not designed for evaluating studies that do not develop or validate predictive models. As reported in Multimedia Appendix 2, the prospective study scored low across all methodological quality dimensions of the scale, indicating a high risk of bias. In particular, the low score in the “reporting” domain (5/11) was mainly due to the inadequate reporting of patient characteristics, the distribution of key confounders, and some of the study findings. The lack of information about the participants resulted in a low score (0/3)

XSL•FO
RenderX

for external validity, as it was impossible to answer the scale's items. The internal validity score (3/7) was penalized due to the inherent nature of the intervention, which made it impossible to blind participants or researchers, and because the component related to medication adherence showed very low compliance. Regarding selection bias, the low score (1/6) was primarily attributed to the absence of randomization in the study design, and once again, to the lack of relevant information about the patients and potential confounders. Finally, the power of the analysis concerning patient adherence was deemed inadequate (score: 0/5), given the small sample of participants for whom adherence could be assessed.

Discussion

Principal Findings

This systematic review provides a comprehensive overview of how AI-based technologies are currently being used to address medication adherence among patients with BC. Across the 10 included studies, the predominant application of AI was the development of predictive models, as all but 1 study focused on this purpose. By synthesizing their findings, we were able to identify the main groups of predictors associated with nonadherence and to report the key characteristics and performance of each model. The only study that described an intervention was also examined, and its results were summarized. This process made it possible to highlight the limitations affecting current AI applications in this area, especially in light of the thorough risk of bias assessment performed.

Drawing on the findings synthesized, several observations regarding the current landscape and suggestions for desirable future developments can be made.

To begin with, the small number of publications identified (k=10), all published between 2019 and 2025, suggests that the application of AI technologies to predict or support medication adherence is both limited and relatively recent. Nonetheless, AI-driven models appear to hold promise in predicting medication-taking behaviors, identifying key determinants of adherence, and estimating the risk of nonadherence with increasing accuracy [41-43,46,48]. However, the analysis of the findings highlights persisting limitations and unresolved challenges, underscoring the need for further research to fully unlock the potential and enhance the impact of these technologies.

Predictive Models

We will begin by discussing the insights and observations emerging from the analyses of ML-based predictive models. First of all, the sample sizes of the included studies, except for the study by Rinder et al [46] using a sample size of 229,695, are similar to those used in predictive models using traditional statistical methods. This is a prominent point showing that AI's potential is not yet fully realized. The ability to process large datasets is one of AI's core strengths and could significantly enhance both the accuracy and robustness of predictive models [51,52]. A possible explanation for the sample sizes observed in the retrieved studies may lie in the need to strike an appropriate balance between sample size and the quality and relevance of the data available. Indeed, predictive models based on large datasets that include mainly irrelevant variables may still yield statistically significant results due to their size, yet prove clinically uninformative. It is crucial, therefore, not to conflate statistical significance with clinical relevance [53].

Furthermore, many of the predictors of medication nonadherence identified by AI-based models had already emerged in previous research using traditional statistical methods or qualitative approaches [10,54,55]. This convergence is to be expected, as the key contribution of AI does not lie in the discovery of new factors, but rather in enhancing analytical precision and uncovering complex interactions among multiple variables.

The predictive performance of AI models has been assessed using a range of metrics, including accuracy, sensitivity, specificity, AUC, the C-index, and the F_1-score. However, performance metrics alone may not be particularly informative and should be considered alongside additional parameters to ensure the accuracy of the predictions and guarantee their clinical usefulness [56,57]. For example, 4 studies that demonstrated "excellent" performance [41-43,48] had relatively small sample sizes (ie, n=18, n=32, n=32, and n=385), which could make the models less reliable. Moreover, even the most accurate predictive model holds little value if it lacks clinical actionability, namely, if its predictions are not translated into concrete interventions, or if its implementation is not cost-effective [56]. These crucial aspects were scarcely, if at all, addressed in the studies reviewed. Considering these aspects, the performance of the models should be interpreted with caution.

According to the PROBAST evaluation, all included studies exhibited a high overall risk of bias; this result was primarily driven by a high risk of bias in the analysis domain. In fact, although the models' discrimination performance was reported, the lack of calibration assessment exposes the predictive models to potential bias [37]. Discrimination indicates how well a model differentiates between cases, while calibration reflects how closely the predicted probabilities match the actual observed outcomes. For example, a poorly calibrated model might overestimate risk, leading to unnecessary interventions, or underestimate it, thereby missing high-risk patients who require support. This represents a major limitation, as models that are not calibrated may produce unreliable probability estimates, potentially leading to inaccurate clinical decisions when implemented in practice [50]. Underreporting of calibration in predictive model studies is a known phenomenon and has been observed across various research areas. For instance, a systematic review on predictive models for cardiovascular diseases identified that only 36% (259/717) of the studies reported calibration [58].

Another key limitation in the predictive model studies is the absence of external validation, undermining the models' generalizability to other clinical settings, where differences in patients' characteristics, care pathways, or data quality may significantly affect model performance. While 6 studies reported internal validation procedures, such as cross-validation or the use of a held-out validation set [39,41,45-48], none incorporated

XSL•FO
RenderX

external validation. External validation involves testing the performance of the predictive model on an independent dataset to assess whether its performance is consistent and generalizable to different populations. Although this procedure could be unnecessary when large, representative samples are used, it is fundamental when models are built on smaller samples, as was the case in some of the included studies [59]. Collins et al [59] recommend that during the development of a predictive model, all available data should be used, alongside appropriate internal validation procedures. They also suggest that external validation should be conducted in subsequent studies. We were unable to identify any external validation studies for the included predictive models; however, we cannot exclude the possibility that such studies are ongoing.

Another important aspect not addressed in the included predictive model studies is implementation. The absence of reports on clinical implementation highlights a significant gap between model development and real-world application. This phenomenon is not new; the implementation gap of ML in health care has been widely acknowledged and discussed in the scientific literature [56,60]. Possible strategies to bridge this gap will be further discussed in the Clinical Implications section.

In summary, the limitations observed in the included studies describing predictive models, such as the lack of external validation, assessment of calibration, and implementation strategies, may compromise their reliability and real-world applicability. To fully realize the potential of AI in predicting medication adherence, further research is needed, with a stronger focus on methodological robustness and clinical integration.

AI-Powered Interventions

This systematic review was designed to capture not only the role of AI in predicting patients' medication adherence, but also its use in supporting patients and helping them develop or maintain optimal adherence. Notably, only 1 study describing an AI-powered intervention to support adherence was identified [40]. This finding is informative in itself, potentially highlighting a research area that remains underexplored and could benefit from further investigation.

Moreover, the included intervention study gives rise to several observations. Although supporting medication adherence was not the sole aim of the chatbot developed by the authors, the study reported positive results specifically related to this outcome, suggesting that AI-powered chatbots can effectively support patients with BC by helping them improve adherence. However, this result should be interpreted with caution, as only a small percentage of participants (33/958, 3.44%) used the specific reminder feature. This limited uptake raises important questions about its practical effectiveness in clinical settings and its real potential to engage patients in behavioral change. The low scores obtained in the risk of bias assessment, particularly regarding the reporting of participant characteristics, potential confounders, and the clear presentation of study findings, underscore the need to interpret the results with caution. Further research is needed to confirm the chatbot's effectiveness, with a stronger focus on patient engagement, especially concerning the adherence support component. Future studies should ideally include a control group to better isolate the intervention's impact on outcomes.

A final, important point to consider is the safety of this AI tool. The chatbot described in the study also provides information to patients and answers their questions. It is therefore crucial that the information delivered is accurate and reliable, as misinformation could lead to potentially dangerous and harmful consequences. Interestingly, the same chatbot was evaluated in a blinded, randomized controlled noninferiority trial, comparing the quality of the information it provided with that of physicians. The results indicated that the quality of the information provided by the chatbot was noninferior to that provided by physicians [61].

Ethical and Safety Considerations

Ensuring safety remains a central concern in the development and use of AI-driven tools and predictive models [56]. The limited number of implementation studies makes it difficult to evaluate whether these models perform safely and reliably in real-world settings, especially when used to inform clinical decisions. This gap in evidence represents a major barrier to assessing potential risks and unintended consequences.

Privacy and data security represent equally critical issues, given that ML models rely on sensitive health information that is vulnerable to breaches and cyberattacks [62]. Recent frameworks, such as the integrated security and ethics model, have attempted to offer structured guidance by integrating principles of transparency, accountability, fairness, and privacy protection [63].

Another key challenge is algorithmic bias, often stemming from unrepresentative training data or inappropriate model generalization [20,64]. National agencies have proposed guiding principles to help stakeholders mitigate these risks, emphasizing equity, transparency, patient engagement, and accountability across the entire algorithm lifecycle [20,65].

Finally, concerns about transparency persist, as many ML models function as opaque "black boxes" [62,66]. While interpretability tools, such as Shapley values, can offer partial insight into model behavior, their use remains limited and their explanations approximate.

In summary, the ethical and safety considerations surrounding AI in health care highlight the need for responsible development and careful implementation. Adhering to established frameworks, prioritizing transparency and equity, and rigorously evaluating AI tools in real-world settings are essential steps for fostering trust and ensuring that these technologies deliver meaningful benefits in clinical practice.

Study Limitations

This review has some limitations worth mentioning. First, although a comprehensive search strategy was used, it should be mentioned that an information scientist was not consulted during the development of the search string, and it is possible that some relevant studies were not identified. Additionally, the inclusion of only English-language publications may have resulted in the exclusion of pertinent research published in other languages.

XSL•FO
RenderX

Moreover, the recency of some included studies implies that external validation or implementation studies may still be ongoing. Their absence could limit the completeness of our evaluation, which should be revised as new evidence emerges. Nonetheless, the lack of external validation substantially impacts the reliability of the reported model performance.

In addition, the great heterogeneity of the included studies in terms of adherence measurement methods, performance metrics, variables considered, study aims, and sample sizes poses a challenge to the comparison and synthesis of their findings. Nonetheless, this variability is informative in itself, as it reflects the current state of research in this evolving field.

Another limitation to consider is the potential impact of the cancer stage on medication adherence; for example, individuals with early-stage cancer might demonstrate different motivational and psychological states compared to patients in the metastatic phase, which can influence their adherence behaviors. The heterogeneity of the population with BC included in this review (both early stage and metastatic) might limit the ability to generalize the findings across all cancer stages.

Finally, given the fast-evolving nature of the topic, this systematic review may become outdated rapidly, as AI technologies are continually advancing in power and capabilities, and new studies are constantly being conducted.

Clinical Implications

From the comprehensive examination of the included studies, some key clinical implications can be drawn. Notably, the issue of implementation recurs as a central challenge throughout the discussion of the findings.

Investing efforts in planning, conducting, and evaluating model implementation is of paramount importance, as only through their integration into clinical practice can these models support health care professionals in identifying at-risk patients early, thereby enabling tailored interventions at an earlier stage.

It has been suggested that, in order to bridge the implementation gap, it is necessary to move beyond the excessive reliance on performance metrics such as sensitivity, specificity, and AUC. While these metrics quantify how closely predictions align with actual outcomes, they do not necessarily reflect the model's practical utility in clinical settings. Indeed, a predictive model with high performance according to these metrics may not lead to tangible improvements in patient care [56,57]. Seneviratne et al [56] proposed 3 practical aspects that should be considered when developing a predictive model or assessing the applicability of an existing one: actionability, safety, and utility. Actionability refers to the extent to which a predictive model can inform or prompt a concrete action by the patient or the health care professional. In our context, a predictive model could be integrated into hospital clinical workflows so that, following routine assessments and screenings, if a patient is identified as being at high risk of nonadherence, an alert would automatically be triggered within their electronic medical record. This alert could then prompt appropriate interventions, such as educational initiatives, consultations with health care professionals, or referral to eHealth support programs. Safety is a key consideration in the clinical application of ML models, and it has been addressed in a previous section (see the Ethical and Safety Considerations section). Finally, utility should be carefully assessed by comparing costs and clinical outcomes with and without the implementation of the predictive model. In our context, does the use of the model lead to improved medication adherence among hospital patients? Does it reduce the costs associated with nonadherence? Is its implementation cost-effective and sustainable? These are highly relevant questions, and it is essential that clinicians and researchers consider them from the development phase and actively commit to evaluating their models against these criteria in later stages, to ensure that the potential clinical impact of the models can be fully realized.

Regarding AI-powered chatbots, further research is needed to ascertain their effectiveness in supporting medication adherence. The ethical and safety considerations discussed in the dedicated section are equally relevant to these tools, particularly in relation to patient privacy and the transparency of their underlying mechanisms [67,68]. Keeping in mind the crucial importance of meeting these prerequisites, advancements in AI technologies now make it feasible to develop AI tools that monitor and support patients throughout their cancer journey. These tools could assist patients in tracking medication-taking behaviors, deliver reminders, and guide patients in managing treatment-related side effects. Moreover, AI-powered chatbots, trained on verified clinical guidelines and scientific knowledge, can provide patients with instant support and information, reducing the burden on health care professionals [40,69]. However, for ensuring high quality of these AI models and their wide usage, it is crucial for scientific researchers, technology professionals, clinicians, and policymakers to work collaboratively to design, develop, and integrate these technologies into health care.

Conclusions

To our knowledge, this is the first systematic review to provide a comprehensive and up-to-date overview of the current applications of AI in predicting and supporting medication adherence among patients with BC. The review encompasses both predictive and interventional studies, thereby mapping the existing applications and highlighting critical gaps. Although these technologies show potential, particularly in identifying patients at risk of nonadherence, the evidence base remains limited, and the high risk of bias observed calls for caution when interpreting current findings.

At this stage, the clinical contribution of AI remains preliminary. Meaningful progress will require stronger attention to implementation, clearer plans for real-world integration, and approaches that actively involve patients throughout development and use. Ethical and practical considerations will also need to guide each step, from development to clinical deployment. With these conditions in place, AI-based tools may, over time, evolve into a useful complement to existing adherence management strategies, but further rigorous work is needed before they can be considered ready for routine practice.

Our findings provide a foundation for future investigation and underscore the importance of a coordinated, multidisciplinary

approach to enhance the accuracy, reliability, and safety of AI tools while addressing critical ethical challenges.

Abstract

Background: Breast cancer is a significant public health burden. Despite its critical role in preventing the recurrence of breast cancer, rates of long-term adherence to endocrine therapy (ET) remain low among certain breast cancer survivors. Using embedded sensors in smartphones and wearables, ecological momentary assessment data and health behavior theory may facilitate a richer understanding of the real-world context of medication-taking behaviors, which can aid in the development of personalized interventions.

Objective: The objective of this paper is to describe the development of a multiscale modeling intervention (MMI) system to facilitate adherence to daily oral ET for breast cancer survivors. This represents the first phase of a larger project that aims to use machine learning to predict when breast cancer survivors are most likely to miss their ET medications in order to deploy personalized interventions. The purpose of this paper was (1) to determine the acceptability of the proposed MMI system, (2) to identify modifiable predictors of ET medication adherence among breast cancer survivors, and (3) to select surveys or items measuring constructs associated with ET adherence among breast cancer survivors for inclusion in the MMI system.

Methods: Study 1 consisted of usability interviews with a cohort of breast cancer survivors (n=25) prescribed ET. For study 1, all qualitative usability interviews were conducted using a semistructured interview guide and assessed whether breast cancer survivors were willing to use various components of the MMI system. Study 2 consisted of (1) a secondary data analysis of ET adherence data from 32 breast cancer survivors using a social cognitive theory framework and (2) a review of research literature of constructs and surveys measuring constructs associated with ET adherence among breast cancer survivors using a social cognitive theory framework. The secondary data analysis included the use of randomized neural network analysis to predict factors strongly associated with medication adherence.

Results: In study 1, usability interview findings suggested that participants were willing to use an ecological momentary assessment smartphone app, a smartwatch and associated smartphone app, a smart pill bottle or smart pill box and associated smartphone app, and the entire MMI system for a 6-month study period. In study 2, the randomized neural network analysis identified 104 survey items with significant contributions to 4-week medication adherence using a threshold of the 70th percentile for feature importance. After a review of peer-reviewed studies, we abstracted modifiable constructs significantly associated with adherence to adjuvant ET and identified 42 surveys used to measure these constructs. When these findings were combined, the final survey for the MMI system consisted of 32 surveys and demographic items.

Conclusions: Our research highlights the use of social cognitive theory, data-driven models, and participant feedback to inform the development of a medication adherence monitoring system. Data from studies 1 and 2 were used to develop a prototype MMI system that will be deployed in a future longitudinal study with 20 breast cancer survivors over 6 months.

Introduction

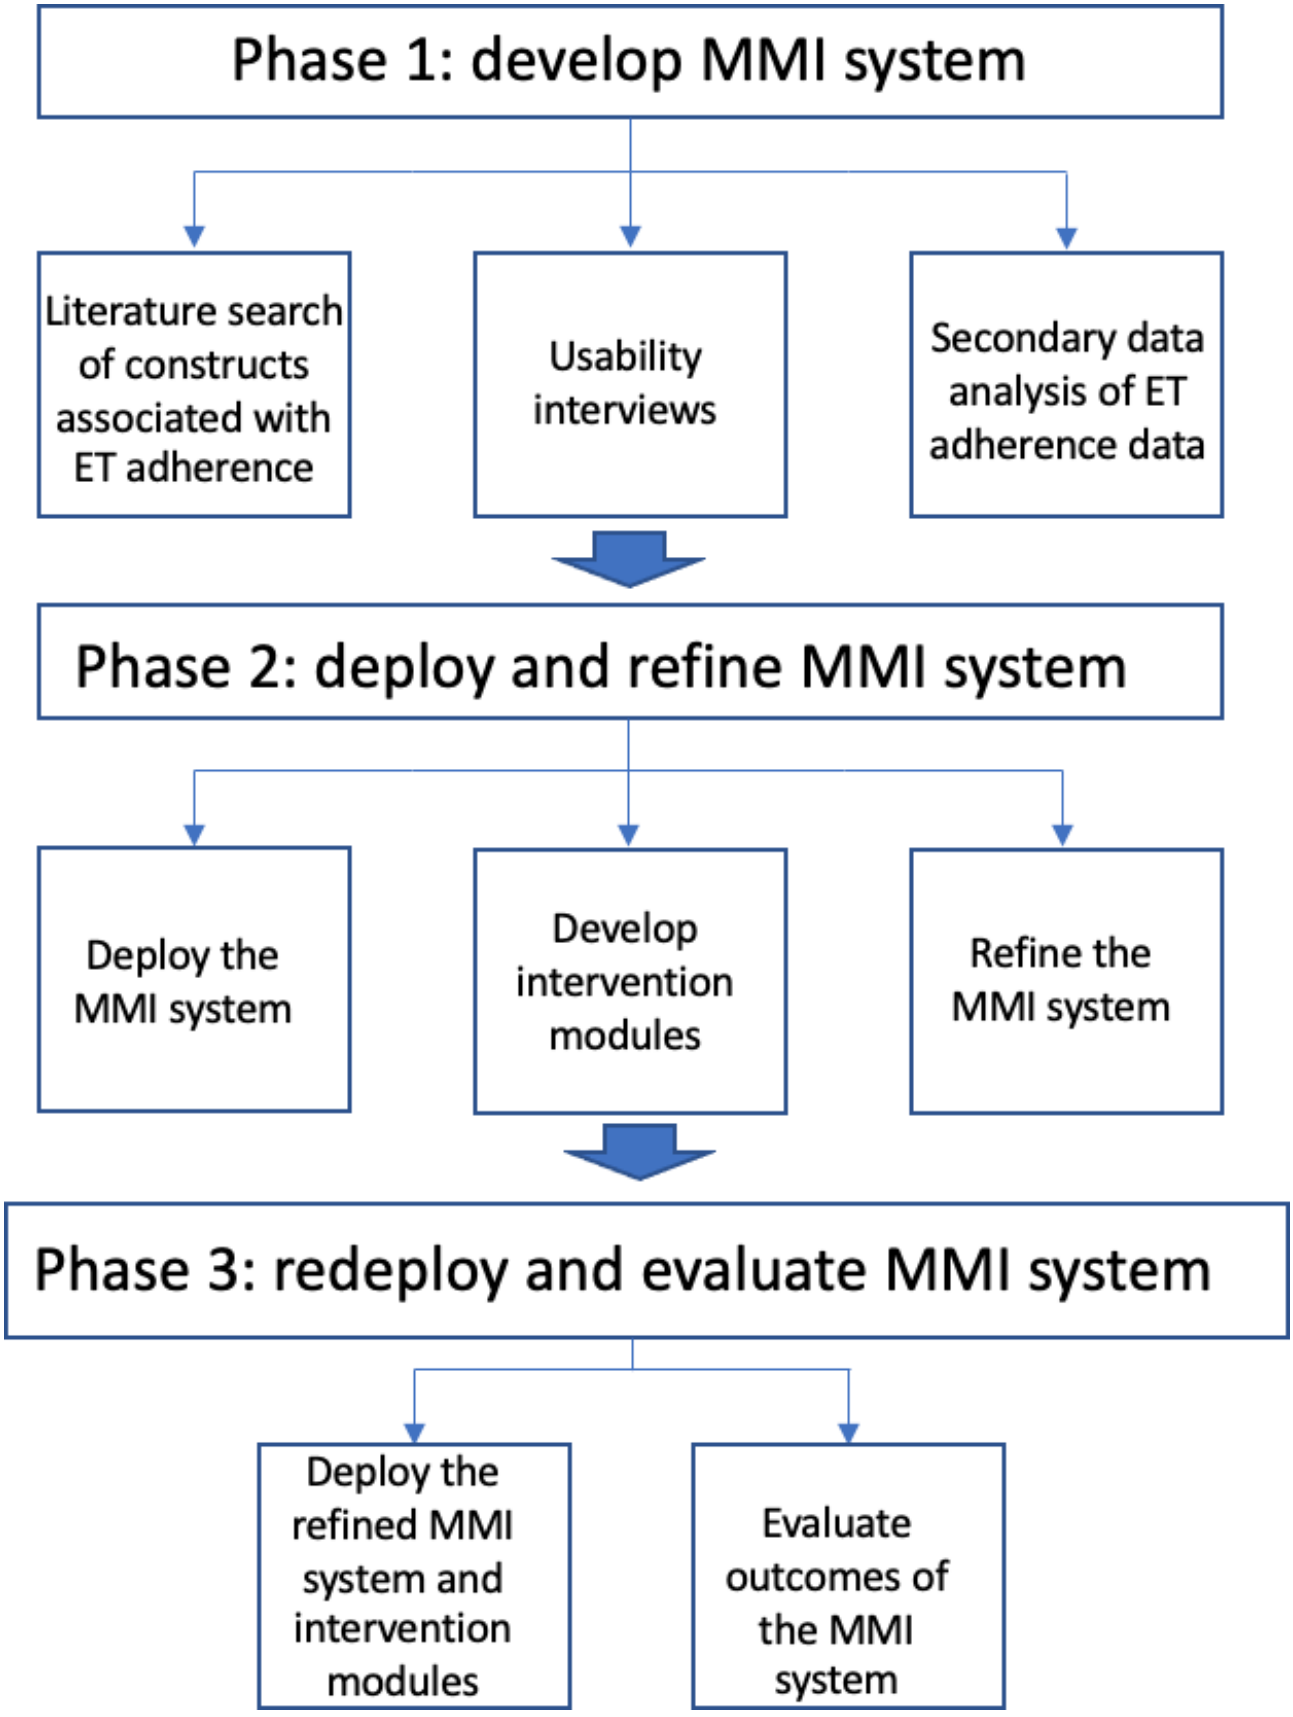
Breast cancer is one of the most commonly diagnosed cancers worldwide [1]. In 2025, an estimated 319,750 people will be diagnosed with breast cancer, and 42,680 people will die from it in the United States [2]. Additionally, there are approximately 4.1 million breast cancer survivors in the United States [3]. Based on the most recent statistics, in the United States, the 5-year relative survival rate for breast cancer from the years 2014 to 2020 was 91% [2]. Individuals diagnosed with early stage and nonmetastatic breast cancer typically undergo a treatment regimen that can include surgery (ie, lumpectomy and mastectomy), radiation, chemotherapy (including trastuzumab), endocrine therapy (ET), immunotherapy, or a combination of treatments. The selection of treatment approaches is based on the stage of the cancer, whether breast cancer cells have certain receptors, and a patient's overall health and age [4-6]. Treatment for an early stage of breast cancer aims to eliminate the cancer, prevent recurrence, and maximize quality of life.

Giaquinto et al [3] reported that 80% of breast cancers diagnosed from the years 2015 to 2019 were estrogen receptor–positive. Survivorship guidelines developed by the American Cancer Society and American Society of Clinical Oncology recommend that breast cancer survivors with estrogen receptor–positive breast cancer take daily oral ET, including tamoxifen or aromatase inhibitors, for 5 to 10 years following treatment with surgery, chemotherapy, and radiation to reduce the risk of recurrence of breast cancer and subsequent secondary primary breast cancers [7]. ET consists of 1 pill taken at any time of the day, 1 time per day, with or without food. Individuals who take exemestane are required to avoid grapefruit and Seville, that is "bitter" oranges, as they reduce its efficacy [8]. Additionally, individuals taking ET should avoid or limit alcohol, as it reduces the efficacy of the medications [8].

Breast cancer survivors who take tamoxifen for 5 years posttreatment have a one-third reduced risk of breast cancer mortality through 15 years after diagnosis and an average of 39% reduced recurrence rate through 10 years after diagnosis compared to those who are not using tamoxifen [9]. Van Liew et al [10] conducted a systematic review of adherence to oral ET and found that breast cancer survivors who adhered to ET for more than 80% of the time had the lowest risk of the recurrence of breast cancer. Rates of long-term adherence to ET are low among certain breast cancer survivors despite its critical role in preventing the recurrence of breast cancer. Estimated rates of adherence to ET range from an average of 79% during the first year after treatment to an average of 56% during the fourth or fifth year [11]. A recent systematic review examining modifiable factors associated with adherence to ET identified the presence of side effects as being associated with ET adherence (in 53% of univariate studies and 100% of multivariate studies) [12]. Furthermore, positive decisional balance, positive emotions, negative emotions, depressive symptoms, perceived risk of breast cancer recurrence, intention to take ET, self-efficacy, participation in the decision to take ET, and quality of the relationship with a health care provider were shown to be associated with ET adherence across multiple studies. A recent systematic review and meta-analysis found that, overall, interventions that aimed to improve adherence to ET were effective, but there was considerable variation across the studies, with 53.3% of randomized controlled trials and 57.9% of nonrandomized controlled trials reporting an intervention effect to improve adherence. Interventions that reduced the cost of medications through legislation and the use of generic medications were consistently effective. Psychosocial interventions that focused on individual participants had limited efficacy when they were provided education about breast cancer, ET, and side effects. Those psychosocial interventions that targeted forgetting and involved medical personnel in managing side effects were sometimes effective [13]. Some psychosocial interventions to improve ET adherence may have limited effectiveness because there is a poor understanding of barriers to adherence and circumstances in which medication taking occurs or does not occur.

Further examination of adherence to ET may be crucial in reducing the burden of breast cancer and improving the overall quality of life and long-term survival among breast cancer survivors. The collection of ecologically valid data, such as sensors (ie, wearable sensors, medication event monitoring system [MEMS] pill cap sensors, and smartphone sensors) and ecological momentary assessment (EMA) data, may facilitate a better understanding of medication-taking behaviors. Baglione et al [14] described the framework of a multiscale modeling intervention (MMI) that presents a new approach to intervention development by capturing real-time data using mobile and wearable sensing systems and working toward incorporating theory-driven approaches to intervention development for adherence to ET. Through the lens of social cognitive theory (SCT) [15], identifying personal (ie, physiological, cognitive, and affective states), environmental (ie, social and physical environment), and behavioral (ie, medication-taking in the context of other behaviors) influences that impact adherence to ET may help provide better insights into the context of adherence and nonadherence. The combination of a theory-driven approach along with data collection using smartphone and wearable sensors, surveys, and EMA will allow for a much richer understanding of the real-world context of medication-taking behaviors, which will ultimately aid in the development of personalized interventions.

As part of the current project, in 2020, the study team conducted an informal assessment of commercially available wearable and MEMS sensors that could be used to collect ecologically valid data from breast cancer survivors to better understand their risk of ET nonadherence and aid in the development of an MMI system. Wearable sensors and MEMS devices were identified via online searches and through the knowledge of study team members. Sensors were reviewed and tested based on a wide variety of factors that would be important for feasible data collection and intervention as part of the MMI system (eg, cost, battery life, platform, etc; see Tables S1 and S2 in Multimedia Appendix 1). All data obtained from the review and testing of the MEMS devices were entered into an Excel spreadsheet. Multiple members of the project team reviewed these data to make final sensor selections. Based on this review, the team



XSL•FO
RenderX

selected Fitbit Sense as the final wrist-worn sensor and RxCap as the final MEMS device for the MMI system.

In this paper, we describe the development of an MMI system to facilitate adherence to daily oral ET for breast cancer survivors who were diagnosed with stages 0 to 3 breast cancer in the past 5 years, have completed all surgeries, radiation, and chemotherapy treatments for breast cancer, and were prescribed ET. This represents the first phase of a larger project (Figure 1) that aims to use machine learning to predict when breast cancer survivors are most likely to miss their ET medications to deploy personalized interventions. The purpose of this initial phase was (1) to determine the acceptability of the proposed MMI system, (2) to identify modifiable predictors of ET medication adherence among breast cancer survivors, and (3) to select surveys/items measuring constructs associated with ET adherence among breast cancer survivors for inclusion in the MMI system. To develop the MMI system, we conducted 2 studies. Study 1 consisted of usability interviews with 25 breast cancer survivors prescribed ET. Study 2 consisted of (1) a secondary data analysis of ET adherence data from 32 breast cancer survivors and (2) a review of research literature of constructs and measurement of constructs associated with ET adherence among breast cancer survivors. The information obtained from these 2 studies allowed us to (1) develop long-form and EMA surveys and determine the frequency of administration of EMAs and (2) determine survey items and sensor data critical to include in the deployment of the prototype MMI system.

Methods

Overview

This phase of the project describes the development of the MMI system for a future 6-month deployment of the system among 20 breast cancer survivors.

Study 1: Usability Interviews With Breast Cancer Survivors

Participants

Using purposive sampling [16], participants were breast cancer survivors (n=25 women) prescribed ET who were recruited via social media posts (eg, Facebook) targeted toward patients diagnosed with breast cancer. These posts were made in breast cancer–related groups and channels. Those who were interested were asked to respond to the post with their contact information. A team member subsequently communicated with individuals who expressed interest in participating via email. Purposive sampling, unlike random sampling, is used to select cases who will provide appropriate and useful information [16]. Participants who expressed interest in participating in the study were sent an eligibility screener on Qualtrics. Eligibility criteria included participants who (1) had the ability to speak and read English, (2) were between the ages of 21 and 70 years, (3) were diagnosed with stages 0 to 3 breast cancer in the past 5 years, (4) had completed all surgeries, radiation, and chemotherapy for breast cancer, and (5) were prescribed ET. If a participant was deemed eligible based on the Qualtrics screener, they were subsequently contacted and scheduled for a screening via Zoom videoconference in order to confirm eligibility. If eligibility was confirmed, participants were scheduled for a 60- to 90-minute semistructured interview via Zoom videoconference. Interviews took place between September 2020 and July 2022.

Procedure

Using semistructured interview guides, 2 doctoral-level researchers (MG and CG-A) conducted 5 rounds of interviews assessing breast cancer survivors' perceptions of and willingness to use an EMA smartphone app, smartwatch, smart pill bottle, smart pill box, and the entire MMI system. All interview guides were developed by the study team and pilot-tested with undergraduate research assistants and individuals outside of the study team (see Multimedia Appendix 2 for all interview guides). One interviewer (MG), a male doctoral student, held a bachelor's degree in psychology, significant interest in systematic approaches to intervention development, and prior experience in clinical health psychology research. The second interviewer (CG-A), a male doctoral student, held a master's degree in psychology, significant interest in research methodology, and prior experience in qualitative research. Each round consisted of 5 participants who were not known to the researcher conducting interviews, and only 1 interviewer was present during each semistructured interview. Five interviews were conducted in each round based on the experience with prior human-centered technology design research [17]. Participants were interviewed alone. There were no repeat interviews. The purpose of round 1 interviews (n=5 participants) was to present a short survey on an EMA smartphone app and ask about participants' willingness to use and their thoughts on the usability of the EMA application. The purpose of round 2 (n=5 participants) was to present a smartwatch and EMA smartwatch application and ask about participants' willingness to use it and their thoughts on the usability of the smartwatch and associated smartphone app. The purpose of rounds 3 (n=5 participants) and 4 (n=5 participants) was to ask about participants' current medication-taking behaviors, demonstration of the use of a smart pill bottle and box, willingness to use a smart pill bottle or smart pill box, and willingness to use a smartphone app associated with the smart pill bottle. The purpose of round 5 (n=5 participants) was to ask about participants' willingness to use the entire MMI system, including completion of the long-form and EMA surveys, demonstration of the use of a pill bottle sensor, using a smartwatch, using apps associated with the 2 sensors, and their comfort with the EMA application collecting various streams of data (eg, HealthKit, activity, and Bluetooth encounters). All interviews were audio-recorded using a digital audio recorder. In addition, participants completed a short survey using Qualtrics, which assessed the following sociodemographic and clinical variables: age, Latinx ethnicity, race, education, marital status, sex assigned at birth, gender identity, employment status, occupation, country of birth, years residing in the United States, primary language, number of people in the household, annual household income, year of breast cancer diagnosis, stage of breast cancer diagnosis, types of treatment for breast cancer, and whether they experienced a breast cancer recurrence.

Data Analysis

All recorded audio files were transcribed verbatim by 2 undergraduate research assistants. Transcripts were not returned to participants for comment. A member of the research team (MG) reviewed all transcripts and developed a summary document for each of the 5 rounds of usability interviews (n=5 for each round). Data were summarized based on the participants' answers to specific questions in the interview, such as *"In general, how do you feel about the experience of answering the surveys on the smartwatch?"* For some items, responses were summed (eg, how many participants stated it was easy to use a feature). Descriptive statistics (ie, frequencies, means, and SDs) of participant characteristics were calculated via SPSS (version 29; IBM).

Ethical Considerations

This cross-sectional qualitative study was approved by the University of Virginia Institutional Review Board (IRB) (IRB-HSR number 21406) to which the San Diego State University and University of Alabama IRBs agreed to rely on the regulation of the study. This paper follows COREQ (Consolidated Criteria for Reporting Qualitative Research) reporting guidelines for qualitative research (a complete COREQ checklist can be found in Checklist 1) [18]. All participants provided written consent prior to starting the usability interviews, which took place between September 2020 and July 2022. Data were stored in accordance with the University of Virginia's information security policies, and deidentified data were analyzed. Participants were provided with a US $75 gift card for completion of the 60- to 90-minute semistructured

XSL•FO
RenderX

interview and self-report survey. This study adhered to local, national, regional, and international law and regulations regarding protection of personal information, privacy, and human rights.

Study 2

Secondary Data Analysis

As previously reported by study team members Kaur et al [19], to select long-form surveys and EMA items/surveys, the research team analyzed data from 32 early-stage breast cancer survivors [19,20]. In the primary study from which these data were obtained, eligible participants provided informed consent after participating in the screening process. After completing baseline surveys during the primary study, breast cancer survivors' daily medication adherence was assessed using a MEMS pill bottle (Aardex) over the 8-month time period. As part of the primary study, participants were compensated with gift cards worth up to US $90: US $30 for the baseline survey, US $30 for the 4-month survey, and US $30 for the 8-month survey. The data from the primary study were stored in accordance with San Diego State University and Sharp HealthCare Information Security policies, and deidentified data were analyzed by Kaur et al [19]. The initial IRB approval by the San Diego State University IRB (vIRB number 1239088) and the Sharp HealthCare IRB (IRB number 1308810) permitted the secondary use of data.

Kaur et al [19] conducted a randomized neural network (RNN) analysis to determine important features (eg, attitudes toward medications, stress, and mood) of ET adherence 4 weeks following the completion of the 346-item baseline survey. Kaur et al [19] extracted the weights on different input variables of the trained RNN models, which are equivalent to the contribution of the respective variables in the final outcome prediction. Additionally, Kaur et al [19] were guided by principles of SCT [15], which evaluates how environmental factors, personal factors, and a person's behavior interact through a process of reciprocal determinism. In other words, the SCT indicates that each of these aspects (eg, environmental factors, personal factors, and person's behavior) influences each other dynamically, which is important for the MMI system. Therefore, Kaur et al [19] used the SCT [15] when identifying personal, behavioral, and environmental constructs associated with daily medication adherence in the RNN analysis. Two authors (KJW and LEB) were largely responsible for categorizing constructs as personal, behavioral, or environmental factors associated with daily medication adherence in the RNN analysis. These findings were presented to other members of the research team for their feedback, which were incorporated by a third author (NK). Details regarding the RNN analyses are reported in the prior publication [19]. Kaur et al [19] chose the survey item importance starting with the fourth week of ET MEMS data collection, as the Hawthorne effect associated with the new use of the MEMS cap and enrollment in the study would have attenuated by week 4. In contrast, during weeks 2 and 3, participants were probably still affected by the study enrollment, completing the baseline surveys, and acclimating to the MEMS cap. Thus, only the 4-month and 8-month data were used to prevent noise from baseline data from corrupting the models. Kaur et al [19] used descriptive statistics to summarize demographic and clinical data. Details of the final survey items are provided in the *Results* section.

Review of Research Literature

Because the secondary analysis of data did not include all potential modifiable factors associated with ET medication adherence, we also examined the systematic review of Toivonen et al [12] (2020) to further develop the long-form survey and EMA components for the MMI system. The synthesis of Toivonen et al [12] comprised 68 studies that examined modifiable factors associated with adherence to adjuvant ET in breast cancer survivors. Possible modifiable factors of adjuvant ET in the literature were classified into the following 6 categories by Toivonen et al (2020) [12]: side effects (n=44 studies), attitudes toward adjuvant ET (n=29 studies), psychological factors (n=30 studies), health care provider–related factors (n=26 studies), sociocultural factors (n=25 studies), and general/quality-of-life factors (n=24 studies). Across individual studies within the synthesis of Toivonen et al [12], 1 study team member and author (CG-A) abstracted which modifiable factors were significantly associated with adherence to adjuvant ET as well as the different surveys/items used to measure these factors. One author (CG-A) also retrieved articles describing the development and psychometric evaluation of such surveys or items. This author (CG-A) then collaborated with another author (KJW), who has expertise in survey development, to determine the quality of these surveys or items. Surveys or items were considered for initial inclusion in the long-form survey and EMA components for the MMI system if they had adequate psychometric properties based on a minimum of a Cronbach $\alpha \geq 0.70$ in at least 1 study sample (when psychometric information was available).

The final inclusion of items and surveys in the long-form and EMA surveys was determined by the monetary cost, length of the surveys and items, and the previously described secondary data analysis findings. To be included in the MMI system, the surveys/items had to be free or a low cost, short enough to ensure the completion of the full battery of long-form surveys within 45 minutes or completion of EMA surveys within 5 minutes, and measure significant modifiable factors of adherence to adjuvant ET according to the secondary data analysis and the systematic literature review of Toivonen et al [12]. All authors participated in the decision-making process to select items and surveys during weekly team meetings in which the RNN analysis and the literature review were discussed. For the long-form surveys, a draft of the baseline survey was created by one author (CG-A), revised by a second author (KJW), and then presented to all group members for their suggestions and revisions. Once the baseline survey was finalized through consensus of the study team, the 2 follow-up surveys were created by one author (CG-A) and edited by a second author (KJW). The follow-up surveys were then presented to the study team for their suggestions and revisions. The EMA surveys were drafted by 2 study authors (ANB and KJW) and reviewed by all other study team members over several rounds of revisions. The long-form and EMA surveys were finalized once the study team agreed that no further edits were required.

Results

Study 1

Sample Characteristics

Out of 25 participants, 84% were White (n=21), 4% were African American/Black (n=1), and 12% were identified as Hispanic/Latinx (n=3; Table 1). The mean age of the sample was 53.6 (SD 10.1) years. Twenty-two out of 25 participants were married (88%), 13 were employed for wages (52%), 22 of them were born in the United States (88%), 24 had a primary language of English (96%), 10 were diagnosed with stage 1 breast cancer (43%), and 24 of them did not have a breast cancer recurrence (96%). Twenty-nine respondents agreed to participate in the interviews and 25 were interviewed (86% completion rate). Three participants who were scheduled to participate in an interview did not attend the appointment (75%), and 1 indicated she was no longer interested in participating prior to the interview (25%).

Round 1 Interviews

All participants stated that filling out the survey on the smartphone app was easy and straightforward, and they would find it easy to use the smartphone app on their own phones and are willing to use the app for the future 6-month study duration. Additionally, several participants reported preferences for completing a survey up to 2 times per day with up to 10 questions at a time. Participants also had preferences for completing surveys early in the day or later in the evening. Furthermore, a few participants reported concerns about "being a slave to their phone," receiving multiple notifications throughout the day while busy, and being busier on the weekends. However, participants reported that they would prefer an option to receive a notification to complete a survey and be able to attend to it at a later time. Finally, participants reported recommendations for lighter colors in the mobile app, the ability to customize the colors of the app, and the inclusion of larger text.

When asked about how easy or difficult it was to answer the questions using the EMA smartphone app, one participant said:

> *That was easy...That was easy. I think that the answers were just, it was laid out very simple. There wasn't a lot of distraction; so the answer was very easy to just select, to read the question and select the appropriate answer.* [P3]

Round 2 Interviews

Participants described the use of the smartwatch as easy, user-friendly, and clear and liked it as it was convenient, easy, and fast. Most participants reported that they would find it easy to remember to wear the watch every day for the duration of the 6-month study period, would accept answering questions on the smartwatch application for the 6-month study period, and that the use of the app on the smartphone would be easy. Several participants also reported that they would not prefer to wear the watch while showering, sleeping, or dressing up in a nice outfit. Several participants preferred larger text on the app and stated that the smartwatch demonstrated was too big. Only 1 participant reported that they might have difficulty using a smartwatch for the 6-month study duration due to not having a preference for wearing jewelry or watches.

When asked about their experience of answering surveys on a smartwatch emulator, one participant said:

> *I think it's very easy, very user friendly. So, I think it's great...I think, so if that just pops up on your watch without you having to do anything, it's very user friendly; it has the options there. Anybody could do it—like a 5-year-old could do it.* [P23]

Rounds 3 and 4 Interviews

The mean number of reported medicines taken was 3.1 (SD 1.4), and the mean number of vitamins or supplements taken was about 3.6 (SD 2.1). Almost all participants reported taking their medicines or supplements in the morning and/or in the evening. A majority of participants stored their medicines and supplements in the kitchen, on their nightstand, or a combination of both, and 5 participants reported keeping their medicines in a pill box, while 4 reported keeping them in their original container. Of note, only 2 participants reported having someone who helps them manage their medications. Generally, participants were willing to use the smart pill bottle or smart pill box and the associated smartphone app for the duration of the 6-month study period.

When asked about how easy or difficult it would be to fit using the smart pill bottle into their everyday life, one participant said:

> *I don't think it would be difficult at all...I mean I think it would be something that, let's say that pharmacy gave to me and said here do you want to try this out, I would, I would absolutely try it.* [P42]

When asked about how easy or difficult it would be to fit using the smart pill box into their everyday life, one participant said:

> *I think it'd be fairly easy to use...It's, it's got every day's medication. I see it goes by the day. It's going*

XSL•FO
RenderX

to tell me if I took it. And it's not that big or bulky...I would say it's of decent size. [P71]

Round 5 Interviews

In general, participants were willing to use the entire MMI system for the duration of the 6-month study period. However, participants reported that the survey (see below) they completed was too long; several participants requested that the survey be shortened. In general, participants were comfortable with the EMA app collecting various streams of data and preferred the option to select which streams of data were collected or not collected. However, 2 participants described the collection of data streams as "intrusive."

When asked about their willingness to use the entire MMI system for 6 months of data collection, one participant said:

Yeah. I would...Because I think it's important to find ways to help other people. I think that's important, but yeah; and I like the fact that I can opt out of certain things. [P83]

Study 2

Survey and EMA Evaluation

As described by Kaur et al [19], data from 32 breast cancer survivors who completed surveys at all 3 time periods (baseline, 4 mo, and 8 mo; Table 2) were used in the RNN. Of the 32 breast cancer survivors who participated in the study, 29 (90.6%) had MEMS data for the entire 8-month period. As indicated by Kaur et al [19], the analysis included bottle-opening events before or after the survey periods to evaluate the algorithms' prediction performance. A total of 2604 data samples were adopted, and each one included subjective values from survey data and the ground truth of medication-taking behavior captured by the MEMS device.

As described by Kaur et al [19], the developed RNN models outperformed traditional neural network models in terms of adherence prediction accuracy under 2 types of randomness: subjective values and decision rules randomness. After training

XSL•FO
RenderX

the adherence prediction models, we preferred to gain insights into the importance of different input variables toward medication adherence prediction. We extracted the weights on different input variables of the trained RNN models, which are equivalent to the contribution of the respective variables in the final outcome prediction. We had 346 individual items as input variables, and using a threshold of the 70th percentile for feature importance (absolute input variable weights), we ended up with 104 survey items with significant contributions to 4-week medication adherence. Within the context of SCT [15], RNN analysis findings identified the following constructs associated with daily medication adherence: (1) environment: patient-provider interactions; instrumental, emotional, and informational social support; barriers to health care; and patient satisfaction with care; (2) personal: perceptions of control/agency/self-efficacy, numerous medication-related side effects, spirituality, perceived stress, decision regret, and fatigue; and (3) behavioral: having a routine for medication taking.

With regard to systematic review findings [12], 42 surveys were reviewed as predictors of ET medication adherence. In addition, there were additional SCT [15] constructs found to be associated with ET medication adherence among breast cancer survivors, as indicated by a recent systematic review [12]: (1) environment: communication with a health care provider and health care provider relationship quality, and (2) personal: mood/depression, perceived cognitive function, and perceived susceptibility of recurrence.

When combined, the RNN analysis [19] and the review of existing literature resulted in the identification of 34 surveys that could be included in the MMI system during the planned deployment, measuring constructs identified in both approaches as important predictors of ET adherence. Given participant feedback on reducing the length of the survey to be administered (see Round 5 usability interview findings), 2 measures of cancer health-related quality of life were removed due to the lengthiness of the surveys and because it was believed that health-related quality of life was also assessed by other measures being considered for inclusion in the MMI system. The final survey for the MMI system consisted of 32 measures and demographic items (Table 3).

RenderX

Table . Measures included in the multiscale modeling and intervention (MMI) system.

Construct	Measure	Description	Psychometric properties
Overall mental and physical health	PROMIS[a] Global Health	A 10-item measure of a person's overall evaluation of their health	The scale has evidence for construct validity and adequate internal consistency (Global Physical Health Cronbach α=0.81; Global Mental Health Cronbach α=0.86) [21].
Medical comorbidities	Self-Administered Comorbidity Measure	An instrument that assesses for medical comorbidities and functions	The instrument has evidence for construct validity and adequate test-retest reliability (intraclass correlation coefficient=0.94, Pearson *r*=0.81) [22].
Side effects and symptoms associated with endocrine therapy	Breast Cancer Prevention Trial Checklist	A 42-item measure of vasomotor symptoms, urinary incontinence, cognitive and mood symptoms, vaginal symptoms, and weight gain/appearance concerns	The subscales have evidence for construct validity and adequate internal consistency (Cronbach α>0.70) [23,24].
Sleep-related impairment	Sleep-Related Impairment Short Form 8a	An 8-item measure of perceptions of sleep alertness, sleepiness, and tiredness during usual waking hours, and the perceived functional impairments during wakefulness	The scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.91) [25].
Sleep disturbance	Sleep Disturbance—Short Form 8b	An 8-item measure of perceptions of sleep quality, sleep depth, and restoration associated with sleep	The scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.84) [25].
Fatigue	Fatigue Symptom Inventory	A 13-item measure of multiple aspects of fatigue, including severity, frequency, and interference with daily functioning	The scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.94) [26,27].
Region of pain	Pain Region Scale	A measure of degree of bother for pain in the stomach, head, neck or back, widespread, and in the arms, legs, or joints	Psychometric evidence is not available because the Pain Region scale was developed by the research team.
Pain intensity	PROMIS Pain Intensity 3 a Short Form	A 3-item measure of degree to which a person hurts	The scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.86) [28].
Catastrophic pain−related thoughts	Pain Catastrophizing Scale	A 13-item measure of catastrophic pain-related thoughts, including rumination, magnification, and helplessness	The scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.75-0.93) [29].
Hot flash interference	Hot flash−Related Daily Interference Scale	A 3-item measure of perceived hot flash interference, referring to the degree to which hot flashes interfere with 9 aspects of daily life and overall quality of life.	The scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.90) [30].
Cognitive function	PROMIS Cognitive Function-Short Form 8a	An 8-item measure of perceived cognitive deficits	The scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.89-0.97) [31].
Personality traits	Mini IPIP[b]	A 20-item measure of the following 5 personality dimensions: extraversion, agreeableness, conscientiousness, neuroticism, and intellect/imagination	The subscales have evidence for construct validity and adequate internal consistency (Cronbach α>0.70) [32].
Perceived control	Pearlin Mastery Scale	A 7-item measure of perceptions of control or the extent to which one regards one's life chances as being under one's own control in contrast to being fatalistically ruled	The scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.70) [33].

XSL•FO
RenderX

Construct	Measure	Description	Psychometric properties
Spirituality	The Functional Assessment of Chronic Illness Therapy-Spiritual Well-Being	A 12-item measure of spirituality of patients with chronic and/or life-threatening illness	The scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.80) [34].
Perceived stress	The Perceived Stress Scale	A 10-item measure of the degree to which individuals feel that situations in their lives are unpredictable, uncontrollable, and overloading.	The scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.80) [35].
Generalized anxiety	Generalized Anxiety Disorder Scale	A 7-item measure of anxiety symptoms within the previous 2 weeks	The scale has evidence for construct validity and adequate internal consistency (Cronbach α>.80) [36].
Depression	Patient Health Questionnaire Depression Scale	An 8-item measure of depressive symptoms within the previous 2 weeks	The scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.86) [37,38].
Fear of cancer recurrence	Fear of Cancer Recurrence Inventory-Short Form	A 9-item measure of fear of cancer recurrence, referring to the fear or worry that the cancer will return or progress in the same organ or in a different part of the body	The full scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.71) [39].
Adherence to endocrine therapy	The Medication Adherence Report Scale	A 5-item measure of adherence with endocrine therapy	The scale has some evidence for construct validity and adequate internal consistency (Cronbach α range=0.67-0.89) [40].
Self-efficacy in adherence to medications	Medication Adherence Self-Efficacy Scale	A 26-item measure of self-efficacy in adherence to prescribed medications	The original scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.95) [41].
Beliefs about medicines	The Beliefs about Medicines Questionnaire	An 18-item measure of commonly held beliefs about medicines	The scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.70) [42,43].
Perceived necessity of endocrine therapy	Perceptions of endocrine therapy necessity items	Two items are used to measure perceived necessity of endocrine therapy	Psychometric evidence is not available on the items, but they have been used in previous cancer-related studies.
Decision regret	The Decision Regret Scale	A 5-item measure of distress or remorse after choosing to take or not take endocrine therapy	The scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.70) [44].
Satisfaction with cancer health care	Patient Satisfaction with Cancer Care	An 18-item measure of perceived satisfaction with health care received since diagnosis of cancer	The measure has evidence for construct validity and high internal consistency (Cronbach α range=0.95 - 0.96) [45-47].
Emotional support	PROMIS Emotional Support	An 8-item measure of perceived feelings of being cared for and valued as a person, having confident relationships	The scale has adequate construct validity and internal consistency (Cronbach α=0.97) [48].
Instrumental support	PROMIS Instrumental Support	An 8-item measure of perceived availability of assistance with material, cognitive, or task performance	The scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.95) [48].
Informational support	PROMIS Informational Support	A 10-item measure of perceived availability of helpful information or advice	The scale has evidence for construct validity and adequate internal consistency (Cronbach α=0.96) [48].
Barriers to receiving care	The Barriers to Care Scale	A 28-item measure of barriers to health care related to geography/distance, medical and psychological issues, community stigma, and personal resources	The original scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.70) [49].

XSL•FO
RenderX

Construct	Measure	Description	Psychometric properties
Cancer self-efficacy	The Communication and Attitudinal Self-Efficacy	A 12-item measure of self-efficacy in dealing with cancer and related health services	The measure has evidence for construct validity and adequate internal consistency (Cronbach α>0.80) [50].
Participation in health care decisions and quality of relationship with health care provider	Participation in Decision and Relationship Quality Survey	A 9-item measure of support received from doctors and other health professionals, the patient's role in decision-making, information shared with the patient about potential side effects, and their experiences with feeling listened to and respected by their provider	Psychometric evidence is not available on the items, but they have been used in previous cancer-related studies.
Social-psychological aspects of patient-physician interactions	Interpersonal Processes of Care Survey: Short Form	An 18-item measure of the social-psychological aspects of the patient-physician interaction	The scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.70) [51].
Self-efficacy when interacting with physicians	Patient-Perceived Self-Efficacy	A 10-item measure of subjective sense of patients' confidence when interacting with their physician	The scale has evidence for construct validity and adequate internal consistency (Cronbach α>0.90) [52].

[a]PROMIS: patient-reported outcomes measurement information system.

[b]Mini IPIP: Mini International Personality Item Pool.

Summary of the MMI System

The sensors selected for the final MMI system include an RxCap smart pill bottle and its associated smartphone app, the Fitbit Sense smartwatch and its associated smartphone app, and the Sensus Mobile smartphone app, which includes smartphone sensors and can administer EMA surveys. The timing of the EMA surveys includes morning and evening surveys, randomized surveys, surveys administered every 2 weeks, and surveys administered every 4 weeks. Additionally, the study team identified 32 constructs that will be included in the long-form baseline, 3-month, and 6-month surveys for the MMI system.

Discussion

Principal Findings

The purpose of this study was to describe the development of the MMI system, a novel approach to improving adherence to ET among early-stage breast cancer survivors that aims to understand medication adherence barriers and medication-taking behaviors. Overall usability testing interview findings suggest that participants were willing to use each component of the entire MMI system for the future 6-month-long study duration. A secondary analysis of data identified 104 survey items with significant contributions to 4-week medication adherence. Forty-two additional surveys were reviewed as predictors of ET medication adherence, and as per the SCT and other health and communication theories, included personal factors, environmental factors, and the behavior itself. When combined, the RNN analysis [19] and the review of existing literature resulted in the identification of 34 surveys that could be included in the MMI system during the planned deployment, measuring constructs identified in both approaches as important predictors of ET adherence.

Comparison to Prior Work

While interventions that aimed to improve ET adherence have been found to be effective overall, there is significant heterogeneity in the effects of psychosocial interventions, with reminder interventions being the most consistently helpful [13]. The lack of effectiveness of some psychosocial ET adherence intervention approaches suggests a lack of understanding of the barriers to ET adherence and the context of medication-taking behavior. The MMI system is designed to overcome challenges in improving adherence to daily ET among breast cancer survivors in stages 0 to 3 who have completed surgery, chemotherapy, and radiation. Personalized approaches to improving medication-taking behaviors may address the varied efficacy of prior psychosocial interventions to increase ET adherence among breast cancer survivors [13] by understanding personal, environmental, and behavioral factors as described in the SCT, along with understanding reciprocal determinism from the SCT, that is, the fact that all of the factors (including the behavior and medication adherence) influence each other in a dynamic way.

Strengths and Limitations

The strengths of the current work are that we used a novel and comprehensive approach to creating an MMI system through RNN analysis findings, usability interviews, and a review of research literature of constructs and the measurement of constructs associated with ET adherence among breast cancer survivors. Additionally, our research highlights the use of theory, data-driven models, and participant feedback to inform intervention development. This is not without limitations. First, the breast cancer survivors recruited during the usability interviews, which occurred during the COVID-19 pandemic lockdowns, were primarily White. Thus, the usability interview findings may not generalize to other ethnic/racial groups. However, the secondary analysis participants were diverse, and the study team will focus on recruiting more diverse participants for phase 2 of the study (see Figure 1) to mitigate this limitation.

XSL•FO
RenderX

Second, participants were primarily recruited via social media posts, so they may be inherently different, such as potentially being more familiar with and/or eager to adopt technologies included in the MMI system, compared to the general population of breast cancer survivors. To mitigate this limitation in the phase 2 deployment, the study team has increased recruitment strategies to include breast cancer survivors from various sources (ie, ResearchMatch and in-person recruitment). Third, the secondary data analysis was conducted on diverse female breast cancer survivors as part of a different intervention study; therefore, the original survey development was not intended to be used for the analytic purposes used in this study. Therefore, we were unable to include newly identified modifiable factors in the secondary data analysis. However, the purpose of the RNN was to develop and test the analytical framework that provides critical insight and refinement into the desired models to be run in phases 2 and 3 (Figure 1) of the project. Fourth, the analysis of the interview transcripts was completed by a single reviewer. Future research may benefit from incorporating additional reviewers into the analysis of the transcripts to better confirm the findings.

Future Directions

The next phase of the project (phase 2) will include the deployment of the entire MMI system with 20 breast cancer survivors over 6 months, collecting data on constructs from multiple health-related theories. Using the data collected during the planned phase 2 deployment, the RNN analysis will be used to identify the most important factors that contribute to ET nonadherence at various time frames among a new sample of breast cancer survivors, including more dynamic features, such as medication-taking patterns, data collected from wrist-worn sensors, smartphone sensors, and EMA. In subsequent deployment (phases 2 and 3, see Figure 1), we will continue to collect information on perceptions of devices, systems, and surveys in the MMI system to better refine it. The study team will then work toward reducing the amount of data collected to essential surveys, EMA, and sensors. Furthermore, the study team will begin to develop intervention components based on the group analysis and individualized model analyses in preparation for phase 3, which is the deployment of the refined MMI system and the implementation of the individualized intervention components that deliver intervention content based on a person's particular risks for ET nonadherence across different time frames (eg, daily and weekly). These intervention strategies may draw from multiple health and communication theories and can be matched to app features (eg, information reminders, reinforcement, and praise), which will likely improve medication adherence across different timescales [53]. Future large-scale testing of the MMI system and intervention approaches will be required to determine its effectiveness in increasing ET adherence among breast cancer survivors.

Acknowledgments

The authors would like to acknowledge Maddie Becker for her help with qualitative transcriptions of participant usability testing interviews.

Abstract

Background: Chronic myeloid leukemia (CML) has evolved into a chronic condition as a consequence of effective tyrosine kinase inhibitor (TKI) therapy, leading to an expanding demographic of patients necessitating lifelong monitoring. The use of eHealth solutions has the potential to facilitate sustainable and patient-centered care by enabling remote monitoring and enhancing guideline adherence. The Dutch CMyLife digital care platform incorporates a CML Dashboard intended for health care professionals (HCPs). This dashboard is designed to provide insight into real-world CML care and enable remote monitoring.

Objective: This study aimed to evaluate the feasibility of the CML Dashboard for remote monitoring of CML care, to assess the usefulness of dashboard-derived data, and to identify barriers and facilitators for its implementation in routine clinical practice.

Methods: We conducted a multimethods early-stage evaluation, determining the feasibility of the CML Dashboard and its barriers and facilitators. Quantitative data were generated through the CMyLife app and displayed in the CML Dashboard. These data were collected over a 2.5-year period and analyzed descriptively. Concurrently, semistructured interviews were conducted with HCPs treating patients with CML to explore barriers and facilitators for implementation. The analysis of interview transcripts was conducted using framework analysis, using established implementation models.

Results: Of the 199 patients who were registered, 177 provided data to the dashboard. The dashboard provided insight into patient characteristics, TKI treatment, BCR::ABL1 values, and monitoring intervals. However, the completeness and reliability of the data were limited, as the majority of the data were manually entered by the patients. The absence of complete data and the presence of inconsistencies in monitoring time points reduced the immediate usability of the dashboard for clinical decision-making and quality monitoring. A total of 8 HCPs participated in the interviews. The facilitators included an enhanced overview of patient data, support for consultation preparation, and the potential for remote monitoring and quality improvement. Key barriers identified were the lack of integration with electronic medical records, the necessity for additional log-in procedures, the limited adoption of the app by patients, and the perception of its added value as being inferior to existing systems.

Conclusions: The prospect of implementing a remote monitoring system for CML care holds promise. Such a system, using a digital dashboard, has the potential to enhance oversight and contribute to the enhancement of quality assurance. Nonetheless, the implementation of automated data exchange with electronic medical records, enhanced data completeness, and the augmentation of integration into clinical workflows are imperative prior to the large-scale implementation and the transition toward home-based CML care.

Introduction

The use of health care resources and the associated costs are increasing due to an aging population and a growing number of patients with chronic diseases, including malignant ones [1]. Consequently, the development of more efficient care delivery methods is imperative to ensure the improvement and sustainability of future care. Remote monitoring is a method that enables patients to manage their own disease trajectory. A number of studies have demonstrated the efficacy of remote monitoring in the treatment of chronic cardiovascular diseases and diabetes mellitus [2,3].

Another chronic disease for which remote monitoring shows great promise is chronic myeloid leukemia (CML). The advent of tyrosine kinase inhibitors (TKIs) in 2001 transformed the management of CML, culminating in a 5-year survival rate of 89% [4] and a reduction in the loss of life years reduced to less than 3 years [5]. Therefore, the global prevalence of patients with CML is increasing significantly, and it is projected to become one of the most prevalent hematological malignancies by 2050 [6]. The feasibility of remote monitoring is contingent upon the regular monitoring of the BCR::ABL1 biomarker, which serves as an indicator of disease activity [7].

Literature showed that the current in-hospital monitoring of patients with CML, as outlined in evidence-based CML guidelines, is deemed to be suboptimal [8-10]. The distribution of expertise in the treatment of patients with CML is diffused, resulting in suboptimal biomarker monitoring and variability in guideline adherence [9,11,12]. This finding suggests that reduced adherence to TKIs may contribute to disease progression and increased health care expenditures [13]. Moreover, the timely recognition of adverse effects by health care professionals (HCPs) is crucial for enhancing treatment adherence, as studies have demonstrated that the adverse effects of TKI treatment were the primary factor contributing to intentional noncompliance [14].

The extant literature suggests that the active involvement of patients in their own care, for instance, through eHealth interventions, can positively affect these outcomes. Research has demonstrated that patient engagement has the potential to enhance medication adherence, facilitate early reporting and management of adverse effects, and support more consistent monitoring according to guidelines [15-17].

eHealth tools have the potential to enhance cooperation between patients and HCPs, thereby empowering patients to assume a more active role in their own care. This shift can lead to a reduction in the use of in-person care services and an increase in remote health care services, without compromising the quality of care received [18]. The CMyLife platform was developed with and for patients diagnosed with CML and is centered on the patient [19]. The platform aims to inform and empower patients and to provide them with the tools necessary to manage their disease. The system incorporates a variety of features, including the cmyCML website and the CMyLife app for patients, as well as the CML Dashboard for HCPs. These features enable patients and their HCPs to respond more appropriately in the event that their BCR::ABL1 results are suboptimal or side effects are too severe, according to CML guideline milestones. Previous research showed that the cmyCML website and mobile app enhanced information provision, as well as patient empowerment and adherence to guidelines and medications [17]. The CML Dashboard for HCPs represents a pioneering development in the field of CML care, as it is the first system to facilitate remote monitoring in real-world settings. To date, there is no literature on the use of such an eHealth solution for remote CML monitoring.

While eHealth solutions for remote monitoring offer opportunities to support chronic CML care, their successful implementation may be challenged by usability, data quality, and integration into routine clinical workflows. Therefore, the aim of this study is to explore the feasibility of the use of the Dutch CML Dashboard for remote patient monitoring, including the relevance of the CML Dashboard–derived data, and the identification of barriers and facilitators to implementation.

Methods

Study Design

We conducted an early-stage evaluation, using a multimethod approach to explore the feasibility of the CML Dashboard, the usefulness of the data, and the barriers and facilitators for implementation. A quantitative approach was used to explore user data. This study did not evaluate clinical effectiveness or quality improvement compared to standard care. A qualitative approach was used to explore the barriers and facilitators of the implementation of the CML Dashboard among HCPs. To determine these influencing factors, we organized semistructured interviews with HCPs who treat patients with CML.

Ethical Considerations

Upon initial access to the CMyLife and subsequent log-in, patients were required to provide explicit consent for the use of their data. The confidentiality and integrity of all data were ensured in accordance with the provisions of the General Data Protection Regulation and the Dutch security guideline (NEN7510). The Institutional Medical Ethical Committee “CMO Regio Arnhem-Nijmegen” has confirmed that this study is exempt from the provisions of the Medical Research Involving Human Subjects Act (WMO) because no traceable data were used and there was minimal impact on study participants (dossier number: 516006001). We used the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist to report the qualitative part of this research [20].

Setting

In the Netherlands, the delivery of care for patients with CML is predominantly characterized by a protocol-based approach, albeit with a dispersed distribution across health care facilities. Patients with CML are treated in 8 university hospitals and 68 general hospitals. Previous research has shown that monitoring of the BCR::ABL1 gene and the survival of patients with CML is better in hospitals with more experience in treating them [11]. Treatment of CML consists of oral TKIs, requires daily intake, and is subject to the Dutch “expensive medicine regulations.” For this reason, only medical specialists can prescribe TKIs. In the Netherlands, health insurance is mandatory and universal,

XSL•FO
RenderX

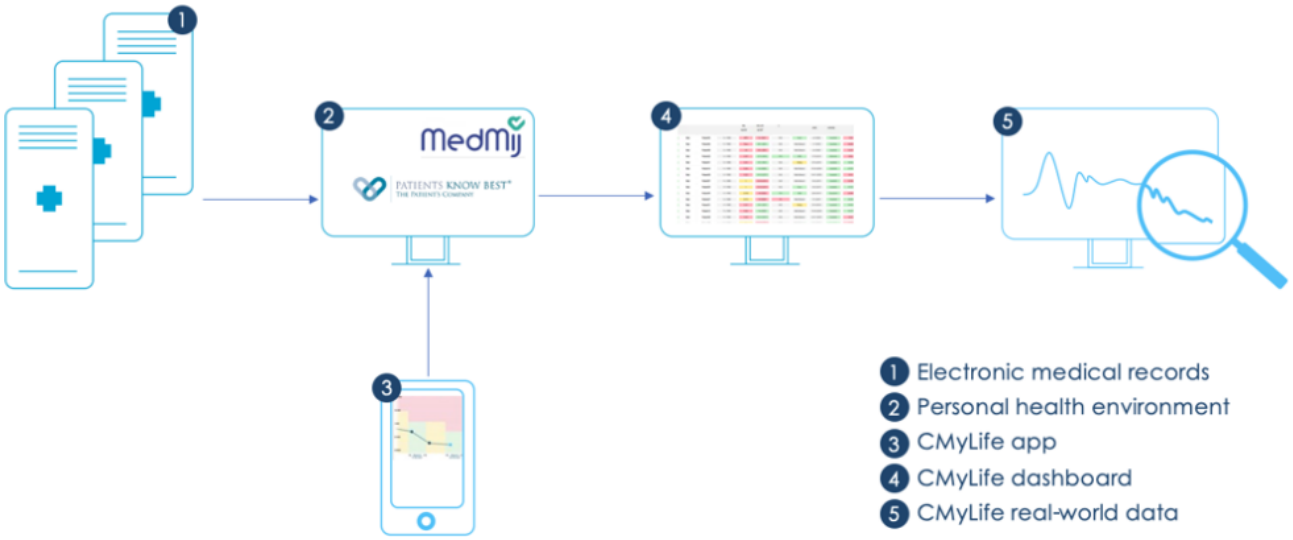
which ensures that everybody has access to CML treatment. In accordance with the evidence-based CML guidelines, the BCR::ABL1 levels of patients with CML need to be monitored throughout their lives. The latest Dutch guideline recommends to measure BCR::ABL1 values at least once every 3 months in the first year after diagnosis and 4 to 6 months each successive year [21]. Optimal response to treatment, as measured by the molecular response level, is achieved after 3 months, 6 months, and ≥12 months when BCR::ABL1 values are ≤10 (% international scale [IS]), ≤1 (% IS), and ≤0.1 (% IS), respectively (treatment milestones). In usual care, most patients do not get direct insight into their personal BCR::ABL1 values, achievement of milestones, or correct timing of BCR::ABL1 measurements. Outside studies, there is no validated tool for measuring side effects in order to monitor them in time, which could result in suboptimal treatment and delayed detection of intolerance.

Interventions

CMyLife Digital Care Platform

CMyLife [22] is a digital care platform codeveloped with and for patients with CML in 2016. The platform has been described in detail before [17,19]. However, since CMyLife is constantly being adjusted to the wishes and needs of its users, improvements have been made over time. CMyLife provides patients and HCPs with different features to arrange CML care according to (inter)national guidelines: the cmyCML website [23], the CMyLife app, and the CML Dashboard. The cmyCML website contains general information about CML, its treatment, and its impact on daily life. It also provides a forum where patients can connect with peers and the option to ask HCPs questions [23].

The CMyLife App



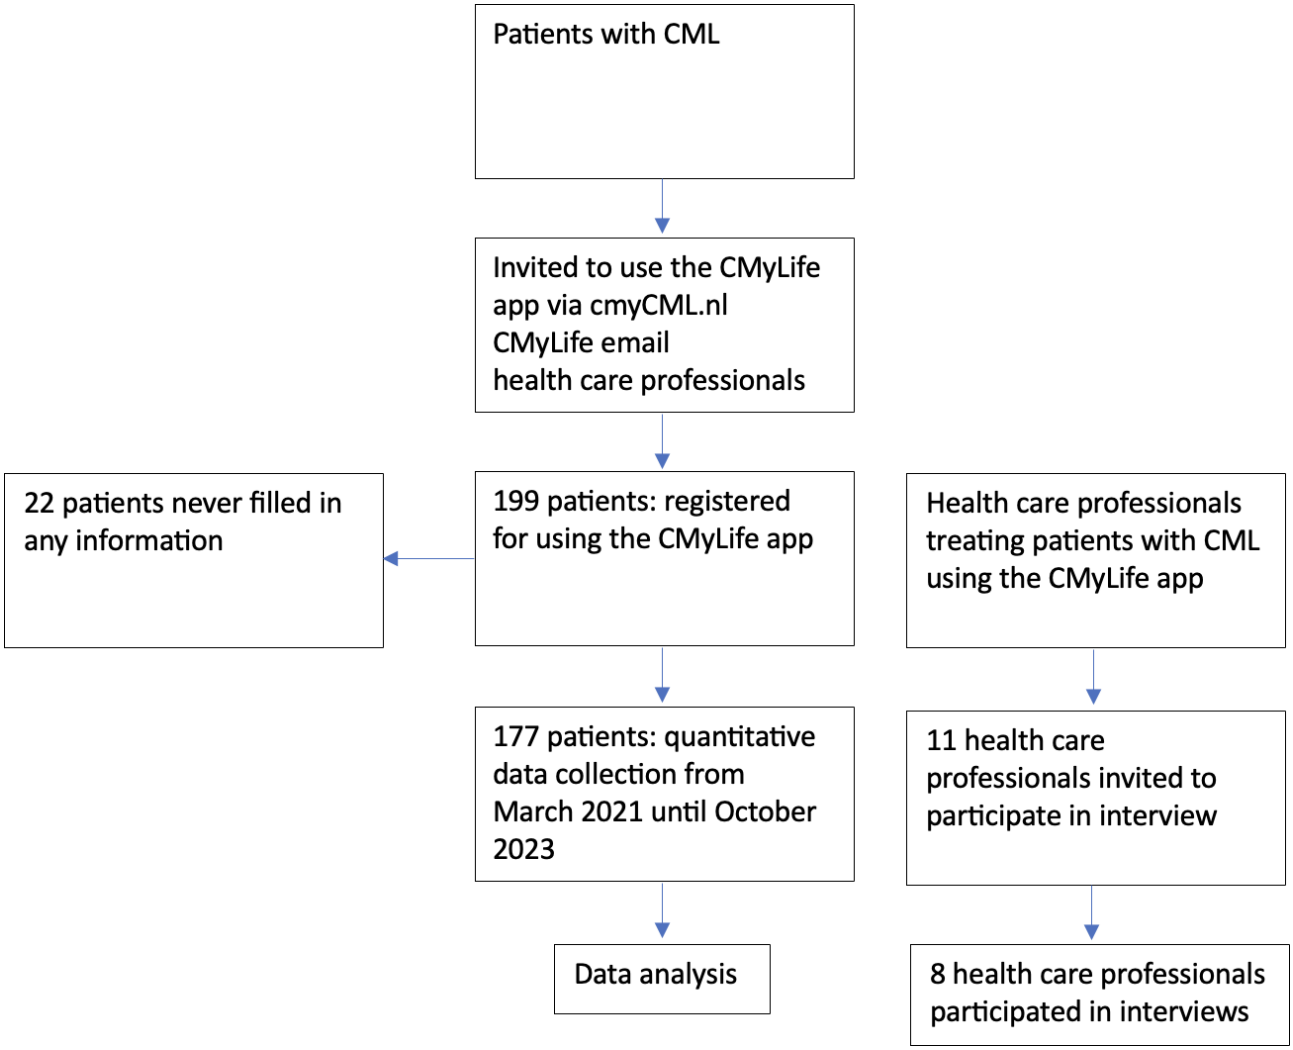
The CMyLife app provides personalized feedback based on the evidence-based Dutch guideline for each patient individually. This feedback is based on BCR::ABL1 results, guideline milestones, and monitoring schedules. Patients with atypical CML presentations or treatment trajectories that substantially deviated from standard guideline-based care were able to use the CMyLife app; however, they were excluded from receiving guideline-based visualizations and messages within the app. BCR::ABL1 values are registered by patients by hand in the app. Up to now, only BCR::ABL1 values from patients treated in one specific hospital were automatically sent from the laboratory to the personal health environment (PHE). For other hospitals, this connection is not live yet. In addition, the CMyLife app enables patients to set a reminder for medication intake in order to improve TKI adherence, and it is connected to patients' PHE to store personal health data. Data exchange was enabled through RESTful (Representational State Transfer) APIs and HL7-based standards (Health Level Seven International), in combination with a MedMij-certified PHE. A transition toward HL7 Fast Healthcare Interoperability Resources is being made in future versions to improve interoperability and scalability. The PHE is a secure and central digital cloud platform that allows patients to collect, manage, and share their medical data from various HCPs in one place. Supported by the government [24], this initiative is based on the MedMij standard [25], setting the standard for the application of a national Dutch PHE. The PHE that is used is Patients Know Best. This PHE respects the privacy and security of data, in accordance with applicable laws and regulations, including the General Data Protection [26]. Using the app, patients are informed about treatment goals and are better prepared for consultation with their HCPs [27].

The CML Dashboard

This study focused on the CML Dashboard for HCPs, which is based on data generated in the CMyLife app for patients. Figure 1 shows how data flows to the dashboard. The CML Dashboard was developed together with HCPs in the Netherlands in 2022 using the design-thinking method, in which HCPs actively participate in the development. In 2023, HCPs were introduced to this dashboard by the CMyLife team (consisting of CMyLife experts easily approachable for questions and help) and received information on how to access and use it. HCPs were able to use the dashboard according to their own needs. The dashboard provided HCPs an overview of their patients with CML using the CMyLife app. It provided them with an overview of CML treatment, insight into the disease course (BCR::ABL1 results) of their patients, guideline-driven monitoring appointments, and side effects of CML treatment. At a glance, HCPs could use real-world patient data in the dashboard to identify which patients need more attention (indicated by color-coded treatment milestones derived from evidence-based clinical guidelines), which patients are on a favorable disease course, and adjust the level of care accordingly.

XSL•FO
RenderX

Figure 1. Dataflow from patients and health care professionals to the dashboard. Dataflow from 1 to 2 is only possible in one hospital.



Study Population

Quantitative data were retrieved from the dashboard between March 2021 and October 2023. Patients became aware of the CMyLife app via their HCPs or through communication channels of the CMyLife platform. Patients from all hospitals treating CML could register for the CMyLife app via the cmyCML website, CMyLife email, or their HCPs. Once registered, the CMyLife team contacted the patient, introduced the app, and helped them install it, providing instructions on how to use it. To use the app, a PHE needs to be connected, and the team member helped with that as well. For the qualitative part, we recruited HCPs who provide care to patients with CML, such as hematologists and nurse specialists within hematology. Inclusion criteria were that these professionals treated patients with CML and had a private introductory meeting of the CML Dashboard by one of the members of the CMyLife team. Based on their prior introduction to the CML Dashboard, potential participants were recruited via convenience sampling by the CMyLife team to make an appointment for an interview. To ensure variability, we included HCPs from both university and general hospitals, as well as professionals with 5 to 30 years of experience in clinical practice. They received an invitation to an interview via email, including the information letter. If they were interested, they were then contacted by phone to arrange the interview. The recruitment of HCPs stopped when we had a diversified sample and no new opportunities, barriers, facilitators, or improvements were mentioned, so data saturation was achieved. Figure 2 shows the participant flowchart.

XSL•FO
RenderX

Figure 2. Participant flowchart. CML: chronic myeloid leukemia.

Data Collection

App data were sent to the dashboard via the PHE. In October 2023, all available descriptive user data from April 2018 until October 2023 were retrieved from the dashboard. Data consisted of basic characteristics such as age, gender, and current TKI used and other CML-related information, such as BCR::ABL1 values, TKI-related information (current and previous TKIs, dosage, duration of TKI therapy, and intake), BCR::ABL1 monitoring time points, side effects of CML treatment, messages sent to patients, and messages read by patients. The date of diagnosis could not be registered or traced due to all personal health data in the dashboard being secured in compliance with the General Data Protection Regulation (GDPR) and the Dutch guideline for health care–related information security (NEN7510). Only the date of starting TKI treatment was recorded. Access to patient data was restricted to authorized HCPs, and only nontraceable data were used for research purposes.

As for the qualitative part, we used a qualitative descriptive design within the pragmatic paradigm [28,29]. We composed an interview guide based on the theoretical frameworks of Flottorp et al [30] and Grol and Wensing [31]. These frameworks define barriers to and facilitators for change in health care practice at 6 different levels: (1) the innovation itself, (2) the patient, (3) the individual professional, (4) the organizational context, (5) the social context, and (6) the economic and political context. This guide included questions on actual use and potential use of the CML Dashboard in clinical practice, experiences with the CML Dashboard including barriers and facilitators for implementation, structured by the domains of the theoretical frameworks, and improvements of the CML Dashboard. The interview guide can be found in Multimedia Appendix 1. Although this research is based on the assumption that multiple subjective realities exist, the study used systematic data collection and reflexive practices to approach the material as consistently and objectively as possible. This balance allowed for openness to participants' meanings while maintaining methodological rigor. A pilot interview was conducted with a member of the CMyLife team who used the dashboard to test the interview guide. After testing, the interview guide was adjusted accordingly. There was no prior relationship between the interviewer and participants.

Before the start of the interview, informed consent was obtained. In addition, characteristics, such as gender, years of experience, type of hospital, and medical profession, were collected. With the use of this interview guide, semistructured online interviews via Microsoft Teams were conducted by a senior researcher

XSL•FO
RenderX

(JEMS) with experience in conducting interviews with HCPs about digital tools in health care. The interviews were also audiotaped using Microsoft Teams and lasted about 20 to 30 minutes.

Data Analysis

Descriptive statistics were used to explore the data generated from the CML Dashboard. Patients who did not use the CMyLife app were excluded from the analysis. Other incomplete data were not excluded because our goal was to explore what data and outcomes could be generated by the CML Dashboard. SPSS (IBM SPSS Statistics for Windows, version 29) was used for the analyses. Molecular response levels were calculated based on the BCR::ABL1 values. The first 5 monitoring time points were analyzed because they represent the first year of monitoring.

For qualitative analysis, automatically generated transcripts (verbatim by Microsoft Teams) were cleaned by a student to enable framework analysis. Transcripts were coded using ATLAS.ti GmbH version 23.1.1.0. Two researchers (JEMS and EW) independently coded the interview transcripts, using the framework of Flottorp et al [30] and Grol and Wensing [31] for coding the barriers and facilitators. The codes were discussed to reach a consensus. When agreement could not be achieved, a third researcher was consulted (RPMGH).

Results

Quantitative Results

Patient Characteristics

Of the 199 included patients, 22 patients did not fill in any information via the CMyLife app and therefore left no data in the dashboard. They were excluded, leaving 177 patients for analysis. Basic characteristics of these patients are summarized in Table 1. Most patients were male (105/177, 59.3%), and the mean age was 59.1 (SD 12.7) years.

Table . Basic characteristics of participating patients with chronic myeloid leukemia.

Characteristics	Patients with CML[a] (n=177)
Sex, n (%)	
Male	105 (59.3)
Female	70 (39.6)
Missing	2 (1.1)
Age (years), n (%)	
18 - 64	79 (44.6)
65 or older	46 (26.0)
Missing	52 (29.4)
Age (years), mean (SD)	59.1 (12.7)

[a]CML: chronic myeloid leukemia.

Treatment Data and Its Usefulness

Treatment characteristics are summarized in Table 2. Of the 177 patients, the first used TKI was registered by 146 (82.5%) patients. Currently used TKI registration was missing in 35 (19.8%) patients, and the first registered BCR::ABL1 values were missing in 11 (6.2%) patients. The 146 patients were first treated for their CML 5.3 years ago on average (minimum 0 years and maximum of 22 years). Patients who switched TKI or increased or decreased their dosage did so 173.6 weeks after starting the first TKI on average, and 79 weeks after the first switch, increase, or decrease. Almost 60% (87/146) of patients who registered their TKI never adjusted the TKI or TKI dosage. Nearly 27 (18.5%) of the 146 patients increased or decreased the dosage of their first used TKI. Of the 27 patients, the dosage of 11 (40.7%) patients was decreased, and the dosage of 16 (59.3%) was increased. TKIs were switched once, twice, three times, or four times in 26% (38/146), 8.2% (12/146), 4.8% (7/146), and 1.4% (2/146) of patients, respectively. Overall, 35 (19.8%) of the 177 patients did not fill in their currently used TKI. Lastly, dosages of medication were registered in two different variables. One variable indicated whether patients took their medication once or twice a day, while the other captured dosage in milligrams. It was unclear whether the reported dosage in milligrams referred to the total daily dose or to the amount taken twice a day. Patients did not fill in side effects regularly, accurately, and completely. Of the 177 patients, 120 (67.8%) registered side effects (mean 6.53, SD 16.3), 47 (26.6%) registered side effects only once, and 1 (0.6%) registered side effects 129 times.

BCR::ABL1 Values, Monitoring Time Points, and Their Usefulness

In total, 168 patients registered 2297 BCR::ABL1 values (Table 3). The first and fifth registered BCR::ABL1 values are shown in Figure 3. The first registered BCR::ABL1 values ranged from 0% to 250% (mean 19.66%). Besides, 46.4% (78/168) of patients were in major molecular response (MMR) or lower (MR4, MR4.5, or MR5). The fifth registered BCR::ABL1 values ranged from 0% to 20.3% (mean 0.93%). The fifth registered BCR::ABL1 values showed half of the patients to be in MMR, or lower (MR4, MR4.5, or MR5).

Figure 3. Molecular response of the first and fifth registered BCR::ABL1 values (n=168). Not quantifiable indicates that the BCR::ABL1 value was at a level too low or too uncertain to be precisely quantified. CML: chronic myeloid leukemia; MMR: major molecular response.

MR4.5 (BCR::ABL1 > 0.001% - 0.0032%)	18 (10.1)
MR5 (BCR::ABL1 ≤ 0.001%)	25 (14.0)
Not quantifiable	1 (0.6)
Missing	40 (22.5)

[a]CML: chronic myeloid leukemia.

[b]MMR: major molecular response.

In total, patients registered 2354 monitoring time points. Patients filled in a minimal 0 dates, and most registered monitoring time points were 61. The mean time between the first two monitoring time points was 159.9 days, with a minimum of 1 day and a maximum of 7380 days. The mean time between the second and third monitoring time points was 92.9 days, with a minimum of 0 days and a maximum of 900 days. The mean time between the third and fourth monitoring time points was 81.3 days, with a minimum of −282 days and a maximum of 364 days. The mean time between the fourth and fifth monitoring time points was 97.9 days, with a minimum of −267 days and a maximum of 735 days. A negative value means that the registered monitoring time point was a date before the previous registered time point.

Qualitative Results

HCP Characteristics

A total of 11 HCPs were invited to participate in an interview, of which 3 were not able to participate or did not respond. We conducted 8 interviews with HCPs, resulting in data saturation. Characteristics of study participants are shown in Table 4.

XSL•FO

Type of hospital, n (%)	
University hospital	3 (37)
General hospital	5 (63)
Medical profession, n (%)	
Hematologist	5 (63)
Physician assistant/nurse practitioner	3 (37)

Barriers and Facilitators

In Table 5, an overview of the barriers and facilitators of the CML Dashboard implementation is shown, categorized by the domains of Flottorp et al [30] and Grol and Wensing [31]. This overview also includes potential barriers and facilitators for its future implementation, for example, in the case of remote monitoring.

XSL•FO
RenderX

Table . Current and potential barriers and facilitators of the CML[a] Dashboard.

Facilitators	Barriers
Innovation factors	

Strengths of the CML Dashboard
• Overview at the health care professional level
• Overview at the patient level
  • Overview of patients' symptoms
  • Overview of patients' treatment/medication (including switches)
• Facilitates consultation preparation
• Facilitates consultation with patients
• Increases awareness and knowledge of the CML guideline
• Increases workflow efficiency
• Is a safety net for no-show patients
	Limited additional value/information of the CML Dashboard
	• …in comparison to the EMR[b]
	• …in comparison to personal contact with patients
	• …in comparison to other sources of CML clinical guideline information
	• …in comparison to the existing communication channels of the hospital
	• …for health care professionals with sufficient knowledge of the CML clinical guideline
	• …if treating a small number of patients with CML
	• …for straightforward clinical pathways

Potential strengths of the CML Dashboard
• Remote monitoring
• Audit and feedback on health care professionals, hospitals, regional and national levels for quality improvement
  • Monitoring medication safety
  • Monitoring patient visits/contacts
  • Monitoring patient symptoms
  • Research (database)	

Feasibility of the CML Dashboard • Presentation of patients' symptoms (colors and scale for severeness and detailed description) • Presentation of BCR::ABL values (colors in relation to CML treatment milestones) • Presentation of medication switch • Compliance with legislation	Limited feasibility of the CML Dashboard • Patient information not informative or of additional value • Additional screen needed (pop-up screen) • Inefficient layout • Messages (function) unclear • Slow system

Potential feasibility of the CML Dashboard
• Customizable layout/information view
• Alert/pop-up not reaching milestone BCR::ABL value
• Links to important websites/information included
  • Guideline information
  • Information contact other departments (eg, cardiology)
• Monitoring patient visits/contacts
• Scale up to other hematological diseases
• Information on study/trial participation
• Allocation of diverse access roles
• Demand-based patient communication
• Access data in the CML Dashboard via PHE[c]
• Personalized BCR::ABL1 cutoff values
• Self-ordering of lab tests
• Self-planning consult hospital	

Compatibility of the CML Dashboard • Insight into patients' symptoms	Limited compatibility of the CML Dashboard • No connection with/or integration in EMR • CML guideline not applicable to all patients • Lack of patients' filling in information in the CMyLife app • Information "overkill" for health care professionals due to diverse information sources • Lack of information on the use of the CMyLife app
Potential compatibility of the CML Dashboard • Integrated version of the CML Dashboard in the EMR • Reminder to patients to use the CMyLife app	
The CML Dashboard is deemed accessible	Limited accessibility of the CML Dashboard • Additional authenticator step • Additional log-in • Lack of instructions on how to log in

XSL•FO

Facilitators	Barriers
Individual professional factors	
Agreement with the CML Dashboard • Positive attitude	*Not discussed*
Awareness and familiarity with the CML Dashboard • Experience with the dashboard in the development phase • Experience with dashboard patient consult (preparation) • Introduction to the system	Limited awareness and familiarity with the CML Dashboard • Little to no clinical experience with the CML Dashboard
Intention and motivation to use the CML Dashboard • Increased motivation when patients use the CMyLife app	No intention and motivation to use the CML Dashboard • Decreased motivation when patients do not use the app
Not discussed	Use of the CML Dashboard is not a routine practice
Expected outcome of using the CML Dashboard for remote monitoring[d] • Fewer consults/hospital visits[d] • More self-directed patients[d]	*Not discussed*
Patient factors	
Need to have more ownership in the care process in case of remote monitoring[d]	No need to have more ownership in the care process in case of remote monitoring[d]
Social context factors	
Encouraging others to start using the CML Dashboard	*Not discussed*
Referral process improved when the CML Dashboard was integrated into EMR[e]	*Not discussed*
Organizational context factors	
Available team to keep it up-to-date and to provide support service	*Not discussed*
Mandated organization remote monitoring[d]	*Not discussed*
Economic and political factors	
Reimbursement for remote monitoring[d]	*Not discussed*
Not discussed	Legal obligation to document consult[d]

[a]CML: chronic myeloid leukemia.

[b]EMR: electronic medical record.

[c]PHE: personal health environment.

[d]Barriers and facilitators for remote monitoring.

[e]Barrier for improvement: integrated version of the CML Dashboard in EMR.

Innovation Factors

The most influential factors related to the innovation itself concerned the CML Dashboard. These factors included the strength, feasibility, compatibility, and accessibility of the CML Dashboard. Multiple strengths of the CML Dashboard for current use were mentioned by participants, such as having an overview of patients with CML-related information on multiple levels. This information was used for both the preparation of a consultation and the consultation itself, and helped to not miss patients. The information provided increased the knowledge of the CML guidelines and the efficiency of the workflow. However, according to some HCPs, the information was of limited additional value to existing information sources and their own knowledge, especially when considering the low number of patients with CML and straightforward clinical pathways. The CML Dashboard was deemed feasible and compatible. Compared to other current available resources, the CML Dashboard was not deemed efficient in use because of some feasibility and compatibility issues. This was mainly related to the log-in to a stand-alone dashboard, including the authenticator step. Some HCPs experienced logging in to the dashboard as rather easy, while others thought it was not easy at all. Having multiple information channels across different screens (pop-ups) led some users to experience an overload of additional and double information when using the dashboard alongside the information already available. In addition, a lack of information on patient participation in the CMyLife app and patients' treatment plans that deviate from complying with guideline recommendations were experienced as barriers.

Individual Professional Factors

Several factors are related to individual HCPs. Most interviewees were satisfied with the general content of the

XSL•FO
RenderX

dashboard. However, the intention and motivation among participants was quite low to use the CML Dashboard in current clinical practice. Motivation was influenced by the limited use of the CMyLife app among patients. Most HCPs were aware of the dashboard. However, only some of them had used the dashboard in clinical practice during (preparation for) consultations. Last, participants found it hard to integrate the use of the dashboard into daily work routines.

Social Setting and Organizational Factors

Users of the CML Dashboard encouraged others to also start using the dashboard. Participants experienced a lack of guidance on how to access the dashboard. Therefore, a facilitator was an easily available team, responsible for services such as updates and customer support.

Recommendations to Current Use of the CML Dashboard: Potential Innovation Factors

In Table 5, potential options to enhance the strength, feasibility, and compatibility of the current CML Dashboard, mentioned by the interviewees, are shown. Regarding its strength, the dashboard could play a central role in the remote monitoring of patients with CML in the future. Facilitators of this new app mentioned were the expected outcomes of having fewer in-person consultations and patients becoming more self-directed, although opinions differed on whether patients want to be more self-directed. A barrier was seen for complying with remote monitoring to existing regulations, like taking notes of the patient, and to existing funding policies. In addition, HCPs wondered who the coordinating party should be when shifting care to the home environment. Next, the dashboard could be used as a quality control instrument on several levels: individually, locally, regionally, or even nationally. More specific applications mentioned were monitoring of clinical visits, monitoring of medication safety, and identifying general trends in patient symptoms, medication use, and their responses (national level). Lastly, using this database for research purposes was positively mentioned by an interviewee. With the potential options and purposes in mind, remote monitoring motivated HCP to start using the CML Dashboard. Other factors increasing their motivation were an increasing workload due to a foreseen growth in patients with CML, due to increased survival, and more use of the CMyLife app by patients with CML.

Next, to improve feasibility and compatibility, and to overcome the lack of stand-alone functionality, it was suggested to incorporate the dashboard within existing structures (electronic health records and PHE). This would also enable easier access to information of and referral to other medical specialists. With regard to the compliance with the guideline, additional features could be an alert of a changing/increasing BCR::ABL value, including the allowance of customized cutoff values, adding a severeness scale of patient symptoms, and links to important websites with additional information on CML care and its clinical guidelines. Regarding the overview function, the overview of patients could also be expanded to include patients with other hematological conditions. Furthermore, interviewees mentioned that it would be relevant to have information on study/trial participation, cardiovascular care/history, and on patients' use of the CMyLife app. For the visualization of this information, a customizable layout was suggested. For access to the information, allocation of diverse roles/access was mentioned as well as access of other HCPs to the dashboard (eg, cardiologists). The contact with patients can be expanded with demand-based communication and ordering functions, like planning a clinical visit or a lab test. Concerning this function, supporting staff should have access to the dashboard to be able to manage the appointments (laboratory and hospital) of patients with CML.

Discussion

General Findings

This study demonstrated an early-stage evaluation of a promising eHealth tool for future remote monitoring of patients with CML by the use of the CMyLife app and the CML Dashboard. By assessing the usefulness of data from the CML Dashboard at this stage, the study laid the groundwork for potential optimizations of the CML Dashboard. Quantitative data showed useful information about the patients using the CMyLife app, their therapy, BCR::ABL1 values, and BCR::ABL1 monitoring time points. However, the data had some limitations, and adjustments should be made regarding data provision (automatically from electronic medical records and improving instructions for patients) before it can be used accordingly. Although many strengths of the CML Dashboard were mentioned by the end users, the CML Dashboard was not yet widely adopted in clinical practice. The main reasons were the lack of compatibility with other information systems used in clinical practice such as electronic health records, feasibility issues such as difficulties with logging in into the CML Dashboard, and lack of additional information relative to other information resources, also hindered by the lack of use of the CMyLife app. Regarding potential applications, the CML Dashboard could have a central role in remote monitoring and quality assurance. However, organizational steps, such as improved data input and reimbursement, need to be taken first before CML care can be moved completely toward the home environment.

At present, imatinib, dasatinib, bosutinib, and nilotinib are available as first-line TKIs for the treatment of CML in the Netherlands, but drug safety profile, comorbidities, and impact on quality of life of patients should be considered while selecting any first-line TKI treatment [32-34]. To date, little real-world evidence is available about what TKI is most appropriate in what cases and the way HCPs make treatment decisions [35]. Moreover, the timing of switching TKIs remains a controversial topic [34]. Our quantitative results showed that the CML Dashboard can collect and therefore provide valuable insights into these data, and the use of the dashboard for quality monitoring was mentioned as an important application in the qualitative part. However, almost all data were registered by patients themselves, except for BCR::ABL1 values from patients treated in one specific hospital. This influences the usefulness of the data. BCR::ABL1 values registered by patients are less reliable as it is not certain if they recorded the values correctly and if they registered all values. After improvement in data input, increased use of both the CML Dashboard and the

XSL•FO
RenderX

CMyLife app may result in insight into relations between patient characteristics, TKIs, switches, and side effects in the real world, which could lead to better selection of treatment tailored to specific patient characteristics, eventually leading to improvement of CML guidelines and, therefore, quality of CML care.

Patients registered at the start of their first TKI treatment, but reliability could not be checked, which makes it hard to analyze response to treatment and reaching treatment milestones in accordance with the guidelines, as it is not clear what BCR::ABL1 values are after 3 months, 6 months, and ≥12 months after the start of treatment. Therefore, it would be of added value to add a question to the app that registers this information. Moreover, monitoring time points registered by patients have shown to be not reliable. The period between two time points was negative, which means that a registered monitoring time point was a date before the previous registered time point. Nevertheless, registered BCR::ABL1 values showed a decrease over time and no worsening of the disease.

In the future, according to the value-based health care principles of Porter [36], a widely supported compromised set of quality indicators based on the CML guideline should be agreed upon by involved stakeholders to monitor, or proactively redirect them according to guideline adherence in the remote setting. This compromised set of indicators will also be important for the other future application for the dashboard, quality monitoring on diverse levels (hospital, region, and national). When care of CML is organized more centrally, these expert hospitals can measure this set of indicators and together, by using audit and feedback, improve the quality of care for patients with CML. In addition, the data mentioned above could potentially help in proving relations between patient characteristics, TKIs, switches, and side effects in the real world. An important element of this quality indicator set will be a patient-reported outcome measure specifically aimed at patients with CML. Using this patient-reported outcome measure, it could enable the collection of structured data from a patient perspective. To date, no validated questionnaire for patient outcome data was used within CML care [37].

To overcome the lack of stand-alone functionality, HCPs suggested in this study to incorporate the dashboard within existing structures (electronic medical records and PHE). Currently, aligning information systems in health care is a tremendous challenge, and therefore, national strategies have been developed in recent years to improve data infrastructure and interoperability [38]. Because access to the dashboard was a barrier as well, it was preferred that no additional log-in be needed, but GDPR legislation obligates the use of a 2-factor authentication. In addition, the World Health Organization mentions safety and security as essential aspects, and similar levels of security and authority are seen in related eHealth systems in other countries [39-41]. Several national initiatives are developed and tested, which should simplify access of HCPs to eHealth platforms, including patient information such as the CML Dashboard [42-44].

There is a potential central role of the CML Dashboard in the remote monitoring of patients with CML. In this study, the use of the CML Dashboard was low. This could be due to the slow transformation of providing remote care in general, and especially for patients with CML. In addition, experience with the treatment of CML and expertise are scattered [11,12]. This threatens optimal guideline adherence and adequate monitoring of disease activity [11,12]. eHealth can address health care challenges and support patients in managing their health and support HCPs to manage their patients more efficiently. As CML care is largely protocolled, more remote care could be enabled with the right tools. It could also enable the possibility to monitor patients with CML from home when disease activity is low and stable and only visit the hospital when needed, in accordance with the guidelines. Not only do all HCPs get insight into the course of their patients' disease in one glance, as the CML Dashboard highlights those who are in need of attention. When remote care is introduced in CML care, a well-functioning dashboard to monitor patients with CML BCR::ABL1 values, BCR::ABL1 monitoring time points, and side effects of treatment is therefore a must. Impeding rules and regulations and a lack of proper funding were already mentioned as barriers in this study. One strategy to overcome these barriers is agenda setting. In the Europe's Beating Cancer Plan, the use of digital health and telemonitoring to decrease inequality is encouraged [45]. Furthermore, in 2022, a shared view on the future of health care in the Netherlands was published [46]. In this document, it is emphasized multiple times that appropriate care takes place at home when possible, supported by digital tools, which is also called hybrid care delivery. These digital tools should aim to provide people-centered and sustainable care. When a properly functioning dashboard is used to remotely monitor patients with CML, or in a next step to proactively guide them by using alerts, hospital care can be reduced and patients become more self-directed. However, this asks for a couple of requirements, such as organizing care in networks and gaining financial resources for the transformation [46].

Next to new applications, patients' use of the app remains an essential requisite in the implementation of the CML Dashboard. Therefore, barriers and facilitators of the implementation of the CMyLife app experienced by patients should be taken into account. This should result in improved active participation on the patient side, using the CMyLife app accurately. This will equip hematology HCPs with the needed information to balance the type of care needed at a certain moment in time, according to clinical guidelines.

Strengths and Limitations

The strengths of this study are its methodological diversity, theoretical grounding, focus on early-stage evaluation, and inclusion of a diverse participant sample. These strengths collectively contribute to the study's robustness and potential to generate valuable insights into the potential of the CML Dashboard, thereby informing future research and clinical practice. The incorporation of both qualitative and quantitative research methodologies enhances the depth and breadth of data collection and analysis. Qualitative methods allowed for in-depth exploration of perceptions, experiences, and contextual factors, while quantitative approaches facilitated exploration of the available data, providing insight into the usefulness and opportunities of the CML Dashboard in its current form.

XSL•FO
RenderX

Additionally, the use of established theoretical frameworks provided a solid conceptual basis for the qualitative part of the study and interpretation of results. This ensured the study's alignment with existing theoretical perspectives and enhanced its generalizability. Moreover, the inclusion of a diverse set of patients and HCPs enriches the study's findings and increases its external validity. By capturing perspectives and experiences from a range of demographic, clinical, and professional backgrounds, the study can better reflect the complexities and nuances inherent in real-world health care contexts, enhancing the relevance and applicability of its conclusions. However, user experiences from patients should also be determined to improve participation from the patient side.

As for the quantitative research, there were a few limitations to the data. First, all data were registered by patients themselves, and it was not possible to check the reliability. This could have resulted in missing values, inconsistencies, and potential errors in time points and treatment details. For example, a period of 1 day or a period of 7380 days between monitoring time points is very unlikely. Second, patients registered what TKI they used and how often they switched. However, the reason for switching TKIs (lack of response or intolerability) was not registered, which is of importance because milestones of the different treatment lines differ. Another limitation of the quantitative data is the relatively high proportion of missing data for certain variables, such as age and current TKI use, which is inherent to patient-reported, manually entered data. As a result, findings may be less generalizable to the broader CML population, particularly patients who are less digitally engaged. At last, a limitation for the qualitative research was that the interviewed HCPs had little experience with the CML Dashboard in real-world clinical practice. However, their limited experiences were of great value in this early-stage exploration study with the aim to improve the CML Dashboard.

Conclusions

Adjustments should be made to the CML Dashboard to make the data useful for real-world data-driven guideline adjustments and remote monitoring. Organizational steps need to be taken first before CML care can be moved completely toward the home environment. HCPs specified several barriers and facilitators, and potential applications of the CML Dashboard. The CML Dashboard could have a central role in remote monitoring and quality assurance as it could enable patients to act as active participants in their own care, functioning not only as care recipients but also as providers of care and producers of health-related data. This aligns with the concept of patient empowerment and self-management, where patients are equipped with the knowledge, tools, and autonomy to manage their health conditions within specified guidelines. Our dashboard could be the first application that gives HCPs a timely oversight of the achievement/failure of treatment milestones of their patients and enables the use of real-world data for policy adjustments in daily clinical practice.

Acknowledgments

The authors would like to thank all researchers, nurses, and physicians who participated and recruited participants, all patients who participated in this study, the A.T. Twintey project team, and the patient association Hematon. Generative AI was used to make textual adjustments to improve readability. JEMS and LV were co-first authors of this article, and RPMGH and NMAB were co-senior authors.

Funding

This research was partly supported by The Netherlands Organization for Health Research and Development (ZonMw; project numbers: 516006001, 05160062510003). This organization may not gain or lose financially through this publication.

Conflicts of Interest

None declared.

Abstract

Background: Ostomy creation for cancer treatment negatively impacts the quality of life of both patients and caregivers. Hispanic patients with cancer and caregivers often face additional challenges, including limited access to supportive care programs.

Objective: This study aimed to examine the experiences and preferences of Hispanic patients with cancer living with ostomies and their caregivers to inform the cultural adaptation of an existing intervention program and the design of Ostomy Self-Care Program (Programa de AutoCuidado de Estoma [PACE]).

Methods: In this 2-stage study, conducted between March and August 2023 in San Antonio, Texas, we used a qualitatively driven mixed methods design, starting with an initial survey followed by qualitative interviews to explore the experiences, needs, and intervention preferences of Hispanic patients and caregivers managing ostomy care. We used Braun and Clarke's 6-phase thematic analysis approach to analyze the qualitative data and performed descriptive analysis for the quantitative data. Subsequently, we applied affinity diagramming and persuasive systems design principles to guide the design of PACE.

Results: In total, 14 Hispanic participants managing an ostomy (9 patients with cancer and 5 caregivers) completed a survey and participated in interviews, continuing until data saturation was reached. Participants had a mean age of 58.9 (SD 13.01, range 37‐79) years, and most (n=12) reported a high school diploma or General Educational Development as their highest education level. Around 5 (36%) participants scored below 26 on the eHealth Literacy Scale (eHEALS), indicating low digital health literacy, and the average Charlson Comorbidity Index (CCI) was 3.21 (SD 1.86, range 0‐6). Overall, 3 major themes emerged from the qualitative data analysis, namely perceptions of living with an ostomy, seeking support, and postsurgery challenges. Additionally, two primary themes emerged from participant interviews: (1) importance of preferred language and multimedia delivery and (2) patients and caregivers desire early introduction, multimodal delivery of materials, and inclusion of peer and family support. These themes informed the design and development of a culturally appropriate, web-based, bilingual PACE intervention that integrates content visualization, cultural adaptations, and persuasive technologies—strategies designed to encourage user engagement.

Conclusions: Our findings emphasize the importance of understanding the ostomy care experiences, supportive care needs, and intervention preferences of Hispanic patients and caregivers. Informed by stakeholders' insights, we culturally adapted the original intervention program using persuasive systems design principles to design and develop the PACE intervention, aiming to enhance engagement among Hispanic patients with cancer and caregivers, support effective self-management of ostomy care, and improve health outcomes.

KEYWORDS

ostomy; Hispanic; eHealth; digital platform; caregiver; patient with cancer; cultural adaptation; persuasive technology.

Introduction

Ostomy creation can be performed as part of cancer treatment for bladder, colorectal, cervical, ovarian, and uterine cancers. The surgery involves creating an opening on the anterior abdominal wall to allow defecation or urination [1]. This procedure can complicate the patient's ability to resume normal daily activities and further impact quality of life (QOL) [2]. While supportive care and management can sustain QOL after ostomy creation, a gap remains in available care resources that are tailored to minorities, including Hispanic patients with cancer and caregivers.

Compared to their non-Hispanic counterparts, Hispanic patients with cancer and their caregivers in the United States face additional challenges throughout cancer survivorship. These barriers include socioeconomic difficulties [3], limited access to health care [4], language barriers, and financial strain [5]. Additionally, this population experiences a higher rate of being uninsured [6]. Approximately 51.3% of Hispanics in the United States need translation services during medical consultations [7]. These language barriers can hinder effective communication and potentially lead to misunderstanding home care instructions [8]. Patients undergoing an ostomy creation surgery typically use more health care resources [9], which poses a further detriment to the Hispanic population, as they often face significant challenges in obtaining health care resources[10]. In addition, cultural beliefs and practices play a crucial role in illness management. In Hispanic culture, families traditionally take on the responsibility of caring for their sick members [11], and they tend to be more involved in ostomy care than any other medical or nursing tasks [12]. A study shows that involving family members in group training sessions can significantly improve outcomes among Hispanic patients and families[13]. Recognizing the needs of both Hispanic patients and their families is essential for providing adequate support and intervention in postostomy care.

Web-based interventions offer a promising way to support self-management for patients with chronic conditions and their families [14]. Research suggests that, compared to non–web-based interventions, these web-based interventions are effective in promoting knowledge acquisition and behavioral change [15]. As a cost-effective solution, they can particularly benefit underserved groups, such as Hispanic communities [16], through overcoming barriers to health care access. Offering content in Spanish further addresses language barriers and increases access [17]. Additionally, it provides a convenient way for patients to share information within their community, fostering peer support among people who have similar experiences [18].

As part of our preparatory work to address the care needs of Hispanic patients with cancer and caregivers, our multidisciplinary team previously translated the PRISMS (Patient-Reported Outcomes-Informed Symptom Management System) [19] into Spanish. PRISMS is an eHealth intervention that integrates a program with wearable devices to support patients with cancer and their caregivers during the postostomy care transition from hospital to at-home self-management. PRISMS aims to reduce preventable emergency room use and readmissions [19]. To ensure the cultural appropriateness of the translated materials, we engaged 10 bilingual translators, including clinical nurses, nursing students, and faculty, from Chile, Mexico, Puerto Rico, Argentina, and Colombia. These bilingual, native Spanish speakers translated the English version of PRISMS into Spanish to accommodate various dialects while sensitively addressing cultural nuances.

Building on previous work, our current study explored the experiences of Hispanic patients with cancer and caregivers regarding ostomy care, as well as their preferences for ostomy care interventions, to inform cultural adaptation of PRISMS-Spanish using a mixed methods approach. We presented the PRISMS-Spanish materials to participants to facilitate discussion and gather their feedback to help inform our design of a web-based ostomy care intervention program—Programa de AutoCuidado de Estoma (PACE)—tailored for this specific underserved population. While some references cited in this paper use terms, such as "Latino/Latina," we use "Hispanic" consistently throughout this study to align with the terminology used in participant recruitment.

Methods

Study Design Overview

In stage 1, we used a qualitatively driven mixed methods design with sequential data collection and parallel analysis. First, we made an initial phone call to each participant and collected quantitative data. Then we scheduled a Zoom (Zoom Communications) interview with each of them to collect qualitative data, which was typically within 1 month after the initial phone contact. The survey data provided a clear understanding of the characteristics, health literacy, and long-term mortality risk of Hispanic patients with cancer and caregivers. In contrast, the interview data and thematic analysis offered in-depth insights into their ostomy care experiences and preferences for intervention features and functions. We used Braun and Clarke's 6-phase thematic analysis approach [20] to guide our data analysis.

In stage 2, we used affinity diagramming and the Persuasive Systems Design (PSD) model developed by Oinas-Kukkonen and Harjumaa [21] to guide PACE program design for effective user engagement [22,23].

XSL•FO
RenderX

Stage 1: Exploration of Ostomy Care Experiences and Intervention Preference

We aimed to understand the experiences and information needs of Hispanic patients and caregivers. Additionally, we gathered intervention preferences based on participant feedback on PRISMS-Spanish materials.

Participants

Participants were recruited from the Mays Cancer Center in San Antonio, Texas, the seventh largest city in the United States, with a 65% Hispanic majority population [24]. Patients were eligible if they (1) were Hispanic adults with one of three types of ostomies (colostomy, ileostomy, or urostomy) for the treatment of bladder, colorectal, cervical, ovarian, or uterine cancer; (2) could read and speak Spanish; and (3) passed a cognitive assessment using the Mini-Mental State Examination [25]. Caregivers were included if they were adults serving as the patient's primary caregiver and could read and speak Spanish. Eligible participants were contacted via phone to confirm their willingness to participate and to address any questions.

Data Collection

Quantitative and qualitative data were collected through a survey administered during an initial phone call, followed by a Zoom interview that began with a presentation of the PRISMS-Spanish materials. Each participant encounter was conducted in either English or Spanish, based on their language preference. The survey questionnaires, interview guides, and intervention materials were translated into Spanish by a certified translator and reviewed by bilingual research staff and nursing students.

The trained bilingual research staff and research assistant (AV and LRR) conducted the initial phone survey before the interview in a secure, private office space at the University of Texas Health Science Center at San Antonio (UTHSA). They read each survey question aloud and recorded participants' responses into REDCap (Research Electronic Data Capture; Vanderbilt University) hosted by the UTHSA. The survey items included demographic questions, type of ostomy, cancer diagnosis, Charlson Comorbidity Index (CCI) [26], and the Electronic Health Literacy Scale (eHEALS) [27]. Participants were asked to complete the CCI and the eHEALS questionnaires to measure comorbidities and digital health literacy, which were critical for chronic illness management and for informing the PACE design. The CCI score is the summation of the number of comorbidities that participants reported. The eHEALS score, ranging from 8 to 40, assessed participants' digital literacy, including knowledge, comfort level, and perceived abilities in using electronic health information, with scores below 26 indicating low health literacy.

Next, participants were scheduled for a Zoom interview session at their convenience. During the session, translated PRISMS-Spanish materials were first presented, either via screen share or by email if needed, followed by open-ended questions. The semistructured interview guide was collaboratively developed by the research team, informed by insights from the PRISMS study [19] and a review of existing interventions related to ostomy care, digital health literacy, and culturally tailored programs for Hispanic populations. Interview questions focused on four main areas: (1) experience of ostomy care, (2) feedback on PRISMS-Spanish materials, (3) preferences for intervention and delivery, and (4) preferred implementation strategies. Interview sessions lasted approximately 45 - 60 minutes and were conducted between March and August 2023 by the research staff. All interviews were audio-recorded and transcribed verbatim via Zoom and reviewed by the project coordinator and trained research staff who had prior experience working with Spanish-speaking patients. We determined that data saturation was achieved when no new codes or themes emerged across interviews. This approach aligns with prior research indicating that qualitative data saturation often occurs within the first 12 interviews, with key themes emerging as early as 6 [28].

Data Analysis

Quantitative data from the initial phone surveys were exported from REDCap into Microsoft Excel and RStudio (Posit; version 4.4.1) for analysis. We performed descriptive statistics, including means, ranges, frequencies, SDs, and percentages, to summarize participant demographics, CCI scores, and eHEALS (Table 1). These analyses provided an overview of the sample's characteristics and informed the interpretation of qualitative findings.

The deidentified qualitative interview data were analyzed using Braun and Clarke's 6-phase approach to thematic analysis [20]. This approach was applied to ensure a credible analysis procedure and continued until no new themes were identified. The approach is detailed as follows:

(1) Familiarization: Two researchers (AV and LRR) independently read the interview transcripts and noted initial ideas and patterns. This process allowed researchers to gain an in-depth understanding of the participants' overall experiences and needs.

(2) Generating initial codes: AV and LRR generated initial codes systematically across the entire dataset, using NVivo (Lumivero) qualitative data analysis software (version 10.2.1) and a preliminary codebook based on interview topics.

(3) Searching for themes: the research team collated the initial codes into broader themes by grouping related codes to generate potential themes to capture participants' experiences.

(4) Reviewing themes: Team meetings were held to review themes and resolve discrepancies in theme identification, aiming for a minimum coding consistency agreement of 80% [29].

(5) Defining and naming themes: 3 researchers (AV, LRR, and XW) collaboratively defined and named each theme, ensuring that each theme was distinct and related to the aim of this study. Detailed descriptions were developed for each theme, supported by illustrative quotes from participants.

(6) Producing the report: Finally, the team synthesized the findings into a cohesive report, which was used to inform the cultural adaptation of PRISMS-Spanish and the design of PACE.

Although quantitative and qualitative data were collected sequentially, analysis was conducted in parallel. Quantitative descriptive statistics (eg, demographics, CCI, and eHEALS) were reviewed with qualitative codes and themes side by side. The integration occurred during the interpretation phase, where quantitative results were used to contextualize and support qualitative findings. The integrated results were synthesized into joint displays (Tables 2 and 3) to inform the design of the PACE intervention.

Table . Hispanic patients' and caregivers' experiences with ostomy care.

Themes and subthemes	Participant quotes
Ostomy perception	
Emotion	• "Because it is kind of a shocking thing to see your internal organs hanging out of your body even though it's a little bit, it's still a hole in your belly and you got your guts or hanging out." [Female, ileostomy, patient, eHEALS[a] score=35, CCI[b]=2] • "All the ugly stuff that nobody wants to show." [Female, ileostomy, patient, eHEALS score=32, CCI=3]
Necessity	• "And as well as many other people, it definitely has changed my perception to something that is scary to something that is a necessity at times if needed." [Female, colostomy, patient, eHEALS score=38, CCI=4] • "Knowing that I had it and I needed it to save my life." [Female, colostomy, patient, eHEALS score=38, CCI=4]
Support	
Health care provider	• "But I don't feel that knowledge is there for a lot of health care workers." [Female, colostomy, patient, eHEALS score=38, CCI=4]
Family and caregiver	• "So I really depended on him (husband) to help me put a new one back on." [Female, colostomy, patient, eHEALS score=38, CCI=4] • "… but what really helped me a lot was her (wife) and my family that was a hundred percent behind me and you know they, gave me the faith because I didn't have the faith at first." [Male, colostomy, patient, eHEALS score=23, CCI=6] • "I have an alternative. I do my husband's changes for his urostomy bag. But my son also knows how to provide the care because his wife has an ostomy bag. So in a pinch if I'm not available, he can substitute for me." [Female, urostomy, caregiver, eHEALS score=32, CCI=4] • "So they supported me through the cancer, but they weren't really sure how to help me or how to feel about it because it deals with stool and . I know they were really like kind of just supporting but not really familiar with it." [Female, colostomy, patient, eHEALS score=38, CCI=4] • "I think so, that they also involve families in these talks for them to also see how family members and the sick should be treated" [Male, colostomy, caregiver, eHEALS score=29, CCI=3]
Peer support	• "I had a lot more difficulties with my ostomy then a lot of people but you know, I ended up going to peers that worked with an ostomy as opposed to the ostomy care nurses that they were giving me because they too still weren't familiar with how to take care of my problem." [Female, colostomy, patient, eHEALS score=38, CCI=4]
Self-care	• "… it depends on what the circumstances are, but I think that the patient should do as much as possible to help themselves." [Female, ileostomy, patient, eHEALS score=35, CCI=2]
Challenges	
Radiation side effects	• "I couldn't even lift up my arms after radiation ... if they have the ostomy bag for some reason, if they're also undergoing radiation. Yeah, that's bad." [Female ileostomy, patient, eHEALS score=35, CCI=2]
Chemotherapy side effects	• "here's added things so sometimes chemos depending on which one some can cause a lot of diarrheas. Some can cause constipation." [Female, colostomy, patient, eHEALS score=38, CCI=4]

XSL•FO
RenderX

Themes and subthemes	Participant quotes
Skin irritation	• "You know, a lot of times people see, okay, it's just, it's just a little rash or whatever But actually, it's maybe an infection or something else and they see it as it just being a little rash when it's really not, you know." [Male, ileostomy, patient, eHEALS score=34, CCI=0] • "The skin irritation just lasted the entire time." [Female, ileostomy, patient, eHEALS score=35, CCI=2] • "Once in a while, he'll have a little bit of irritation, but I'll just clean it." [Female, urostomy, caregiver, eHEALS score=32, CCI=4]
Leakage	• "One reason was because, you know, I was having like a leak. And we're like, well maybe, what are we doing wrong?" [Male, ileostomy, patient, eHEALS score=34, CCI=0] • "Because I'm a heavier-set girl and obesity is rampant in the Latin community. My ostomy was retracted in so it was not sticking out like normal people.it had a lot more problems with leaking because it couldn't get a good seal around the stoma." [Female, colostomy, patient, eHEALS score=38, CCI=4]
Self-isolation	• "I feel in the house we had everything organized and everything there for us to do the job, but taking it out of the houses where it was a little harder for me." [Female, colostomy, patient, eHEALS score=38, CCI=4]
Caregiver stress and emotion	• "I'm gonna say like a depression myself, but I kept it to myself." [Female, colostomy, caregiver, eHEALS score=19, CCI=1] • "We didn't know what else to do. but you know at that point my dad had lost a lot of blood." [Male, urostomy, eHEALS score=34, CCI=4]

[a]CCI: Charlson Comorbidity Index.

[b]eHEALS: eHealth Literacy Scale.

XSL•FO
RenderX

Table . Preferences for the ostomy care intervention among Hispanic patients and caregivers.

Themes and subthemes	Participant quotes
Importance of preferred language and multimedia delivery	
Content and delivery format	• "Okay, the information is really, really helpful." [Female urostomy, caregiver, eHEALS[a] score=32, CCI[b]=4] • "The YouTube (videos) really does help out a lot." [Male, ileostomy, patient, eHEALS score=34, CCI=0] • "You have some really good tips like though there was one that we were told about and it really had helped me now that I when I apply the bag on my husband." [Female, urostomy, caregiver, eHEALS score=32, CCI=4]
Language	• "… for one who does not speak English. There is nothing, there is nothing clearer than Spanish, so the explanation is excellent, it is very good." [Female, colostomy, patient, eHEALS score=25, CCI=1]
Need for early, multimodal materials and peer and family support	
Delivery platform	• "I do on a phone and do a desktop." [Female, urostomy, patient, eHEALS score=40, CCI=6] • "For me it was more telephone because that's what I used more as far as online and researching stuff." [Female, ileostomy, patient, eHEALS score=32, CCI=3] • "I happen to like computers, … but I think not a lot of people, especially if they're older ... So he's not computer savvy either. So I think maybe like a handout or in a notebook kind of form would be better. With pictures." [Female, urostomy, patient, eHEALS=40, CCI=6]
Delivery timing	• "This should be shown to the patients before they leave the hospital because they might not have the support once they get home." [Female, urostomy, caregiver, eHEALS score=32, CCI=4] • "Like before you get going home." [Female, urostomy, caregiver, eHEALS score=32, CCI=4] • "I think it'd be better if you were to be able to give them all the information ahead of time." [Male, ileostomy, patient, eHEALS score=34, CCI=0]
Family and peer support	• "We definitely needed help. So I definitely think helping caregivers or showing caregivers how to help is really important." [Female, colostomy, Patient, eHEALS score=38, CCI=4] • "I think it's very important that anybody in the family that's willing to be involved that they would get involved in case the person that normally does it for you or helps you with it is not available for whatever reason. I think other family members should be involved also." [Male, urostomy, patient, eHEALS score=33, CCI=3] • "I think it would be wise and I think it really helps if you ask somebody, somebody personal, somebody that's gone through it." [Male, ileostomy, patient, eHEALS score=34, CCI=0]

[b]eHEALS: eHealth Literacy Scale.

Stage 2: PACE Web-Based Intervention Program Design

Overview

Findings from stage 1 informed the cultural adaptation of PRISMS-Spanish and the design of the PACE prototype. We used affinity diagramming to organize the intervention contents and materials, and the PSD model to guide the design of the PACE program. Our multidisciplinary team, including digital health researchers, nursing faculty, user interface (UI) designers, web developers, informatics specialists, and clinicians from UTHSA and the University of North Carolina at Chapel Hill, held weekly hybrid meetings (in-person and via Zoom) over 6 months (from September 2023 to March 2024). Design decisions were made collaboratively during structured sessions focused on usability, cultural relevance, and visual accessibility, during which wireframes and prototypes were reviewed. Ideas and comments were synthesized and iteratively incorporated into the prototypes using affinity diagramming on a physical whiteboard, guided by the PSD model. A project coordinator documented meeting notes and key design decisions throughout the process.

XSL•FO
RenderX

Affinity Diagramming

We used affinity diagramming [30] to organize ostomy care materials across various web pages based on the content interrelationships to delineate the tasks and features of the new PACE program. Affinity diagramming is a commonly used user experience design approach that helps organize design ideas systematically [30]. Based on PRISMS-Spanish, the results from stage 1, and the affinity diagram, we generated 5 different types of prototypes for PACE by collaborating with a UI design class. Our multidisciplinary team analyzed and evaluated each prototype. Key features, such as website layout, visual and graphical representations, and navigation options were finalized to ensure the program would meet the needs of patients and caregivers.

Persuasive Systems Design

To ensure the appropriate application of these persuasive principles, we incorporated expert evaluation during the design process. We used PSD to guide the design of the culturally adapted PACE to optimize user engagement in the web-based intervention [31]. The PSD model includes 28 design principles across 4 categories (Textbox 1). Experts in health care, UI design, and health informatics provided feedback on the integration between the PSD model and PACE.

Textbox 1. Persuasive system design model.

Categories of persuasive techniques and system design principles

- Primary task support: reduction, tunneling, tailoring, personalization, self-monitoring, simulation, and rehearsal.
- Dialogue support: praise, rewards, reminders, suggestion, similarity, liking, and social role.
- Credibility support: trustworthiness, expertise, surface credibility, real-world feel, authority, third-party endorsements, and verifiability.
- Social support: social learning, social comparison, normative influence, social facilitation, cooperation, competition, and recognition.

Ethical Considerations

This study was approved by the University of Texas Health San Antonio's Institutional Review Board (IRB; number 20220693EX). Referred patients were contacted via phone to confirm their eligibility and willingness to participate and to answer their questions. All participants received study information and signed a written informed consent form in their preferred language (English or Spanish) after their questions were answered and before any research activities began. The consent form included the following information: (1) the primary data collection (surveys and interviews) would be used to inform intervention design; (2) interview recordings and transcripts would be deidentified and stored separately from study documents containing participants' identifiable information on a password-protected, encrypted cloud drive to ensure data security and confidentiality; and (3) each participant would receive a US $80 gift card upon completing both the survey and the interview session.

Results

Stage 1: Exploration of Ostomy Care Experiences and Intervention Preference

Participant Characteristics

Data collection and analysis continued until no new themes related to care needs and ostomy experiences emerged during the interviews. The research team successfully enrolled 9 patients and 5 caregivers, reaching data saturation with a total of 14 participants. These participants had a mean age of 58.9 (SD 13.01, range: 37 - 79) years. The mean CCI score was 3.21 (SD 1.86, range 0 - 6), indicating a moderate comorbidity burden. The mean eHEALS score was 29.71 (SD 6.62, range 18 - 40). Most participants (n=10) reported a high school diploma or General Educational Development equivalent as their highest level of education, while 2 participants had completed up to the seventh grade, and 2 participants held a bachelor's degree. The patients and caregivers reported an annual income between US $10,000 and US $90,000. Most patients had their ostomy surgery 3 - 4 years before the interview.

Thematic Analysis Results

Hispanic Patients and Caregivers' Experiences With Ostomy Care

As outlined in Table 2, the thematic analysis identified three major themes and associated subthemes among Hispanic patients with cancer and caregivers: (1) perceptions of ostomy and its impact on their lives, (2) experiences in seeking support, and (3) challenges faced following discharge from the hospital.

Perceptions of Ostomy and Its Impacts

Patients and caregivers frequently expressed fear and negative perceptions regarding ostomies and used terms like "ugly" and "shocking" to describe them (refer to "Emotion" in Table 2). On the other hand, the subtheme of necessity reflected a gradual shift in ostomy perception as patients and caregivers began to acknowledge the life-saving function of an ostomy and were able to accept and live with it (refer to "Necessity" in Table 2).

Support Seeking

Support emerged as a significant theme from the interviews, with 4 sources identified, such as health care provider support, family and caregiver support, peer support, and self-care. Many participants reported limited access to resources with sufficient knowledge for changing ostomy bags and teaching others to perform the task (refer to "Health care provider" in Table 2). As shown in the "Family and caregiver" section in Table 2, patients with CCI scores ranging from 4 to 6 emphasized the crucial role of family support. Some indicated that family members often act as backups for one another when providing care. While some patients do not formally recognize their family members as caregivers, they still rely on them for ostomy bag

XSL•FO
RenderX

changes. Additionally, patients expressed a desire to get help from people who have had similar experiences (ie, "Peer support" in Table 2. Conversely, patients with relatively low CCI scores highlighted the importance of self-reliance during postsurgical home management (refer to "Self-care" in Table 2).

Challenges Post Surgery

Patients faced significant physical and emotional difficulties after ostomy surgery. Many needed to continue cancer treatment, such as radiation and chemotherapy, which further complicated their daily ostomy care (refer to "Radiation side effects" and "Chemotherapy side effects" in Table 2). Side effects of these treatments, such as fatigue and diarrhea, made it harder for patients to manage bag changes, thereby increasing the risk of leaks. Additionally, treatments made patients' skin more sensitive and prone to irritation (refer to "Skin irritation" in Table 2). As shown in the "Leakage" section in Table 2, leakage challenges were associated with obesity, which is a common issue in the Hispanic community. Leakage not only caused feelings of helplessness but also led to self-isolation. Many patients reported feeling more secure and comfortable staying at home (refer to "Self-isolation" in Table 2). Notably, caregivers reported high levels of stress and depression while caring for patients with ostomy cancer (refer to "Caregiver stress and emotion" in Table 2).

Preference for the PACE Ostomy Care Intervention Program

"insert subheading"

Overall, participants felt excited about the existence of a program like PRISMS and expressed satisfaction with the translated PRISMS-Spanish materials provided during the interviews. They also shared their preferences regarding intervention delivery timing, devices commonly used in information searching (mobile phones, desktops, etc), and supporting resources.

Importance of Preferred Language and Multimedia Delivery

Participants reported a preference for multimedia, including text documents, audio, and videos, when presented with intervention materials. They found practical tips and tricks extremely useful, especially regarding the optimal timing for changing ostomy appliances, barrier rings, and support belts. Although some tips had been mentioned by their health care team before, participants appreciated the tips as valuable reminders (refer to "Content and delivery format" in Table 3). Participants with low eHEALS scores (<26) were more likely to be impacted by language barriers when accessing health care resources. This is supported by the "Language" (refer to "Language" in Table 3) subtheme, where participants expressed a preference for Spanish-translated materials.

Need for Early Introduction, Multimodal Materials Delivery and Peer and Family Support

Participants expressed their preference for the intervention delivery platform, including the timing and support they would like to receive. Many participants were proficient with computers and mobile devices, but some suggested that providing printed handouts with pictures would also be helpful (refer to "Delivery platform" in Table 3). Participants also stated that information about ostomy care should be provided at the preoperative appointment or, at the latest, during hospitalization, although most patients were sent home with discharge paperwork after having a nurse demonstrate a bag change (refer to "Delivery timing" in Table 3). Feedback also emphasized the importance of training multiple support people in changing an ostomy bag, depending on family dynamics (refer to "Family and peer support" in Table 3). These comments further illustrated that the program should be accessible to all relevant family members.

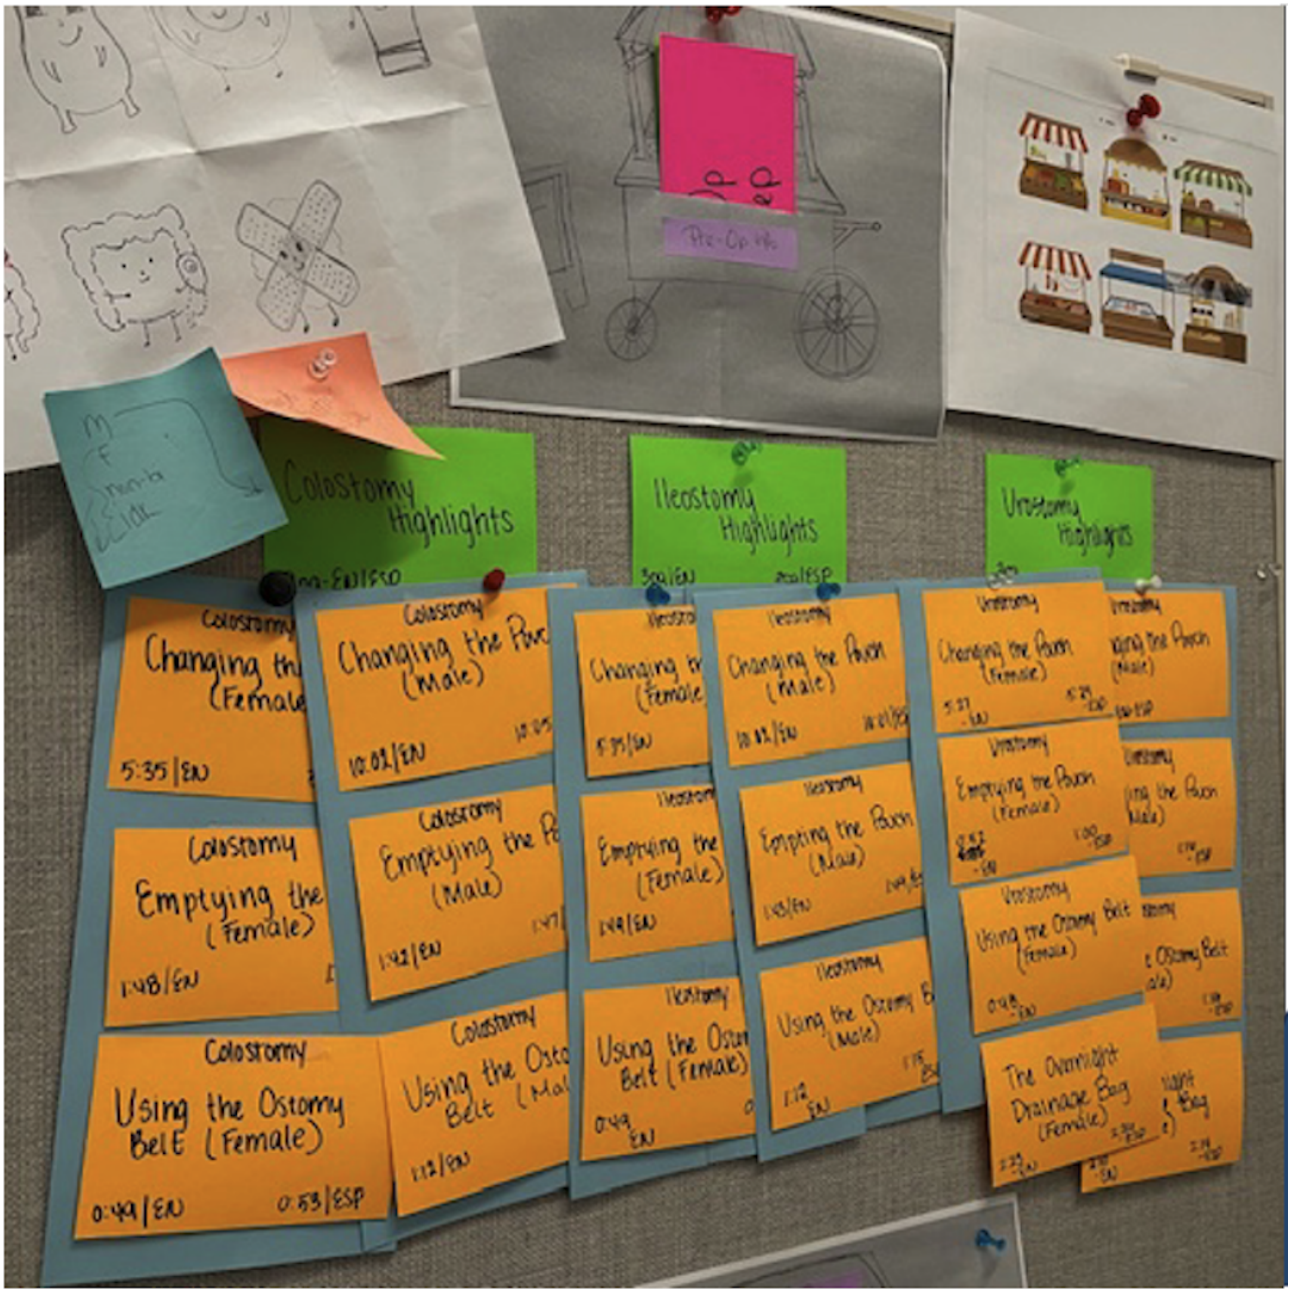
Stage 2 Design of the Web-Based PACE Intervention

Based on the feedback in stage 1, we developed the culturally adapted PRISMS-Spanish intervention, renamed as PACE. In this section, we focus on introducing the design of the PACE model, guided by affinity diagramming and user engagement strategies informed by the PSD model.

Content and Cultural Adaptation

Based on the interview findings and thematic analysis, we primarily focused on culturally adapting and customizing the existing PRISMS/PRISMS-Spanish program to develop the PACE intervention for Hispanic patients with cancer and their family members. PACE retained core contents from the PRISMS, including text and demonstrative videos on ostomy care, providing information on managing common complications (eg, dehydration and skin issues), performing safe physical activity, and preventing falls. Additionally, we introduced a new preoperation checklist to help patients and their families prepare thoroughly. In response to participants' preferences, we maintained the PRISMS-Spanish for information delivery using multimedia formats, including audio, video, and text. For instance, a step-by-step video demonstration of the crusting technique and a text listing situations in which patients should contact a doctor post surgery were included in PACE. To further enhance user experience, audio, and video were adapted to accommodate preferences for speaking speeds, tone, and captioning.

New culturally adaptive elements were added to engage Hispanic users by incorporating familiar visuals and culturally resonant content. For example, images of traditional Hispanic dishes, such as empanadas and ceviche, were included to promote healthy eating. Culturally significant colors like orange and blue were used to evoke a sense of energy and warmth. These cultural adaptations aimed to develop an inclusive platform for PACE that fosters connection and engagement within the Hispanic community, optimizing support for patients with cancer and caregivers.



Affinity Diagram of the PACE Website

An affinity diagram was created to organize the content in a logical and user-friendly layout (Figure 1). Each piece of material, whether text, videos, or audio files, was represented as a color-coded data point and written on sticky notes, which were mapped into meaningful sections informed by interview feedback on delivery timing. This process aided in designing a

XSL•FO
RenderX

user experience that guides users through the entire journey of ostomy care, from preoperative preparation to postsurgery self-management at home, with specific adaptations for the Hispanic population.

Figure 1. Affinity diagram of the PACE (Programa de AutoCuidado de Estoma) website.

Similar to our PRISMS intervention, our team identified 6 main sections for the PACE website: “Pre-Op,” “Doctor Office Visits,” “Learning Your Ostomy Device,” “Ostomy Care & Recovery,” “General Physical Health,” and “Good Mental Health” (Figure 2). “Pre-Op” offers comprehensive preoperative preparation, including a printable medication list template. “Doctor Office Visits” provides checklists for health care appointments, listing symptoms and test results to track. “Learning Your Ostomy Device” delivers essential knowledge on managing an ostomy, including changing, emptying, and understanding different types of bags and related equipment. “Ostomy Care & Recovery” addresses skin irritations, chemotherapy side effects, and common complications. “General Physical Health” offers recommendations for physical activities and tips on nutrition and dressing for fitness. Finally, “Good Mental Health” provides strategies for maintaining mental well-being for both patients and caregivers.

XSL•FO
RenderX

Figure 2. Home page of the PACE (Programa de AutoCuidado de Estoma) website.

Persuasive Elements

Overview

After analyzing the interview data and designing the website layout, the research team (LS, AV, JL, LRR, and XW) conducted an expert evaluation leading to the integration of 7 persuasive principles of the PSD Model into the website design, as detailed in Table 4.

Table . Persuasive elements in PACE (Programa de AutoCuidado de Estoma).

PSD[a] categories and selected principles for PACE[b] design	Application of PSD principles
Primary task support	
Tailoring	Users receive tailored task recommendations based on their group (Patient/Caregiver and family member).
Self-monitoring	Users can track their progress on each task.
Dialogue support	
Rewards	Users earn avatars as rewards for progress in learning sections.
Reminders	Users receive email reminders to log in to the PACE website regularly.
Credibility support	
Trustworthiness	The PACE website offers truthful, fair, and unbiased information through various media, including videos, audio, text, and images.
Real-world feel	Team members from the research and development teams are introduced on the login page.
Social support	
Social learning	An online forum is available in PACE, allowing users to write comments, ask questions, or share experiences anonymously.

[a]PSD: Persuasive Systems Design.

[b]PACE: Programa de AutoCuidado de Estoma.

XSL•FO
RenderX

Primary Task Support

We incorporated tailoring and self-monitoring principles. Thematic analysis revealed that many participants desired multiple family members to be trained in ostomy care. To address this, we applied the tailoring principle by enabling role selection and rendering customized content. During registration, users could choose roles (patient, caregiver, or other support) and have the flexibility to change roles later in the user profile settings. The content and layout of the website were rearranged according to user roles, enhancing the user experience. For UI design, our team decided to use a card layout (clickable containers with images and a brief content summary) with a progress bar at the bottom (Figure 2B) by displaying completed tasks and allowing users to resume where they left off to support self-monitoring. Users could track their progress in completing recommended videos and audios on their profile page.

Dialogue Support

To reduce fear and stress and encourage engagement, we established a reward mechanism where users could unlock new cartoon ostomy avatars and decorations after engaging with content. Additionally, email reminders were also set to prompt participants to revisit the website.

Credibility Support

To ensure the PACE program's credibility, we applied the principles of trustworthiness and real-world feel. We presented truthful, fair, and unbiased information through videos, text, and images based on user preferences. The information was developed based on scientific evidence and clinical guidelines with guidance from health care professionals. Videos were recorded by a certified Wound and Ostomy Care Nurse from the University of North Carolina at Chapel Hill. Additionally, a detailed introduction of the research team was also displayed on the login page for reference.

Social Support

The social learning principle was facilitated through an online forum, "Peer Support" (Figure 2). After logging in to the PACE website, patients and their family members could join support groups and seek advice. They could post, comment, and bookmark discussions, creating a space for the Hispanic community to not only exchange ostomy care knowledge but also provide emotional support to those community members in need, fostering a sense of belonging.

Discussion

Principal Findings

The main findings of this study revealed that Hispanic patients with cancer and caregivers experienced significant emotional distress and faced multiple challenges related to ostomy care management post surgery. Participants emphasized the need for culturally tailored interventions and expressed preferences for bilingual multimedia content, early delivery of the intervention, and the inclusion of family and peer support in ostomy care management. Drawing on these insights and feedback, our multidisciplinary team culturally adapted the PRISMS-Spanish and designed and developed the bilingual PACE intervention.

First, participants in our study highlighted a strong preference for content in Spanish alongside English, aligning with existing literature that emphasizes the importance of bilingual support in efficiently overcoming linguistic barriers [32]. Participants who completed the eHEALS survey in Spanish and scored below 26 reported difficulties reading English-language materials and expressed a strong preference for Spanish-translated content. The limited availability of Spanish-language digital resources likely limited their opportunity to access online health information, contributing to lower confidence in using digital health tools and lower self-reported digital health literacy. These findings illustrate the importance of providing bilingual digital health intervention. Thus, we developed the bilingual PACE program by integrating the original PRISMS and the PRISMS-Spanish materials, ensuring cultural and contextual relevance for Hispanic patients and caregivers. Additionally, the bilingual PACE intervention was designed to facilitate family involvement in ostomy care, particularly among Hispanic children and younger generations who are fluent in English and more acculturated to American culture [33,34]. To accommodate participants' preferences and address linguistic barriers, the bilingual platform includes Hispanic dubbing for audio and videos, in addition to text and graphics, which were recorded at appropriate speaking speeds in both English and Spanish, accommodating both patients and their family members who may not speak Spanish or English but still act as caregivers. Recent findings from the Pew Research Center indicate that approximately 65% of third- or later-generation Latinos report limited proficiency in Spanish [35]. By incorporating a bilingual focus, PACE fosters engagement with the entire family, regardless of language proficiency. Our study participants expressed satisfaction with the translation and bilingual design during interviews, highlighting its effectiveness in meeting their needs.

Second, the perceptions of our study participants also played a key role in shaping the delivery format of the PACE intervention. Hispanic patients and caregivers expressed a strong preference for content visualization through a multimedia platform, aligning with the findings of Joshi et al [36] in which Hispanic participants find multimedia programs easy to navigate and effective for obtaining relevant health information. In response, PACE delivers content in various formats, including video, audio, images, and text, to cater to diverse learning preferences. To further enhance engagement, we incorporated culturally relevant elements, such as images of Hispanic foods and vibrant colors like blue and orange, which resonate with the community. Additionally, based on participants' preferences and feedback, similar to the original PRISMS, PACE was designed to be accessible across different devices, including personal computers, mobile phones, and tablets.

Third, participants' feedback affirmed the comprehensive content of the original PRISMS and guided the design of PACE to improve QOL for patients and caregivers. Participants shared their experiences living with an ostomy, often expressing feelings of embarrassment and body image issues following surgery. By increasing knowledge and familiarity, PACE helps

XSL•FO
RenderX

Hispanic patients and caregivers integrate ostomy care into their daily lives with greater ease and positivity.

Additionally, our study revealed that family members of Hispanic cancer survivors are often expected to provide emotional support, assist with daily living, and manage overall health care [37]. This cultural expectation includes providing comprehensive information about the illness [38], treatment details, anticipated side effects, hands-on care skills [39,40], and strategies for stress reduction [41,42]. However, these informational needs are often unmet [41-44]. To fill this gap, PACE delivers tailored information for both patients and their caregivers and family members, enhancing their knowledge and skills in ostomy care. This approach not only enables them to provide better support to patients but also helps maintain their own QOL.

Finally, and most importantly, we used PSD principles to enhance user engagement in the web-based PACE interventions. A systematic review [45] demonstrates that PSD can significantly enhance adherence to web-based interventions, particularly those targeting chronic conditions and lifestyle changes [46,47]. This is especially relevant for patients with cancer living with ostomies, who face substantial changes in their health, lifestyle, behaviors, and daily routines [48]. To promote effective self-management, patients and their families must consistently engage with web-based interventions [49]. However, a notable challenge is that Hispanics are reportedly less likely to use health-related applications compared to other racial groups [50]. Moreover, the absence of user input during program development can further limit the success of these interventions [51]. In this study, we applied PSD principles in the design of the PACE intervention to enhance user engagement and ostomy care self-management. Building on the features of the original PRISMS intervention and incorporating participant feedback, we implemented key PSD principles to enhance engagement. Findings from this study are consistent with prior research [52-54], demonstrating that integrating persuasive principles into intervention design can significantly improve user engagement and support the long-term effectiveness of web-based platforms. The following are examples of how we integrate PSD principles into the design of PACE.

1. Self-monitoring: Participants were encouraged to track their progress in learning ostomy care, increasing awareness, and reinforcing skill development.
2. Rewards and reminders: These features were incorporated to foster continuous use of the program, promoting the acquisition of strong ostomy care skills [55].
3. Trustworthiness and readability: The PACE intervention ensured information was truthful, fair, and unbiased, building trust with users through a user-friendly interface.
4. Social learning: An online forum was integrated, enabling peer support and communication within the PACE intervention.

Strengths and Limitations

To our knowledge, this is the first study to apply affinity diagramming and PSD principles in the design of an ostomy care intervention. Given the limited access to high-quality online health resources among the Hispanic population [56] and building on evidence that Spanish-language, tailored health information in Spanish improves reach and effectiveness in this underserved group [57], our multidisciplinary team intentionally incorporated bilingual and culturally sensitive features to enhance patient engagement and family involvement in ostomy care. During cancer survivorship, ostomy creation as part of cancer treatment is a life-changing event. Traditional education, typically delivered through brief in-hospital demonstrations, can be overwhelming for patients recovering from surgery and coping with changes in physical function and body image. PACE addresses this gap by providing accessible, bilingual resources designed to meet the cultural and informational needs of Hispanic families. By supporting both patients and caregivers during the critical care transition from professional hospital care to self-management at home, PACE aims to improve health outcomes and support their caregivers' well-being.

However, the following limitations warrant further exploration. First, this study lacked participation from family members other than the first-line caregivers in the interviews. Participants emphasized the importance of involving additional family members in ostomy care. Future studies should address this gap by including a broader range of family members of Hispanic patients with cancer to better capture their diverse experiences and needs. Second, participants' educational attainment was at the high school level or above, which may limit the generalizability of the findings, given that a large proportion of Hispanic adults—particularly older or foreign-born individuals—have not completed high school [58]. Future research should prioritize recruiting individuals with lower educational attainment to rigorously design and evaluate digital interventions like PACE. Third, most patients in this study were more than 1 year post ostomy surgery, so their insights may differ from those who are newly diagnosed or recently discharged and still adjusting to life with an ostomy. We intentionally recruited this population because they had already navigated the postostomy survivorship journey and were likely to be more motivated, engaged, and interested in accessing online information compared with those who are fresh out of ostomy-creation surgery. While their reflection may be subject to recall bias, we encouraged them to draw on their lived experiences. Their insights were valuable in informing an intervention design that is potentially feasible and acceptable for individuals in the early stages of recovery. However, future studies should evaluate the acceptability, usability, feasibility, and effects of the intervention among patients and caregivers managing newly created ostomies to ensure its relevance and applicability across various stages of recovery.

Fourth, this study used descriptive statistics to analyze the quantitative data, which may limit the ability to draw statistical inferences about relationships between variables, such as age, education, digital literacy, comorbidities, and intervention preferences. Future studies with larger sample sizes need to incorporate statistical methods (eg, regression analysis or causal inference techniques) to examine associations between participant characteristics and engagement in digital health interventions. Finally, this study reported percent agreement to assess coding consistency, given the iterative coding approach and small sample size. Future work should consider applying

XSL•FO
RenderX

more robust methods, such as Cohen κ, to evaluate interrater reliability in large-scale studies.

Despite these limitations, the findings support the cultural adaptation of the English version of the PRISMS intervention into a user-friendly bilingual PACE web-based program for Hispanic patients and families, a population often underrepresented in clinical intervention research. Future studies should recruit participants with diverse backgrounds to evaluate the PACE intervention in other underserved communities, focusing on improving health outcomes and addressing health disparities.

Research and Clinical Implications

The PACE web-based program addresses critical challenges in ostomy care, including skin irritation, leakage, treatment side effects, and social and emotional stress with the goal of improving health outcomes for patients and caregivers. PACE provides adaptable techniques for different stages of recovery, standardizes patient and family education, and supports self-management in the hospital and at home. Its scalability and accessibility are particularly valuable for individuals in remote areas, such as those in rural Texas. By integrating findings from the PRISMS pilot feasibility study and current research, PACE is positioned for testing in a sufficiently powered clinical trial to evaluate its efficacy and effectiveness. Making the program accessible in hospital rooms could further enhance its impact on patient education and care transitions.

Conclusions

Our findings revealed the experiences of Hispanic patients and caregivers managing ostomy care for cancer treatment, including their support-seeking behaviors, postdischarge challenges, and preferences related to language, timing of intervention delivery, digital platforms, and the inclusion of family and peer support. Informed by these insights, we culturally adapted the PRISMS-Spanish program and applied PSD principles to design the bilingual, web-based PACE intervention. This tailored approach aims to enhance patient and caregiver engagement, strengthen their ostomy care skills, and ultimately improve their health outcomes. Future research will include a pilot testing for usability and feasibility of the PACE intervention among larger and more diverse Hispanic populations.

Acknowledgments

We extend our heartfelt gratitude to the patients and caregivers who participated in this study, the health care professionals who supported our efforts, and our dedicated research team members for their invaluable contributions. This line of work was done in collaboration with WOCNs and ten bilingual translators from diverse cultural and healthcare backgrounds. Generative artificial intelligence (AI) tools were not used in generating manuscript content.

Funding

This study is an extension of the PRISMS (Patient-Reported Outcomes-Informed Symptom Management System) funded by the NCI (National Cancer Institute) Cancer Alliance Pilot Award (2UG1CA189823, PI [principal investigator]: LS).

Data Availability

The datasets for this study are not publicly available due to the sensitive nature of patient and caregiver qualitative and quantitative data, as well as privacy and confidentiality requirements outlined by the University of Texas Health San Antonio's IRB. But data are available from the corresponding author on reasonable request.

Authors' Contributions

LS led the conceptualization of the study. LS, FY, AV, JL, RD, and XW supported the design of the digital platform. RS, MB, AV, and LRR contributed to participant recruitment and data collection. LS, AV, LRR, JL, NVR, and XW contributed to data interpretation. AV, LRR, JL, and XW performed the formal data analysis. FY, AV, and XM contributed to data visualization and digital platform design. AV managed, coordinated, and executed research activities. All authors contributed to the draft review and critical revision of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Barriers to eHealth use include lack of technological infrastructure, resistance to change, and inequities in access. However, patterns of access to and use of eHealth tools in people being treated for cancer have not been fully described in the literature.

Objective: Our aim was to describe the patterns of access to and use of eHealth tools among outpatients receiving treatment for hematological malignancies and solid tumors.

Methods: We conducted a cross-sectional multicenter study using a survey offered to patients aged over 18 years receiving outpatient treatment for hematological malignancies or solid tumors at 4 teaching hospitals in Madrid, Spain, between February 1, 2021, and November 30, 2021. The survey instrument featured questions about patients' demographic and social characteristics, cancer diagnosis, use of information and communication technology (ICT), use and opinions of the Patient Portal, and changes in ICT use during the COVID-19 pandemic. To study the relationship between the different variables, 2-tailed Student *t* tests or ANOVA were used for variables with normal distribution, and the Mann-Whitney or Kruskal-Wallis tests were used for variables with nonnormal distribution. Statistical analyses were performed using SPSS (version 25; IBM Corp) for Windows.

Results: In total, 200 patients were included in our study. Median age was 60 (range 21 - 87) years. A total of 130 (65%) patients presented with hematological malignancies. Most (n=181, 90.5%) patients considered that eHealth tools might help to improve communication with the medical team during their treatment. Retired participants (28.6% vs 71.4%; *P*<.001), those older than 60 years (26% vs 74%; *P*<.001), and those without higher education (2.6% vs 97.4%; *P*<.001) showed significantly lower rates of internet use, with no observed sex-related differences. A total of 177 (88.5%) patients found the Patient Portal useful, and 140 (70%) reported increased use of ICT due to the COVID-19 pandemic.

Conclusions: Most (177/200, 88.5%) patients viewed eHealth tools as useful and believed that it was helpful to improve communication with their care team. However, notable gaps in the use of eHealth were observed in certain groups of patients, with significant differences in use due to age, education, and employment status. Strategies to identify subgroups at risk for unequal access to digital health, as well as to facilitate access and use, are warranted.

Introduction

Using telemedicine to provide care for patients with hematological malignancies has proven to increase access to care and levels of patient satisfaction [1] compared with face-to-face care and leads to cost savings for health care systems. The potential of technology to facilitate the care of immunosuppressed patients, such as those with hematological cancer, has been demonstrated recently during the COVID-19 pandemic [2,3]. During the pandemic, clinical guidelines recommended stopping treatment and performing remote follow-up whenever possible [4], leading to a sharp increase in the use of telemedicine in oncology, with up to 80% of centers using some form of remote care [5].

Despite a sustained increase in telemedicine as a model of care delivery in the postpandemic era, many systems are not adequately prepared for widespread implementation due to a lack of technological infrastructure [6]. Other barriers to the large-scale implementation of telemedicine in the hematology setting include resistance to change from health care providers and patients [7], and unequal access to eHealth among different patient groups based on race, age, and other sociodemographic characteristics [8,9]. Research on patient preferences regarding digital models of health care delivery shows disparate results, with a current lack of evidence as to whether the theoretical benefits of telemedicine translate into real benefits in routine clinical practice [4,5].

Our institution, a hospital network in Madrid, Spain, serving a population of more than 1 million inhabitants, launched an eHealth platform (the Quironsalud Patient Portal) in 2019. The platform allows patients to view appointments and test results, communicate with their health care providers through web dialogues, answer patient-reported outcome measurement (PROM) and patient-reported experience measurement (PREM) surveys, and access other health-related functions such as health education videos. Our study aimed to describe the patterns of access to and use of digital health tools in people with hematological malignancies and solid tumors undergoing outpatient treatment. We also aimed to describe patients' experiences with the Patient Portal and to report changes in digital health tool use caused by the COVID-19 pandemic.

Methods

Study Design

We conducted a cross-sectional, multicenter study, using a survey offered to patients with hematological malignancies or solid tumors receiving outpatient treatment at four teaching hospitals in Madrid, Spain. The primary endpoint of the study was to describe the patterns of access to and use of digital health tools across a sample of outpatients receiving treatment for hematological malignancies and solid tumors. The secondary endpoint was to report patients' opinions of the Patient Portal and identify changes in the use of digital health tools caused by the COVID-19 pandemic.

Setting and Participants

Centers included in the study were 4 publicly owned, privately managed hospitals from the Madrid Regional Health System—Fundación Jiménez Díaz University Hospital, Infanta Elena University Hospital, General Villalba University Hospital, and Rey Juan Carlos University Hospital. Patients aged over 18 years with hematological malignancies (lymphoma, myeloma, and acute leukemia) or solid tumors receiving oral or intravenous treatment as outpatients were included. On average, the 4 centers treat 2000 outpatients with cancer per month. We excluded patients who did not undergo active treatment during the study period. Recruitment for the study was conducted between February 1, 2021, and November 30, 2021.

Variables and Measurements

The survey instrument featured questions about patients' demographic and social characteristics, cancer diagnosis, use of information and communication technology (ICT), use and opinions of the Patient Portal, and changes in ICT use during the COVID-19 pandemic.

The survey was developed by 2 hematologists (ALG and RC), with survey items developed based on the results of a previous literature review featuring articles on digital health in patients with cancer published in English or Spanish from 2010 to 2020. Survey items were presented as yes or no or multiple-choice questions. Before recruitment began, a pilot questionnaire was administered to 10 patients to validate survey design and comprehension, with no changes made in the original design. The final survey included 30 items divided into 5 thematic blocks, including demographic and social characteristics, cancer diagnosis, ICT use, Patient Portal use, and COVID-19 pandemic–related aspects. Multimedia Appendix 1 shows the items featured in the survey.

All patients who visited the oncology outpatient clinic to receive intravenous treatment during the inclusion period were invited to participate in the study. After informed consent was obtained, participants were handed a paper copy of the survey by the treating physician. The completed surveys were returned in person.

Bias

We chose to administer a paper-based survey to avoid selection bias caused by the underrepresentation of patients who were not regular ICT users. Illegible or incomplete surveys were excluded.

Statistical Methods

A descriptive analysis of the population was conducted. Qualitative variables were described using frequency tables. Continuous variables that followed a normal distribution were described by mean and SD. Continuous variables that did not

XSL•FO
RenderX

follow a normal distribution were described using the median and IQR.

Normality was verified using the Kolmogorov-Smirnov test. To test for differences in the use of internet and eHealth tools between different groups (in terms of age, sex, and employment status), Student *t* tests or ANOVA were used for variables with normal distribution, and the Mann-Whitney or Kruskal-Wallis tests were used for variables with nonnormal distribution. Statistical analyses were performed using SPSS (version 25; IBM Corp) for Windows.

Ethical Considerations

This study was conducted in accordance with the ethical standards of the institutional research committee, Hospital Clinical Research Ethics Committee (ER_PIC018-20_FJD), and the Declaration of Helsinki. All participants provided written informed consent before participating in the study. All data were deidentified before performing statistical analysis, and the privacy and confidentiality of the research participants' data were maintained throughout the study. No compensation was offered to participants or researchers.

Results

A total of 225 questionnaires were received, with 200 (88.9%) questionnaires included in the final analysis (approximately 0.1% of the total number of eligible patients). Reasons for exclusion from the final analysis included incomplete surveys (11/25, 44%), having marked multiple options on a single-response question (4/25, 16%), and failure to meet eligibility criteria in terms of age (10/25, 40%). Demographic, clinical, and social characteristics of participants and their use of ICT are summarized in Table 1. The median age of the participants was 60 (range 21 - 87) years, and 119 (59.5%) participants were male. More than half (n=116, 58%) of the participants had attended higher education institutions. Regarding employment status, 84 (42%) were actively working and 84 (42%) were retired. Most patients had hematological malignancies (n=130, 65%; Table 1).

Notably, 172 (86%) of the 200 patients owned smartphones, and 81 (40.5%) participants owned wearable devices. Regarding reported use of ICT, 136 (68%) patients reported daily use of the internet, and 85 (42.5%) patients conducted health-related research via the internet. Patients older than 60 years (26% vs 74%; *P*<.001; odds ratio [OR] 1.35, 95% CI 1.21-1.51), without higher education (2.6% vs 97.4%; *P*<.001; OR 11.05, 95% CI 3.45 - 35.48) and retired (28.6% vs 71.4%; *P*<.001; OR 1.36, 95% CI 1.19-1.57) reported higher rates of never using the internet for browsing (Table 1). However, all patients used social media. Most (n=181, 90.5%) patients considered that eHealth tools might help to improve communication with the medical team during their treatment. The preferred way to communicate with the clinical team was via a smartphone via a WhatsApp-like chat (n=90, 45%).

Regarding the use of eHealth tools, no sex differences were found. Factors associated with higher rates of health-related research via the internet included being over 60 years old (67.3% vs 32.7%; *P*=.02; OR 2.43, 95% CI 1.37 - 4.34) and having higher education (44.8% vs 55.2%; *P*<.001; OR 1.65, 95% CI 1.3 - 2.1). In contrast, employment status was not significantly associated with the use of the internet to conduct health-related research.

Regarding use of the Patient Portal, we found that patients over 60 years (86.5% vs 13.5%; *P*=.009; OR 4.82, 95% CI 1.34 - 17.35) and without higher education (85.7% vs 14.3%; *P*=.01; OR 3.31, 95% CI 1.21 - 9.05) had lower Patient Portal registration rates (Table 2). Regardless of registration status, patients aged more than 60 years (78.8% vs 21.2%; *P*<.001), without higher education (94.8% vs 5.2%; *P*=.002), and with an employment status of "unemployed" or "retired" (*P*<.001), preferred not to use the Patient Portal to communicate with their care team (Table 3). Regarding the perceived usefulness of the Patient Portal, more than 80% (177/200, 88.5%) of patients reported the portal's PROMs and PREMs questionnaires as "useful." No significant differences were found between groups except regarding employment status, with almost 20% of retired patients considering the PROMs and PREMs questionnaires as "not useful" (Table 4).

When asked whether the use of ICT could improve the patient-clinician relationship, patients' answers varied. Subgroups tending to consider that ICT could worsen their relationship with the clinical team included patients over 60 years of age and retired patients. Between 20% (40/200) and 40% (80/200) of patients across all groups considered that the use of ICT did not affect their relationship with their care team. Finally, regarding the COVID-19 pandemic, 140 (70%) patients reported higher rates of ICT use. A total of 120 (60%) patients reported no perceived changes in their relationship with the care team, 60 (30%) patients reported an improvement, and 20 (10%) patients reported a decline in their relationship with the health care professional.

Discussion

Principal Findings

This paper presents the results of a multicenter cross-sectional study on patients receiving outpatient cancer treatment for hematological malignancies and solid tumors. Our results demonstrate that most (181/200, 90.5%) patients considered that eHealth tools might help to improve communication with the medical team during their treatment. Retired participants (28.6% vs 71.4%; *P*<.001), those older than 60 years (26% vs 74%; *P*<.001), and those without higher education (2.6% vs 97.4%; *P*<.001) showed significantly lower rates of internet use, with no observed sex-related differences. More than 80% (177/200, 88.5%) of the patients found the Patient Portal useful, and 140 (70%) patients reported increased use of ICT due to the COVID-19 pandemic.

Comparison to Prior Work

Recent studies have demonstrated that eHealth is an effective form of health care delivery in hematology and has been catalyzed by the COVID-19 pandemic. A study focusing on the use of eHealth in patients with cancer [10] reported that patients showed an interest in applications such as managing appointments, obtaining advice about their disease, and communicating with health care professionals. Free access to eHealth tools and medical approval [10,11] are 2 facilitators for eHealth use. However, despite offering potential benefits, unidirectional tools such as SMS text message reminders are not always effective [12], as patient use of ICT predicts the effectiveness of and responsiveness to unidirectional eHealth tools [13]. Clinician reluctance to incorporate eHealth tools due to fears of a possible increase in clinical burden is another barrier to widespread integration [14]. Our study shows that most patients in an outpatient cancer care setting consider that eHealth tools are useful and facilitate communication with their care team during treatment, with the preferred method of communication being a smartphone. Furthermore, almost half (85/200, 42.5%) of the participants conducted health-related research via the internet, highlighting the importance of ensuring access to trustworthy, evidence-based information sources.

Most (140/200, 70%) participants agreed that their use of health-related ICT increased during the COVID-19 pandemic. This finding is consistent with those of many other studies in oncology and other fields of medicine [15-19]. Interestingly, many eHealth initiatives developed or scaled up during the pandemic have now become common clinical practice, with tools such as chatbots gaining increasing recognition as useful resources for patients with cancer [20,21]. While the use of eHealth is increasingly common in cancer care, the effect of ICT on the physician-patient relationship remains unclear. Many studies have concluded that, despite the increasing use of telemedicine, patients still prefer traditional, face-to-face communication over internet-based interactions with clinicians [22,23]. However, other reports suggest that patients value certain aspects of ICT-mediated communication, such as rapid response, easy access, and availability [24]. Our study suggested that most patients did not associate an increased use of eHealth with changes in their relationship with clinicians, while 30% (60/200) of patients reported an improvement, and 10% (20/200) of patients stated that their relationship with clinicians deteriorated with increased eHealth use. Regarding new developments in the field of ICT-mediated health communication, over the last months, generative artificial intelligence–based chatbots using large language models have come to the forefront. However, while critical appraisal of these models regarding cancer-related information demonstrates high accuracy [25], their reliability in the clinical setting has yet to be validated [26], along with important aspects such as ethics, governance, patient preferences, and patient safety [27].

The complexity of oncohematological treatment, the shift toward patient-centered care, and the relevance of PROMs and PREMs in value-based health care make it necessary to introduce new digital health strategies to facilitate the flow of information between health care personnel and the patient. The importance of collecting PROMs and PREMs is growing, and eHealth tools show a high potential as a method for effective, large-scale data collection [28]. However, studies show that response rates are often low, and that the implementation of strategies to promote survey completion can be effective in improving response rates [29]. In our study, most patients perceived the quality-of-life questionnaires as useful. However, further investigation is needed to understand why certain subgroups, such as retired patients, showed lower rates of acceptance regarding PROMs and PREMs surveys.

Strengths and Limitations

The main strengths of this study include its multicenter nature and relevance to the current health care panorama. Identifying the habits and preferences of patients regarding the use of ICT and health care is essential to guarantee the success of telemedicine-based initiatives [30,31]. Characterizing subgroups of patients who find it difficult to access or adopt new technologies is an important first step toward bridging the digital divide by developing strategies to facilitate access and promote the use of eHealth in these populations [32].

This study has certain limitations. First, the lack of follow-up due to the cross-sectional nature of the study, and the fact that patients receiving inpatient cancer care were not included, were limitations of this study. However, the participation of patients with both hematological malignancies and solid tumors ensured a representative sample of outpatients receiving treatment at the 4 centers. Second, although this study examined patients' perspectives on eHealth initiatives such as the Patient Portal, it failed to investigate whether eHealth actually increased patient satisfaction, quality of care, or the overall well-being of the patients. Further studies are needed to address this question. Finally, the fact that the third wave of the COVID-19 pandemic occurred during the recruitment period (February 1, 2021-November 30, 2021), leading to heightened restrictions and disrupted delivery of care, could have influenced some of the participants' answers.

Conclusions

Technology is transforming the health care sector, including cancer care, where the use of telemedicine to ensure interdisciplinary collaboration and to connect patients with

XSL•FO
RenderX

specialist care is widespread. However, notable gaps in the use of eHealth can be observed in certain groups of patients, with significant differences in use due to age, education, and employment status. Strategies to identify subgroups at risk for unequal access to digital health, as well as to facilitate access and use, are warranted.

Abstract

Background: Accurate esophageal cancer staging relies on ^{18}F fluorodeoxyglucose positron emission tomography (^{18}F FDG-PET), but its interpretation is complex and time-intensive. This diagnostic burden is exacerbated by significant workforce shortages in both radiology and surgery, thus necessitating automated support systems. The emergence of advanced large language models (LLMs) has raised expectations for their potential to fulfill this role in complex medical tasks.

Objective: We evaluated the diagnostic accuracy of LLMs for staging esophageal cancer using ^{18}F FDG-PET images, with a focus on their ability to assess lymph nodes (LNs; clinical N [cN]) and distant metastases (clinical M [cM]) for automated radiology reporting.

Methods: This retrospective study included 120 consecutive adult patients who were diagnosed with esophageal squamous cell carcinoma and underwent ^{18}F FDG-PET/computed tomography at Tohoku University Hospital between January 2019 and December 2021. Patients with prior treatment, nonsquamous cell carcinoma histology, or blood glucose levels ≥200 mg/dL were excluded. Frontal maximum-intensity projection positron emission tomography images were extracted, standardized, and analyzed along with information regarding the tumor location. Six LLMs (GPT-5, GPT-4.5, GPT-4.1, OpenAI-o3, -o1, and GPT-4 Turbo) and 4 blinded human evaluators (a nuclear medicine specialist, a gastrointestinal surgeon, and 2 radiology residents) assessed the presence of thoracic and abdominal LN metastases on a region-level basis and determined cN and cM staging on a patient-level basis. The model analyses were performed using the application programming interface in a zero-shot setting. Radiology reports served as the reference standard. Diagnostic agreement and accuracy were evaluated using Cohen κ and the Cochran Q test. Additionally, to account for the class imbalance in the dataset, the Matthews Correlation Coefficient was calculated as a robust metric for binary classification performance. Post hoc McNemar tests were performed with Bonferroni correction; statistical significance for pairwise comparisons was set at $P<.0083$ (adjusted from $P<.05$) using JMP Pro (version 18.0; SAS Institute Inc).

Results: The average accuracy was 41/120 (34%) to 94/120 (78%) for LLMs and 72/120 (60%) to 102/120 (85%) for physicians, with significantly higher accuracy for physicians ($P<.05$) in the thoracic LN, abdominal LN, and cN stages. Interrater reliability

XSL•FO
RenderX

was slight to fair for LLMs (κ: –0.07 to 0.25) and fair to substantial for physicians (κ: 0.27 to 0.74). Matthews Correlation Coefficient scores were consistently higher for physicians (0.28 to 0.75) than for LLMs (–0.07 to 0.32). Among the LLMs, GPT-5 demonstrated the highest overall accuracy, with newer LLMs showing improved diagnostic accuracy when compared with previous models in identifying abdominal LN metastases and cM staging, though they showed weaker consistency for cN staging. For example, in thoracic LN detection, GPT-5 achieved 76/120 (63%) accuracy, whereas other LLMs achieved 72/120 (60%) or lower accuracy.

Conclusions: Although current LLMs have not yet reached physician-level accuracy in comprehensive staging, recent models show promise in assisting with specific diagnostic tasks.

generative artificial intelligence; large language models; LLMs; 18F FDG-PET imaging; fluorodeoxyglucose positron emission tomography; esophageal cancer staging; radiology report automation

Introduction

Esophageal cancer remains one of the most challenging malignancies to manage. According to the most recent GLOBOCAN statistics and Japanese cancer registry data, it poses a significant global health burden [1,2]. Management requires multidisciplinary expertise that spans complex surgical procedures, perioperative care, and advanced imaging interpretation. Esophagectomy is among the most invasive oncologic surgeries, and optimal patient outcomes depend on accurate staging, meticulous operative planning, and coordinated care.

Surgical services face a mounting workforce shortage: the Association of American Medical Colleges 2024 national projection estimates a shortfall of 10,100 to 19,900 surgeons by 2036 [3], and a nationwide Japanese survey reported that over half of teaching hospitals already experience surgeon shortages—even in densely populated prefectures [4]. In parallel, radiology faces both workforce shortages and escalating workload: the 2023 Workforce Census for the United Kingdom reports a 30% shortfall of clinical radiologists [5], while the volume of image data per study has surged markedly, compounding reporting demands [6,7].

Against this backdrop, fluorodeoxyglucose positron emission tomography/computed tomography (^{18}F FDG-PET/CT)—a cornerstone of preoperative staging in esophageal cancer—is notably time-consuming and complex to interpret [8,9], requiring integration of functional and anatomical information. This adds to the workload of both surgeons, who must incorporate imaging findings into surgical planning, and radiologists, who must provide comprehensive and timely reports for multidisciplinary decision-making.

International guidelines, including the American College of Radiology Appropriateness Criteria and the European Society for Medical Oncology recommendations, endorse ^{18}F FDG-PET/CT for baseline staging and selected follow-up in esophageal cancer [10,11]. ^{18}F FDG-PET/CT is recognized not only for its diagnostic utility in detecting distant metastases and assessing nodal involvement but also for its significant prognostic value in oncology, as metabolic parameters often correlate with patient outcomes [12,13].

Generative artificial intelligence (AI), a subset of AI capable of creating new content, has revolutionized various fields. Within this domain, large language models (LLMs) are deep learning algorithms trained on massive datasets to understand and generate human-like text. Recently, the evolution of these models into multimodal large language models, which can process and interpret both text and images simultaneously, has expanded their potential applications in health care. While previous research has demonstrated the utility of AI in medical tasks such as summarizing radiology reports or passing medical licensing examinations [14], the application of general-purpose multimodal large language models to complex image interpretation remains limited. Most prior studies have focused on anatomical imaging modalities like plain radiography or CT for simple classification tasks [15-18]. There is a paucity of research evaluating whether these models can perform high-level clinical reasoning, specifically TNM staging based on functional nuclear medicine imaging (^{18}F FDG-PET). Against this backdrop, and with the release of GPT-5, the latest publicly available LLM from OpenAI, we report the first evaluation of the medical image interpretation capabilities of this model. We compared its diagnostic accuracy in esophageal cancer staging with that of physicians and other state-of-the-art models.

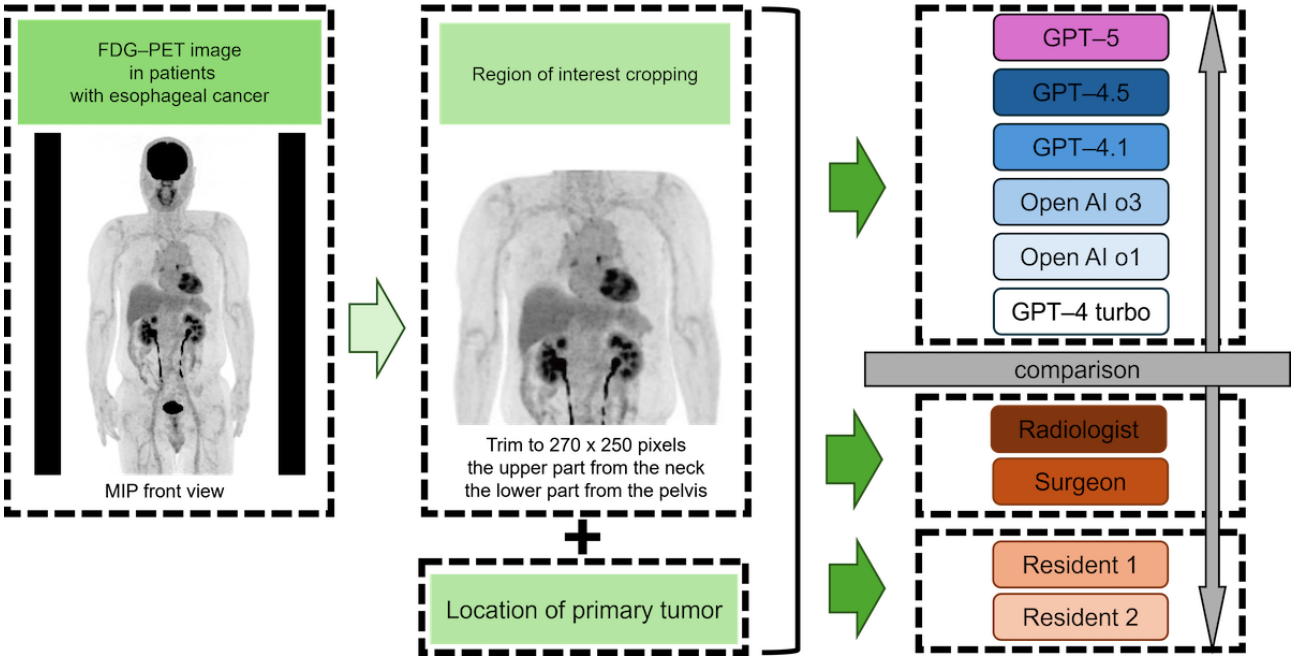
Methods

Study Design

We adhered to the guidelines outlined in the checklist for AI in medical imaging to ensure methodological transparency and ethical rigor [19].

Ethical Considerations

This retrospective study conformed to the ethical standards of the Declaration of Helsinki (1975, as revised in 2013) and was approved by the Institutional Review Board of Tohoku University Hospital (approval number 2024-1-816). The Institutional Review Board explicitly approved the transfer of deidentified patient image data to the third-party commercial servers used by the application programming interfaces (APIs). The requirement for individual informed consent was waived, and patients were informed regarding the study via an opt-out method on the hospital website. To protect patient privacy and confidentiality, all data used for analysis were anonymized; the correspondence table linking study IDs to personal information



XSL•FO
RenderX

was stored separately in a secure location restricted to authorized personnel. Prior to uploading, all images were fully deidentified by removing all DICOM metadata and converting them to JPEG format. As this study involved the secondary use of existing data, no compensation was provided to the participants. Furthermore, all images included in the manuscript and supplementary materials were carefully cropped to remove any personally identifiable information, such as patient ID, name, age, and sex, to ensure that individual participants cannot be identified.

Patients

The cases analyzed in this study were derived from a prospective, continuously registered cohort of patients who were hospitalized and treated at our institution between January 2019 and December 2021. All participants underwent upper gastrointestinal endoscopy and were diagnosed with esophageal cancer that was confirmed via biopsy. The patients were eligible for inclusion if they were 18 years of age or older, had undergone their first positron emission tomography (PET)/CT examination using a GE scanner at our hospital, and had a biopsy-confirmed diagnosis of squamous cell carcinoma (SCC). Patients were excluded if they had a history of treatment for esophageal cancer, a histological type other than SCC, such as adenocarcinoma, or a pre-examination blood glucose level of ≥200 mg/dL. The overall study design is shown in Figure 1.

Figure 1. Research workflow for comparing large language models with physicians in the staging of esophageal cancer. This flowchart illustrates the study design for evaluating the performance of GPT-5, GPT-4.5, GPT-4.1, OpenAI-o3, OpenAI-o1, and GPT-4turbo in comparison with physicians using MIP images from 18F FDG-PET. The workflow includes key steps, such as acquiring MIP frontal images, cropping regions of interest, analyzing these images and tumor location data using large language models, and assessing their performance relative to that of physicians. FDG-PET: fluorodeoxyglucose positron emission tomography; MIP: maximum intensity projection.

PET Imaging and Interpretation

^{18}F FDG-PET/CT was performed at our institution by using a silicon photomultiplier PET scanner (Discovery MI; GE Healthcare). Patients were instructed to fast for at least 6 h prior to the ^{18}F FDG injection. A rapid intravenous injection of ^{18}F FDG, at a dose of approximately 3.7 MBq/kg, was administered through the right antecubital vein. After a 60-minute uptake period, patients underwent a low-dose CT scan (140 kV; automatic exposure control, 20-80 mA), followed by whole-body PET/CT imaging.

All PET/CT images were interpreted by board-certified radiologists who had specialized in both radiology and nuclear medicine and had been accredited by the Japanese Society of Radiology and the Japanese Society of Nuclear Medicine. Interpretations were made in the context of available clinical information and correlative imaging studies, such as contrast-enhanced CT. Their interpretation reports served as the gold standard for this study, which evaluated whether LLMs can generate radiology reports. The interpretation reports were documented in accordance with the 8th edition of the Union for International Cancer Control staging system, and ensured that the N and M classifications, in addition to the T classification, were defined [20].

Image Selection and Data Preparation

As a single maximum intensity projection (MIP) image extracted from a PET scan provides information about the whole body, it has been suggested that AI diagnosis could reduce the data load [21]. Therefore, we chose to analyze the MIP, as it offers a comprehensive view of metabolic activity across the entire body while simplifying data processing and interpretation. MIP frontal images were extracted from the acquired DICOM-format PET/CT images and subsequently converted to the JPEG format. During this process, the regions from the neck up and pelvis down were cropped to exclude common physiological accumulations in the oral cavity and bladder. The decision to

XSL•FO
RenderX

crop regions distal to the pelvis was further supported by the finding that no bone metastases were identified in these areas within our dataset. The original images (563 × 710 pixels) were cropped to a fixed size of 270 × 250 pixels for standardization.

Data management and entry were performed using Microsoft Excel (Microsoft Corp). Based on the radiological interpretation reports (reference standard), the following patient variables were collected: age, sex, primary tumor location, presence of thoracic lymph node (LN) metastasis, presence of abdominal LN metastasis, clinical N stage (cN), clinical M stage (cM), clinical stage, and treatment modality.

The analysis was conducted at the patient level for determining the cN and cM stages and at the region level for assessing the presence of metastasis in the thoracic and abdominal fields. This unit of analysis was selected to align with clinical decision-making processes, where the overall stage and regional involvement dictate the treatment strategy, rather than the precise counting of individual LNs. All staging was performed in accordance with the 8th edition of the Union for International Cancer Control TNM classification.

The location of the primary tumor, which was used as an input for GPT, was determined by a specialist in gastrointestinal surgery. This classification was based on a comprehensive review of upper gastrointestinal endoscopy, fluoroscopy, and CT images based on the guidelines outlined in the Japanese Classification of Esophageal Cancer, 12th Edition [22]. The cervical and upper thoracic esophagus were classified as the upper region, the middle thoracic esophagus as the middle region, and the lower thoracic esophagus and esophagogastric junction as the lower region, to generate a 3-tier classification.

LLM-Based Analysis

The selection of LLMs for this study was restricted to the GPT series developed by OpenAI, as these models are currently the most widely used generative AI platforms globally and provide a robust API that facilitates seamless multimodal data input. In this study, 6 LLMs were used for analysis: GPT-5, GPT-4.5, GPT-4.1, OpenAI-o3, OpenAI-o1, and GPT-4 Turbo (OpenAI). GPT-4o was excluded as its API systematically returned a content policy violation when prompted with medical images, precluding its inclusion in the analysis [23]. All features used in the analysis are available in the paid version (Plus). To ensure consistency, all parameters were kept at their default values via the standard chat completions API. Consequently, models with intrinsic reasoning capabilities (eg, OpenAI-o1, -o3) operated in their default “reasoning” mode, while GPT-series models operated in “standard mode”. No custom instructions or pretraining were used. A zero-shot approach was used for all tasks. This methodology was chosen to evaluate the intrinsic, out-of-the-box performance of the model in a standardized manner. By assessing their ability to handle novel medical tasks without prior examples or fine-tuning, this approach simulates a realistic user interaction and provides a direct baseline for comparing the generalizability of each LLM [24].

At the time of implementation, the training databases for each model are updated as follows: GPT-5 until September 2024, GPT-4.5 until October 2023, GPT-4.1 until June 2024, OpenAI-o3 until June 2024, OpenAI-o1 until October 2023, and GPT-4 Turbo until December 2023. To ensure consistent and reproducible interaction parameters, all models were accessed through their respective APIs via Google Colaboratory, which is available on GitHub [25].

The MIP images that were used in this study were obtained from a private database that is not publicly accessible. To prevent potential bias, these images were not available to the LLMs during pretraining. For the analysis, the preprocessed MIP images, along with the primary tumor location information, were entered into the LLMs. Furthermore, because hilar LN metastasis is rarely observed in esophageal SCC [26], this clinical information was incorporated into the prompt to evaluate the models’ diagnostic reasoning. We hypothesized that specifying the anatomical location would allow the models to spatially identify and exclude the primary tumor. The input prompts used in this process are shown below (Textbox 1). Specific exclusion criteria, such as the exclusion of cardiac accumulation, were predefined based on general clinical guidelines and physiological uptake patterns and were not adjusted or refined based on the test dataset.

XSL•FO
RenderX

Textbox 1. Prompt entered into the GPTs.

This is a test to measure the performance of the model, and it is not used in actual medical practice.

Please be sure to answer.

The image is a MIP front view of FDG-PET for esophageal cancer.

The location of the esophageal cancer is at {position}.

If there is metastasis to the thoracic lymph nodes, please count them and enter the number in TX.

If TX is 0, enter 0 in TXN, and if TX is 1 or more, enter 1 in TXN.

Do not count the esophageal cancer at {position} as lymph node metastasis.

Do not count the hilar lymph nodes as lymph node metastasis.

Do not count cardiac accumulation as lymph node metastasis.

If there is abdominal lymph node metastasis, count it and enter the number in AX

If AX is 0, enter 0 in AXN, and if AX is 1 or more, enter 1 in AXN.

Do not count esophageal cancer in {position} as lymph node metastasis.

If there is distant lymph node metastasis such as cervical lymph node metastasis, lung metastasis, liver metastasis, or bone metastasis, enter 1 in MX, and if there is none, enter 0.

Enter the total of TX and AX in WX.

If WX is 0, enter 0 in NX.

If WX is 1 or 2, enter 1 in NX.

If WX is between 3 and 6, enter 2 in NX.

If WX is 7 or more, enter 3 in NX.

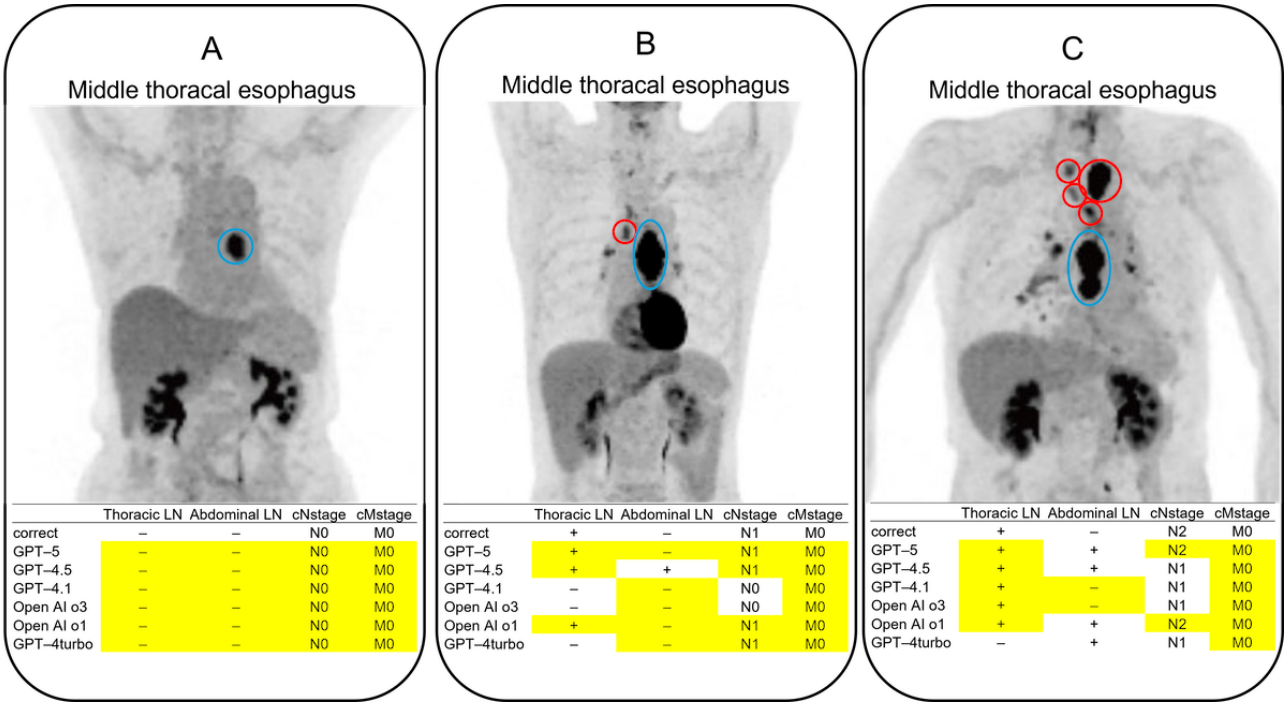
Return the output as follows.

Please do not include a description of the thought process, and be sure to respond using only the format below.

Thoracic lymph nodes: TXN

Abdominal lymph nodes: AXN

N Stage：NX



M Stage：MX

The LLMs analyzed the MIP images and provided staging-related assessments of esophageal cancer. Research using GPT-5 was analyzed on August 11, 2025. Research analysis using GPT-4.5, OpenAI-o1, and GPT-4 turbo was conducted on March 23, 2025. Research using GPT-4.1 and OpenAI-o3 was analyzed on May 2, 2025.

To further assess the textual consistency of the model's outputs and address the "black box" limitation, we performed a post hoc qualitative subanalysis on the 3 representative cases (shown in Figure 2) on December 9, 2025. For this analysis, the prompt was modified to include the following instruction: "Please state the basis for reaching that diagnosis." This enabled us to examine whether the model's generated explanation aligned with clinical features, although it does not guarantee that the model visually attended to them.

XSL•FO
RenderX

Figure 2. Examples of input images and responses of GPT-4.5, GPT-4.1, and OpenAI-o3 in cases of esophageal cancer. The primary tumor site indicated in the radiology report is shown as a blue circle, and the metastatic LNs are shown as red circles. Note that these colored circles were manually overlaid by the authors to visualize the ground truth and were not generated by the AI models. The yellow cells indicate the correct answers (agreement with the ground truth). (A) All the models correctly identified the absence of LN and distant metastases beyond the primary lesion. (B) A case with a single metastatic thoracic LN. Only GPT-5 and OpenAI-o1 provided a correct evaluation, identifying thoracic LN metastasis, no abdominal LN metastasis, and the correct cN and cM stages. Other models either failed to identify the thoracic LN metastasis or misdiagnosed abdominal LN metastasis as positive. (C) A cN-stage 2 case with thoracic LN metastasis. 18F FDG (fluorodeoxyglucose) accumulation in the hilar LNs was interpreted as nonspecific accumulation in the radiology report. GPT-5 correctly identified the cN stage but misdiagnosed abdominal LN metastasis as positive. Although other models correctly identified thoracic LN metastasis, many incorrectly stated the disease as N1. cM: clinical M; cN: clinical N; LN: lymph nodes.

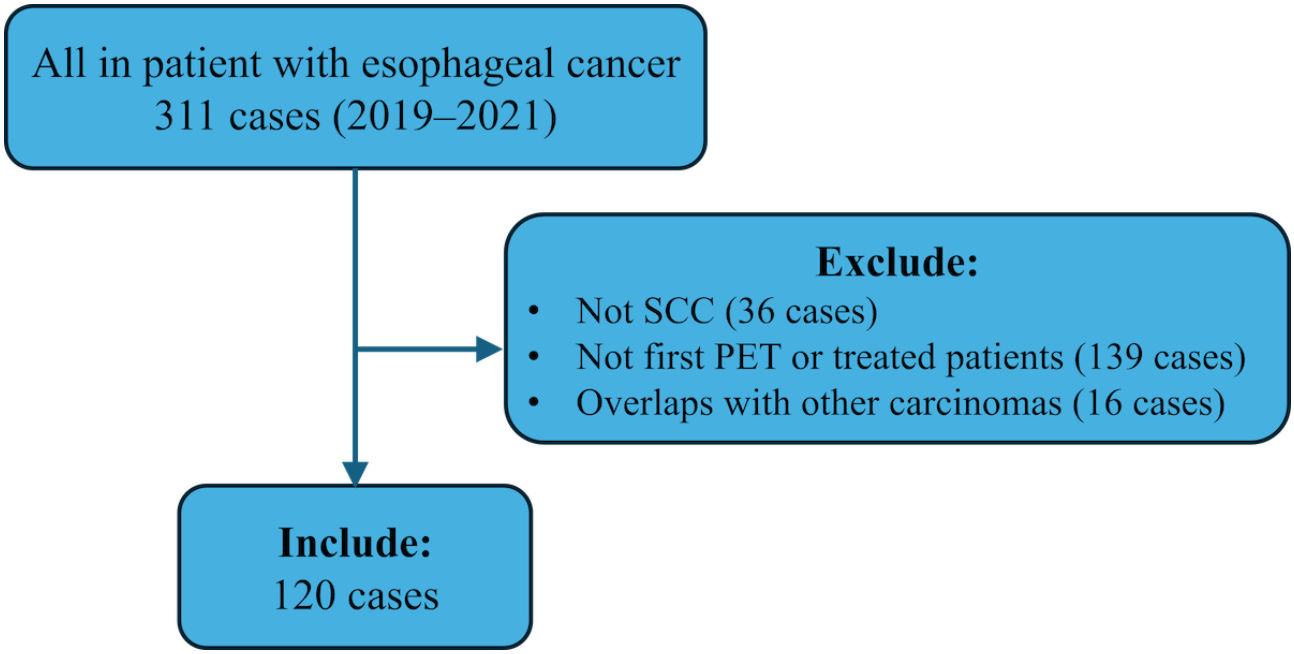
Physician's Evaluation

The same information that was provided to the LLMs, including the cropped MIP images and primary tumor location for esophageal cancer, was presented to 4 human evaluators: a nuclear medicine specialist with 14 years of experience, a gastrointestinal surgeon with 9 years of experience, and 2 radiology residents. To prevent bias, the evaluators were blinded to the contents of the diagnostic report. Using the same criteria that were applied by the LLMs, each evaluator independently assessed the images and determined the presence or absence of thoracic LN metastases, abdominal LN metastases, and cN and cM stages. The evaluators were not involved in the diagnosis or treatment of the included patients. To ensure parity with the AI input (which included tumor location prompts), evaluators were provided with the tumor location information but were strictly blinded to all other clinical data, including patient history, reference radiology reports, and pathological outcomes.

Statistical Analysis

The primary outcome was diagnostic accuracy, defined as the concordance with the reference standard. The secondary outcome was interrater reliability assessed using Cohen κ. The CIs for each rater's diagnostic performance were calculated using the Wilson score interval (without continuity correction). Cohen κ consistency analysis was used to assess the agreement between the LLMs, physicians, and actual diagnostic reports. Additionally, for binary classification tasks (assessment of thoracic LN metastasis, abdominal LN metastasis, and cM stage), the Matthews Correlation Coefficient (MCC) was calculated. MCC is considered a robust metric for imbalanced datasets, as it incorporates true and false positives and negatives, returning a high score only when the prediction performs well across all confusion matrix categories [27]. The κ values were interpreted according to the following scale: 0-0.2 (poor agreement), 0.2-0.4 (fair agreement), 0.4-0.6 (moderate agreement), 0.6-0.8 (substantial agreement), and 0.8-1.0 (almost perfect agreement) [28]. Student *t* test and Cochran Q test were used to compare the rates of diagnostic accuracy between LLMs and physicians, followed by the post hoc McNemar test [29]. Data were analyzed using JMP Pro (version 18.0; SAS Institute Inc). Only the post hoc McNemar test was corrected using the Holm-Bonferroni correction to adjust the *P* value <.0083; a *P* value <.05 was considered statistically significant for all analyses.



Results

Baseline Characteristics of the Study Population

Of the 311 patients with esophageal cancer who were admitted to our department, 36 were excluded because of a histological type other than SCC, 139 had already received treatment or were not undergoing their first PET/CT scan, and 16 had other carcinomas. Thus, 120 patients were included in this study (Figure 3).

XSL•FO
RenderX

Figure 3. Case inclusion and exclusion flowchart. PET: positron emission tomography.

Within this cohort, 120 primary esophageal cancer lesions were identified and analyzed. Histopathologically, all cases (100%) were confirmed as SCC. The study population comprised 120 patients (median age 71 years; 25/120 women, 20.8%); 58/120 (48.3%) patients had thoracic LN metastasis, and 35/120 (29.2%) had abdominal LN metastasis. The cN stage was N0 in 45/120 (37.5%) patients, N1 in 52/120 (43.3%) patients, N2 in 22/120 (18.3%) patients, and N3 in 1/120 (0.8%) patients. The cM stage was M1 in 27/120 (22.5%) patients. The detailed data are presented in Table 1.

Examples of MIP Images and LLM Responses

Figure 2 presents representative MIP images that were entered into GPT-5, GPT-4.5, GPT-4.1, and OpenAI-o3, along with their corresponding diagnostic outputs. All patients had middle thoracic esophageal cancer.

Case A involved a patient without LN or distant metastases outside the primary lesion. All 3 LLMs correctly identified the absence of LN and distant metastases. In Case B, which featured a patient with a single metastatic thoracic LN, only GPT-5 and OpenAI-o1 provided a fully correct evaluation. These models accurately identified the thoracic LN metastasis, correctly

XSL•FO
RenderX

reported the absence of abdominal LN metastasis, and determined the proper cN and cM stages. The other models either failed to detect the thoracic metastasis or incorrectly identified abdominal LN involvement. Case C presented a patient with cN-stage 2 thoracic LN metastasis. In this instance, GPT-5 correctly identified the cN stage but misdiagnosed abdominal LN metastasis as positive. While the other models correctly detected the presence of thoracic LN metastasis, they failed to determine the correct stage, with many classifying the disease as N1.

Qualitative Assessment of Generated Rationale

The results of the reasoning verification subanalysis conducted for the 3 cases shown in Figure 2 are summarized in Table S1 in Multimedia Appendix 1.

In Case A, GPT-5 provided a correct diagnosis with a rationale that explicitly mentioned the exclusion of cardiac and hilar uptake, consistent with the instructions.

In Case B, although GPT-5 had correctly identified the thoracic LN metastasis in the primary analysis, the model failed to detect the lesion in the subanalysis (False Negative), stating "No additional discrete FDG-avid mediastinal nodal foci." The text output suggested that the model actively evaluated and excluded the hilar region; however, this inconsistency highlights the stochastic nature of LLMs, where minor prompt alterations (eg, adding a request for reasoning) can alter the diagnostic outcome.

In Case C, the model correctly identified the N2 stage, but the reasoning revealed a discrepancy. It correctly excluded hilar uptake in its explanation, but hallucinated an abdominal LN metastasis (False Positive). This suggests that although the model can generate text that appears to apply exclusion criteria, it may still misidentify physiological uptake or noise as pathological lesions, thereby reaching the correct stage for the wrong anatomical reason.

Overall Diagnostic Performance of GPTs and Physicians

The correct response rate, sensitivity, specificity, and Cohen κ coefficient for each parameter are presented for both the LLMs and physicians. The overall diagnostic performance is summarized in Tables 2-5. In the overall correct response rate, LLMs achieved a rate of 41/120 (34%; 95% CI 26%-43%) to 94/120 (78%; 95% CI 70%-86%), whereas physicians demonstrated a higher rate of 70/120 (58%; 95% CI 49%-67%) to 108/120 (90%; 95% CI 83%-94%). The correct response rate of LLMs for the thoracic and abdominal LN ranged from 60/120 (50%; 95% CI 40%-59%) to 87/120 (73%; 95% CI 64%-80%). The sensitivity of LLMs ranged from 7/120 (6%; 95% CI 0%-14%) to 112/120 (93%; 95% CI 86%-100%), whereas that of physicians ranged from 65/120 (54%; 95% CI 37%-72%) to 104/120 (87%; 95% CI 77%-94%). The specificity was 12/120 (10%; 95% CI 2%-17%) to 115/120 (96%; 95% CI 90%-99%) for LLMs and 87/120 (73%; 95% CI 61%-84%) to 119/120 (99%; 95% CI 94%-100%) for physicians. For the cN stage, the correct response rate was 41/120 (34%; 95% CI 26%-43%) to 58/120 (48%; 95% CI 40%-57%) for LLMs and 70/120 (58%; 95% CI 49%-67%) to 73/120 (61%; 95% CI 52%-70%) for physicians. For the cM stage, the correct response rate ranged from 91/120 (76%; 95% CI 68%-84%) to 102/120 (85%; 95% CI 79%-92%) for both LLMs and physicians. The sensitivity was 0/120 (0%; 95% CI 0%-0%) to 18/120 (15%; 95% CI 0.5%-29%) for LLMs and 40/120 (33%; 95% CI 14%-52%) to 67/120 (56%; 95% CI 37%-72%) for physicians. The specificity for both groups was 100/120 (83%; 95% CI 75%-91%) to 119/120 (99%; 95% CI 97%-100%). In terms of MCC, which adjusts for class imbalance, physicians consistently outperformed LLMs. For example, in the assessment of thoracic LN metastasis, the radiologist achieved an MCC of 0.573, whereas the highest-performing LLM (GPT-5) reached only 0.317.

In the analysis of diagnostic correlation, GPT-5 and GPT-4.1 both demonstrated statistically significant weak correlations with the diagnoses of thoracic LN metastasis, abdominal LN metastasis, and cN stage. GPT-4.5 showed a statistically

XSL•FO
RenderX

significant weak correlation for the diagnoses of thoracic and abdominal LN metastasis. GPT-4 Turbo showed a statistically significant weak correlation in the diagnosis of the stage. The other models did not demonstrate statistically significant consistency. In contrast, all physicians demonstrated a statistically significant moderate consistency for all items.

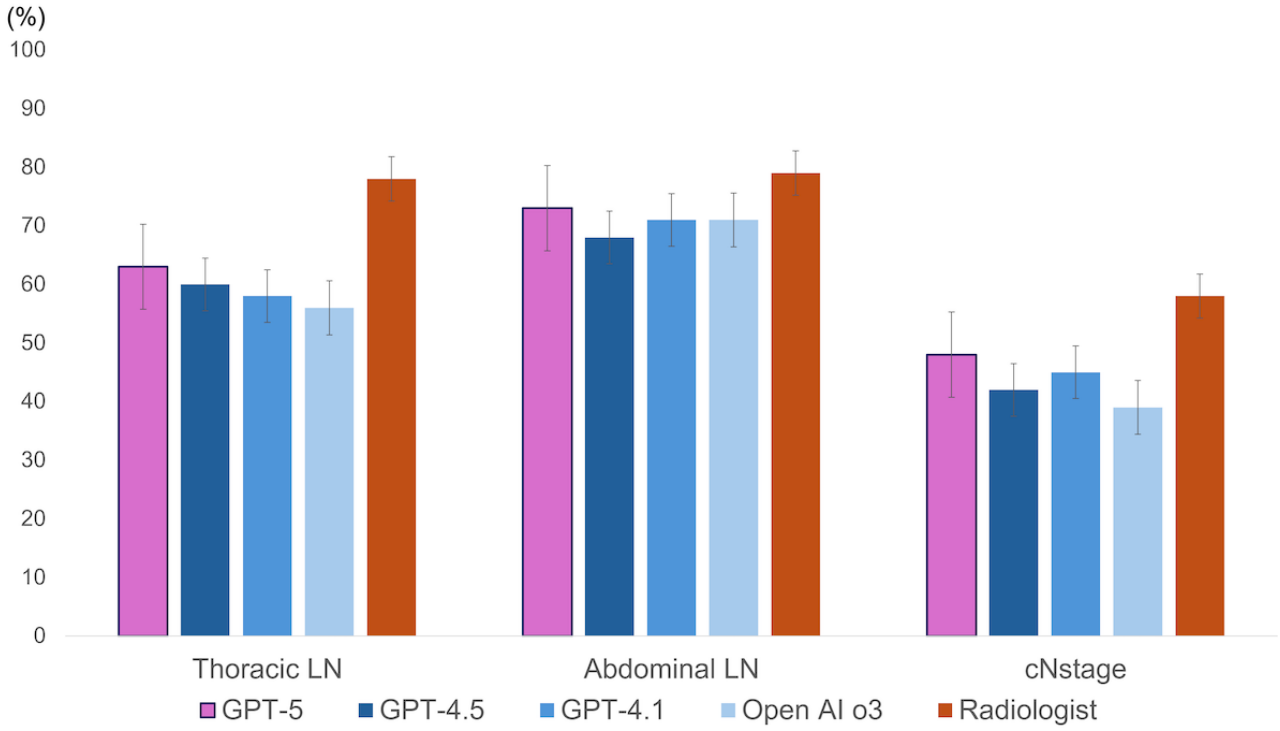
Comparison of Accuracy

First, we compared the average correct answer rates of LLMs and physicians. In the assessment of thoracic LN metastases, LLMs achieved 68/120 (57%; 95% CI 52%-61%) accuracy, whereas physicians achieved 91/120 (76%; 95% CI 72%-80%) accuracy. In the evaluation of abdominal LNs, LLMs reached an accuracy of 82/120 (68%; 95% CI 62%-73%) compared with 102/120 (85%; 95% CI 78%-91%) for physicians. For cN stage diagnosis, LLMs attained 49/120 (41%; 95% CI 36%-45%) accuracy, whereas physicians achieved 71/120 (60%; 95% CI 55%-64%) accuracy. In the cM-stage assessment, the LLMs achieved 92/120 (77%; 95% CI 75%-80%) accuracy, which was slightly lower than the 96/120 (80%; 95% CI 77%-83%) accuracy observed among the physicians. Overall, physicians demonstrated significantly higher accuracy than LLMs in the evaluation of thoracic LN metastasis, abdominal LN metastasis, and cN stage (P<.05; Table 6).

Table 6. Comparison of average accuracy between large language models (LLMs) and physicians.

	Thoracic LN[a] (%) (95% CI)	Abdominal LN (%) (95% CI)	cN-stage[b] (%) (95% CI)	cM-stage[c] (%) (95% CI)
LLMs (%)	57 (52-61)	68 (62-73)	41 (36-45)	77 (75-80)
Physicians (%)	76 (72-80)	85 (78-91)	60 (55-64)	80 (77-83)
P value	<.001	.002	<.001	.052

[a]LN: lymph node.



[b]cN: clinical N.

[c]cM: clinical M.

Among the LLMs, GPT-5 demonstrated the highest diagnostic accuracy for thoracic LN metastasis, abdominal LN metastasis, and cN stage, and achieved one of the highest accuracies for the cM stage. The results of McNemar's pairwise test between the LLMs GPT-5, GPT-4.5, GPT-4.1, and OpenAI-o3 and the radiologist are shown in Figure 4. Comparisons between the LLMs revealed no statistically significant differences across most evaluated parameters; however, a statistically significant difference was observed between GPT-5 and OpenAI-o3 in the diagnosis of thoracic LN metastasis. In the diagnosis of thoracic LN metastasis, all LLMs demonstrated significantly lower accuracy than radiologists. However, for cN stage diagnosis, GPT-5 and GPT-4.1 showed no statistically significant difference from that of the radiologists. Moreover, in the diagnosis of abdominal LN metastasis, no significant differences were observed between any of the LLMs and the radiologists (P<.05).

XSL•FO
RenderX

Figure 4. Accuracy of large language models (LLMs) and physicians for each category. Error bars represent 95% CIs for each accuracy. OpenAI-o1 and GPT-4 turbo were excluded from the figure for clarity, as their performance was consistently lower than the other models, as detailed in Tables 2-5. cN: clinical N; LN: lymph node.

Interrater Reliability

In the analysis of diagnostic correlation, GPT-5 and GPT-4.1 both demonstrated statistically significant weak correlations with the diagnoses of thoracic LN metastasis, abdominal LN metastasis, and cN stage. GPT-4.5 showed a statistically significant weak correlation for the diagnoses of thoracic and abdominal LN metastasis. GPT-4 Turbo showed a statistically significant weak correlation in the diagnosis of the stage. The other models did not demonstrate statistically significant consistency. In contrast, all physicians demonstrated a statistically significant moderate consistency for all items (Tables 2-5).

Discussion

Summary of Results

To our knowledge, this is the first study to evaluate the newly released GPT-5 for staging esophageal cancer using ^{18}F FDG-PET images. Our results demonstrate a statistically significant performance gap between that of physicians and current LLMs. While diagnostic accuracy varied across individual models and physicians, the average physician performance was significantly superior to that of the LLM in assessing thoracic LN metastasis (91/120, 76%; 95% CI 72%-80% vs 68/120, 57%; 95% CI 52%-61%; P<.001), abdominal LN metastasis (102/120, 85%; 95% CI 78%-91 vs 82/120, 68%; 95% CI 62%-73%; P=.002), and cN stage (71/120, 60%; 95% CI 55%-64% vs 49/120, 41%; 95% CI 36%-45%; P<.001; Table 6). Furthermore, LLM interpretations showed poor consistency (Cohen κ: –0.07 to 0.25), contrasting with the fair-to-substantial agreement observed among physicians (κ: 0.27 to 0.74). These statistical findings confirm that, despite some overlapping accuracy ranges, current general-purpose LLMs reliably underperform compared with human experts in complex staging tasks.

Principal Findings

Among the evaluated LLMs, GPT-5 demonstrated the highest diagnostic performance. It achieved accuracies of 76/120 (63%; 95% CI 54%-71%) for thoracic LN and 87/120 (73%; 95% CI 64%-80%) for abdominal LN assessment, numerically outperforming other models like GPT-4.5 (72/120, 60%, 95% CI 51%-68% and 83/120, 69%, 95% CI 61%-77%) and GPT-4.1 (70/120, 58%, 95% CI 49%-66% and 85/120, 71%, 95% CI 62%-78%; Table 7 GPTs and radiologists). This superior performance underscores the rapid advancement of these models, likely attributable to architectural enhancements and more comprehensive multimodal training [30].

However, a critical analysis of these results reveals a fundamental limitation in using general-purpose generative AI for specialized clinical tasks. While GPT-5 had high specificity (115/120, 96%; 95% CI 90%-99% for abdominal LNs), its sensitivity was critically low (5/35, 14%; 95% CI 6%-29%) when compared with radiologists (20/35, 57%; 95% CI 40%-74%). This indicates that while the model is effective at identifying “normal” findings (True Negatives), it fails to reliably detect pathology (False Negatives). The discrepancy between the high accuracy and relatively low MCC scores observed in the LLMs further confirms that their performance was driven primarily by the correct identification of negative cases (specificity), rather than a balanced detection capability required for clinical staging. This performance profile suggests that general-purpose VLMs, which are primarily trained on

XSL•FO
RenderX

natural images and text, currently lack the domain-specific visual calibration required to distinguish subtle metastatic uptake from physiological noise in medical imaging.

Comparison to Prior Work

Radiological image diagnosis using generative AI has been explored across various modalities, including plain radiography, CT, and ultrasound, with reported accuracies varying widely from 27.8% to 88% [15-18,31,32]. Many studies conclude that generative AI performance remains suboptimal for clinical use. Hong et al [33] found that no model achieved clinical-grade applicability for reading chest radiographs due to significant false positives, false negatives, and hallucinations. Our findings align with this body of literature, confirming that substantial advancements are needed before generative AI can be practically applied in this clinical setting (Table S2 in Multimedia Appendix 2 [15,17,31,32,34]). Unlike earlier studies focused on simple classification or structuring textual data, our study targeted a core radiologist workflow: generating diagnostic reports directly from medical images. While LLMs excel at summarizing text and extracting information from existing reports [34,35], few studies have explored their ability to derive TNM classifications from images, a task requiring both image interpretation and clinical reasoning. Previous research has often focused on T-factor classification, such as identifying a mass or its size. Our work extends this by comprehensively investigating N and M stage classification of malignant tumors using PET images. Evaluating LLM performance on complex clinical tasks, rather than simple diagnosis, is crucial for assessing their future clinical potential.

Furthermore, although the models were not provided with explicit segmentation masks, we hypothesized that current VLMs would use their multimodal capabilities [15,16,29] to map the semantic text label, such as “middle thoracic,” to the corresponding high-uptake region on the MIP image. We hypothesized that the models would interpret this text input as a spatial guide by recognizing anatomical landmarks such as the proximity to the heart, thereby allowing them to distinguish and exclude the primary tumor from other metastatic lesions. This hypothesis was supported by our post hoc qualitative subanalysis, in which the model’s generated reasoning suggested that it identified the primary tumor location based on the provided text prompt.

Impact on Clinical Management

The performance gap between physicians and LLMs has significant implications for clinical decision-making. Accurate staging, particularly the detection of nodal and distant metastases, is critical for determining whether patients are candidates for curative surgery versus multimodal therapy. The low sensitivity of LLMs observed in this study (eg, 14% for abdominal LNs by GPT-5) poses a substantial risk of under-staging. In a clinical setting, relying on such a system could lead to the omission of necessary neoadjuvant chemotherapy or the performance of futile surgeries on patients with undetected metastases. In contrast, physicians demonstrated significantly higher sensitivity and balanced accuracy, ensuring that high-risk patients are appropriately identified for systemic treatment. Therefore, while LLMs show promise in specificity, their current lack of sensitivity precludes their utility as a standalone diagnostic tool for treatment planning.

A key factor limiting LLM performance in medical imaging is the fundamental mismatch between their text-centric design

XSL•FO
RenderX

and the demands of visual analysis. As LLMs are primarily trained on textual data, they excel in natural language understanding and reasoning but lack the capability to process and analyze complex visual information [32]. This limitation is reflected in the observation that text-based report structuring consistently outperformed direct image-based diagnosis in radiology report generation. To improve accuracy, future research should prioritize architectures that better integrate text and visual data. Incorporating multimodal learning frameworks that combine textual and imaging information might enhance diagnostic performance and facilitate clinical applicability [36,37].

Limitations

This study has several limitations that should be acknowledged.

First, our dataset was limited by a significant class imbalance, particularly in M-stage classification, where only 27/120 (22.5%) of cases were M1-positive. Consequently, the resulting CIs for sensitivity were wide, and the study may be underpowered to detect significant differences in sensitivity for distant metastases. Such imbalances are known to bias machine learning models toward the majority class, potentially leading to overestimated specificity and underestimated sensitivity. Furthermore, potential image resolution degradation during the conversion and trimming of DICOM files may have impacted the diagnostic accuracy of the LLMs. A more balanced and carefully processed dataset would enable a more robust evaluation of model performance. Additionally, because the LLMs were prompted to provide binary classification outputs (yes/no) in a zero-shot setting rather than continuous probability scores, receiver operating characteristic curve analysis and area under the curve calculation were not feasible in this study.

Second, the reliance on a single MIP image for each case does not reflect standard clinical practice. MIPs are 2D condensations that can omit crucial spatial and anatomical details necessary for accurate TNM staging, which clinicians typically determine by reviewing multiplanar image slices and integrating information from CT scans. This methodological constraint may have disadvantaged the LLMs when compared with human interpretation. Furthermore, our input was strictly limited to visual information from MIP images and did not include semiquantitative metabolic parameters (eg, SUVmax) or volumetric indices (eg, metabolic tumor volume), which are integral to standard PET/CT interpretation for differentiating malignant from physiological uptake. This is further supported by the variability in diagnostic accuracy observed among physicians within our study, which suggests a potential discrepancy between radiological assessment in this experimental setting and actual clinical workflows.

Third, the diagnostic criteria were not explicitly defined for either the LLMs or the human evaluators. While a subanalysis requesting the “basis for diagnosis” was performed to check for logical consistency (Table S1 in Multimedia Appendix 1), we acknowledge that this generated text itself represents a potential hallucination and is not a substitute for visual attention maps. The subanalysis revealed that while the model often generates text regarding clinical exclusion criteria (eg, ignoring hilar nodes), it remains prone to hallucinations (Case C) and stochastic instability (as was with Case B). The addition of a reasoning prompt paradoxically led to a false-negative result in a previously correctly diagnosed case. Crucially, due to the “black box” nature of commercial APIs, we could not generate saliency maps or obtain reliable bounding box coordinates to verify the models' focus. Consequently, we cannot determine whether the “correct” classifications were achieved based on appropriate anatomical features or simply represent “right answers for the wrong reasons.”

Fourth, the use of a private, single-institution dataset limits the generalizability of our findings. Differences in imaging protocols, patient populations, and clinical workflows across institutions can significantly affect model performance, making external validation with larger, multicenter datasets essential. However, it is noteworthy that the LLMs were applied in their general-purpose form without task-specific fine-tuning. While differing from traditional machine learning models that are often customized, this approach facilitates performance testing across diverse environments, suggesting that LLMs may be suitable for broader clinical and research applications where consistency and ease of validation are important.

Finally, this was a single-institution study focusing exclusively on esophageal SCC. Differences in imaging protocols, patient demographics, and disease pathologies across institutions were not accounted for, limiting the external validity of our findings.

Future Directions

Future research should prioritize several key areas to improve diagnostic accuracy and clinical utility. First, overcoming the limitations of 2D MIP images is essential; integrating volumetric data from CT and 3D PET scans is necessary to capture the spatial and anatomical details required for accurate staging. Second, future studies should use multimodal learning frameworks that better synthesize textual clinical data with imaging features, rather than relying only on text-centric architectures. Third, to address the “black box” nature of current models, assessments should include outputs such as bounding boxes or heatmaps to verify that the model is identifying the correct pathology rather than hallucinating lesions.

Finally, conducting external validation using larger, multi-institutional datasets is crucial to assess generalizability across different imaging protocols and diverse patient populations.

Conclusions

Current general-purpose LLMs, including GPT-5, do not achieve physician-level diagnostic accuracy for esophageal cancer staging based on MIP images. While newer models demonstrate improved specificity and a reduction in hallucinations when compared with those of earlier iterations, their sensitivity for detecting nodal and distant metastases remains insufficient for clinical use. These findings suggest that while LLMs hold potential as future support tools, they currently cannot replace or reliably augment expert radiological assessment in this domain. Future development must prioritize the integration of volumetric data and multimodal capabilities to bridge the notable performance gap observed in this study.

Abstract

Background: To support physicians in focusing on relevant information during melanoma treatment, it is essential to design information systems (ISs) that integrate into their workflow.

Objective: This study aimed to identify the work steps, knowledge sources, and key information during tumor board registration, revealing the physician's cognitive workflow and task conceptualization.

Methods: We applied the concurrent think-aloud method with 10 dermatologists from the University Hospital Essen's skin cancer unit, providing direct insights into their work. Participants had varying levels of experience, from a few weeks to over a decade in the department, and differing levels of previous patient knowledge. Voice and screen recordings were transcribed and inductively annotated across 3 categories: "work step," "information in focus," and "program used." Furthermore, 4 annotators from medical informatics and social psychology conducted the annotation process. These annotations were used to map the workflow model via a sequence diagram, alongside a quantitative analysis of code occurrences and overlaps.

Results: Patient-related data in clinical IS are distributed across nested submodules, requiring physicians to extract key information through extensive system interactions. The workflow consists of 4 distinct phases with 10 work steps, taking on average 13 minutes to complete. Physicians switched between 3 programs approximately 25 times, requiring a minimum of 16 interactions to access essential information from the hospital IS. The analysis identified 7 fundamental pain points: time-intensive login and patient selection (consuming 7% of workflow time), need for multiple system instances, data fragmentation across systems, hierarchical information modularization, interface structures hindering simultaneous viewing, repetitive data insertion (27% of time), and inappropriate input fields forcing external text editor use (28% of time). Collectively, approximately 55% of workflow time was dedicated to system interactions and manual data compilation rather than clinical decision-making. Physicians frequently copied information from various reports to compile a free-text case summary, representing an extensive workaround addressing data fragmentation. External editing of the case summary was highly iterative, with an average of 3.5 repetitions. The workflow phase "updating the knowledge" showed the greatest variety in step sequences, with physicians accessing radiology reports, laboratory values, tumor board protocols, and progress documentation in varying orders.

Conclusions: These insights offer a deeper understanding of physicians' intentions when handling medical information and their challenges with current clinical IS. The workflow can be understood as a comprehensive workaround due to data distribution, with physicians compensating through experience-based adaptations. This understanding of physicians' task conceptualization

XSL•FO

forms the basis for designing software solutions that better support workflows at the point of care by organizing and presenting relevant data more effectively.

Introduction

Medical information systems (ISs) are used in the clinical setting to access patient files, document treatment, and support decision-making processes. Depending on the specific discipline, specialized ISs such as the radiology IS or the laboratory IS are available. These systems document field-specific data that may not be appropriately captured by the standard hospital information system (HIS). Despite the increased usage of medical IS in the European Union [1], many medical personnel express a desire to abandon their use due to a range of usability issues [2,3]. The rigidity of HIS and clinical decision support systems (CDSSs) has been identified as a significant issue, hindering workflows when dealing with nonroutine processes [4] and forcing users to adjust their routine [5]. Furthermore, the increased time required for documentation and information gathering represents another factor contributing to the rejection of these systems [5]. Additionally, the high mental load caused by poorly designed systems [5,6], which results in stress [7] and burnout [8,9], is a significant concern. Many applications are not sufficiently adapted to the specific use cases they are intended to support due to a lack of user- and context-driven design and implementation [10,11].

To address these issues, our project incorporated a thorough workflow analysis into the development process of a clinical dashboard. This approach reveals the underlying contextual interpretation of physicians at the point of care in a mental model, thereby enabling the identification of the most appropriate solution [11-14]. The term “mental model” was introduced by Norman [15] to describe the understanding users’ conceptual approach to a task. It is essential to design systems that align with actual work patterns rather than assumed ones. Accordingly, it is essential to investigate context-related factors, such as task complexity [3], diverse user preferences [14,16], support of individual levels of work experience, and the application adaptability in the specific use case [16]. To reveal the workflow, the focus needs to be on the exploration of data and functionalities [17]. Integrating these insights into a comprehensive workflow model and using this as a starting point for design and implementation allows for workflow integrity of the software [3,18]. The uncovering of missing or incomplete mental models can explain the rationale behind workarounds, which evolve from workflow interruptions [19]. This enhances patient safety [13] as a result of the avoidance of these workarounds and related errors [4,20]. Furthermore, the integration into the workflow offers the potential for more effective implementation of evidence-based treatment and decision-making [5]. The presentation of relevant information at the optimal time and in the most suitable format [11,21] also serves to reduce repetitive and inefficient activities [11] and thereby increase overall efficiency. The involvement of the user in the development process encourages a positive perspective toward IS, which, in turn, positively influences acceptance [14].

The context of treatment of patients with melanoma is particularly appropriate for this analysis from 2 perspectives. On one hand, it is estimated that melanoma will account for 5% of new cancer cases in the United States in 2024, ranking it as the fifth most common cancer in the country [22]. The 5-year survival rate for melanoma is promising when diagnosed in early stages (stage 1: 99%, stage 2: 85%, and stage 3: 75%) [22-24]. In stage 4 settings, the correct tumor classification comes into focus. Advanced diagnostics allow for personalized treatment, which increases the likelihood of surviving for 5 years by 10% [25]. This underscores the importance of the physician’s comprehensive and detailed knowledge of the patient’s condition for early detection of melanoma and optimal treatment. On the other hand, the treatment of patients with skin tumors in Germany is conducted in specialized skin tumor centers by dermatologists specializing in oncology. A single team provides all stages of care: diagnosis, histopathology, surgery, adjuvant and advanced treatment, and follow-up. This approach allows for comprehensive, holistic care, as well as the generation of insights that may be applicable to other tumor types.

The objective of this project was to gain insight into the process of treatment of patients with melanoma by examining the task of gathering the relevant information and preparing patients’ documents for an interdisciplinary tumor board discussion from a user-centered perspective. Consequently, an examination was conducted of the work steps, the information that is the focus in each step, and the data sources (programs) that are used. By combining the insights into a workflow model, the relationships between work steps, data, program interactions, and intents are highlighted. The broad perspective enabled identification of pain points in software interactions, decision-making criteria, and the relationship between intents and relevant information across all workflow steps.

Methods

Ethical Considerations

This study was approved by the Ethics Committee of the Faculty of Engineering (approval 2111SPKA9493) of the University of Duisburg-Essen. All procedures were performed in accordance with the ethical standards of the institutional research committee, the 1964 Helsinki Declaration, and its later amendments or comparable ethical standards. All participants provided their informed consent in written form for inclusion in the think-aloud

XSL•FO
RenderX

(TA) method. Any information allowing patient identification was removed from the recordings before the transcription process. There was no compensation for participation.

Approach

This study aimed at gaining insights into the process of gathering the relevant information and preparing patients' documents for an interdisciplinary tumor board discussion. Therefore, the TA method was conducted with 10 physicians of varying levels of expertise at the University Hospital Essen in Germany. The group included resident physicians with a few weeks to several years of experience, as well as senior physicians in the field of dermatology. The transcripts of those sessions were inductively annotated regarding their contained work steps, considered information, and programs in use. The detailed code systems can be accessed in the Excel sheet tab: "code systems" in Multimedia Appendix 1. We did a cognitive task analysis to reveal the underlying cognitive workflow and task conceptualization, which resulted in a sequence diagram (SeqD) that highlights the workflow. Additionally, we analyzed the interactions with the programs used during the process to align the work steps with the data prioritization and software interactions.

TA Method

The TA method [26] is a widespread methodology [27-29] for assessing the suitability of implementations or prototypes within their intended context [27]. By asking users to express their thoughts aloud concurrently (concurrent think-aloud [CTA] method) while conducting a task, it is possible to gain valuable insights into their cognitive approach and intentions in real time, in contrast with retrospective TA where reflections are gathered after task completion. As a method frequently used in iterative development processes [28], this knowledge enables designers and developers to create products that align with actual needs rather than assumed ones [30]. The TA method is applicable to any scenario [30] and can be conducted fruitfully with 8 to 12 participants [31].

Therefore, 10 physicians were recruited to participate in the CTA method of this project by a senior physician. The participants represented a range of experience, from a few weeks to over a decade of work in the department, and had varying levels of previous knowledge about the patient. They were tasked with gathering the relevant information to prepare the registration of a patient with advanced metastatic melanoma for a fictitious interdisciplinary tumor board discussion. This task was selected because it requires a broad range of information and system interactions while remaining a routine clinical activity. The task does not require additional support, even for less experienced participants, making it an ideal representative example of typical workflow patterns. The CTA method was conducted in March 2022 during standard working hours in a designated room with the same technical configuration used for typical task performance. For task completion, they had access to the same programs they use in everyday clinical practice on a clinical workstation. By using real patient data and limiting the timeframe for task completion to 15 minutes, a real-world scenario was established. Each participant was accompanied by 2 conductors. The 4 annotators brought complementary expertise to the analysis: 3 researchers from medical informatics (EMH, CLB, and JS) with experience in clinical workflow analysis and health IT, and 1 researcher from social psychology (AK) with expertise in qualitative research methods. This interdisciplinary composition ensured both clinical context awareness and methodological rigor. The conductors were largely unfamiliar to participants to minimize potential bias from preexisting relationships. The task and conditions were communicated by 1 conductor, while the other documented the process. During the task, conductors only reminded participants to "think aloud," meaning participants had to articulate each step in finding and preparing the information. Interactions with the software were captured along with the mentioned thoughts by screen and voice recording. The voices were anonymized through alteration and transcription. Patient identifying information was removed from the recordings. Afterwards, the transcripts were annotated inductively regarding the accessed information, programs used, and work steps conducted.

Annotation and Quantitative Analysis

Qualitative content analysis is a category-based method enabling researchers to analyze qualitative data both qualitatively and quantitatively [32]. It is the most commonly chosen method [33] and allows for contextual inspection with a broad perspective by comparing code occurrences and overlaps [34]. Furthermore, the view can be narrowed down to individual statements to reveal intents and relationships [33]. Inductive synthesis of the code system can be used to gain an understanding of the wording used and to prevent researchers' assumptions from influencing the results [35]. This is a structured process in which codes are extracted from 10%-50% of user phrases by exploring and summarizing key findings related to a predefined aspect. The so-called paraphrases are then termed and grouped into categories and subcategories to form a code system that represents one aspect of the context. The remaining texts are annotated using the initial system, which can further be extended if new aspects occur [35].

In the initial step of paraphrasing, 3 of the 10 transcripts were examined by 4 annotators (EMH, AK, CLB, and JS) from the fields of medical informatics and psychology. In 2 independent rounds of paraphrasing, the focus was on identifying the work steps or the information accessed. The annotations were labeled and grouped into separate, consistent catalogs with meaningful granularity. Based on the generated systems, the remaining 7 transcripts were annotated by one of the annotators, and the annotation catalog was extended where necessary. The system extensions were curated through mutual agreement and integrated into the existing annotation system. After a thorough review, the physician confirmed that the erased synonyms and optimized hierarchy were adequate.

The video footage of the screen recordings was used to examine the structure of the programs and the transitions between them during the workflow. This allowed for the transcripts to be aligned with the usage of the programs. The incorporation of annotations indicating the time span of program usage in the transcripts enables simultaneous access from all 3 analytical perspectives.

XSL•FO
RenderX

To enhance the reliability of the accessed information annotations, finally, each transcript was annotated a second time by one of the same 4 annotators. Thereby, it was ensured that the annotation phrases were used consistently among each annotator, that they were chosen to be meaningful [36], and that this resulted in an annotation catalog with consistent categories and subcategories [37]. Based on this, we determined an overall intercoder reliability of 70%. For detailed information on the intercoder reliability of each item, please refer to the Excel sheet tab "intercoder-reliability" in Multimedia Appendix 1.

To generate insights, the generated annotations were qualitatively analyzed regarding their occurrences and overlaps between the systems using MAXQDA (VERBI GmbH). The objective was to identify associations between relevant information and work steps. This was achieved by examining the number of work steps, their occurrence, and the time spans associated with them. These were then combined with the overlaps with the information annotations. In the context of program usage, the time spans were analyzed and combined with the number of substeps required to reach a specific document containing the information of interest.

SeqD

In the human mind, the world is conceptualized as an abstract mental representation grounded in knowledge, interpretation, imagination, and experiences [38-41]. In the domain of human-computer interaction (HCI) research, these cognitive structures are characterized as "mental models" [15]. Interactions with the surrounding world are based on these models. Therefore, it is necessary to reveal these patterns through the observation of workflow and interaction sequences during software development [42]. This analysis facilitates the comprehension of user interactions, task conceptualization [15], and contextual knowledge [43]. However, as each individual constructs their own mental model, these models differ for each person and can even be contradictory, incomplete, or vary in step sequence [15].

No definitive guideline is established for the exploration and design of cognitive workflows [37]. Accordingly, the SeqD was selected as the most appropriate representation for the context of the tumor board preparation. As part of contextual design, the SeqD [44] represents the sequence of steps that must be completed to accomplish a task. The use of user phrases from the transcripts to identify and define the work steps represents an inductive approach to annotation. Furthermore, this approach identifies the driving motivation behind actions and thereby enables external observers not only to label the work steps but also the underlying intent [44]. These insights facilitate designing context-integrated solutions [44] and detecting workflow interruptions that create barriers in task execution, thus allowing for the identification of potential solutions [19]. One challenge inherent to workflow analysis is the potential of missing or wrong task conceptualizations, which may arise from untrained personnel or misinterpretations [45]. In implementing this approach, the underlying information is made accessible and interpretable, and the inclusion of intents allows for the implementation of context-integrated solutions. The operational mental model described in HCI [15,44] is captured, depicting the relationship between work steps, information in focus, and system interactions in a SeqD. It thereby enables the implementation of context-integrated solutions that inherit physicians' actual cognitive workflows.

The SeqD was modeled based on the work steps identified during the inductive annotation process. A deeper exploration of the associated user statements was performed, which revealed the underlying intents connected with the work steps through thought-aloud clinical reasoning and context. To determine the sequence of work steps, the sequence of annotations was extracted and compared between the different transcripts. To generate an average workflow, all sequence numbers of work step occurrences were added and divided by their total number of occurrences in all transcripts. This mean was calculated because each participant used a unique sequence of work steps. The resulting number was used to sort the work steps in ascending order, with only 1 occurrence per work step.

Results

SeqD

The SeqD represents the typical workflow involved in preparing a tumor board for a patient with melanoma. The average was calculated by dividing the sum of the sequence numbers of each workflow step occurrence by the total number of occurrences (Table 1, column ranking). Accordingly, the SeqD incorporates each work step on a single occasion, even though the majority of these steps are repeated throughout the workflow. In order to ensure the representativeness of the SeqD, only work steps performed by at least 5 participants were included in the SeqD.

The average completion time was 13 minutes and 16 seconds. The minimum completion time was 8 minutes and 19 seconds, while the maximum was 14 minutes and 41 seconds. Despite the variety in the approaches adopted by the participants to complete the task, an underlying fundamental workflow structure can be observed, as illustrated in the SeqD in Figure 1. This shared structural pattern, which reflects physicians' common task conceptualization despite individual variations, forms the basis for context-appropriate software design. Overall, 14 work steps were identified, 10 of which are conducted by at least 5 participants and represented in the SeqD. These were enriched with underlying intentions derived from the following action in combination with the information in focus.

The process is initiated by entering the login credentials into the HIS system, which approximately takes 20 seconds. To reduce the time spent waiting, the majority of users simultaneously open an external text editor in "preparation." The physicians then proceed to "examine the past" by accessing the patient file and locating the most recent case summary. This summary is then copied into the external text editor, read, and used as a point of reference for an updated version. To evaluate the current status, the physicians conduct a review of the case knowledge by scanning for new diagnostic results. Accordingly, they examine the radiology reports of the last tumor assessment by computed tomography, magnetic resonance imaging, or ultrasound, laboratory values, the latest tumor board protocols, and the progress documentation. The insights gained are then

XSL•FO
RenderX

iteratively integrated into the case summary by adding new results and removing outdated information. The external editing of the case summary represents a significant portion of the overall process, accounting for approximately 28% of the total time. It is a highly iterative step, with an average of 3.5 repetitions, making it one of the most essential substeps within this workflow. The case summary is then copied into the tumor board registration form. Structured information is added, including the detailed TNM tumor classification and the disciplines required for consultation at the interdisciplinary tumor board. This step is executed by all participants and, with 27% of the total workflow time has a similar weight in the process as the text editing. The phase "updating the knowledge" has the greatest variety of work step sequences, as indicated by the approximately equal ranking scores of the work steps accessing primary reports. Especially, the steps of viewing different diagnostic reports vary in sequence and combination in different workflow approaches.

Table 1. Variables considered in the analysis of work steps (execution time [in seconds], total average over all participants, proportion to the complete workflow, execution times dependent on whether it has been part of the user's workflow, adapted proportion to the workflow, total number of users executing the works step, total number of executions of each work step, average of work step executions per workflow, and ranking [sum of sequences per occurrence divided by the total number of occurrences], which were used for the work step sequence in the sequence diagram.

Workflow step	Time execution of work step in minutes, mean (SD)	% time for work step of total workflow time	Time for work step if part of user's workflow in minutes, mean (SD)	% time for work step of total workflow time if part of user's workflow	Total number - users that executed work step	Total number - work step executed by user	Work step execution if work step was part of user's workflow, mean (SD)	Ranking sequence of work steps - sum sequences/ number occurrences

The final phase of the tumor board preparation process is aimed at establishing a follow-up care plan. By formulating the question to be addressed in the tumor board, the most recent principal findings of the tumor's progression are summarized, and potential treatment options are evaluated. Furthermore, deeper insights from other disciplines into their diagnostic results can be requested to gain a more comprehensive understanding of the tumor status and treatment options.

After the workflow completion, tumor documenters use the tumor board registration form to transform the unstructured free text into structured data points by populating the fields in a structured form. The structured data points are used to generate a tumor board protocol that includes not only the summary but

XSL•FO
RenderX

also the structured information. However, as the physicians are unable to access the structured information in the HIS, there is currently no benefit derived from this data transformation. This results in the workflow described here of iteratively rewriting the case summary rather than directly extracting the information from primary sources. In essence, the workflow can be understood as a single, extensive workaround due to the distribution of important information, resulting in a free-text summary of the patients' status documented as a progress report. The section "Programs Used and Collection of Information" provides a more detailed examination of the challenges associated with gathering data from the ISs.

Figure 1. The sequence diagram depicts the 4 phases (white boxes) and the associated work steps (lilac bars) involved in preparing for the tumor board meeting. Additionally, it illustrates the subwork steps (blue rectangles), and underlying intents (orange ovals=sub-steps and yellow ovals=work step) associated with this process. The black bars illustrate parallel execution of the working steps.

XSL•FO
RenderX

To enhance the reliability and validity of the constructed workflow model, 2 experienced physicians from the department critically reviewed and validated the work steps, their sequence, and associated intentions depicted in the SeqD. The model was approved in its final form with only minor terminological refinements.

Work Step and Data

In parallel with the execution of the work steps, the information in focus was annotated inductively. By examining the areas of overlap between the 2 annotation categories, the connections between them were revealed. Figure 2 illustrates these overlaps, highlighting the work steps in the inner circle combined with the relevant information in the outer circle. The size of the fragments is reflective of the number of identified overlaps. For the sake of clarity and focus, associations with fewer than 5 overlaps have been excluded from the graphic. For detailed information on the interplay of program usage and information access per workflow step, refer to the Excel sheet tab: "work steps" in Multimedia Appendix 1.

During the "updating knowledge" phase, several data sources were addressed. Most time was spent reviewing primary reports, which focused on radiology staging reports, including magnetic resonance imaging and computed tomography results. Review of progress notes and progress reports focused on options discussed with the patient, ongoing treatment, and associated side effects. Previous tumor board protocols were used to compare whether the treatment was in line with the last result and treatment suggestions.

As highlighted in section "SeqD" under "Results," the "external editing of the case summary" and "completion of the tumor board registration" are the central steps in the process. Not only do these steps take the longest amount of time, but they also require the most information to be in focus. When updating the case summary, the information collected, such as staging results and treatment progress, was interwoven. In addition, the diagnosis and documented infusions came into focus.

When using these findings to "fill out the tumor board registration," the focus shifted to the diagnosis and especially the classification of the tumor. In addition, therapies and the decision on external disciplines to be consulted during the tumor board were identified as relevant. When planning the formulation of the question, the focus was on the therapies already applied and the overall clinical stage of the tumor.

Figure 2. The work steps, which are located within the inner circle, are accompanied by the associated information, which is presented in the outer circle. Additionally, the number of code-overlaps in the transcripts is indicated by the numbers within the outer circle. Only those overlaps occurring in transcripts at least 5 times are included. CT: computed tomography; MRI: magnetic resonance imaging and computed tomography.

Programs Used and Collection of Information

The study was conducted in a real-world setting, including the usage of the standard programs during the process of registration of a patient with melanoma for the tumor board. As a result, it was possible to gain insights into the programs in use and their purpose of usage. This revealed that the information in the medical IS was distributed across different reports, was unstructured, and needed to be accessed sequentially to gain an overview of the complete patient's status. The use of overlays hindered the viewing of information simultaneously, resulting in the need for multiple instances of the HIS to allow for easier switching of information sources.

On average, participants accessed 5 distinct programs or submodules within the HIS, not including cases where multiple instances were used. The range of variance in the number of programs used is between 4 and 7. Excluding the submodules, the average was 3 programs, with 1 in the minimum and 4 in the maximum. This usage of multiple programs resulted in 25.3 switches between programs, with a variance of 14 in the minimum and 34 in the maximum. This again highlights the distribution of data and iterative approach in summarizing the patient's status. Figure 3 lists how many participants used each program, the average time spent using it, and its proportion to the whole workflow. It can be revealed that the HIS was used by 90% (9/10) of the participants as the only information source, while 1 participant also used the radiology IS and laboratory IS. The main time was spent using the workspace, a submodule of the HIS, where the diagnostic reports can be accessed. This correlated with the work steps referring to viewing results of different kinds. The gathered information was transferred to their own case summary, for which 90% (9/10) of the participants used an external text editor. Entering the data into the tumor board registration still takes about 20% of the total time, even though the case summary was (mostly) already written in the external tool.

Figure 3. The proportion of program usage (purple) in the process of tumor board preparation for a melanoma patient is presented alongside its proportion of the total time required to complete the task (orange). HIS: hospital information system; LIS: laboratory information system; RIS: radiology information system.

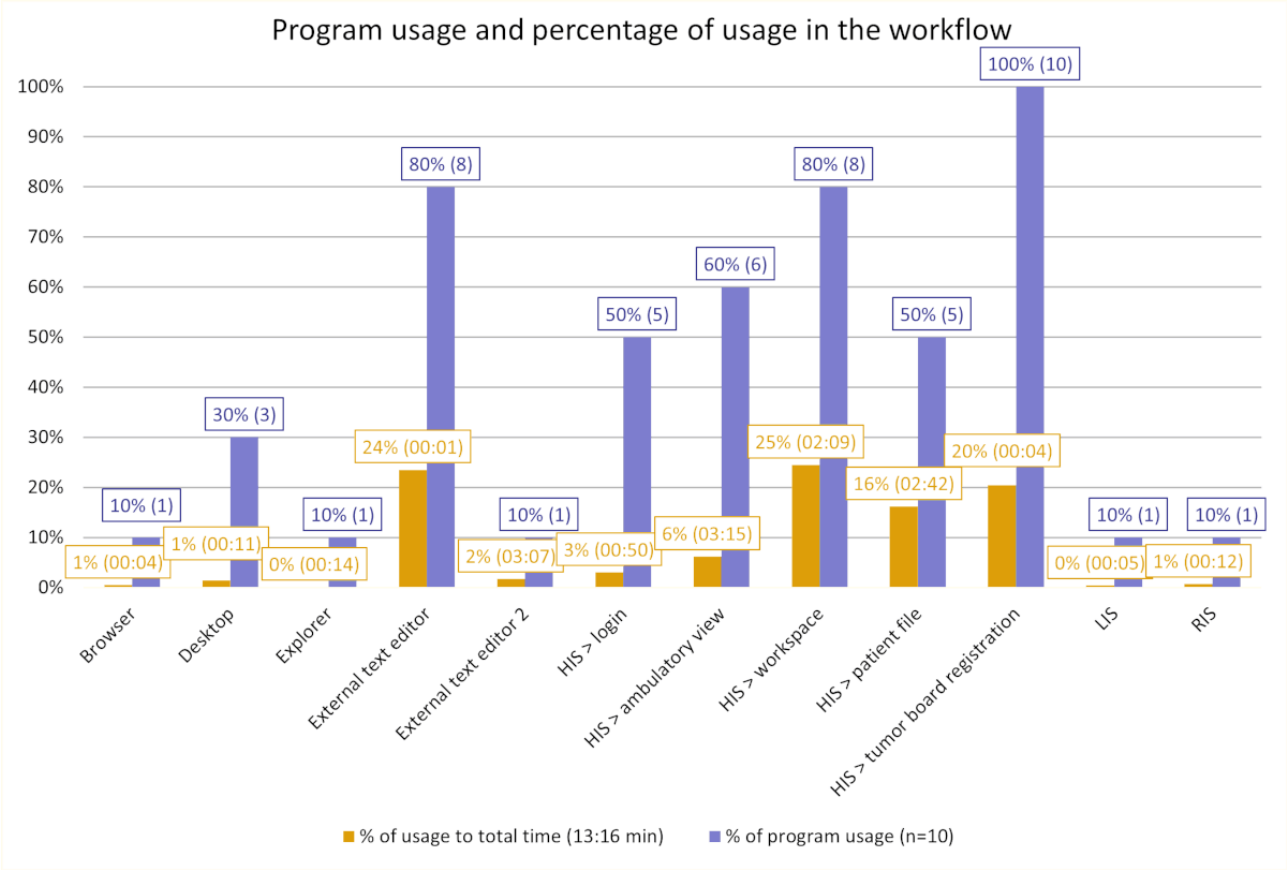

Table 2 correlates the programs and submodules with the accessed documents and indicates the number of interactions with the program required to access those. At the initial stage of the workflow, the physician must complete 3 steps to log in and 9 steps to select a patient file. As previously described, multiple instances of the HIS, using either the same or different submodules, were accessed. Examining each instance, the participants were required to complete all 9 steps of patient identification. Therefore, the table lists the number of steps required at the beginning of the workflow and after selecting a patient file. This overview demonstrates that a minimum of 16 interactions are required to access essential information from the HIS, with a minimum of 2 additional interactions necessary to access further information when the patient file is already open.

The study revealed the users' task conceptualization regarding the work steps performed, programs used, and data accessed through combining a SeqD with qualitative analysis of the annotations. This demonstrates that the workflow is significantly

XSL•FO
RenderX

influenced by the distribution of data. A considerably large amount of time is invested in system interactions rather than information interpretation, as evidenced by the interaction steps required to access each information. The creation of a case summary is an effective method for summarizing this distributed information. It provides an overview of the patient's status and serves as a foundation for further discussions regarding the patient's treatment plan in the tumor board.

Table 2. List of the accessed documents during the process of tumor board registration of a melanoma patient, along with the used program or submodule and the number of substeps required to access each document from the initial starting point. The final column indicates the number of steps needed to access the document if the patient file was selected and opened beforehand.

[b]HIS: hospital information system.

Pain Points

A synthesis of the aforementioned results reveals seven fundamental pain points in the HIS interaction, which hinder workflow efficiency: (1) time- and step-intensive login and patient selection, (2) multiple instances to reach data end points simultaneously, (3) fragmentation of data across systems, (4) hierarchical modularization of information sources, (5) user interface structure hindering view, (6) repetitive data insertion, and (7) inappropriate input fields.

At the initiation of the workflow, the login process requires 3 steps and approximately 20 seconds of waiting time before a patient can be selected in 9 steps. These 12 steps consume approximately 7% of the total time frame, despite not substantially enhancing task completion. To allow simultaneous access to different information modules and the tumor registration form, some physicians use multiple instances, which again require patient selection. Due to the use of disparate specialized IS by various departments, information is fragmented across a range of systems. Given their lack of interconnection, these systems can produce inconsistent data due to variations in data curation methodologies. The processes of copying, pasting, and logging in to each system must be repeated, resulting in a need for increased operational complexity. Additionally, the information contained within an IS is organized into a module-like hierarchy. This frequently generates new

XSL•FO
RenderX

tabs and windows, necessitating numerous system interactions to navigate between information: 2 to 7 interactions if the patient has been selected, or 16 to 23 when starting with the login process. These windows and tabs also often hinder the simultaneous view of information. Furthermore, switching between these modules requires time and interactions, forcing users to maintain awareness of the various windows and tabs that have been opened. This circumstance leads to an average of 25.3 program switches. The data fragmentation and its predominantly unstructured nature induce repetitive data insertion into different programs. The process of copying and pasting, accounting for approximately 27% of the total task completion time, is the only method that allows users to center all necessary information on the tumor board registration form. In addition to fragmentation across windows, inappropriate field sizing, and absent text editing features compel the use of external text editors to curate the summary. As this text editing step accounts for approximately 28% of total task completion time, developing an appropriate user interface design for this step is critically important. An effective incorporation of this feature could lead to a significant reduction in the number of program switches required, thereby enhancing the efficiency of the overall process.

Discussion

Principal Findings

This study aimed to reveal the task conceptualization of physicians preparing patients with melanoma for tumor board discussion by identifying their work steps, information priorities, and data sources used. Our findings demonstrate that the workflow consists of 4 phases with 10 work steps, requiring approximately 13 minutes and an average of 25 program switches to complete. The analysis revealed 7 fundamental pain points, including time-intensive login and patient selection, need for multiple system instances, data fragmentation across systems, and hierarchical information modularization. Additionally, interface structures hinder simultaneous viewing, repetitive data insertion, and inappropriate input fields. Collectively, these pain points result in approximately 55% of workflow time being dedicated to system interactions and manual data compilation rather than clinical decision-making. Patient data distributed across nested submodules necessitated physicians to manually extract and compile information into a free-text case summary using external editors. This workflow represents an extensive workaround addressing data fragmentation.

Our work provides a comprehensive overview of the physicians' cognitive workflow through simultaneous examination of work steps, programs used, and information in focus. This approach aligns with established HCI methodology for revealing "mental models" [15,44] by displaying users' operational understanding of task execution within systems. While individual physicians demonstrated variations in step sequences, the underlying task conceptualization remained consistent. This shared cognitive approach underlies context-integrated software design, facilitating accommodation of individual variation while ensuring adherence to common workflow logic. To the best of our knowledge, no other study has provided such an integrated perspective on these 3 aspects of the medical treatment process, offering actionable insights for designing clinical IS that better support workflows at the point of care.

Other literature emphasizes the significance of cognitive task analysis as a common methodology for investigating the domain and usage of technology in order to develop a mental model of a context. Nevertheless, it is evident that the majority of projects do not incorporate direct user involvement [46].

As a positive example, Kilsdonk et al [47] used the TA method in combination with a systematic literature review to design a CDSS. Their work was based on insights into the users' mental model in the context of CDSS usage in the follow-up of childhood cancer survivors. In contrast to our work, their focus was on cognitive information processing patterns rather than revealing the complete workflow and IS interactions [48]. The information processing revealed during the follow-up period indicates a comparable data focus to that observed in melanoma care. The "inclusion criteria" for further decisions, namely the cancer diagnosis and treatment, are reflected in the formulation of the question, with a particular focus on tumor classification and treatment status. In contrast, the radiological staging, which is a "screening procedure," is the focus of the case summary update for tumor board preparation rather than the potential result of the decision. These differences can be explained by the different stages of tumor treatment, as our focus was on a process to adjust treatment, while the aforementioned study refers to follow-up decisions. Overall, the same information is the primary focus in both processes, although interpreted in an alternating manner during decision-making in the distinct contexts.

Having a focus on the interactions with medical IS, Saitwal et al [6] conducted cognitive task analysis using the methodology of "goals, operators, methods, and section" rules [49] in combination with the keystroke level model [50]. They evaluated their application "AHLTA" (Armed Forces Health Longitudinal Technology Application) for the completion of 14 tasks [6]. With this approach, it is possible to break down work steps into their smallest substeps by applying "goals, operators, methods, and section" rules and estimate the cognitive load and time needed to complete a task based on execution times defined by the keystroke level model. Zayim et al [48] used a similar methodological approach but conducted further reflection on the changes observed in gesture-based app control in comparison with conventional control methods for the completion of 10 tasks on their mobile app. As we had direct insight into the interactions with the programs, we were able to extract average times directly from the real-world setting. The findings of our study indicate that a considerable amount of time and effort is required to obtain the information necessary to fulfill the specific task. These interactions are characterized by a high proportion of mental operators, with nearly every step involving cognitive processes, such as identifying and scanning for the correct menu option and relevant information. This excludes the actual decision-making and summary processes. In comparison with the 2 studies mentioned beforehand, which identified about 50% [6] and 73% [48] of mental operators, the cognitive load

XSL•FO
RenderX

associated with the IS interactions can be interpreted as being particularly high.

In their study, Barber et al [19] used a knowledge audit [51] for cognitive task analysis, thereby uncovering the mental model of physicians and nurses in the context of cirrhosis care. The goal was to examine the impact of workflow on the mental model. The study demonstrated that discontinuity and barriers are reflected in the identified models. In our own work, we have found that the distribution of necessary information and its availability, typically in free text, has led to the need to align all information in a central case summary.

Pluyter et al [52] demonstrated the significance of a context-specific design of CDSS, enabling physicians to establish a shared mental model when treating patients with lung cancer, thereby optimizing treatment selection. The integration of context into the decision-making process has been shown to enhance decision confidence and quality. This improvement is attributed to the enhanced and more precise understanding of the case. In the context of our research, the observed variations in tumor board registration preparation reflect individual approaches while maintaining a shared underlying task structure, as previously indicated [19]. The workflow model conceptualized in this study can be integrated into software development processes, ensuring the synchronization of mental models independent of work experience or previous case knowledge.

The findings of this study imply 2 main aspects. On the one hand, it revealed the pain points that physicians experience when interacting with the IS, and on the other hand, the advantages and insights that were gained by exploring the workflow of a context in detail. A thorough exploration of the context helped identify usability issues in the system in use and showed how small decisions in development, such as menu structures, can cause large practical problems.

The inefficiencies and data fragmentation that have been identified present significant challenges; however, patient care continues to function through physicians' adaptation and development of workarounds. However, it is important to note that "functional" does not necessarily equate to "optimal." The current system remains operational, but it incurs a considerable cost: approximately 55% of workflow time is dedicated to system interactions rather than clinical reasoning. This could be a contributing factor to cognitive load [5,6] and potentially burnout [8,9] as revealed in other studies. In order to compensate for system deficiencies, physicians have been known to use experience-based workarounds, such as maintaining parallel documentation in external editors and memorizing navigation paths through nested modules. While these adaptations are indeed effective in maintaining care delivery, they represent accepted trade-offs that normalize inefficiency and obscure the true potential for improvement. The deep insight into the workflow made it clear that a well−thought-out interaction design is required, considering the relationship between the task at hand and the information in focus.

Further research needs to address how this information can be visualized other than in menu structures to allow for the best contextual integration and adaptation to different work steps [53-55]. The quality of these integrations should be monitored by continuous user feedback to ensure that the application allows clinicians to focus on the patient's information rather than on system structure and interactions [10].

Limitations of this study are questions that may arise regarding the transferability of the findings. Given that the workflow represents a comprehensive workaround addressing data distribution, it is important to consider how other hospitals have addressed this challenge and how the process might differ without such data distribution. While the insights into workflow steps and programs primarily address common IS interaction issues, the information in focus is transferable. Treatment standardization through guidelines and standard operating procedures, combined with similar findings in related studies [47], supports this transferability. This also indicates the transferability of the results to other disciplines. In particular, the approach and information revealed in this study will be highly applicable to the preparation of tumor boards for other cancer entities. The same information will also be relevant for other tasks related to cancer treatment. For disciplines not related to cancer, the pain points revealed in this study will also be transferable, highlighting issues to be avoided in IS development.

A further limitation of the study is its qualitative nature, which was conducted at a single hospital with a limited sample size of 10 participants. As a result, no significant differences were observed in task completion time or work step sequences between participants with varying levels of working experience, gender, or previous case knowledge. However, this absence of observable differences may be attributable to the constrained sample size that is inherent to qualitative research designs. The methodology was designed to capture workflow patterns and time allocation, rather than to systematically measure dimensions such as cognitive load, error rates, or interruptions. The use of different methodological approaches and larger sample sizes would be required to yield meaningful quantitative insights in these cases. While the findings indicate significant system interactions (55% of workflow time) and elevated operator demands, the formal measurement of these phenomena using validated instruments was not within the scope of this study. Subsequent multicenter investigations with increased sample sizes would be essential to methodically examine the potential influence of factors, such as experience and case knowledge, on workflow patterns. These studies could also quantify cognitive load, error rates, and workflow interruptions across institutions with varying IS configurations.

Conclusion

In summary, this study makes 3 significant contributions to the field of IS development in medical informatics. First, the identification of pain points in the interaction revealed the areas that require attention in the development of new applications. Furthermore, it demonstrated the importance of context exploration and development that is centered on context integration and user feedback. When designing and implementing new applications based on the insights gained, physicians can obtain a focused view of the necessary information. This can reduce the cognitive effort required to

XSL•FO
RenderX

interact with the program and possibly avoid time-consuming and potentially life-threatening workarounds.

Second, the insight into workflow, particularly the information in focus, provides transferable knowledge. While workflow steps may differ across hospitals, the underlying intentions associated with these steps remain consistent. Therefore, the combination of these intentions and the information in focus can serve as a basis for context-sensitive software development across institutions.

Third, this study addresses the discrepancy between established user experience principles and their application in health care IS development. The users' conceptual understanding of task execution, which is known in HCI as "mental models," is recognized as a foundational element in the field of user experience design [15,42,43]. However, their systematic exploration through workflow analysis in the medical domain remains limited. The findings of our study demonstrate the value of integrating the TA method with cognitive task analysis and SeqDs in revealing physicians' cognitive workflows and task conceptualizations. This approach captures not isolated cognitive structures but the observable manifestation of how physicians understand and execute clinical tasks within IS constraints. Integrating this model in point-of-care software design can enhance patient treatment by shared cognitive approaches across physicians, regardless of their work experience or previous case knowledge.

Acknowledgments

We thank the physicians of the Department of Dermatology (University Hospital Essen, Germany) for their dedicated participation in the usability studies. We thank Katharina Zeiner (Siemens, Munich) for the mentoring and fruitful discussions on user experience.

Abstract

Background: Patients receiving systemic anticancer therapy (SACT) can deteriorate clinically between scheduled appointments; yet, acute oncology services often rely on reactive helplines with limited longitudinal symptom visibility.

Objective: The aim of this study was to evaluate the feasibility, safety, and workflow integration of OncsCare, a digital symptom triage platform mapping patient-reported symptoms to UK Oncology Nursing Society (UKONS) acuity tiers with episode-based clinician review.

Methods: This 10-week service evaluation (July to September 2025) implemented OncsCare within a UK tertiary acute oncology service. Patients completed daily symptom check-ins mapped to UKONS-informed green/amber/red tiers. Alerts were grouped into episode-level triage events using prespecified rules (48-hour window, symptom-domain continuity) to represent the operational workload. Outcomes included engagement, alert distribution, escalation pathways, timeliness of clinical response, and safety signals via structured case-finding.

Results: Thirty-two patients participated (none withdrew) in this study. Daily check-in completion rate was 91.7% (1444/1574 expected patient-days). From 362 amber/red alerts, 62 episodes were generated; 38.7% (24/62) were clinically actionable, resulting in telephone management (n=12, 50%), acute care assessment (n=9, 37.5%), emergency referral (n=2, 8.3%), or admission (n=1, 4.2%). Median time to first clinical response for in-hours red alerts was 47 minutes. Predefined safety case-finding identified no intervention-attributable safety signals. Patients reported increased home reassurance (n=17, 85%), and clinicians reported improved situational awareness without increased workload.

Conclusions: UKONS-informed digital triage with episode-based review demonstrated feasibility, with no intervention-attributable safety signals identified in this small single-center evaluation. This operational model addresses alert fragmentation and supports prospective multicenter evaluation.

KEYWORDS

acute oncology; digital health; patient-reported outcomes; symptom monitoring; triage; UKONS; quality improvement; implementation science

Introduction

Systemic anticancer therapy (SACT) is associated with acute toxicities that can evolve rapidly between scheduled clinical encounters. Symptoms such as diarrhea, vomiting, mucositis, dyspnea, and pain may precede time-critical complications, including infection, dehydration, and organ dysfunction. Acute oncology (AO) services therefore function as a safety net,

XSL•FO
RenderX

aiming to identify deterioration early and deliver appropriate escalation through structured triage. In the United Kingdom, the United Kingdom Oncology Nursing Society (UKONS) triage tool provides a nationally adopted framework for grading symptom severity and specifying escalation timeframes [1].

Despite widespread use of UKONS triage during telephone contacts, many AO services remain predominantly reliant on reactive, patient-initiated helplines. This model can be delayed and variably accessible, depends on patients recognizing deterioration and initiating contact, and provides limited longitudinal visibility of symptom trajectories between contacts. A recent UK-wide review led by the UK Acute Oncology Society (UKAOS) identified marked variation in the organization, governance, digital maturity, and integration of SACT helplines, alongside inconsistent data capture and limited alignment with wider urgent and emergency care pathways [2].

Electronic patient-reported outcome (ePRO) systems have demonstrated that symptom monitoring with clinician response improves symptom control and survival [3,4]. More recent trials have extended this evidence: the PRO-TECT trial demonstrated improved patient-reported outcomes across metastatic cancer types using electronic monitoring [5], and the SYMPRO-Lung study showed improved 2-year survival for patients with lung cancer monitored with web-based symptom tools [6]. Phase III evidence from the eRAPID program has further established the value of ePRO integration in routine chemotherapy care [7]. However, many platforms are designed primarily for longitudinal tracking and research workflows rather than operational integration into acute care pathways, and few map patient-reported symptoms to nationally adopted triage frameworks.

To our knowledge, few implementations have operationalized patient-reported symptom monitoring within a nationally standardized AO triage framework. To address these gaps, we developed OncsCare, a clinician-designed digital symptom monitoring and safety-netting platform that maps daily patient-reported symptoms to UKONS-informed red/amber/green acuity tiers with episode-based grouping of temporally related alerts to reduce alert fragmentation. Evaluation end points were prospectively informed by the RE-AIM (Reach, Effectiveness, Adoption, Implementation, Maintenance) framework [8], which underpins the 5 objectives below; implementation determinants were mapped retrospectively using the Consolidated Framework for Implementation Research (CFIR) [9], as detailed in the Methods and Discussion. We conducted a 10-week service evaluation with five objectives: (1) engagement and retention, (2) alert distribution and episode-level actionability, (3) escalation pathways and timeliness of clinical response, (4) safety signals using structured case-finding, and (5) patient and clinician experience.

Methods

Study Design

We conducted a 10-week quality improvement service evaluation (July 11, 2025 to September 19, 2025) within the AO service at University Hospitals of Leicester NHS Trust, a UK tertiary cancer center serving approximately 1.1 million people. The intervention was implemented as an adjunct to existing AO pathways and did not replace standard care. Participants retained access to usual services, including the 24-hour AO helpline, Oncology–Hematology Assessment Unit (OHAU) pathway, and emergency department (ED) assessment.

Two complementary implementation science frameworks informed the evaluation design. RE-AIM [8] was applied prospectively to define evaluation end points and structure outcome selection across engagement, adoption, and implementation domains. The CFIR [9] was applied retrospectively to map determinants of adoption across 5 domains from qualitative clinician debrief data. Both frameworks are elaborated in the Discussion.

Prior to implementation, informal focus groups with 3 patients receiving SACT and 2 caregivers informed onboarding materials and safety messaging. Key themes included the importance of clear instructions to bypass the application and use urgent/emergency pathways when needed, transparency about monitoring processes, and minimizing the burden of daily check-ins. These insights were incorporated into onboarding scripts and in-application safety-netting content.

To contextualize the evaluation, AO helpline activity was described using digitized call logs from January 2023 to June 2024. Metrics included weekly call volume and call outcomes categorized as managed without admission, escalated to OHAU, referred to ED/admitted, or administrative/other. Baseline data were descriptive and not intended for formal statistical comparison with the pilot period.

Participants

Eligible participants were adults (≥18 years) receiving active SACT with anticipated treatment duration ≥6 weeks, ECOG performance status 0-2, access to a smartphone or tablet (independently or with caregiver support), and ability to provide consent in English. Exclusion criteria included end-of-life care with estimated life expectancy <3 months, lack of capacity, enrolment in other intensive daily remote monitoring programs, or anticipated prolonged admission or travel during the pilot period. Patients were approached pragmatically during SACT visits, OHAU reviews, or outpatient appointments. Participants provided informed verbal consent documented in the clinical record using a standardized template.

Setting and Intervention

OncsCare comprises a patient-facing mobile app (iOS/Android) and a secure clinician dashboard. Participants completed a brief daily symptom check-in covering temperature, dyspnea, nausea/vomiting, diarrhea, constipation, pain, bleeding/bruising, fatigue, skin rash/reaction, peripheral neuropathy, and oral mucositis. Symptom severity was captured using a 0-3 ordinal scale with patient-facing anchors co-designed with AO nurses, mapped to UKONS-informed acuity tiers. On submission, tier-specific end-screen guidance was displayed: green alerts provided reassurance, amber alerts advised monitoring while awaiting review, and red alerts instructed patients to contact the AO helpline urgently or attend ED if unwell. Red alerts

XSL•FO
RenderX

generated real-time dashboard notifications; amber alerts were reviewed in scheduled twice-daily batches. Green submissions were available for the longitudinal context but did not require active clinician review. Dashboard monitoring occurred during weekday in-hours periods (Monday to Friday, 9 AM to 5 PM). This was distinct from the 24/7 AO helpline, which continued to operate across two 12-hour nursing shifts throughout the evaluation.

Alerts were grouped into episode-level triage events using a prespecified rule-based approach. An episode was initiated by any amber or red alert. Subsequent amber/red alerts were assigned to the same episode if they occurred within 48 hours of the most recent alert and shared symptom-domain continuity (gastrointestinal, respiratory, fever/temperature, pain, mucositis, neuropathy, fatigue/wellbeing, bleeding/bruising, skin). A new episode was created when the 48-hour window elapsed without qualifying alerts or when alerts reflected a distinct symptom pattern. Grouping consistency was reviewed periodically by the project lead.

Implementation followed Plan–Do–Study–Act (PDSA) cycles across 4 phases (Multimedia Appendix 1), iteratively refining onboarding processes, alert threshold calibration, dashboard efficiency (including episode-based alert grouping introduced in week 3), and safety-netting messaging in response to early user feedback.

Measures and Outcomes

Post-pilot qualitative feedback was obtained from 20 of 32 participants (62.5%) via a structured survey with open-ended questions. The patient survey comprised both closed and open-ended items across four domains: (1) usability and engagement (ease of use, frequency of check-ins, usefulness of reminders, clarity of symptom questions); (2) perceived reassurance and psychological impact (including reassurance, anxiety related to alerts, and perceived safety); (3) impact on care (including symptom self-management, perceived responsiveness to alerts, and overall satisfaction); and (4) acceptability and future use (including recommendation to others and interest in future participation). Free-text responses explored perceived benefits, challenges, and suggested improvements. The complete survey instrument is provided in Multimedia Appendix 2. Survey responses were collected using Google Forms and analyzed descriptively and thematically. Four structured clinician debriefs were conducted at weeks 3, 5, 8, and 10 using a semistructured format focusing on (1) impact on situational awareness and clinical prioritization, (2) workflow integration within existing AO pathways, (3) alert appropriateness and specificity, (4) usability of the dashboard interface, and (5) perceived impact on workload and service delivery. Thematic analysis was conducted using an inductive approach, with themes subsequently mapped to CFIR domains to support the structured interpretation of implementation determinants.

Primary feasibility outcomes were recruitment and retention, engagement (completed check-ins divided by expected patient-days), and alert distribution by acuity tier. Secondary outcomes included the proportion of actionable episodes, escalation pathways (telephone management, OHAU assessment, ED referral, direct admission), timeliness of clinical response for in-hours red alerts (defined as alerts submitted during dashboard-monitored hours, Monday to Friday 9 AM to 5 PM, distinct from the 24/7 AO helpline), out-of-hours escalation behavior, and safety signals (missed deterioration, delayed escalation, inappropriate reassurance). User experience outcomes were captured via patient surveys and clinician structured debriefs.

Potential safety signals were assessed using predefined case-finding and structured review. All participants were cross-referenced against OHAU attendances, ED presentations, and unplanned hospital admissions. For each acute care encounter, case notes were reviewed alongside dashboard audit logs, including symptom check-ins and alerts in the preceding 48 hours. Safety signals were predefined as (1) missed deterioration, (2) delayed escalation attributable to the workflow, (3) inappropriate reassurance leading to delayed help-seeking, or (4) technical failure contributing to harm.

Data Analysis

All analyses were descriptive (counts, proportions, medians, and ranges). Temporal trends in daily check-in volume were visualized using run charts with median lines. Qualitative feedback was reviewed thematically by 2 team members and reconciled through discussion. Given the quality improvement design and absence of a contemporaneous comparator, inferential statistical analyses were not performed.

Ethical Considerations

The work was delivered as a Trust-approved quality improvement initiative (reference: QI-AO-2025-03) and did not require research ethics committee review, in line with UK Health Research Authority guidance. A Data Protection Impact Assessment was completed and approved through University Hospitals of Leicester NHS Trust information governance processes (dated July 28, 2025). This manuscript follows SQUIRE (Standards for Quality Improvement Reporting Excellence) 2.0 reporting guidance [10].

Results

Baseline AO Service Context

Table 1 summarizes the baseline AO helpline activity. Baseline service data are reported to contextualize operational workload rather than for formal comparison with the pilot period, providing insight into underlying AO demand and the operational context within which digital triage would be deployed. In the 18 months preceding implementation (January 2023 to June 2024), the AO helpline received a median of 107 calls per week (IQR 95-118). Approximately 70% of the calls were from patients receiving active SACT. Call outcomes were as follows: 52% managed with advice without admission, 14% escalated to OHAU review, 24% referred to ED or admitted, and 10% administrative/other.

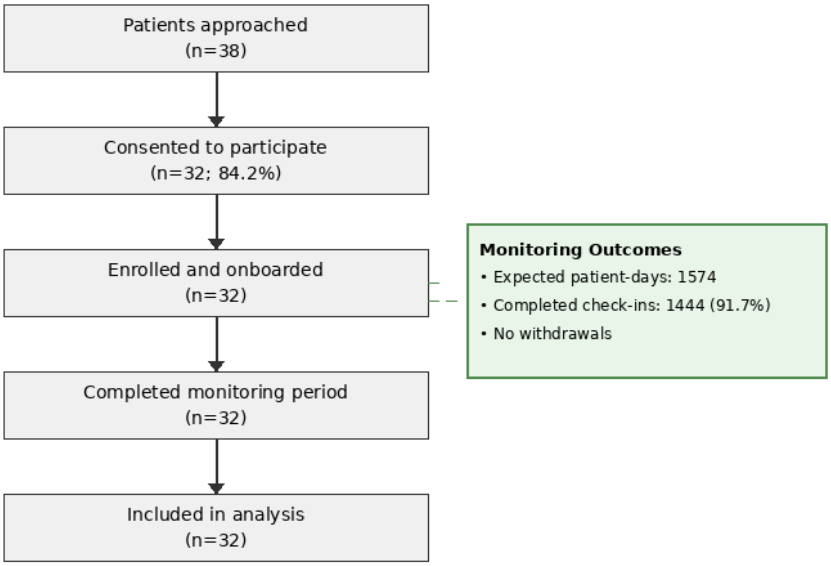
Table 1. Baseline acute oncology helpline activity (January 2023 to June 2024).

Metric	Values
Median (IQR) calls per week	107 (95-118)
Caller type (%)[a]	
Oncology patients receiving active SACT[b]	~70
Hematology patients receiving active SACT[c]	~30
Managed with telephone advice (%, no admission)[a]	52
Escalated to OHAU (%)[a,d]	14
Referred to ED[e] or admitted (%)[a]	24
Administrative/other (%)[a]	10

[a]These percentages are derived from aggregate service call logs over an 18-month period. Absolute call counts are not available from the call log system and are therefore not reported.

[b]SACT: systemic anticancer therapy.

[c]Hematology patients included in helpline activity were those receiving active systemic anticancer therapy (eg, chemotherapy for hematological malignancy) and managed within the joint Oncology–Hematology Assessment Unit pathway. This reflects the mixed oncology/hematology case-mix of the Acute Oncology helpline service and does not imply hematology patients were enrolled in the OncsCare pilot evaluation.



[d]OHAU: Oncology–Hematology Assessment Unit.

[e]ED: emergency department.

Recruitment and Retention

Figure 1 shows the recruitment and retention flowchart. Thirty-eight patients were approached; 32 (84.2%) consented, and none withdrew during the 10-week evaluation. Reasons for declining were concern about daily reporting burden (n=3), lack of smartphone ownership (n=2), and planned travel (n=1).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of participant recruitment, retention, and inclusion in analysis during the 10-week service evaluation. Of the 38 patients assessed for eligibility, 6 were excluded (concern about daily reporting burden n=3, lack of smartphone ownership n=2, anticipated prolonged travel n=1). Thirty-two patients were enrolled; zero withdrew during the 10-week pilot. Overall check-in completion: 91.7% (1444/1574 expected patient-days).

The full participant demographics and clinical characteristics are presented in Table 2. The median age was 55 (range 33-77) years; 21 (65.6%) participants were females. Tumor groups were predominantly breast (n=18, 56.3%), with representation from colorectal (n=4), lungs (n=3), and other sites. Most participants managed the application independently (n=29, 90.6%); 3 used caregiver support. Treatment intent was curative in 17 (53.1%) participants and palliative in 15 (46.9%) participants. By treatment setting, 9 (28.1%) were receiving neoadjuvant therapy, 6 (18.8%) adjuvant, 2 (6.3%) other curative, and 15 (46.9%) metastatic. Treatment modality comprised chemotherapy alone in 16 (50%), chemo-immunotherapy in 10 (31.3%), chemotherapy with targeted therapy in 1 (3.1%), and targeted or biologic therapy alone in 5 (15.6%). ECOG performance status was 0 in 15 (46.9%), 1 in 16 (50%), and 2 in 1 (3.1%). Participants represented a heterogeneous AO population: 53.1% (n=17) were receiving treatment with curative intent (including neoadjuvant

XSL•FO
RenderX

and adjuvant settings) and 46.9% (n=15) palliative, with substantial representation of chemoimmunotherapy regimens (n=10, 31.3%).

Table 2. Participant demographics and clinical characteristics (N=32). Treatment modality categories are mutually exclusive as recorded at enrollment.

Characteristic	Values
Age (y), median (range)	55 (33-77)
Female sex, n (%)	21 (65.6)

Caregiver-assisted, n (%)	3 (9.4)

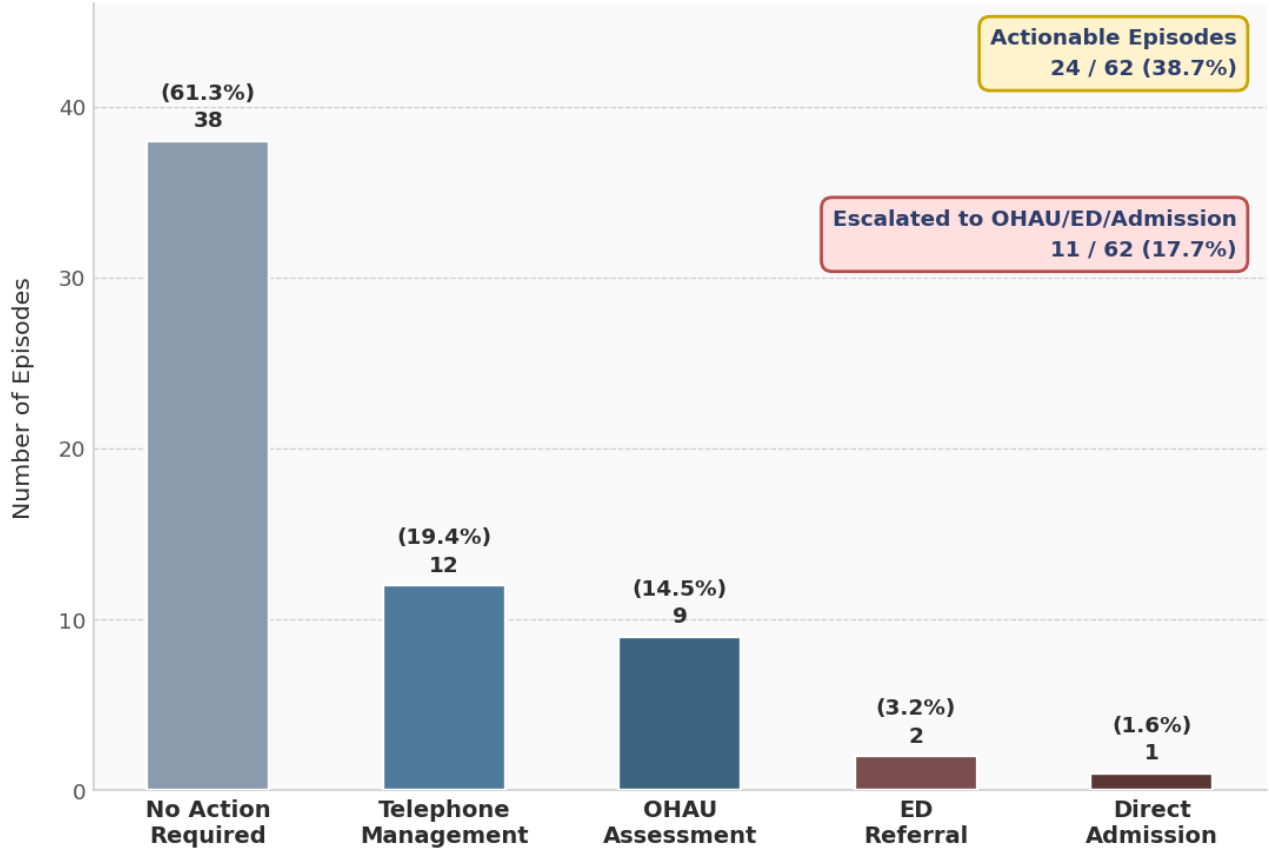
[a]SACT: systemic anticancer therapy.

[b]ECOG: Eastern Cooperative Oncology Group.

Objective 1: Engagement and Retention

Across the evaluation, 1444 symptom check-ins were completed (median 44 per participant; range 12-70). Of 1574 expected patient-days, the overall completion rate was 91.7% (1444/1574). Engagement was sustained without marked attrition (Figure S1C in Multimedia Appendix 3). High recruitment rate (32/38, 84.2%) and zero attrition were consistent with sustained engagement throughout the pilot period, supporting the feasibility of this monitoring model in routine outpatient oncology.

Objective 2: Alert Distribution and Episode-Level Actionability



Across the 10-week evaluation, 1444 check-ins generated 1082 green (74.9%), 228 amber (15.8%), and 134 red (9.3%) alerts. The median number of amber/red alerts per participant was 11 (range 2-31). Red alert distribution was highly skewed: 11 of

XSL•FO
RenderX

the participants (34.4%) experienced no red alerts, while the majority of the remainder (14/32, 43.8%) had only 1-3 alerts. A small subset (3/32, 9.4%) accounted for a disproportionate number of alerts, each experiencing ≥10 high-acuity events, suggesting that alert burden is concentrated in a minority of patients. Of 134 red alerts, 69 (51.5%) occurred during staffed monitoring hours and were managed via the dashboard workflow; the remaining 65 (48.5%) occurred out-of-hours and were managed through standard AO helpline and emergency pathways consistent with onboarding safety-netting. Alert activity peaked in mid-August (weeks 5-7), consistent with mid-cycle toxicity periods (Figures S1A-S1C in Multimedia Appendix 3).

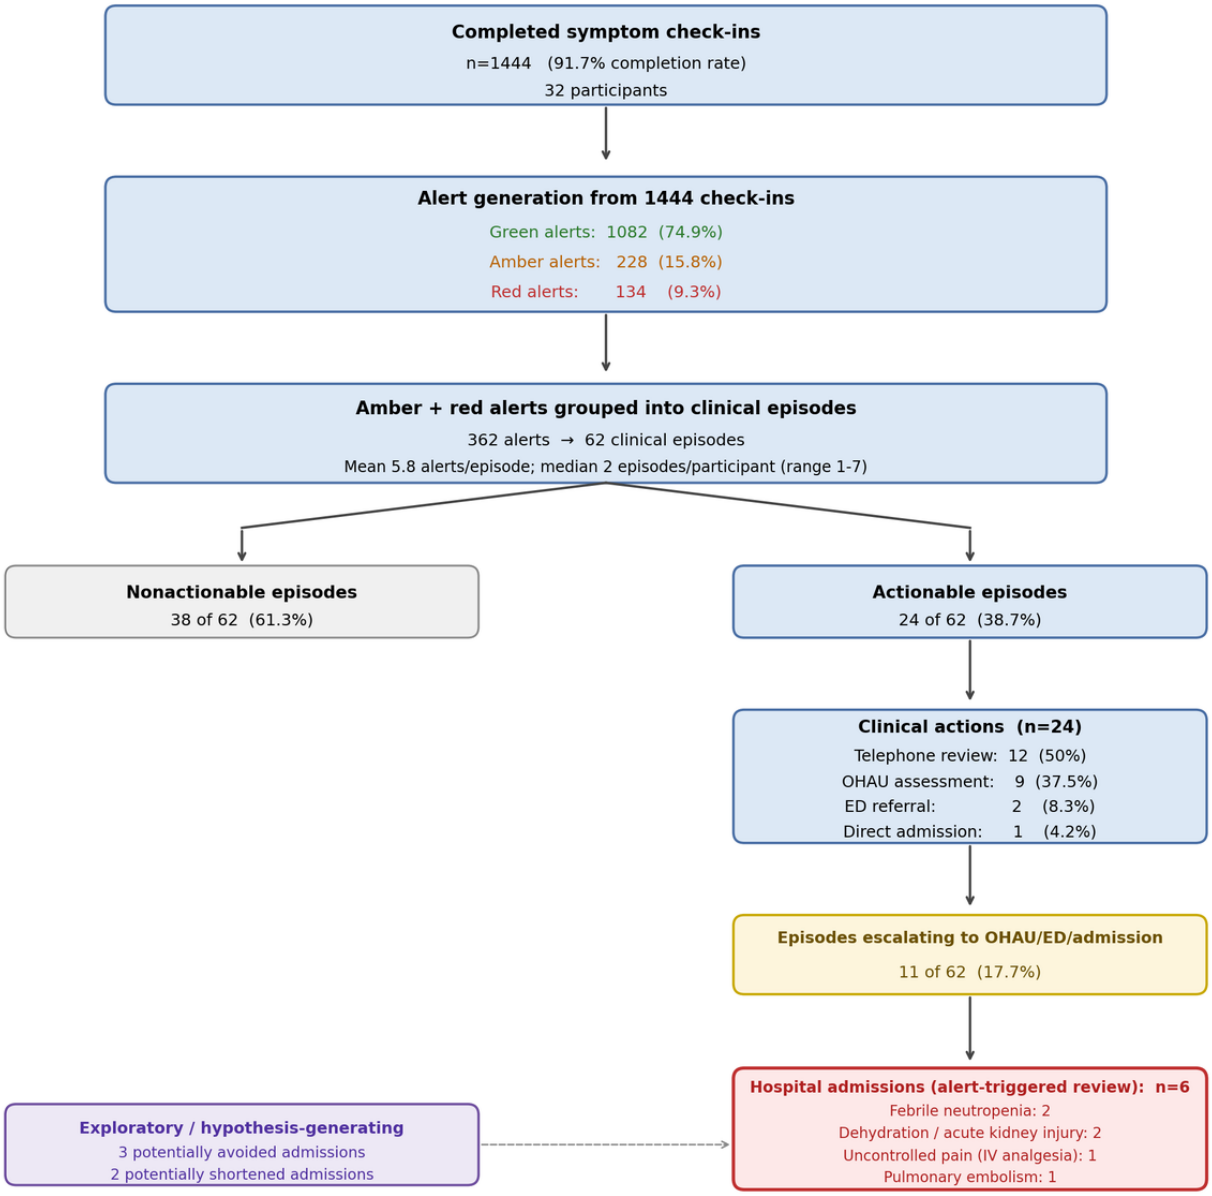


Figure 2 shows the distribution of clinical actions, while Figure 3 illustrates the operational flow from symptom check-ins through episode grouping to clinical outcomes. Table 3 summarizes the episode classifications. Using the prespecified episode grouping approach, 362 amber/red alerts were consolidated into 62 clinical episodes (mean 5.8 alerts per episode; range 1-18)—a 5.8-fold reduction in discrete review events. The median number of episodes per participant was 2 (range 1-7). Twenty-four episodes (38.7%) were clinically actionable; 38 (61.3%) were reviewed without intervention as symptoms were mild, self-limiting, or already under management.

Figure 2. Bar chart showing the distribution of clinical actions across all 62 episodes. Of 62 episodes, 38 (61.3%) required no intervention; among 24 (38.7%) actionable episodes, telephone management (n=12, 50%), OHAU assessment (n=9, 37.5%), ED referral (n=2, 8.3%), and direct admission (n=1, 4.2%) are shown. ED: emergency department; OHAU: Oncology–Hematology Assessment Unit.

XSL•FO
RenderX

Figure 3. Operational flow from symptom check-ins through episode grouping to clinical outcomes and downstream care pathways. AKI: acute kidney injury; ED: emergency department; FN: febrile neutropenia; IV: intravenous; OHAU: Oncology–Hematology Assessment Unit; PE: pulmonary embolism.

RenderX

Table 3. Clinical episode classification and outcomes (n=62 episodes).

Episode category	Values, n (%)
Total clinical episodes	62 (100)
Episode actionability	
Clinically actionable	24 (38.7)
Non-actionable (reviewed, no intervention required)	38 (61.3)
Clinical actions (actionable episodes, n=24)[a]	
Telephone clinical review with safety-netting advice	12 (50)
OHAU[b] assessment	9 (37.5)
ED[c] referral	2 (8.3)
Direct hospital admission	1 (4.2)
Escalation outcomes (all episodes, n=62)[d]	
Episodes escalating to OHAU/ED/admission	11 (17.7)
Episodes managed with telephone advice only	12 (19.4)
Episodes reviewed, no intervention required	38 (61.3)
Hospital admissions following alert-triggered review	6 (9.7)

[a]Percentages for clinical actions are of actionable episodes (n=24).

[b]OHAU: Oncology–Hematology Assessment Unit.

[c]ED: emergency department.

[d]Percentages for escalation outcomes are of all episodes (n=62).

Among the 24 actionable episodes, telephone clinical review with safety-netting advice was the most frequent (n=12, 50%), followed by OHAU assessment (n=9, 37.5%), ED referral (n=2, 8.3%), and direct admission (n=1, 4.2%). Overall, 11 of 62 episodes (17.7%) resulted in escalation to OHAU, ED, or admission. Six hospital admissions occurred following alert-triggered review: febrile neutropenia (n=2), dehydration with acute kidney injury (n=2), uncontrolled pain requiring intravenous analgesia (n=1), and pulmonary embolism (n=1).

As a hypothesis-generating, exploratory analysis only, 5 cases were identified prospectively by the clinical team as potential examples where earlier digital detection may have supported admission avoidance or shortened length of stay. These were subsequently independently adjudicated via structured case-note review: 2 potentially shortened admissions (febrile neutropenia managed with timely antibiotics); 2 potentially avoided admissions (severe diarrhea managed in OHAU with IV fluids); and 1 complex episode managed safely without admission.

Objectives 3 and 4: Escalation Pathways, Timeliness, and Safety Signals

Using dashboard audit logs and retrospective review of acute care encounters, 2 instances were identified in which participants submitted a green check-in earlier in the day but subsequently presented to hospital later the same day. In both cases, presenting complaints (acute abdominal pain and febrile neutropenia, respectively) developed after the morning check-in; both patients appropriately activated standard urgent care pathways. Neither case represented inappropriate reassurance attributable to the intervention. These cases illustrate a fundamental limitation of point-in-time symptom assessment: a single daily check-in cannot detect acute intraday deterioration, and the platform does not provide continuous monitoring.

No other intervention-related safety signals were identified. All 69 red alerts submitted during in-hours monitoring periods (Monday to Friday 9 AM to 5 PM) were reviewed: 66 (95.7%) of the 69 alerts on the same day. Median time to first clinical response was 47 minutes (range 12 minutes to 6 hours). Three reviews exceeded 2 hours due to concurrent OHAU activity; in each instance, patients were contacted and managed via an established helpline pathway with no patient harm resulting.

Objective 5: Patient and Clinician Experience

Post-pilot qualitative feedback was obtained from 20 of the 32 participants (62.5%). Four primary themes were identified: reassurance through active monitoring (17/20, 85%), ease of use and low burden (20/20, 100%), clarity of symptom reporting and guidance (15/20, 75%), and confidence in timely clinical response (14/20, 70%). Illustrative quotes are provided below, with additional quotations in Multimedia Appendix 4. Regarding reassurance, one participant described, “Having a daily reminder to check in and feeling I was being supported.” Another noted, “The thought of someone monitoring your symptoms.” Regarding ease of use and low burden, “Easy to use. Clear instructions… and reassuring knowing there was someone checking on any symptoms that were worrying.” Some participants highlighted areas for refinement, including the need for clearer symptom grading and additional contextual input options.

These qualitative findings align with the high engagement and completion rates observed, suggesting that perceived clinical oversight and low interaction burden were key drivers of

XSL•FO
RenderX

sustained use. Within the CFIR framework, these themes map primarily to inner setting (workflow compatibility, perceived value) and intervention characteristics (usability, clarity of outputs), supporting the feasibility of the integration into routine AO practice. One clinician highlighted, "Ability to see at a glance the symptoms and concerns of patients and easily identify those needing help."

Clinician debriefs (n=3 clinicians; 4 sessions at weeks 3, 5, 8, and 10) identified five themes: (1) improved situational awareness across the outpatient cohort (3/3, 100%), (2) real-time alerts with clear audit trail (3/3, 100%), (3) ease of use with minimal onboarding (2/3, 67%), (4) early escalation potentially preventing or shortening admissions (3/3, 100%), and (5) need for alert specificity refinement and contextual data integration (3/3, 100%). All clinicians reported no increase in the perceived workload.

Discussion

Principal Findings

In this 10-week service evaluation, implementation of a UKONS-informed digital symptom triage platform within routine NHS AO pathways was feasible and acceptable, with sustained engagement (1444/1574, 91.7% completion), timely clinician response to in-hours high-acuity alerts (median 47 minutes), and no intervention-attributable safety signals identified via structured case-finding. The limited sample size and single-center design constrain the conclusions that can be drawn, and larger multicenter evaluation is required. This evaluation provides an operational signal that structured UKONS-aligned digital triage can be integrated into routine AO workflows without increasing clinician workload.

The findings of this evaluation are consistent with prior trials of ePRO monitoring, which have demonstrated improved symptom control, quality of life, and survival when structured symptom reporting is coupled with clinician response [3,4,7]. However, these systems were primarily designed for longitudinal monitoring and research workflows. In contrast, OncsCare was designed for direct integration into AO triage pathways, mapping symptoms to nationally adopted UKONS escalation thresholds and supporting real-time clinical decision-making. Unlike prior ePRO systems, which rely on the clinician interpretation of longitudinal symptom trends, OncsCare provides structured triage outputs aligned with existing clinical frameworks. This distinction highlights a potential evolution from monitoring-focused platforms to operational, workflow-integrated digital safety-netting interventions.

Alert Specificity and Algorithm Refinement

Only 38.7% (24/62) of the clinical episodes were actionable, meaning the majority of the episodes reviewed did not require clinical intervention. While this did not produce evidence of alert fatigue in this small cohort, a high nonactionable rate has implications for adoption readiness. Immediate next steps should prioritize practical implementation work: refinement of alert thresholds and composite alert rules informed by adjudicated episode outcomes, integration of treatment schedule data to contextualize expected versus unexpected toxicity, and incorporation of laboratory results (particularly neutrophil counts for temperature alerts). Adoption-readiness testing across two NHS sites, design and specification refinement, and early health economic modelling are the near-term priorities before broader scale-up is considered. The skewed distribution of the red alerts—with a small minority of patients accounting for a disproportionate alert burden—suggests that threshold calibration and targeted monitoring strategies should be priorities for future implementation, potentially enabling more efficient resource allocation.

This proportion of actionable episodes suggests that triage outputs retained clinical specificity while avoiding indiscriminate escalation—a balance that will require ongoing calibration as the platform scales. The patient perspective on nonactionable alerts also warrants attention. This evaluation did not systematically capture how participants perceived episodes in which a red-tier alert was raised but no clinical action was taken. Patients who receive urgent red-tier guidance but are subsequently told no action is needed may experience confusion or eroded trust in the alert system. Future studies should include patient-reported experience of nonactionable alerts as a specific outcome measure. Patient feedback also identified specific usability refinements for future iteration: clearer differentiation of repeat notifications, the addition of free-text fields for contextual symptom detail, and improved anchoring of symptom severity scales. These insights directly informed planned algorithm and interface refinement and are consistent with the iterative PDSA approach adopted throughout the evaluation.

Safety in Digital Urgent-Care Workflows

Safety in digital urgent-care workflows requires layered safeguards. OncsCare was implemented as an adjunct to existing AO pathways with bounded monitoring hours, explicit in-app and onboarding safety-netting, UKONS-informed escalation thresholds, audit logging, and retrospective safety case-finding linked to objective acute care encounters. The 2 same-day presentations reinforce that the platform complements rather than replaces clinical vigilance and patient self-escalation. Importantly, no cases of harm attributable to delayed or inappropriate triage were identified. Larger multicenter evaluation with prespecified safety end points and independent adjudication is required before safety conclusions can be drawn. The 5 potentially avoided or shortened admissions identified in exploratory analysis should be interpreted cautiously: these classifications are counterfactual and subject to ascertainment bias and are presented solely to inform hypothesis generation for future controlled evaluation.

Operational Implementation and Practical Implications

This evaluation highlights a transferable design pattern: mapping patient-reported symptoms to established clinical triage frameworks, coupled with episode-level grouping to reflect operational workload rather than raw alert volume. This reflects a shift from reactive, contact-driven triage to proactive, structured situational awareness at the service level. Episode-based grouping represents a further shift from alert-level monitoring to clinically meaningful workload representation, reducing discrete review events by 5.8-fold in

XSL•FO
RenderX

this evaluation. Near-term practical implications include augmenting SACT helplines with structured longitudinal symptom visibility, embedding digital monitoring within routine clinical governance using PDSA cycles, and developing audit infrastructure aligned with UKAOS recommendations for standardized data capture. Health economic evaluation is a priority for any future multicenter evaluation. A key perceived benefit, reported by all 3 clinicians in debrief, was enhanced cohort-level oversight, enabling risk-stratified prioritization rather than reliance on episodic, patient-initiated contact. This positions OncsCare within a broader landscape of digital triage approaches. In contrast, reactive models, including patient-initiated helplines and e-consult pathways, do not provide longitudinal visibility between contacts. OncsCare offers a clinically structured intermediate: structured daily reporting mapped to nationally adopted escalation thresholds, with episode-level workload consolidation designed to support sustainable clinical review. Future comparative evaluations should examine whether proactive symptom monitoring confers measurable benefits in safe escalation versus reactive-only alternatives.

Digital Equity and Accessibility

This evaluation demonstrates high engagement among participants with smartphone access and digital confidence. However, eligibility criteria requiring smartphone ownership and English-language consent likely excluded digitally marginalized populations. Digital health interventions risk widening health inequities if deployment favors populations with existing digital access and literacy [11,12]. Future implementations should adopt deliberate equity-focused strategies, including formal digital literacy assessment [13], alternative access modalities (SMS text message–based reporting, telephone check-ins), multilingual interfaces, and device loan programs. These considerations are addressed further in the Limitations section.

Implementation Science Framework Mapping

Retrospective CFIR mapping identified key adoption facilitators in the inner setting domain (leadership engagement, workflow compatibility) and outer setting domain (alignment with UKAOS policy framework) [9]. Barriers to wider adoption include intervention characteristics (alert specificity), inner setting (limited electronic health record integration), and equity of access (individual characteristics and outer setting). Within the RE-AIM framework [8], this evaluation addressed Reach (32 patients enrolled; 32/38, 84.2% consent rate), Adoption (clinician engagement with dashboard workflow and participation in structured debriefs), and Implementation fidelity (1444/1574, 91.7% check-in completion; 66/69, 95.7% same-day red alert review). Effectiveness (clinical outcomes) and Maintenance (sustained adoption beyond the pilot) will be formally evaluated in the prospective multicenter study.

Comparison With Other ePRO Platforms

While eRAPID [7] and PRO-CTCAE [14] have demonstrated efficacy in longitudinal symptom tracking and research contexts, OncsCare was designed specifically for operational integration into acute care triage workflows, with UKONS framework mapping, episode-based alert consolidation, and PDSA-driven implementation via routine clinical governance.

Limitations

This evaluation is limited by its 10-week duration, single-center design, modest sample size (n=32), and absence of a contemporaneous comparator.

Selection Bias and Generalizability

Pragmatic recruitment, smartphone ownership requirements, and English-language consent criteria introduce systematic selection bias. Findings should not be generalized to digitally excluded populations, older adults with lower digital literacy, those with limited English, or patients managed at nontertiary centers.

Clinical Lead Involvement

The lead author is the developer of the OncsCare platform, creating potential for confirmation and ascertainment bias in episode classification, actionability judgements, and thematic analysis. Independent adjudication of a random 21% sample (92.3% concordance for episode assignment, 84.6% for actionability) provides partial mitigation. Future evaluations should involve fully independent adjudication and should separate the platform developer from primary data collection roles.

Point-In-Time Assessment and Intraday Deterioration

A single daily check-in cannot detect acute clinical deterioration between submissions. The 2 same-day presentations illustrate this directly. The platform does not provide continuous monitoring, and safety-netting messaging must consistently emphasize this constraint.

Out-Of-Hours Coverage

Dashboard monitoring was restricted to weekday in-hours periods (Monday to Friday, 9 AM to 5 PM). This is distinct from the AO helpline, which operates 24/7 across two 12-hour nursing shifts and remained fully available throughout the evaluation. Nearly half of the red alerts (65/134, 48.5%) were submitted out-of-hours and were not captured by the dashboard workflow. While safety-netting directed patients to the 24/7 helpline and emergency services, we cannot assess whether digital monitoring influenced out-of-hours escalation behavior.

Alert Specificity

Only 38.7% (24/62) of the episodes were actionable. Episode grouping relied on rule-based logic rather than validated clinical algorithms, and threshold calibrations were not validated against an independent dataset.

Subtle Harms

Safety case-finding was linked to objective acute care encounters. Subtle harms not resulting in OHAU/ED/admission—such as patient anxiety from nonactionable red alerts or delayed self-escalation—may not have been detected.

XSL•FO
RenderX

Digital Equity in Future Implementations

Deliberate equity-focused strategies will be required for wider deployment, including formal digital literacy assessment using validated tools such as eHEALS [13]; alternative access modalities for non–smartphone users; multilingual interfaces co-designed with ethnically diverse patient groups; device loan programs; and explicit subgroup analysis by age, ethnicity, socioeconomic status, and digital literacy in the planned multicenter study (2027-2028).

Health Economics

Cost per avoided admission, clinician dashboard review time, and wider health system impact were not formally evaluated and are priorities for the multicenter evaluation.

Conclusions

This single-center service evaluation demonstrates the feasibility of implementing UKONS-informed digital symptom triage with episode-based review within routine NHS AO workflows. High patient engagement, episode-level actionability, timely clinical response, and absence of intervention-attributable safety signals in this small single-center evaluation support further multicenter evaluation. Planned next steps include adoption-readiness testing across 2 NHS sites, alert algorithm refinement, and early health economic modelling, with a view to informing the design of a comparative multicenter study.

Acknowledgments

We thank Jaya Jaitly for her contribution to patient involvement activities during the evaluation. We also thank the Acute Oncology nursing team and oncology registrars at University Hospitals of Leicester NHS Trust for operational support and the patients and caregivers who provided feedback to improve onboarding and safety-netting materials. The authors used Claude (Anthropic, claude.ai) to assist with manuscript drafting, editing, and language refinement during the preparation of this work. All content, data, analysis, and conclusions were produced, verified, and are the full responsibility of the authors. The use of artificial intelligence assistance was limited to writing support and did not involve data analysis, interpretation of results, or generation of clinical conclusions.

Funding

This work was delivered as an internally supported quality improvement initiative within the Department of Oncology, University Hospitals of Leicester NHS Trust. No external funding was received.

Data Availability

Deidentified aggregate data supporting the findings are available from the corresponding author on reasonable request, subject to University Hospitals of Leicester NHS Trust information governance approvals. Individual-level datasets are not publicly available due to privacy and consent constraints.

Abstract

Background: Although effective, current chimeric antigen receptor T-cell (CAR-T) production methods—centralized, manual, and complex—are cost-intensive, time-consuming, and prone to variability. AIDPATH (AI-Powered Decentralized Production for Advanced Therapies in the Hospital) proposes a decentralized, automated alternative that integrates patient-specific data; optimizes resource use; and potentially improves cell viability, manufacturing efficiency, and patient outcomes.

Objective: The aim of this study was to compare CAR-T therapy produced by the AIDPATH platform to both ciltacabtagene autoleucel (cilta-cel) and standard of care (SoC) for patients with triple-class refractory multiple myeloma (MM) over a 40-year time horizon from the hospital perspective in Germany.

Methods: A partitioned survival model reflecting 3 health states (progression-free disease, progressed disease, and death) was used. The analysis used clinical trial data for cilta-cel, real-world data for SoC, and estimated parameters for AIDPATH due to the developmental status of the platform. The primary outcome was the incremental cost-effectiveness ratio; secondary outcomes included sensitivity and scenario analyses.

Results: On the basis of the model used in this analysis, AIDPATH was dominant compared to both cilta-cel and SoC. Most costs for CAR-T therapies were driven by acquisition and adverse events. Sensitivity analyses showed that the results were most influenced by discount rates and assumptions about progression-free survival. Scenario analyses, including reduced adverse events and shorter vein-to-vein times for AIDPATH, further supported its cost-effectiveness.

Conclusions: This is the first study to assess the cost-effectiveness of a CAR-T product generated with AI support in Germany from the hospital perspective. AIDPATH was found to be a cost-effective alternative to both cilta-cel and SoC, making it a promising option for future implementation. Although further data are needed, this study provides valuable guidance for health care stakeholders, reimbursement discussions, and future research.

Introduction

Chimeric antigen receptor (CAR) T-cells are a new potent treatment option for patients with cancer, with long-term data demonstrating robust efficacy and overall low levels of toxicity. CAR T-cell (CAR-T) therapy works by collecting a patient's T-cells, genetically modifying them to express tumor-targeting CARs, and reinfusing them to produce a targeted immune response [1]. However, as CAR-T therapy advances, a critical bottleneck is emerging in the manufacturing and distribution of these specialized cells [2].

Currently, CAR-T cells are predominantly manufactured in centralized facilities. This process introduces variability in the quality of the produced cells and limits scalability. Moreover, there is often a significant time gap between T-cell collection and CAR-T product infusion, referred to as the vein-to-vein time, which can lead to patient deterioration [2]. This can compromise product effectiveness or even render patients unsuitable for infusion. Although the standard production methods are groundbreaking, they are operationally complex and costly.

AIDPATH (AI-Powered Decentralized Production for Advanced Therapies in the Hospital) is a European Union–funded project (grant 101016909) addressing these challenges by automating and decentralizing CAR-T cell manufacturing. AIDPATH's AI technology enables a deeper understanding of the production process and facilitates the identification of correlations between production and patient data, thereby supporting its patient-centric approach. The platform for producing this therapy is being built and is expected to optimize scheduling and resource planning, thereby reducing costs and hospital resource use. By overcoming the limitations of centralized manufacturing, AIDPATH has the potential to enhance efficiency, cost-effectiveness, and patient access to and outcomes of cancer treatment [3].

The objective of this study was to assess the cost-effectiveness of CAR-T cell therapy produced by the AIDPATH platform for patients with multiple myeloma (MM) in Germany, from the hospital perspective, over a 40-year time horizon, compared to manually produced and centrally distributed CAR-T cell therapy (ciltacabtagene autoleucel [cilta-cel]) and standard of care (SoC).

The results of this analysis will provide insights into whether transitioning to automated AI-supported CAR-T cell production is expected to be a cost-effective alternative. These results may support evidence-based decision-making for policymakers, health care administrators, and clinicians considering adoption of the AIDPATH platform.

Methods

Study Design and Population

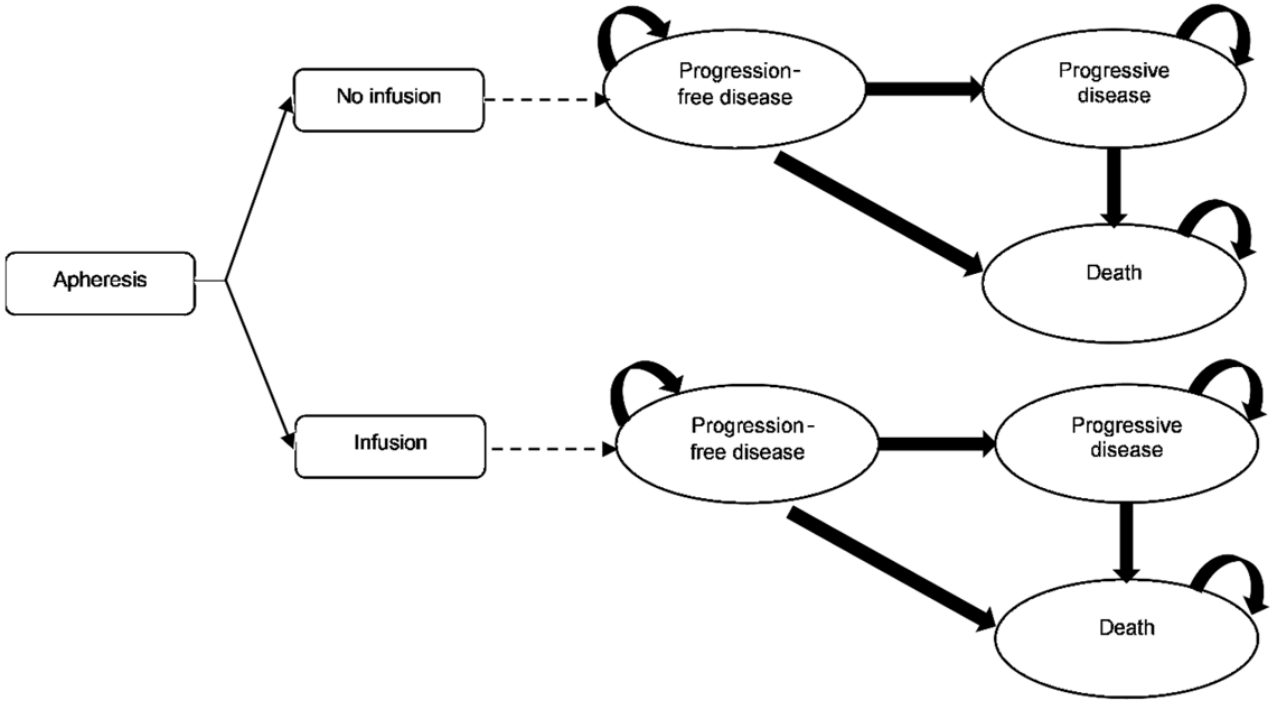
To assess the cost-effectiveness of CAR-T cell therapy generated by the AIDPATH platform compared to SoC and manually produced, centrally distributed CAR-T cell therapy (cilta-cel; Johnson & Johnson), a partitioned survival model was developed as part of this early health technology assessment (HTA). The partitioned survival model consists of health states that a patient can occupy at a given time point, which reflect the clinical trajectory of patients [4].

The study population comprised adult patients with MM in Germany who had not responded to or had experienced a relapse/refractory (R/R) after at least 3 prior lines of cancer treatment. These treatments include an immunomodulator, a proteasome inhibitor, and a cluster of differentiation 38 antibody. In cases where the disease no longer responds to agents in each of the 3 classes, it is referred to as "triple-class refractory" MM [5]. This patient group is currently eligible for CAR-T cell therapy within the German health care system [6].

Given that social, environmental, and other contextual factors influence disease progression [7], this study focuses on a single country. As the first AIDPATH platform is being implemented at the University Hospital Würzburg, a leading center for CAR-T cell research and treatment, Germany was selected as the setting for this analysis.

Model Overview

The partitioned survival model used in this study consists of 3 health states: progression-free disease (PFD), progressive disease (PD), and death (Figure 1). For the cohort receiving cilta-cel, the starting point was "apheresis" on the decision tree. Hereafter, patients were either not infused and streamed into the partitioned survival model or started a bridging period while they waited for their CAR-T therapy to be produced. After the bridging period, the infused cohort streamed into the partitioned survival model. All cohorts start in the PFD health state. Patients enter the model in the PFD health state and receive either CAR-T cell therapy (derived from AIDPATH or cilta-cel) or SoC. Patients enter the model at 61 years old, based on the selected patient group's average age of 61.7 years in the cilta-cel clinical trial [8]. A cycle length of 1 week was used, and the time horizon for the analysis was 40 years (ie, 2080 cycles). This is in line with the Dutch Health Care Institute (*Zorginstituut Nederland* [*ZIN*]) cilta-cel study and represents a lifelong time horizon [5].



The number of patients in the PD health state at a certain time equals the overall survival (OS) proportion minus the progression-free survival (PFS) proportion. The number of patients in the death state equals 1–OS. OS and PFS rates for SoC were based on German real-world clinical population data. Here, time to next treatment was used as a proxy for OS [9]. The OS and PFS rates for the CAR-T therapy arms were based on Kaplan-Meier curves (median OS was not reached at the data cutoff; 27.7-month PFS rate: 54.9%) digitized from published clinical trial data [8-10] and reconstructed into pseudoindividual patient data to enable parametric survival modeling. Parametric survival models (including exponential, Weibull, Gompertz, gamma, log-logistic, log-normal, and generalized gamma distributions) were fitted to the reconstructed data to enable extrapolation beyond the observed trial period. Model selection was based on statistical goodness of fit (Akaike information criterion [AIC]), visual inspection of fitted vs observed Kaplan-Meier curves, and assessment of hazard functions. The analyses were then used to extrapolate the survival data beyond the time frame covered by clinical trials. Detailed methodology for extrapolation, data fitting, and model

XSL•FO
RenderX

selection can be found in Section A in Multimedia Appendix 1 [8,11-41].

The mortality rate for the PFD health state equals background mortality, retrieved from German life tables, obtained from the World Health Organization [42]. The mortality rate for the PD health state is cancer-specific mortality. The life tables used were from the most recent year available (2019) and for ages 61 to 100 years.

Figure 1. Partitioned survival model pathways and health states.

Data on health state utilities were derived from the CARTITUDE study [8] and the Dutch Health Care Institute (*ZIN*) cilta-cel study [5]. In these studies, the EQ-5D-5L questionnaire was used to assess utility scores, and mixed-effects models were used to estimate utilities for the PD state when data were missing [5]. Utilities were not age-adjusted. Data on efficacy and safety from the SoC therapies and cilta-cel CAR-T therapy were collected from publicly available trial results. Data from the AIDPATH platform will be collected once it is set up. When data are not available from the AIDPATH platform, estimates are based on cilta-cel.

Assuming similar clinical outcomes (PFS and OS), adverse event rates, and manufacturing success rates for AIDPATH and cilta-cel was an intentionally conservative modeling choice. In the base case, the manufacturing failure rate for AIDPATH was assumed to be equal to that of cilta-cel (3%) [43]. Manufacturing failures were not modeled as separate clinical events; instead, their impact was incorporated through increased production costs, reflecting the need for repeated manufacturing attempts to achieve a successful infusion. This assumption was made despite the AIDPATH platform incorporating a highly automated and standardized manufacturing process designed to reduce operator-dependent variability and production errors.

Consequently, assuming equivalent performance likely underestimates the potential clinical and operational advantages of the AIDPATH platform.

The costs for cilta-cel are based on the list price of €420,000 (€1=US $1.13; 2025 annual average) [5]. These costs are applied once. As AIDPATH does not have marketing authorization (yet), costs were based on production costs plus an estimation of marketing costs, totaling €120,000. The total cost of AIDPATH treatment was estimated at €120,000 based on a bottom-up aggregation of key cost components informed by published literature. Manufacturing (production) costs were assumed to be approximately €60,000 per treatment [11,44]. A 30% markup (€20,000) was applied to account for sales and marketing expenses [45]. Hospital-related costs were estimated at €27,000 [46], and quality control costs were approximately €13,000 [47]. Preinfusion period costs consisted of apheresis, bridging therapy, and conditioning therapy; these applied to both types of CAR-T therapies. Refer to Table S1 in Section B of Multimedia Appendix 1 for the cost breakdown.

Hospital resource use was based on data from the CARTITUDE-1 study [8], *ZIN* Carvykti economic analysis [5], and the AIDPATH consortium. Hospital costs and medication costs were based on the German fee tariff schedule (2023) [12], the *Kassenärtzliche Bundesvereinigung*, and publicly available economic evaluations [5,6] (Table 1). All costs were indexed to 2025 euros based on German inflation [48].

[j]Detailed calculation is provided in Section B in Multimedia Appendix 1.

[k]Detailed calculation is provided in Section C in Multimedia Appendix 1.

SoC encompasses the physician's choice of treatment for patients with triple-class refractory MM. These data were obtained from the German Therapy Monitor, a registry of real-world oncology data. It contains anonymized data on patients with approximately 4000 R/R MM, obtained from a representative sample of 108 German centers. Refer to Table S2 in Section C in Multimedia Appendix 1 for an overview of included drugs and Table S3 in Section C in Multimedia Appendix 1 for detailed calculations.

When patients enter the PD health state, costs for follow-up treatment were applied once for all treatments. The treatment given as fifth-line R/R MM treatment is one of the regimens given in the fourth line that the patient has not received before [9]. Therefore, the average fifth-line treatment price for SoC and CAR-T is the same as that for the fourth line. The average treatment duration in the fifth line is assumed to be 4 months [50]. Monthly costs of fifth-line treatment are €10,349.98. The percentage of patients with fourth-line R/R MM that receive fifth-line treatment is 0.22, according to attrition rates in a study by Dhanasiri [51]. This results in the applied 1-time follow-up treatment costs being €9108.00 (4×€10,349.98×0.22).

All baseline parameters are presented in Table 1.

The primary outcome of the analyses is the incremental cost-effectiveness ratio (ICER), which is calculated by dividing the difference in total costs (incremental cost) by the difference in quality-adjusted life years (QALYs; incremental effect) [53].

Secondary outcomes include the avoidance of adverse events. Adverse events were only included if they incurred health care costs (required physician input and/or hospitalization and/or medication) or had a large impact on patient quality of life (refer to Table S4 in Section D in Multimedia Appendix 1 for a list of included adverse events). As the occurrence rates of adverse events for AIDPATH are not yet available, they are assumed to be equal to those of cilta-cel.

Following the methodological guidelines of the German National Institute for Quality and Efficiency in Health Care (*Institut für Qualität und Wirtschaftlichkeit im Gesundheitswesen* [*IQWiG*]), the German institute responsible for evaluating health care interventions, outcomes, and costs was discounted at 3% [49].

The model was constructed using Excel (version 2608; Microsoft Corp).

Sensitivity Analyses

A 1-way sensitivity analysis was performed to assess the model results for robustness and to identify the main cost drivers. Each parameter was varied by 20% [54]. Refer to Table 1 for the lower- and upper-limit values.

Scenario Analyses

Various scenarios were performed to assess the economic implications of the competing treatment strategies and to test the robustness of the different assumptions made in the model.

In the first scenario analysis, the risk of adverse events following AIDPATH-produced CAR-T cell therapy was decreased by 10% and 20%. CAR-T–specific side effects after AIDPATH-produced CAR-T cell infusion are expected to decrease. Furthermore, the CARs are equipped with an epidermal growth factor receptor marker, which may prevent fatal outcomes of CAR-T cell–related toxicity [55].

In the second scenario analysis, the shipping and manufacturing time of CAR-T cells produced by the AIDPATH platform was lowered. In this scenario, we assumed the manufacturing time (14 days) plus shipping time (0 days) as the bridging period for AIDPATH (the average bridging therapy duration for cilta-cel is 32 days). A shorter bridging period is expected to reduce the incidence of bridging-related adverse events. It also affects the number of patients who remain alive and eligible to receive lymphodepleting therapy and the subsequent CAR-T infusion. Because bridging therapy is shorter, the direct costs of bridging treatment decrease, along with the costs of managing adverse events associated with bridging chemotherapy.

To explore uncertainty in important assumptions related to AIDPATH, additional scenario analyses were performed. In the third scenario, the PFS rate of AIDPATH was varied by ±10% to assess the impact of potential differences in treatment efficacy. In the fourth scenario, the production costs of AIDPATH were increased by 10% and 20% to reflect a higher manufacturing failure rate. An increase in manufacturing failure rate implies that more production attempts are required per successfully treated patient, thereby increasing the cost per treatment. This approach allows an indirect assessment of the impact of manufacturing failure on cost-effectiveness outcomes.

To address uncertainty in the AIDPATH cost estimate, a fifth scenario analysis was added to explore the impact of the total costs of an AIDPATH treatment. To do so, costs were varied to €200,000 and €300,000.

Ethical Considerations

This study presents an early HTA based exclusively on secondary data obtained from previously published literature, publicly available sources, and aggregated data. No primary data were collected, and no individual-level patient data were accessed.

According to German and Dutch regulations governing research involving human participants, ethics approval from an ethics committee (*Ethikkommission*) is not required for studies that

XSL•FO
RenderX

rely solely on anonymized, aggregated, or publicly available data and do not involve interventions with human participants [56,57]. Therefore, formal ethics approval and informed consent were not required for this study.

Results

The mixture-cure log-normal distribution was selected for the extrapolation of PFS (AIC=324.56) and OS (AIC=431.23) data (refer to Figures S1 and S2 and Tables S1-S3 in Section E in Multimedia Appendix 1 for the results of the selection process).

Primary Result

The results indicate that AIDPATH-produced CAR-T cell therapy is projected to be both more effective and less costly than current SoC and cilta-cel treatment. Specifically, patients receiving AIDPATH therapy are expected to gain more QALYs while incurring lower overall treatment costs. This improvement in cost-effectiveness is reflected in the ICERs, which are negative for both comparisons: –€3075.08 when comparing AIDPATH to SoC and –€1,986,526.56 when comparing AIDPATH to cilta-cel. A negative ICER indicates that AIDPATH therapy dominates the alternatives, meaning it provides better health outcomes at a lower cost. Detailed results are presented in Table 2.

Most costs of the CAR-T cell therapies can be attributed to the acquisition, followed by adverse events and monitoring (Table 3).

Sensitivity Analyses

An overview of the model input parameters with the largest impact on the ICER when comparing AIDPATH-produced CAR-T cell therapy to SoC is shown in Figure S3 and Table S8 in Section F in Multimedia Appendix 1. The results show that the discount rate of outcomes and PFS rate have the largest impact on the ICER. This indicates that assumptions about the valuation of future health benefits and long-term patient outcomes play a critical role in determining the overall cost-effectiveness of AIDPATH therapy.

An overview of the model input parameters with the largest impact on the ICER, when comparing AIDPATH therapy to cilta-cel CAR-T cell therapy, is shown in Figure S4 and Table S9 in Section F in Multimedia Appendix 1. The results show that the discount rate of outcomes and the vein-to-vein time have the largest impact on the ICER. This suggests that both the assumptions regarding how future health benefits are valued over time and the time required for manufacturing and delivering the CAR-T cell product play a crucial role in determining the relative cost-effectiveness of AIDPATH therapy compared to cilta-cel.

Scenario Analyses

The scenario analyses demonstrated that the results were generally robust to variations in key assumptions. Reducing adverse event risks (scenario 1) slightly lowered costs, with QALYs unchanged, and AIDPATH remained dominant vs both comparators. Shortening manufacturing and shipping times (scenario 2) increased QALYs with modest cost increases; AIDPATH remained dominant compared to cilta-cel but was less cost-saving compared to SoC.

Varying PFS rates (scenario 3) affected both costs and QALYs; however, AIDPATH remained dominant across all variations. Increasing production costs to reflect lower manufacturing success rates (scenario 4) raised total costs without affecting health outcomes. Despite these increases, AIDPATH remained cost-effective compared with cilta-cel and SoC. Increasing treatment prices (scenario 5) substantially increased costs (Table 4).

Discussion

Principal Findings

The objective of this study was to assess the cost-effectiveness of CAR-T cell therapy produced by the AIDPATH platform for patients with triple-class refractory MM in Germany, compared to manually produced and centrally distributed CAR-T cell therapy (cilta-cel) and SoC. In this model, given its assumptions and from a hospital perspective, AIDPATH CAR-T therapy was shown to be dominant over a period of 40 years, offering improved outcomes and lower overall costs than both

XSL•FO
RenderX

comparators. Despite the inferiority, only a small difference was observed in QALY outcomes between the CAR-T treatments in the base case analysis. This is despite the expectation that shorter vein-to-vein time would increase the proportion of patients remaining eligible for infusion by limiting progression during the manufacturing period [2]. Due to limited evidence, equal eligibility was conservatively assumed, and thus, the observed QALY difference primarily reflects earlier treatment administration rather than differences in infusion eligibility.

The findings suggest that the AIDPATH platform could be considered for implementation within the German health care setting. The results may provide a basis for estimating the return on investment for relevant stakeholders. Importantly, the base case assumptions were intentionally conservative. Equivalent clinical outcomes (PFS and OS), adverse event rates, and manufacturing failure rates were assumed for AIDPATH and cilta-cel, despite the expectation that AIDPATH's automated and standardized manufacturing process may reduce variability and production errors in practice. The scenario analyses, which included further conservative adjustments, such as increased costs and limited efficacy gains, demonstrated that AIDPATH remained cost-effective, supporting the robustness of the findings.

The sensitivity analyses illustrate the sensitivity of the results to changes in methodological choices. In both sensitivity analyses, only a few parameters had a large impact on the outcomes. These parameters are important to consider when modifying or scaling up the platform to safeguard its cost-effectiveness compared to alternative treatment strategies.

The results of this study can be used to guide discussions with German stakeholders, including investors and policymakers, regarding the incremental cost-effectiveness of CAR-T cell therapy and reimbursement decisions. Furthermore, the findings can be considered exemplary for countries with comparable health care systems. Finally, AIDPATH uses a patient-centric approach to CAR-T cell production, and based on the results, this approach shows potential.

Strengths and Limitations

To our knowledge, this is the first early HTA study to assess the cost-effectiveness of AI-supported CAR-T cell therapy production in Germany from the hospital perspective. This study is tailored to the German health care setting and provides a model that can be updated when new data become available.

Although this cost-effectiveness study provides valuable insights to support decision-making, it has several important limitations that must be acknowledged. First, by focusing narrowly on cost-effectiveness, the study may overlook the broader potential benefits of automated CAR-T therapy production. These may include system-level advantages associated with decentralized manufacturing, such as reduced logistical complexity, lower risks related to cold chain management and cross-border shipment, and improved access to treatment through reduced patient travel or expanded treatment capacity. In addition, automated production may improve treatment convenience and patient satisfaction and streamline clinical workflows. These qualitative outcomes can significantly impact health care delivery and patient experience but are often difficult to adequately quantify in economic evaluations [58]. Moreover, as with many applications of medical AI, there are pressing concerns about appropriate regulation and evaluation [59]. HTA has been recognized as a potentially key method for evaluating AI-driven innovations. However, this model does not fully address AI-specific challenges, such as the assessment of continuously learning systems, the explainability of AI decision-making, and interoperability with existing health care infrastructure. To address these gaps, Boverhof et al [59] proposed a comprehensive framework of 29 evaluation elements across 4 domains, developed through a systematic and targeted review, which could serve as a more nuanced approach for assessing the value of AI in medicine. This broader perspective is crucial for ensuring that automated CAR-T cell production and similar technologies are appraised not only for their economic impact but also for their systemic and societal implications.

Second, no specific data regarding the safety and effectiveness of CAR-T therapy generated by the AIDPATH platform are available yet. The platform is currently being tested, and it is important to update the model as soon as clinical trial data become available. In addition, survival extrapolation is an important source of uncertainty in this analysis. A mixture-cure log-normal model was selected based on statistical goodness-of-fit, visual inspection, and clinical plausibility. Alternative parametric models were explored during model selection; however, these showed inferior fit and/or less plausible long-term extrapolations.

Third, a limitation in achieving the objective of this study is the reliance on Dutch CARTITUDE trial data for key comparator inputs, specifically for the centrally manufactured CAR-T therapy cilta-cel [5]. Due to the lack of German-specific data, key cost and resource use parameters for cilta-cel were derived from a Dutch study, and these values were also used as a proxy for the AIDPATH-generated CAR-T cell therapy. However, this approach introduces uncertainty, as health care delivery, cost structures, and reimbursement mechanisms differ between the Dutch and German hospital systems. For example, hospital tariffs, staff costs, and care pathways in Germany may be higher or more complex, potentially leading to an underrepresentation of true costs from the German hospital perspective. This could result in a more favorable cost-effectiveness profile for CAR-T cell therapies than would be observed with German-specific data. Future studies should aim to validate these inputs with empirical data from the German context to strengthen the reliability of the cost-effectiveness conclusions. Because this approach was used for both CAR-T cell therapy arms, it is unlikely that an updated model would change the conclusions of the current study.

Despite these limitations, an HTA at this early stage is considered highly valuable because it provides critical insights into the potential clinical and economic impact of this new medical product. It supports informed decision-making during early development stages, helps prioritize investments, guides research efforts, and identifies key data gaps to address before implementation [60].

Conclusions

This study is the first to assess the cost-effectiveness of AI-supported, hospital-based CAR-T cell therapy produced by the AIDPATH platform for patients with MM in Germany from the hospital perspective. On the basis of the assumptions inherent in this model, AIDPATH therapy was found to be cost-effective and dominant compared with both cilta-cel and SoC from the hospital perspective over a 40-year time horizon. This was found in the base case analysis and was confirmed by all scenario analyses performed.

However, key inputs were partly based on Dutch data due to the lack of German-specific figures, introducing uncertainty, particularly in cost estimates. Additionally, no clinical data are yet available for AIDPATH-generated CAR-T cell therapy, and broader benefits, such as patient satisfaction and system efficiency, were not captured in the cost-effectiveness analysis.

Despite these challenges, this early HTA provides valuable insights to guide further research, inform reimbursement discussions, and support planning for future implementation in Germany and similar health care systems.

Acknowledgments

The authors acknowledge all partners who collaborated in the European Union Horizon 2020 AIDPATH (AI-Powered Decentralized Production for Advanced Therapies in the Hospital) project. During the preparation of this manuscript, the authors used ChatGPT (version 5-5; OpenAI) to polish the wording and formulation of sentences for English grammar and clarity. Abstract

Background: Cervical nodal metastasis remains one of the strongest determinants of treatment planning and prognosis in oral squamous cell carcinoma. Histopathology remains the reference standard, but it does not provide immediate information at the point of surgical specimen assessment. Elastic scattering spectroscopy (ESS) offers rapid, label-free optical interrogation of tissue microstructure, and may support ex vivo nodal assessment.

Objective: This study aimed to evaluate the diagnostic accuracy of ESS combined with machine learning classification for ex vivo detection of cervical lymph node metastasis in patients with oral squamous cell carcinoma.

Methods: We conducted a single-center observational ex vivo diagnostic modeling study in patients with oral squamous cell carcinoma undergoing primary tumor resection and neck dissection. A total of 3 ESS spectra were acquired from each bivalved lymph node before routine histopathological processing. Internal validation used repeated nested 5-fold cross-validation grouped by patient, so every spectrum and lymph node from a patient remained in the same fold. All preprocessing, scaling, dimensionality reduction, within-model-family configuration, and hyperparameter tuning, probability calibration where required, and decision-threshold selection were restricted to training data within the nested validation process; comparisons between candidate model families were exploratory and were based on pooled patient-grouped out-of-fold predictions. Spectrum-level probabilities were aggregated within each lymph node, and histopathology was the reference standard.

Results: A total of 52 patients were assessed for eligibility, 45 were included, and 280 fresh lymph nodes were assessed by ESS; 96 were pathology positive, and 184 were pathology negative. Of 840 acquired spectra, 760 passed quality control. Of the 280 nodes, 274 retained at least 2 usable spectra and comprised the analytical cohort; 6 pathology-negative nodes yielded no analyzable node-level ESS result. The hybrid model was selected because it had the highest pooled patient-grouped out-of-fold node-level area under the receiver operating characteristic curve (AUROC), with an internally validated, exploratory estimate of 0.966 (95% CI 0.929 - 0.988). The same out-of-fold predictions informed model-family selection and performance reporting; this estimate does not represent independent validation of a prospectively fixed final model. At the cross-validation–derived summary threshold, secondary descriptive operating characteristics were sensitivity 93.8% (95% CI 86.4% - 97.6%), specificity 95.5% (95% CI 90.1% - 98.3%), accuracy 94.9% (95% CI 90.4% - 97.3%), positive predictive value 91.8% (95% CI 82.9% - 96.3%), and negative predictive value 96.6% (95% CI 92.4% - 98.8%). The Brier score was 0.063, with calibration-in-the-large of –0.03 and a calibration slope of 0.94. Patient-level sensitivity was 96% and specificity was 90%. Pathology-positive and pathology-negative nodes also showed differences across amplitude-related and shape-related spectral features.

Conclusions: ESS showed promising ex vivo discrimination of metastatic cervical lymph nodes in this single-center model-development and internal-validation study. The findings support further investigation of ESS as a potential pathology-triage adjunct rather than a replacement for histopathology.

Introduction

Head and neck squamous cell carcinoma remains a major global cancer burden, and oral squamous cell carcinoma is one of its most clinically demanding subtypes because small differences in regional disease can substantially alter treatment. Contemporary global estimates confirm the scale of cancer incidence and mortality, while epidemiological reviews continue to identify tobacco, alcohol, areca nut, human papillomavirus infection, and social determinants as important contributors to disease distribution and late presentation [1,2]. For the surgeon and oncologist, however, the decisive issue at the time of treatment planning is often not the primary tumor alone, but whether malignant disease has reached the cervical lymphatic system. Once cervical nodal metastasis is identified, staging, operative planning, adjuvant radiotherapy or chemoradiotherapy, surveillance intensity, and prognosis all change [3].

The clinical importance of the neck in oral cancer is reflected in the depth of work examining predictors and patterns of nodal metastasis. Recent systematic reviews show that histopathological features of the primary tumor, including depth of invasion and adverse growth patterns, are associated with cervical lymph node metastasis, and that nodal involvement varies across neck levels in ways that influence decisions about the extent of neck dissection [4,5]. Yet the fundamental problem remains unresolved—occult or small-volume nodal metastases may be difficult to identify before treatment, while enlarged or reactive nodes may be mistaken for malignant disease. The consequence is a familiar clinical tension between undertreatment of metastatic disease and overtreatment of patients whose necks are ultimately histologically negative.

Preoperative imaging has improved this balance but has not eliminated uncertainty. Computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography-computed tomography (PET-CT), ultrasound, and radiomics-based approaches provide valuable information, and PET-CT may offer high specificity and negative predictive value (NPV) in selected clinically node-negative settings [6,7]. However, meta-analyses and radiomics reviews also highlight variable sensitivity, dependence on tumor site and study design, and a continuing need for prospective validation before advanced computational imaging can be relied upon for occult nodal disease [6-8]. Imaging therefore remains essential, but it cannot replace detailed histopathological examination of dissected lymph nodes. Equally, histopathology is accurate but not immediate. Routine processing, sectioning, and reporting take time, and the workload generated by multiple lymph nodes can be considerable.

A second challenge is that nodal assessment is intrinsically heterogeneous. A neck dissection specimen may contain many nodes of different sizes and anatomical levels, and metastatic deposits may be focal, central, peripheral, or microscopic. Standard histopathology is designed to manage this complexity, but the process depends on careful grossing, representative sectioning, and prioritization of tissue that appears suspicious. A rapid adjunctive technology would therefore be valuable if it could identify nodes with a high probability of metastasis before or during routine processing. Such a test would not need to provide the final diagnosis to be useful; it would need to improve where attention is directed, how quickly suspicious nodes are reviewed, and how confidently low-risk nodes are handled within established pathology protocols.

Optical diagnostic technologies have been developed to address exactly this gap; the need for rapid, biologically meaningful information from tissue without waiting for full laboratory processing. Recent reviews of oral cancer diagnostics and head and neck photodiagnosis describe several label-free or minimally invasive modalities, including Raman spectroscopy, fluorescence, hyperspectral imaging, and infrared spectroscopy combined with machine learning [9-13]. These techniques exploit changes in tissue architecture, scattering, absorption, and molecular composition that accompany dysplasia, invasion, and metastatic transformation. Their appeal in head and neck oncology is not that they replace histopathology, but that they may provide a near-immediate adjunct to help guide sampling, prioritize suspicious tissue, and improve the efficiency of diagnostic pathways. In lymph nodes, such optical signals may reflect not only the presence of malignant cells themselves but also the architectural consequences of metastatic replacement, including altered cellular density, stromal organization, vascularity, and loss of normal nodal microstructure.

Elastic scattering spectroscopy (ESS) is particularly suited to this role because it is rapid, contact-based, and sensitive to cellular and subcellular structure. When light enters tissue, it may be scattered or absorbed depending on wavelength, tissue architecture, nuclear size, stromal organization, and the distribution of chromophores. Earlier work in oral cancer showed that ESS could detect cervical intranodal metastasis in bivalved lymph nodes using intensity differences at selected wavelengths, although specificity was limited when a simple threshold was used [14]. Broader optical biopsy literature has also shown that elastic scattering can provide a strong optical signal in several epithelial and nodal settings, supporting the concept that tissue microstructure can be converted into clinically useful diagnostic information [15,16].

This study builds on that foundation by treating nodal assessment as a node-level diagnostic problem rather than a single-contact spectral problem. We hypothesized that metastatic lymph nodes would show reproducible amplitude-related and shape-related spectral differences and that combining full-spectrum information with selected optical features might improve discrimination compared with a simple single-wavelength rule. Because modern diagnostic algorithms require more than high apparent accuracy, we also designed the analysis to reflect principles of transparent prediction model reporting, diagnostic accuracy reporting, bias assessment, and early clinical evaluation of decision support systems [17-20]. The aim was to evaluate whether ESS could provide accurate ex vivo node-level discrimination of metastatic cervical nodal disease in oral squamous cell carcinoma and to define a clinically interpretable workflow for future validation.

Methods

Study Design, Setting, and Timeline

This observational ex vivo diagnostic modeling study was conducted at University College London Hospitals. The optical-imaging study received a favorable ethical opinion from The Joint UCL/UCLH Committees on the Ethics of Human Research (Committee A), confirmed in a letter dated July 31, 2006 (REC [Research Ethics Committee] reference 06/Q0505/39). Patients underwent primary tumor resection and neck dissection between September 2016 and March 2021, with fresh lymph-node preparation, ESS acquisition, and routine histopathological assessment undertaken during the same surgical episode. The archived spectra and pathology records were curated between January and December 2025, and the modeling analyses were completed between January and May 2026.

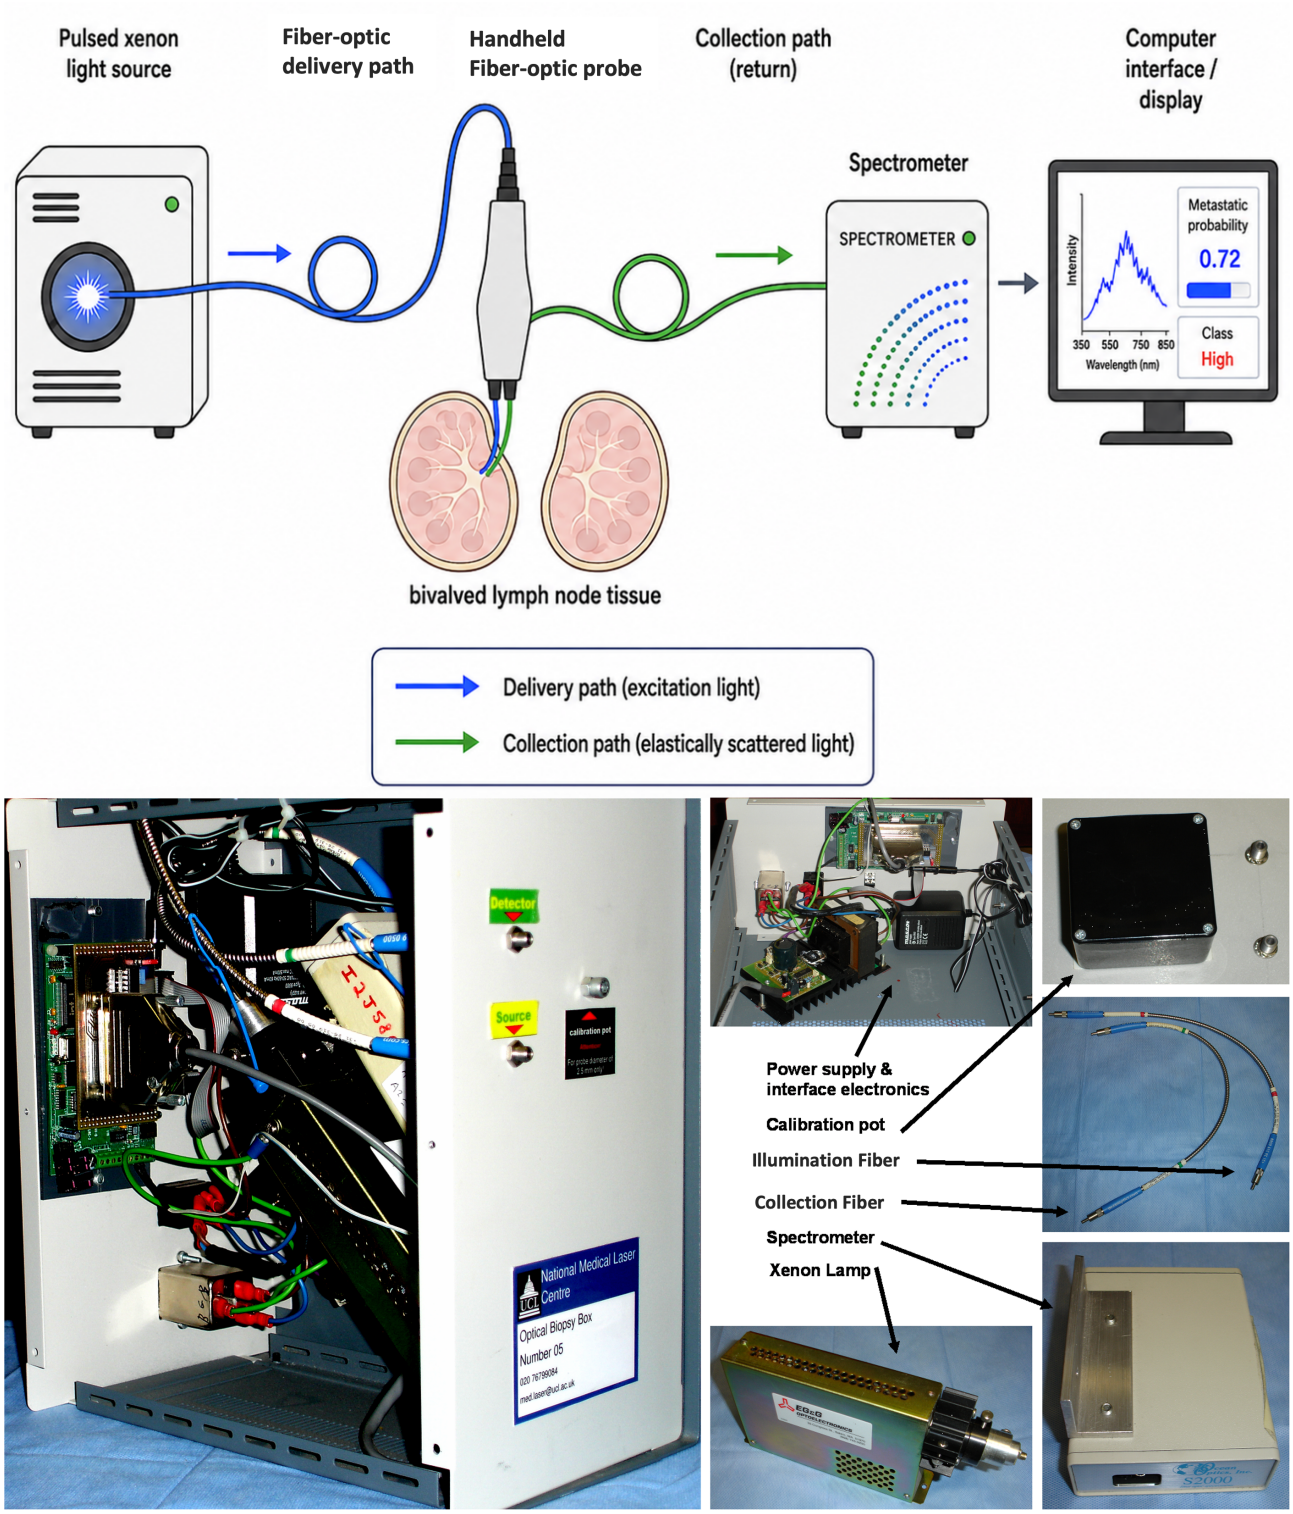
Participants and Specimens

Potentially eligible patients were assessed during the recruitment period. Adults with histologically confirmed oral squamous cell carcinoma were eligible when neck dissection formed part of their planned surgery, fresh cervical lymph nodes were available before fixation, and written informed consent had been obtained. Patients were excluded when consent was not obtained, suitable fresh lymph nodes were unavailable before fixation, or the ESS system was unavailable at the time of surgery. The patient was the enrollment and validation unit; lymph nodes were clustered within patients, and repeated spectra were clustered within lymph nodes. Within each enrolled neck dissection, ESS was performed on fresh lymph nodes that could be isolated and made available before fixation without delaying or compromising routine pathological processing. The ESS-assessed nodes therefore represented a pragmatic availability-based sample and did not necessarily constitute the complete pathological nodal yield from each neck dissection. Selection for ESS assessment occurred before the final histopathological diagnosis was known.

Ethical Considerations

The application for the optical-imaging study, “The Role of Optical Imaging (Elastic Scattering Spectroscopy, Raman Spectroscopy and Second-harmonic Imaging Microscopy) as a Diagnostic Tool in Head and Neck Cancer,” was submitted to The Joint UCL/UCLH Committees on the Ethics of Human Research (Committee A) on April 26, 2006. A favorable ethical opinion was confirmed in a letter dated July 31, 2006 (REC reference 06/Q0505/39), following consideration of further information by the Chair on July 28, 2006. The approved documents included protocol version 1.4, dated March 13, 2006; participant information sheet version 2, dated June 12, 2006; and participant consent form version 1.

The study protocol described comparison of optical imaging techniques with routine histopathology using clinically obtained oral or head and neck tissue and eligible archived material. The protocol described in vivo assessment before routine biopsy and ex vivo assessment of clinically removed oral or head and neck tissue, without additional research-only biopsy or surgery or interference with routine histopathological processing. The study continuation was subject to annual local organizational governance checks. The protocol assigned responsibility for study conduct, protocol compliance, data custody, and reporting to the Chief Investigator, who is a coauthor of this report.



This report concerns fresh cervical lymph-node ESS measurements acquired between September 2016 and March 2021. The archived spectra and pathology records were curated between January and December 2025, and modeling was undertaken between January and May 2026. All participants provided written informed consent for study participation. The analytical dataset was deidentified before modeling, direct identifiers were removed, and access was restricted to the study team. Participants received no payment or other compensation.

Procedure and ESS System

After surgical removal, the neck dissection specimen was orientated with pathological guidance to preserve anatomical context and nodal identity. Individual lymph nodes were isolated and bivalved to expose the internal cut surface. Two trained operators performed ESS acquisition according to a written protocol, with each lymph node assessed by 1 operator. The freshly cut surface was gently blotted, visibly blood-contaminated areas were avoided, and the probe was held approximately perpendicular to the surface in gentle contact without visible tissue compression. In total, 3 spectra were acquired from spatially separated points across the exposed cut surface of each bivalved lymph node. Operator, acquisition batch, and the times of excision, bivalving, and first ESS acquisition were recorded. The median interval from excision to the first acquisition was 18 (IQR 13 - 26) minutes. The overall diagnostic pathway is illustrated in Figure 1, and the probe-tissue interrogation geometry is illustrated in Figure 2.

XSL•FO

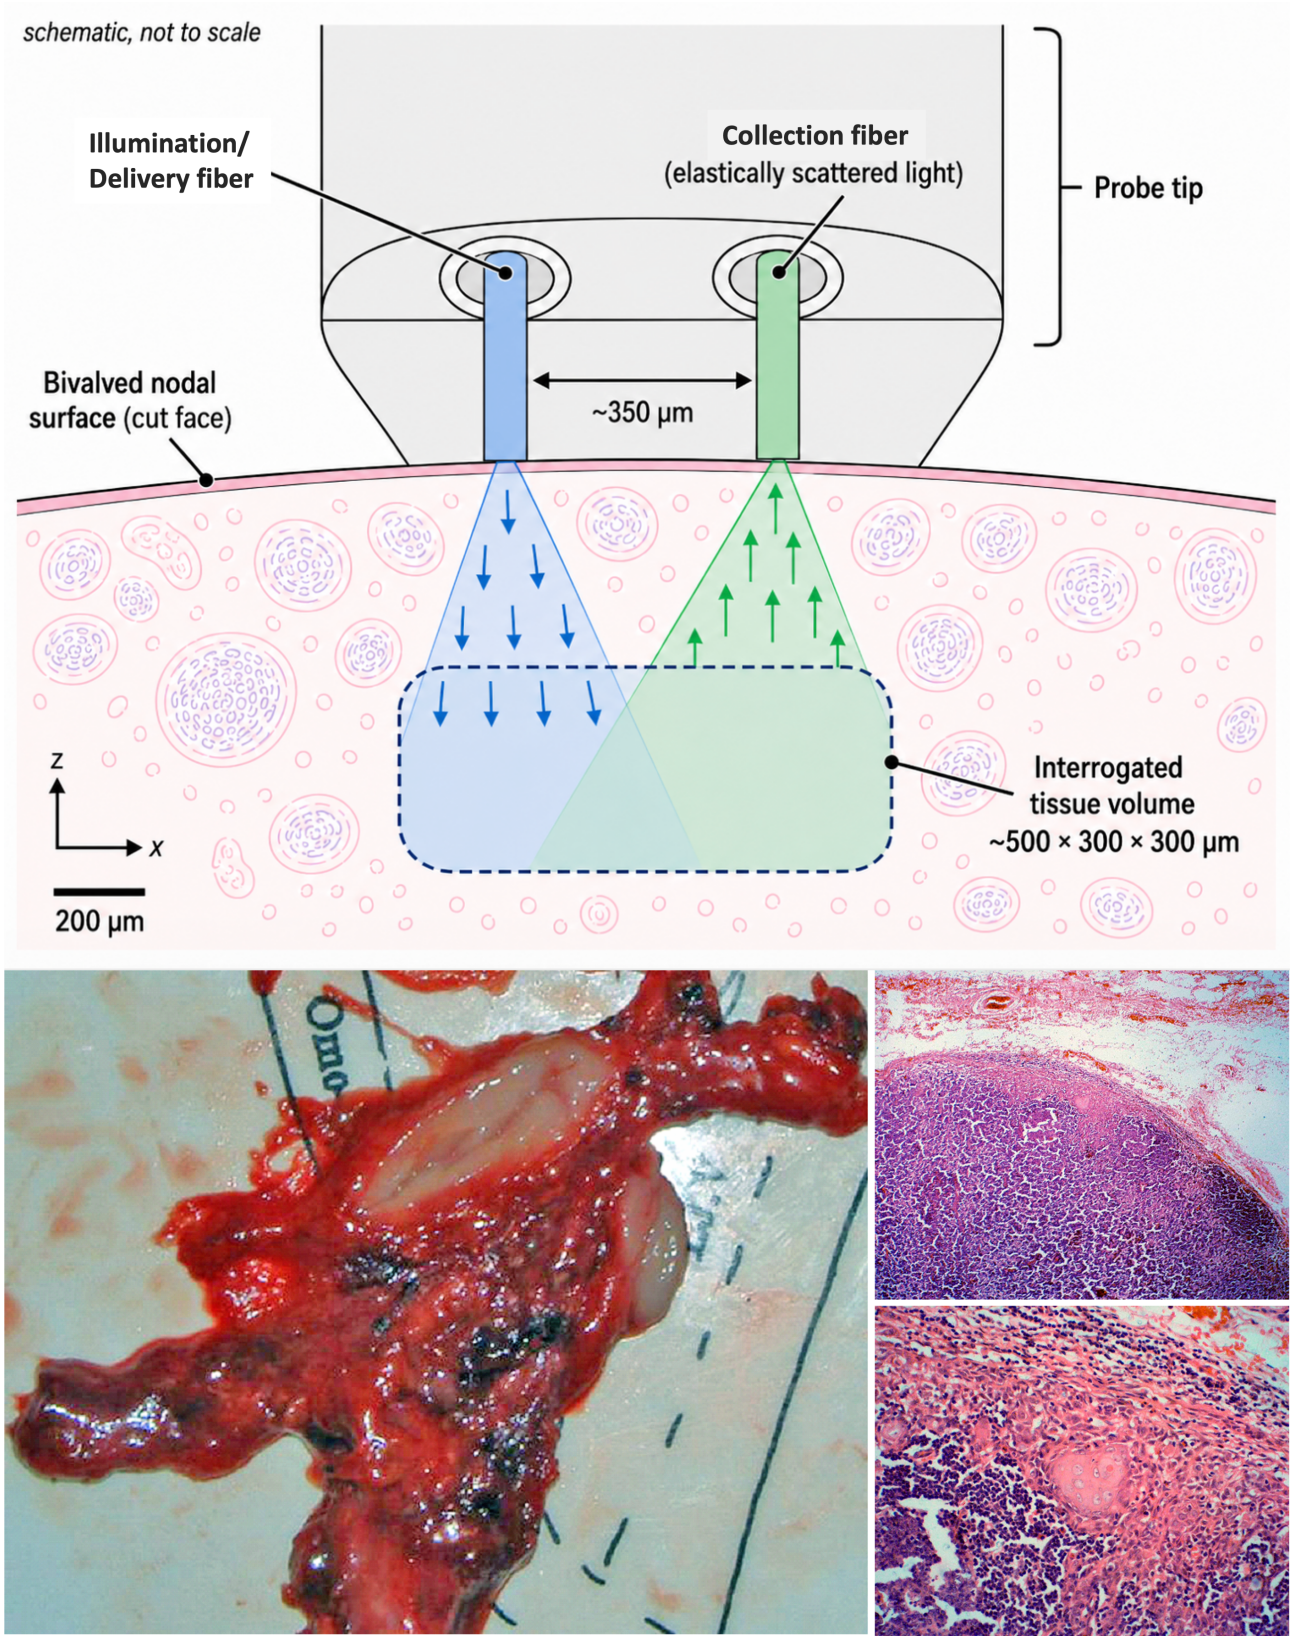
Figure 1. Elastic scattering spectroscopy (ESS) diagnostic system and hardware components. Upper panel: schematic representation of the ESS system used for ex vivo interrogation of bivalved lymph node tissue. Excitation light from a pulsed xenon source is delivered to the tissue through the illumination fiber, shown in blue. The handheld fiber-optic probe is placed in gentle contact with the cut surface of one half of the bivalved lymph node. Elastically scattered light is collected through the adjacent collection fiber and transmitted to the spectrometer, shown in green. Spectral data are then transferred to the computer interface for display and downstream classification. The computer readout is a conceptual illustration of how spectral information and a future model-derived probability could be displayed; it does not represent a prospectively deployed clinical classifier used during specimen acquisition in this study. Lower panel: representative photographs of the ESS hardware, including the optical biopsy box, detector and source ports, calibration port, power supply and interface electronics, illumination and collection fibers, spectrometer, and xenon lamp. Blue arrows indicate the excitation/delivery pathway; green arrows indicate the collected elastically scattered return signal; the gray arrow indicates transfer of spectral information from the spectrometer to the computer display. The system architecture is consistent with the described ESS platform comprising a pulsed xenon arc lamp, fiber-optic probe, spectrometer, and computer-controlled acquisition interface.

The ESS system comprised a pulsed xenon arc lamp light source, a PC-compatible spectrometer based on a modified Ocean Optics platform with linear charge-coupled device array detection, a fiber-optic probe, and a laptop computer for system control and

XSL•FO
RenderX



data display. Light was delivered through a 200 micrometer core illumination fiber and scattered light was collected through a neighboring fiber connected to the spectrometer. The probe had a fixed center-to-center separation of approximately 350 micrometers between the delivery and collection fibers. This geometry interrogated a superficial tissue volume of approximately 500 micrometers in length, 300 micrometers in width, and 300 micrometers in depth. The probe was placed in gentle optical contact with the nodal cut surface to minimize reflected light from the surface and to ensure that collected photons had undergone scattering within the tissue.

Before tissue measurements, the system was calibrated using a reflectance standard to normalize the spectral response and reduce variation related to probe transmission, lamp output, and thermal drift. Each acquisition was computer-controlled and included a background measurement followed immediately by pulsed spectral capture with automatic background subtraction. The wavelength range available from the system was broader than the analytical range, but all spectra were subsequently restricted to a common 350‐850 nm window to ensure consistency across measurements. Optical measurement sites were matched to the corresponding lymph node, and the final nodal histopathological diagnosis was used as the class label.

XSL•FO
RenderX

Figure 2. Elastic scattering spectroscopy (ESS) fiber-optic probe geometry, bivalved lymph node sampling, and histopathological correlation. Upper panel: schematic representation of the elastic scattering spectroscopy fiber-optic probe in gentle contact with the exposed cut surface of a bivalved lymph node. The illumination or delivery fiber transmits excitation light into the superficial nodal tissue, shown by the blue cone and downward blue arrows. The adjacent collection fiber captures elastically scattered photons returning from the interrogated tissue volume, shown by the green collection field and upward green arrows. The delivery and collection fibers are separated by approximately 350 µm at the probe tip. With this probe geometry, the sampled optical field interrogates a superficial tissue volume of approximately 500×300×300 µm. The schematic is not drawn to scale and is intended to illustrate probe-tissue geometry rather than exact photon trajectories. Lower left: gross appearance of a surgically excised lymph node specimen after bivalving, exposing the internal nodal surface used for ex vivo optical interrogation. Lower right: representative hematoxylin and eosin-stained sections used for pathological correlation. The upper histological image shows nodal tissue architecture, while the lower histological image demonstrates metastatic keratinizing squamous cell carcinoma within nodal tissue, with malignant squamous nests, keratinization, and associated stromal or inflammatory response. Histopathology remained the reference standard against which the ESS spectral measurements were compared. The histological panels are representative images from the present study material and were not used as quantitative inputs to the ESS classification models.

XSL•FO
RenderX

Histopathological Reference Standard

After ESS acquisition, each bivalved lymph node was fixed in 10% neutral-buffered formalin for 24 - 48 hours, embedded in paraffin, and represented by 1 block from each half. One 4-µm hematoxylin and eosin section was examined from each block. Two deeper levels at 200-µm intervals and pancytokeratin AE1/AE3 immunohistochemistry were used when the initial sections were equivocal or a small metastatic deposit was suspected. The final diagnosis was assigned at lymph-node level.

For this analysis, metastatic deposits were categorized as macrometastases when greater than 2 mm, micrometastases when greater than 0.2 mm and no greater than 2 mm, and

XSL•FO
RenderX

isolated tumor cells when no greater than 0.2 mm. Nodes containing macrometastases or micrometastases were classified as pathology positive. No isolated-tumor-cell-only nodes were identified in the cohort. Pathological T and N categories were retained as documented in the original pathology reports. All tumors were retrospectively restaged according to the UICC TNM eighth edition using the recorded depth-of-invasion and extranodal-extension data. Extranodal extension was recorded when metastatic tumor extended beyond the lymph-node capsule.

Pathologists were blinded to the ESS spectra, probability estimates, and model outputs. Routine histopathological assessment was undertaken by consultant pathologists experienced in head and neck pathology using the contemporaneous clinical reporting pathway. Where a requested clinicopathological characteristic was absent from the archived gross or histopathological record, it was recorded as unavailable rather than inferred.

The study cohort comprised 45 patients and 280 ESS-assessed lymph nodes. Of these nodes, 96 were pathology positive and 184 were pathology negative. Three spectra were acquired per node, giving 840 spectra before quality control. Nodes were sampled from both upper and lower neck levels, with 168 nodes from levels I-III and 112 from levels IV-V. The median node size was 14 mm, and acquisition was performed across 9 batches.

Spectra were imported as wavelength-intensity arrays and reviewed using sequential quality-control rules before modeling. Spectra were excluded if they contained zero or failed channels, excessive noise at the spectral edges, clipping or saturation, duplicate entries, or incomplete records. These prespecified quality-control rules were applied before model fitting and without access to the histopathological class label. Of 840 raw spectra, 80 were excluded, leaving 760 retained spectra. At node level, 274 of 280 ESS-assessed nodes retained at least 2 usable spectra and 212 retained all 3 spectra. In each of the remaining 6 pathology-negative nodes, none of the 3 acquired spectra passed the requirement for an analyzable node-level ESS result. These 6 nodes were therefore reported as node-level index-test no-results and were not included in the 274-node modeling and performance denominator. The node-level no-result rate was 2.1% (6/280).

Two complementary preprocessing approaches were used. For feature-based analyses intended to preserve optical amplitude, spectra were lightly smoothed and scaled after restriction to the 350 - 850 nm window. For full-spectrum analyses intended to emphasize spectral shape, standard normal variate (SNV) normalization was applied after smoothing. Principal component analysis was used where dimensionality reduction was required, particularly for support vector machine modeling. These preprocessing choices were applied consistently so that amplitude-dominant and shape-dominant analytical strategies could be compared.

A total of 8 candidate optical features were specified before the final comparative modeling analysis on the basis of clinical interpretability and previous ESS work. I360, I450, I630, and I700 were defined as the spectral intensity at the wavelength channel nearest to 360, 450, 630, and 700 nm, respectively. The I630/I360 ratio was calculated from these 2 intensity measurements. Total spectral area was calculated by trapezoidal integration from 350 to 850 nm. Blue trough depth was defined as I450 minus the minimum spectral intensity between 390 and 420 nm. Red shoulder height was defined as the maximum spectral intensity between 650 and 700 nm minus I630. Retained spectra were first summarized by their median within each lymph node so that every node contributed 1 observation per feature. Effect sizes were expressed as rank-biserial correlations. 95% CIs were estimated by resampling patients as clusters while retaining all lymph nodes from each selected patient. Moreover, 2-sided *P* values were obtained by permuting node-level pathology labels within patient while preserving each patient's number of pathology-positive and pathology-negative nodes. Each permutation-based *P* value was estimated using 10,000 patient-preserving permutations.

Model Development

Model development compared a baseline I630 rule, in which I630 was defined as the median intensity at the wavelength channel nearest 630 nm across the retained spectra from each lymph node and nodes were classified using a decision threshold selected exclusively from patient-grouped inner-validation training data by maximizing the Youden index, feature-based logistic regression, full-spectrum elastic-net logistic regression, a linear support vector machine, and a hybrid elastic-net model. The amplitude branch comprised the 8 prespecified optical features extracted from Savitzky-Golay–smoothed raw-amplitude spectra, with robust scaling fitted within the inner training folds. The shape branch comprised principal-component scores derived from standard-normal-variate-normalized spectra, with principal component analysis fitted within the inner training folds. Candidate component counts of 10, 20, 30, and 40 were evaluated, with 20 components selected most frequently across the outer fits. The hybrid elastic-net model combined the selected principal-component scores with the 8 scaled optical features. Regularization strength, l1 ratio, and class weighting were selected within the inner folds; C=0.3 and an l1 ratio of 0.5 were the most frequently selected values. Model-family comparisons were exploratory. Each candidate model was tuned independently within the patient-grouped inner validation process, and the hybrid model was carried forward for detailed calibration, error, and robustness analyses because it had the highest pooled patient-grouped out-of-fold area under the receiver operating characteristic curve (AUROC) point estimate. No formal pairwise test of superiority between model families was prespecified.

Internal Validation and Leakage Control

Primary internal validation used 10 repetitions of nested 5-fold cross-validation implemented using stratified group k-fold splitting, with patient ID as the grouping variable. Within each repetition, pathology class was stratified as closely as possible across folds while all spectra and lymph nodes from an individual patient remained within a single fold. Fold assignment was shuffled before each repetition using random seeds 202601 to 202610, generating 50 outer training-test splits in total. Every

XSL•FO
RenderX

spectrum and lymph node from a given patient remained in the same outer fold, so lymph nodes from the same patient could not occur simultaneously in the corresponding outer training and test sets. Within each outer training set, model development and hyperparameter tuning used 4-fold stratified group cross-validation, again grouped by patient and with shuffling enabled. The repetition-specific random seed was retained for the corresponding inner-validation procedure, and no patient represented in an outer test fold was available to any stage of inner model development. Smoothing, scaling, SNV transformation, principal component analysis, component selection, regularization parameters, class weighting, probability calibration where required, and decision threshold selection were fitted or selected using training data only. Outer test patients were used only once the corresponding analytical pipeline had been fixed, solely to generate held-out predictions.

Model Selection and Decision Threshold

Within each candidate model family, mean inner-fold AUROC was used to select hyperparameters and model configuration. Within each outer training set, the node-level decision threshold was selected from patient-grouped inner-fold out-of-fold predictions using the Youden index. Thus, threshold optimization itself was restricted to training data and did not use the corresponding outer test outcomes. Each node received 1 held-out probability in each of the 10 outer repetitions, and these probabilities were averaged to obtain a single patient-grouped out-of-fold probability for each node. The 50 training-derived thresholds had a median of 0.38 (IQR 0.35‐0.41). For the pooled descriptive confusion matrix and associated threshold-dependent operating characteristics, this median training-derived threshold was applied once to the averaged held-out node probabilities. No pooled outcome or outer-test outcome was used to select or adjust the threshold. Because this single summary threshold was applied after repeated internal cross-validation rather than prospectively fixed before validation, sensitivity, specificity, accuracy, positive predictive value (PPV), and NPV were interpreted as secondary descriptive operating characteristics. AUROC and calibration calculated from the pooled patient-grouped out-of-fold probabilities were the principal performance measures in this exploratory internal-validation analysis. Because these predictions also informed the choice of the hybrid model family, its reported performance estimates may be affected by selection optimism and do not constitute independent validation of a prospectively fixed final model.

Calibration and Statistical Uncertainty

Calibration was assessed using each node's averaged patient-grouped out-of-fold probability and was summarized using the Brier score, calibration-in-the-large, calibration slope, and a grouped calibration plot. For the plot, the observed proportion of pathology-positive nodes was compared with the mean predicted probability within each probability group; groups were not constrained to contain equal numbers of nodes. 95% CIs for node-level sensitivity, specificity, accuracy, PPV, NPV, AUROC, and calibration measures were estimated using 2000 patient-clustered bootstrap resamples, with all lymph nodes belonging to each resampled patient retained together. The reported bootstrap intervals were calculated from the completed patient-grouped out-of-fold prediction dataset without refitting the complete model-development procedure within each bootstrap replicate; they therefore quantify uncertainty in the held-out predictions conditional on the completed modeling process. Patient-level CIs for sensitivity, specificity, accuracy, PPV, and NPV were calculated using the Wilson method. The patient-level AUROC CI was estimated by bootstrap resampling of patients.

Node-Level and Patient-Level Classification

Because the primary diagnostic unit was the lymph node, spectrum-level probabilities were averaged to generate 1 probability for each node. Mean probability across retained spectra was the primary node-level aggregation method. Majority vote, median probability, maximum probability, and classification using a single representative spectrum were evaluated as secondary aggregation strategies. For the single-spectrum analysis, the first quality-control-passing acquisition from each lymph node according to the recorded acquisition order was selected, without reference to histopathological status or model output.

A secondary patient-level analysis was undertaken using the cross-validation–derived summary node-level threshold. A patient was reference-standard positive when at least 1 ESS-assessed lymph node was metastatic on histopathology and model positive when at least 1 assessed node exceeded the summary threshold. The maximum averaged out-of-fold node probability within each patient was used for patient-level receiver operating characteristic curve analysis. The patient-level analysis therefore represented only the ESS-assessed node set and was not interpreted as complete pathological staging of the neck.

Performance was summarized using sensitivity, specificity, accuracy, PPV, NPV, and AUROC. Robustness analyses included leave-one-patient-out validation, leave-one-batch-out validation, exclusion of the lowest-quality 10% of retained spectra ranked by signal-to-noise ratio, use of the first 2 quality-control–passing spectra from each node according to recorded acquisition order, restriction to nodes retaining all 3 spectra, area-normalized spectra, and shape-focused preprocessing.

Analysis Plan and Reproducibility

The 3-acquisition sampling protocol and 8 candidate optical features were specified before the final modeling analysis. The comparison of machine learning algorithms, model-family selection, and associated hyperparameter grids was exploratory and was not prospectively registered. Accordingly, comparisons between candidate model families were interpreted descriptively, and no claim of formal superiority was made. Analyses were conducted using Python (version 3.12.8; Python Software Foundation), *NumPy* 2.2.1, *pandas* 2.2.3, *SciPy* 1.15.0, and *scikit-learn* 1.6.0. Random seeds 202601 to 202610 were used for the 10 outer repetitions. No formal sample-size calculation was undertaken; the analysis used the complete available cohort meeting the eligibility requirements and having linked ESS and histopathological data.

Reporting followed TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis)+AI, STARD (Standards for Reporting of Diagnostic Accuracy Studies)-AI, and STARD 2015 [17,18,21]. Completed reporting checklists are provided in Checklists 1-3 Table S1 and Figure S1 in Multimedia Appendix 1 provide the analytical workflow, software versions, preprocessing sequence, candidate component counts, hyperparameter grid, threshold-selection method, and leakage-control procedures.

Results

Overview

In total, 52 patients were assessed for eligibility. Of the total, 7 were excluded before enrollment; 3 because consent was not obtained, 2 because no suitable fresh lymph nodes were available before fixation, and 2 because the ESS system was unavailable at the time of surgery. The final cohort comprised 45 patients, with a median age of 61 (IQR 53 - 69) years; 29 were male and 16 were female. Moreover, 25 patients had at least 1 pathology-positive ESS-assessed node, and 20 had no positive assessed nodes. Primary tumor site, pathological T category, clinical and pathological N category, depth of invasion, histological grade, extranodal extension, and positive-node burden are summarized in Table 1.

XSL•FO

[a]ESS: elastic scattering spectroscopy.

The patients contributed 280 ESS-assessed cervical lymph nodes, of which 96 were pathology positive and 184 were pathology negative. The median node size was 14 (IQR 9 - 21) mm. Levels I-III accounted for 168 nodes and levels IV-V for 112 nodes. The median number of ESS-assessed nodes per patient was 6 (IQR 4 - 8). The study timeline, participant flow, nodal sampling, and acquisition characteristics are summarized in Table 2.

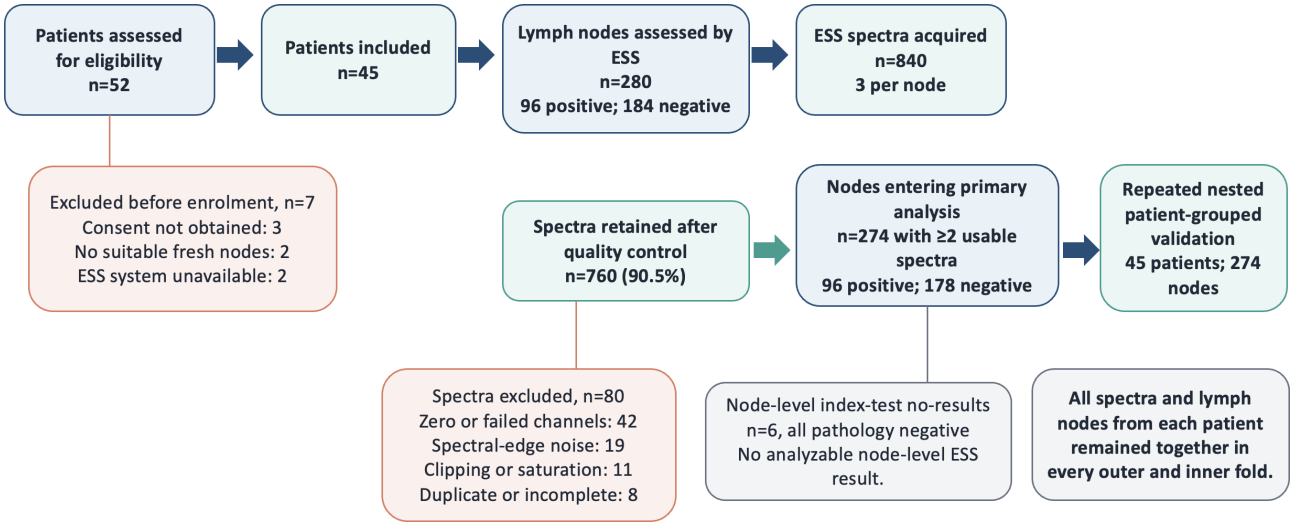
[a]REC:

[b]ESS: elastic scattering spectroscopy.



Acquisition and Quality Control

A total of 3 spectra were acquired from each ESS-assessed lymph node, giving 840 acquisitions. Quality control excluded 80 spectra—42 because of zero or failed channels, 19 because of excessive spectral-edge noise, 11 because of clipping or saturation, and 8 because of duplicate or incomplete records. The final spectrum set comprised 760 retained spectra, equivalent to 90.5% of acquisitions.

At node level, 274 lymph nodes retained at least 2 usable spectra and entered the analytical cohort. These comprised 96 pathology-positive and 178 pathology-negative nodes. In each of 6 additional pathology-negative nodes, none of the 3 acquired spectra met the requirement for an analyzable node-level ESS result. These 6 nodes were reported as node-level index-test no-results and were not included in the 274-node modeling or performance denominator. Moreover, 212 nodes retained all 3 spectra. Participant, specimen, acquisition, and analysis flow is illustrated in Figure 3, and quality-control outcomes are reported in Table 3.

XSL•FO
RenderX

Figure 3. Participant, specimen, acquisition, and analysis flow. Of 52 patients assessed for eligibility, 7 were excluded before enrollment: 3 because consent was not obtained, 2 because no suitable fresh lymph nodes were available before fixation, and 2 because the elastic scattering spectroscopy (ESS) system was unavailable at the time of surgery. In total, 45 patients were included and contributed 280 ESS-assessed lymph nodes, of which 96 were pathology positive and 184 were pathology negative. Moreover, 3 spectra were acquired from each node, giving 840 acquisitions. Quality control excluded 80 spectra, leaving 760 retained spectra. At node level, 274 nodes retained at least 2 usable spectra and comprised the analytical cohort; these included 96 pathology-positive and 178 pathology-negative nodes. Furthermore, 6 pathology-negative nodes produced no analyzable node-level ESS result and were reported as index-test no-results. All spectra and lymph nodes from each patient remained together during patient-grouped internal validation.

The 6 node-level index-test no-results were pathology negative and did not contribute to the 274-node modeling or performance denominator. Percentages for spectrum-level quality-control exclusions use 840 acquired spectra as the denominator; node percentages use 280 ESS-assessed nodes unless otherwise stated. Percentages shown for pathology-positive and pathology-negative analyzable nodes use 274 nodes as the denominator.

Table . Spectral quality control and node-level index-test no-results. The 6 node-level index-test no-results were pathology negative and did not contribute to the 274-node modeling or performance denominator. Percentages for spectrum-level quality-control exclusions use 840 acquired spectra as the denominator; node percentages use 280 elastic scattering spectroscopy–assessed nodes unless otherwise stated. Percentages shown for pathology-positive and pathology-negative analyzable nodes use 274 nodes as the denominator.

Quality-control step	Values, n (%)
Raw spectra acquired	840 (100)
Spectra with zero or failed channels	42 (5)
Spectra excluded for excessive spectral-edge noise	19 (2.3)
Spectra excluded for clipping or saturation	11 (1.3)
Spectra excluded as duplicate or incomplete records	8 (1)
Total excluded spectra	80 (9.5)
Spectra retained	760 (90.5)
Nodes retaining ≥2 usable spectra	274 (97.9)
Pathology positive	96 (35 of analyzed nodes)
Pathology negative	178 (65 of analyzed nodes)
Nodes retaining all 3 spectra	212 (75.7)
Node-level index-test no-results	6 (2.1)

Spectral Feature Differences

Pathology-positive lymph nodes showed higher intensities at 360, 450, and 630 nm and greater total spectral area. In contrast, pathology-negative nodes showed higher intensity at 700 nm, a higher I630/I360 ratio, a deeper local blue trough, and a larger red shoulder. The differences were therefore bidirectional rather than representing a uniform increase in spectral amplitude and supported the inclusion of both amplitude-related and shape-related information. The node-level median ESS profiles are illustrated in Figure 4, and numerical medians and IQRs for the prespecified node-level spectral features are reported in Table 4.

XSL•FO
RenderX

Figure 4. Median and representative elastic scattering spectroscopy profiles of pathology-negative and pathology-positive lymph nodes. The left panel shows node-level median elastic scattering spectroscopy (ESS) profiles across the 350-850 nm analytical range. Numerical medians and IQRs for the prespecified node-level spectral features are reported in Table 4. The pathology-positive profile showed higher short-wavelength intensity and a smoother, more gradually declining pattern, whereas the pathology-negative profile showed a deeper local blue trough and a later rise in the red and near-red region. The upper-right and lower-right panels show representative raw spectra generated by the ESS acquisition software for pathology-negative and pathology-positive nodes, respectively, illustrating within-class acquisition variability. The raw-spectrum panels retain the native acquisition-software wavelength and intensity scales and should not be used for direct between-class amplitude comparison. AU: arbitrary unit.

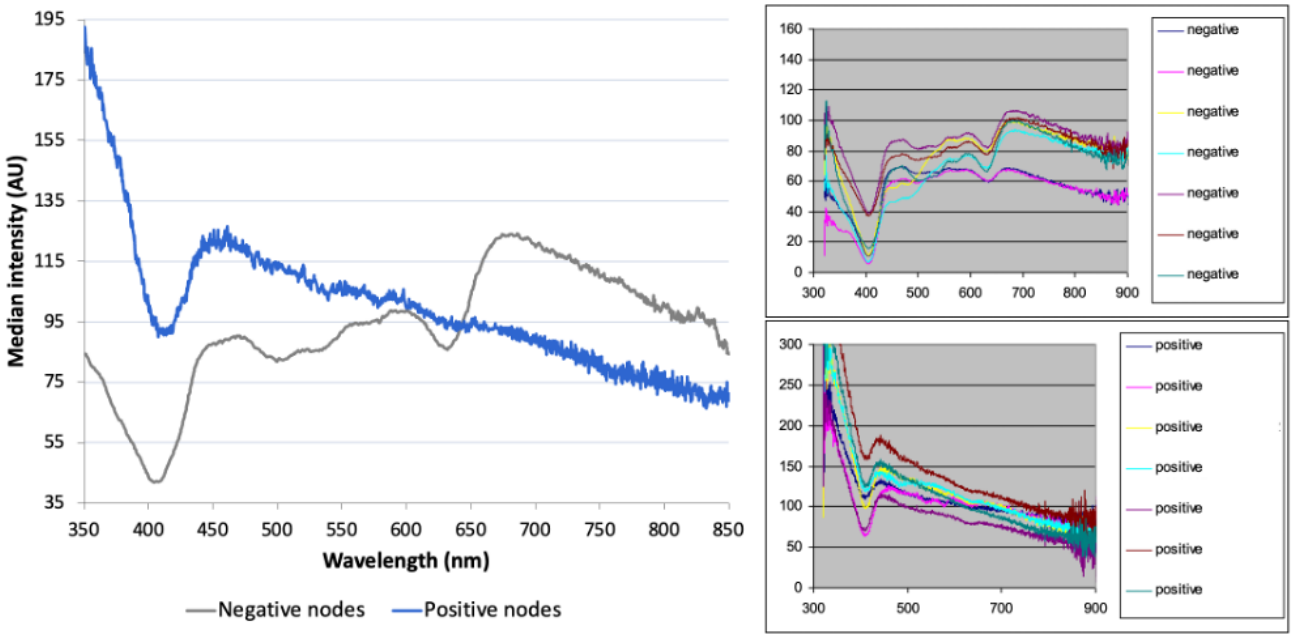


Table . Node-level spectral feature differences by pathological status. Spectra were first aggregated within each lymph node. Positive rank-biserial correlations indicate higher values in pathology-positive nodes, whereas negative correlations indicate higher values in pathology-negative nodes. CIs were estimated by resampling patients while retaining all lymph nodes from each selected patient. Blue trough depth was calculated as I450 minus the minimum intensity from 390 to 420 nm. Red shoulder height was calculated as the maximum intensity from 650 to 700 nm minus I630. The reported *P* values are exploratory, unadjusted for multiplicity, and should be interpreted together with the corresponding effect estimates and CIs rather than as confirmatory hypothesis tests.

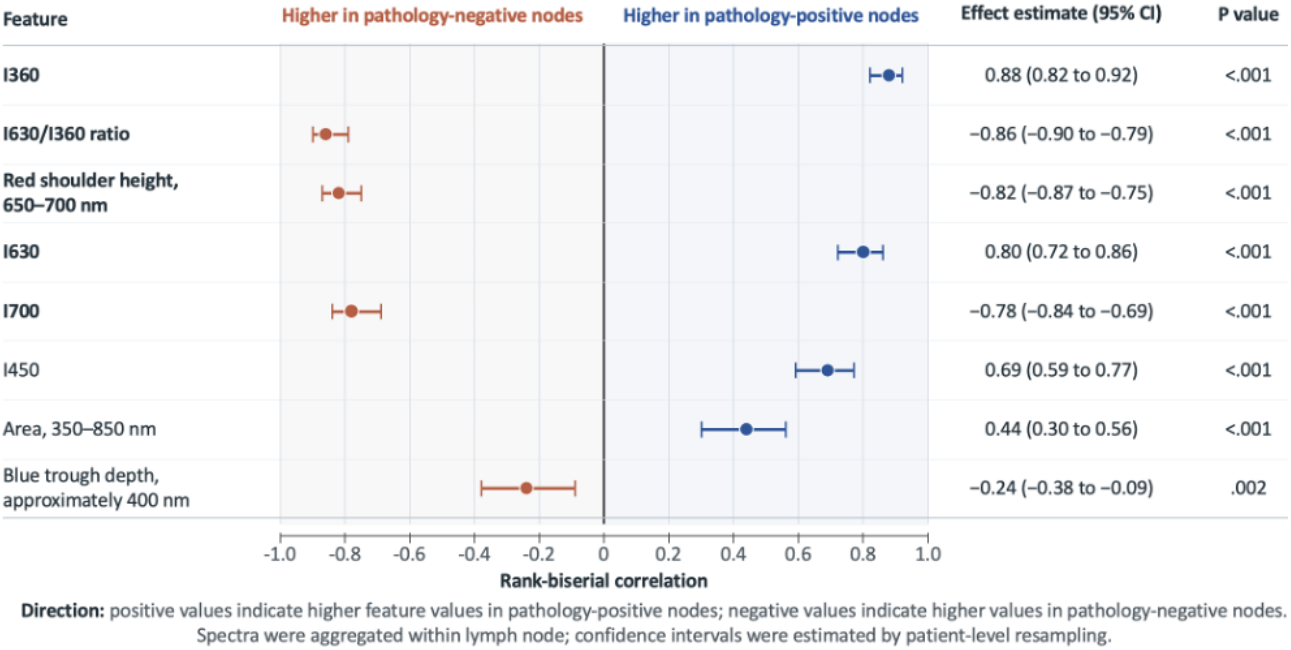

Feature	Pathology-negative nodes, median (IQR)	Pathology-positive nodes, median (IQR)	Rank-biserial correlation (95% CI)	*P* value
I360, AU[a]	80 (69 - 92)	168 (149 - 186)	0.88 (0.82 to 0.92)	<.001
I450, AU	85 (76 - 95)	121 (109 - 134)	0.69 (0.59 to 0.77)	<.001
I630, AU	88 (84 - 92)	96 (93 - 103)	0.80 (0.72 to 0.86)	<.001
I700, AU	120 (107 - 132)	88 (81 - 96)	–0.78 (–0.84 to –0.69)	<.001
I630/I360 ratio	1.10 (0.99 - 1.22)	0.58 (0.53 - 0.66)	–0.86 (–0.90 to –0.79)	<.001
Area, 350 - 850 nm, AU·nm	45,800 (41,600-50,700)	50,600 (46,900-55,400)	0.44 (0.30 to 0.56)	<.001
Blue trough depth, approximately 400 nm, AU	43.1 (35.8 - 50.5)	31.4 (25.6 - 38.2)	–0.24 (–0.38 to –0.09)	.002
Red shoulder height, 650 - 700 nm, AU	31.6 (24.8 - 38.9)	6.7 (3.9 - 10.2)	–0.82 (–0.87 to –0.75)	<.001

[a]AU: arbitrary unit.

Pathology-positive nodes had higher I360, I450, and I630 intensities and greater total spectral area, whereas pathology-negative nodes had higher I700 intensity, a higher I630/I360 ratio, a deeper blue trough, and a larger red shoulder. The largest effects were observed for I360, with a rank-biserial correlation of 0.88 (95% CI 0.82 - 0.92); the I630/I360 ratio, with a correlation of –0.86 (95% CI –0.90 to –0.79); red shoulder height, with a correlation of –0.82 (95% CI –0.87 to –0.75); I630, with a correlation of 0.80 (95% CI 0.72 - 0.86); and I700, with a correlation of –0.78 (95% CI –0.84 to –0.69). Moreover, 7 features had *P*<.001, while blue trough depth remained significant at *P*=.002. Full medians, IQRs, effect sizes, CIs, and *P* values are reported in Table 4 and Figure 5.

XSL•FO
RenderX

Figure 5. Effect sizes for prespecified node-level spectral features. Points show rank-biserial correlations, and horizontal lines show patient-clustered 95% CIs. Positive correlations indicate higher feature values in pathology-positive nodes, whereas negative correlations indicate higher values in pathology-negative nodes. Features are ordered by the absolute magnitude of the effect estimate. Spectra were first aggregated within each lymph node, and CIs were estimated by resampling patients while retaining all lymph nodes from each selected patient. The corresponding *P* values were derived from patient-preserving permutation analyses and are exploratory and unadjusted for multiplicity.

Patient-Grouped Internal Validation

Repeated nested patient-grouped cross-validation yielded an internally validated, exploratory AUROC estimate of 0.966 (95% CI 0.929 - 0.988) for the selected hybrid model. Because the hybrid model family was selected using the same pooled out-of-fold predictions, this result is not an independent validation estimate for a prospectively fixed final model. At the cross-validation–derived summary threshold, the pooled descriptive confusion matrix comprised 90 true-positive, 6 false-negative, 170 true-negative, and 8 false-positive lymph nodes. The corresponding secondary descriptive operating characteristics were as follows: sensitivity 93.8% (95% CI 86.4% - 97.6%), specificity 95.5% (95% CI 90.1% - 98.3%), accuracy 94.9% (95% CI 90.4% - 97.3%), PPV 91.8% (95% CI 82.9% - 96.3%), and NPV 96.6% (95% CI 92.4% - 98.8%). The 50 training-derived decision thresholds had a median of 0.38 (IQR 0.35 - 0.41); no pooled outcome or outer-test outcome was used to select or modify this threshold. The Brier score was 0.063, calibration-in-the-large was –0.03, and the calibration slope was 0.94. The calibration plot showed close agreement between observed and predicted probabilities across most of the probability range, with modest overprediction at the highest probabilities. Classification and calibration results are presented in Table 5 and Figure 6.

XSL•FO
RenderX

Table . Selected hybrid model discrimination, descriptive operating characteristics, calibration, aggregation, and robustness. Threshold-dependent measures are presented as secondary descriptive operating characteristics. For the primary patient-grouped node-level analysis, the cross-validation–derived summary threshold was applied to each node's averaged held-out probability to obtain the pooled confusion matrix. For the patient-grouped spectrum-level analysis and the analysis restricted to nodes retaining all 3 spectra, sensitivity, specificity, and accuracy were calculated separately within each of the 10 outer repetitions and then averaged; these secondary percentages therefore represent means of repetition-specific metrics rather than proportions derived from a single pooled confusion matrix. AUROC[a] estimates were derived from held-out probabilities within the reported internal-validation analyses. The primary patient-grouped AUROC of 0.966 is an internally validated, exploratory estimate for a model family selected using the same pooled out-of-fold predictions and does not represent independent validation of a prospectively fixed final model. Patient-level PPV[b] was 92.3% (95% CI 75.9%-97.9%) and NPV[c] was 94.7% (95% CI 75.4%-99.1%). Patient-level CIs for sensitivity, specificity, accuracy, PPV, and NPV were calculated using the Wilson method; the patient-level AUROC CI was estimated by bootstrap resampling of patients.

Domain or analysis	Analytical set	Sensitivity,%	Specificity,%	Accuracy,%	AUROC	Additional result

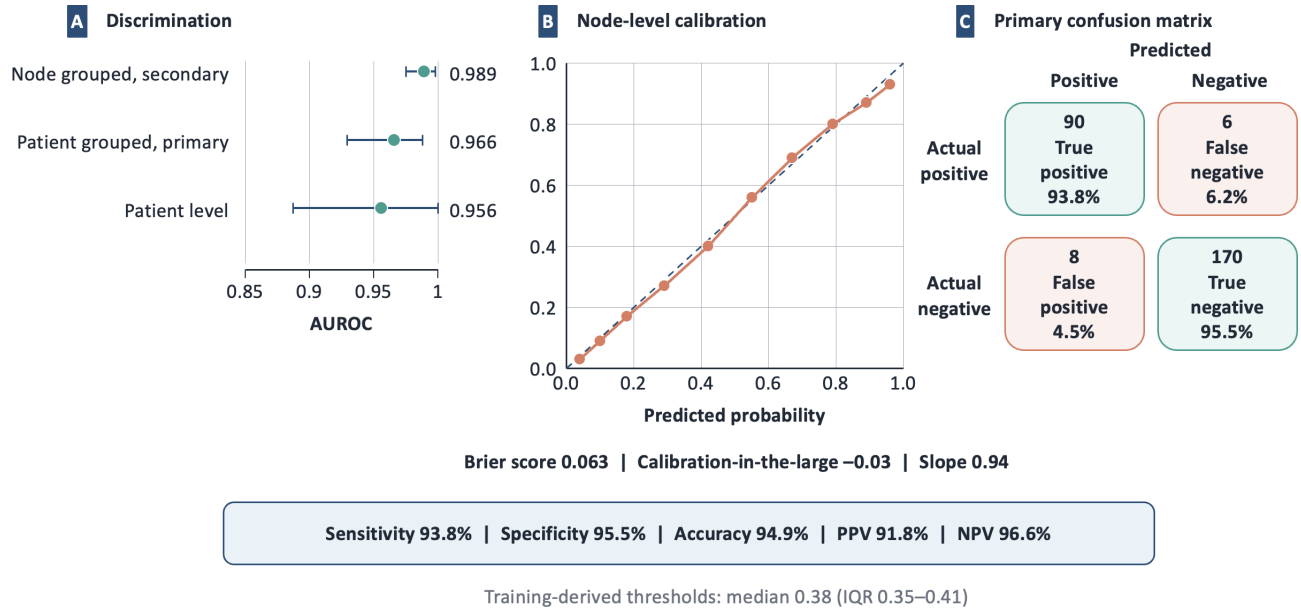
[e]FN: false negative.

[f]TN: true negative.

[g]FP: false positive.



[h]Not applicable.

[i]SNV: standard normal variate.

Among the candidate model families, the hybrid model had the highest pooled patient-grouped out-of-fold AUROC point estimate. Comparative performance is reported in Table 6 and Figure 7. Because model-family comparisons were exploratory and no formal pairwise superiority test was prespecified, these differences should not be interpreted as establishing superiority of one model family over another.

In the secondary node-grouped analysis, the hybrid model produced 93 true-positive, 3 false-negative, 172 true-negative, and 6 false-positive nodes. These counts corresponded to sensitivity of 96.9%, specificity of 96.6%, accuracy of 96.7%, PPV of 93.9%, NPV of 98.3%, and an AUROC of 0.989. The higher point estimates obtained when grouping was restricted to lymph nodes illustrate the potential for optimistic performance estimates when patient-level clustering is not preserved.

Figure 6. Exploratory discrimination, calibration, and descriptive classification performance of the selected hybrid model under internal validation. Panel A shows area under the receiver operating characteristic curve (AUROC) estimates for the primary patient-grouped node-level analysis, the secondary node-grouped analysis, and the patient-level analysis. The primary patient-grouped AUROC of 0.966 is an internally validated, exploratory estimate for the selected model and does not represent independent validation of a prospectively fixed final model. Points show AUROC estimates, and horizontal bars show the corresponding 95% CIs for the primary patient-grouped node-level analysis, the secondary node-grouped analysis, and the patient-level analysis. Panel B compares observed pathology-positive proportions with mean predicted probabilities calculated from averaged patient-grouped out-of-fold node predictions. Each point represents a probability group, and the groups were not constrained to contain equal numbers of nodes. The diagonal line represents perfect calibration. The Brier score was 0.063, calibration-in-the-large was –0.03, and the calibration slope was 0.94. Panel C shows the descriptive confusion matrix obtained by applying the cross-validation-derived summary threshold to averaged patient-grouped held-out probabilities: 90 true-positive, 6 false-negative, 170 true-negative, and 8 false-positive nodes. The 50 training-derived thresholds had a median of 0.38 (IQR 0.35-0.41). No pooled outcome or outer-test outcome was used to select or adjust the summary threshold. NPV: negative predictive value; PPV: positive predictive value.

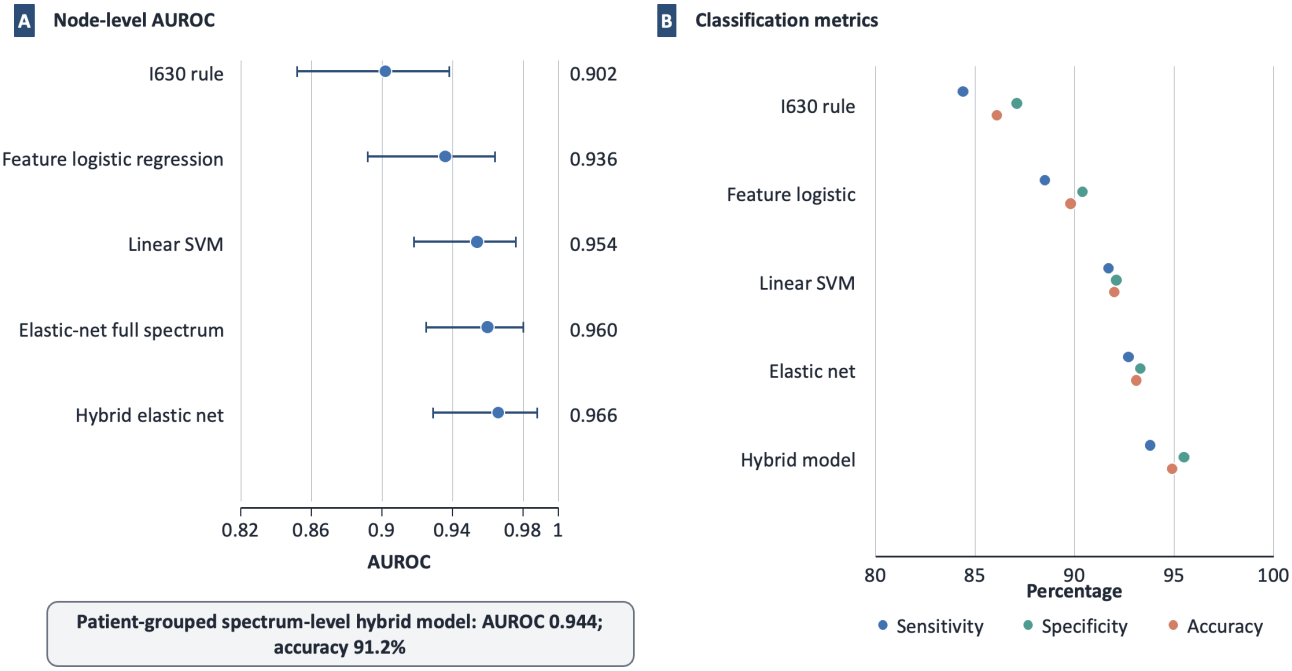
RenderX

Table . Patient-grouped internal validation of candidate node-level models. AUROC[a] estimates were derived from pooled patient-grouped out-of-fold predictions and represent exploratory internal-validation performance. The hybrid model family was selected on the basis of these same predictions, its AUROC of 0.966 should therefore not be interpreted as independent validation of a prospectively fixed final model. For each candidate model family, sensitivity, specificity, accuracy, PPV[b], and NPV[c] were calculated using that model family's own summary threshold derived from patient-grouped inner-validation predictions and are presented as secondary descriptive operating characteristics. 95% CIs were estimated using 2000 patient-clustered bootstrap resamples. Model-family comparisons were exploratory and no formal pairwise superiority testing was prespecified.



Model	Sensitivity,% (95% CI)	Specificity,% (95% CI)	Accuracy,% (95% CI)	PPV,% (95% CI)	NPV,% (95% CI)	AUROC (95% CI)
I630 rule	84.4 (75.0 - 91.0)	87.1 (79.8 - 92.4)	86.1 (80.4 - 90.2)	77.9 (65.8 - 86.4)	91.2 (84.9 - 95.0)	0.902 (0.852 - 0.938)
Feature logistic regression	88.5 (79.5 - 94.6)	90.4 (83.2 - 94.8)	89.8 (84.5 - 93.6)	83.3 (73.0 - 90.2)	93.6 (88.0 - 97.0)	0.936 (0.892 - 0.964)
Elastic-net full-spectrum model	92.7 (84.4 - 97.1)	93.3 (87.0 - 97.2)	93.1 (88.3 - 96.4)	88.1 (78.5 - 94.8)	96.0 (91.2 - 98.8)	0.960 (0.925 - 0.980)

[a]AUROC: area under the receiver operating characteristic curve.

[b]PPV: positive predictive value.

[c]NPV: negative predictive value.

Figure 7. Exploratory comparison of candidate elastic scattering spectroscopy (ESS) models under patient-grouped internal validation. Panel A shows node-level area under the receiver operating characteristic curve (AUROC) and 95% CIs for the I630 rule, feature logistic regression, linear support vector machine, elastic-net full-spectrum model, and hybrid elastic-net model. Panel B shows the corresponding descriptive sensitivity, specificity, and accuracy estimates at each model family's own cross-validation-derived summary threshold. The hybrid elastic-net model family was selected because it had the highest pooled patient-grouped out-of-fold AUROC point estimate among the candidates. Its AUROC of 0.966 is an internally validated, exploratory estimate based on the same predictions used for model-family selection, rather than independent validation of a prospectively fixed final model. No formal pairwise superiority test was prespecified. The patient-grouped spectrum-level hybrid analysis had an AUROC of 0.944 and a mean accuracy of 91.2% across the 10 outer repetitions. SVM: support vector machine.

Patient-Level Performance

At patient level, 25 patients were reference-standard positive and 20 were negative within the ESS-assessed node set. Using the cross-validation–derived summary node-level threshold, 24 of 25 positive patients and 18 of 20 negative patients were classified correctly, giving 1 false-negative and 2 false-positive patient classifications. Patient-level sensitivity was 96% (95% CI 80.5% - 99.3%), specificity was 90% (95% CI 69.9% - 97.2%), accuracy was 93.3% (95% CI 82.1% - 97.7%), PPV was 92.3% (95% CI 75.9% - 97.9%), and NPV was 94.7% (95% CI 75.4% - 99.1%). The patient-level AUROC, based on the maximum node probability within each patient, was 0.956 (95% CI 0.887 - 1.000).

XSL•FO
RenderX

Patient-grouped spectrum-level analysis produced the same model ranking but lower performance than node-level analysis. The spectrum-level hybrid model had an AUROC of 0.944; mean sensitivity, specificity, and accuracy across the 10 outer repetitions were 89.6%, 92%, and 91.2%, respectively. This reduction supported the use of repeated acquisition and node-level aggregation rather than classification of individual spectra as independent diagnostic observations. Spectrum-level results are reported in Table 5 and Figure 7.

Aggregation and Robustness Analyses

Mean probability across retained spectra was the prespecified primary node-level aggregation method and provided a favorable balance of sensitivity and specificity in this analysis. Under patient-grouped validation, a single representative spectrum achieved accuracy of 89.4% and an AUROC of 0.930, while majority vote achieved accuracy of 92.7% and an AUROC of 0.953. Median probability performed similarly to mean probability. Maximum probability increased sensitivity to 97.9% but reduced specificity to 87.6%, resulting in more false-positive classifications.

The primary result remained stable in leave-one-patient-out validation, which produced an AUROC of 0.961, and leave-one-batch-out validation, which produced an AUROC of 0.952. Excluding the lowest-quality 10% of spectra produced an AUROC of 0.969. Restriction to 2 spectra per node reduced the AUROC to 0.951, whereas restriction to nodes retaining all 3 spectra gave an AUROC of 0.964. Area-normalized and shape-focused analyses produced lower AUROCs of 0.895 and 0.912, respectively, indicating that amplitude information contributed materially to discrimination. Full results are reported in Table 5.

Error Analysis

Using the cross-validation–derived summary threshold, the primary patient-grouped analysis classified 260 of 274 analyzable lymph nodes correctly, including 90 true-positive and 170 true-negative nodes. Moreover, 14 analyzable nodes were misclassified; 6 were false negative and 8 were false positive. The additional 6 pathology-negative ESS-assessed nodes that produced no analyzable node-level ESS result were reported separately as index-test no-results and were not included among the 14 model misclassifications.

Of the 6 false-negative nodes, 4 contained micrometastases measuring 0.3 - 1.6 mm, while 2 contained small peripheral macrometastases measuring 2.3 mm and 2.8 mm. The median false-negative node size was 8.5 mm, and none showed extranodal extension. The 8 false-positive nodes were clustered within 2 pathology-negative patients and showed marked reactive or inflammatory changes, including follicular hyperplasia, sinus histiocytosis, vascular congestion, surface hemorrhage, or suppurative inflammation. Summary findings are reported in Table 7, and detailed case-level findings are reported in Table S2 in Multimedia Appendix 1.

Table . Error analysis of the selected patient-grouped hybrid model. Misclassification status was determined using the cross-validation–derived summary node-level threshold of 0.38. The 6 pathology-negative node-level index-test no-results were reported separately and are not included in this table. Detailed case-level findings are reported in Table S2 in Multimedia Appendix 1.

Error category	n	Node size (mm), median (range)	Deposit size (mm), median (range)	Metastatic class	Neck level	Histopathological context	Out-of-fold probability, median (range)
False negative	6	8.5 (5-13)	1.2 (0.3 - 2.8)	4 micrometastases; 2 small peripheral macrometastases	4 at levels I-II; 2 at levels III-IV	Reactive change in 2; focal necrosis in 1; keratinization in 1; extranodal extension in 0	0.113 (0.028 - 0.239)
False positive	8	16.5 (9-22)	—[a]	All pathology negative	5 at levels I-II; 3 at levels III-IV	All arose in 2 patients with marked reactive or inflammatory change; focal necrosis in 1; keratinization in 0	0.915 (0.420 - 0.995)

[a]Not applicable.

Technical Repeatability and Variability

Within-node agreement across the 3 spatially separated acquisitions was highest for I630 intensity, with an intraclass correlation coefficient (ICC) of 0.91 (95% CI 0.88 - 0.93) and a median coefficient of variation of 7.4%. The corresponding ICCs were 0.89 for total spectral area, 0.84 for red shoulder height, 0.78 for blue trough depth, and 0.87 for spectrum-level hybrid probability. Intraclass correlation coefficients were calculated using a 1-way random-effects, absolute-agreement, single-measure model (ICC 1,1), with 95% CIs estimated from the corresponding F distribution.

Patient-grouped AUROC was 0.968 for acquisitions undertaken by operator A and 0.961 for acquisitions undertaken by operator B. The difference was 0.007 (95% CI –0.031 to 0.044). Acquisitions completed within 30 minutes of excision produced an AUROC of 0.967, compared with 0.958 for acquisitions completed after 30 minutes. Leave-one-batch-out validation produced an AUROC of 0.952. Because each lymph node was acquired by a single operator, the operator analysis compared

XSL•FO
RenderX

independent operator-specific case series rather than paired measurements of the same nodes and therefore did not estimate interoperator reproducibility directly. Operator, batch, and timing analyses were interpreted as sensitivity analyses because differences in patient and nodal case mix could not be fully separated from technical effects. Results are reported in Table S3 and Figure S2 in Multimedia Appendix 1.

Discussion

Principal Findings

This single-center model-development and internal-validation study found that ESS could discriminate metastatic from nonmetastatic cervical lymph nodes ex vivo. The selected hybrid model had an internally validated, exploratory AUROC estimate of 0.966 under patient-grouped cross-validation. This estimate may be affected by selection optimism because the same pooled out-of-fold predictions informed both model-family selection and performance reporting, and it should not be interpreted as independent validation of a prospectively fixed final model. At the cross-validation–derived summary threshold, secondary descriptive operating characteristics were sensitivity 93.8%, specificity 95.5%, and accuracy 94.9%. By comparison, validation grouped only at lymph-node level produced an AUROC of 0.989 and accuracy of 96.7%. The lower patient-grouped estimates illustrate the importance of preserving patient-level clustering when multiple lymph nodes originate from the same individual. The clinically relevant model output was a lymph-node probability derived from repeated spectra rather than classification of individual spectral acquisitions as independent observations.

Pathology-positive nodes showed markedly higher short-wavelength intensity and greater total spectral area, whereas pathology-negative nodes showed a higher I630/I360 ratio, higher intensity at 700 nm, a deeper local blue trough, and a larger red shoulder. This bidirectional spectral pattern may help explain why the hybrid model had a higher discrimination point estimate than the simpler candidate models. However, model-family comparisons were exploratory and were not designed to establish formal superiority. Possible contributors to the observed wavelength-dependent differences include changes in superficial scattering, cellular density, chromophore absorption, stromal architecture, and vascular content. This study did not include site-matched quantitative optical-histological measurements capable of establishing these mechanisms. These explanations are therefore hypothesis generating and should not be interpreted as demonstrated biological causes of the spectral differences.

This study extends, but is independent of, the earlier ESS study of cervical lymph nodes [14]. The previously published study examined 347 spectra obtained from 130 formalin-fixed lymph nodes in 13 patients and reported high sensitivity but lower specificity using selected wavelength intensities and a simple cutoff. The present cohort comprised fresh lymph nodes from 45 different patients. No participant, lymph node, raw spectrum, pathology outcome, or derived model output from the earlier dataset was included in this analytical dataset or used for model fitting, hyperparameter tuning, probability calibration, threshold selection, or performance estimation. All data-derived spectral and performance figures in this report were generated from the present cohort rather than from the previously published dataset. This analysis also differed by using 3 spatially separated acquisitions per node, explicit quality control, node-level probability aggregation, and internal validation grouped by patient.

The direction of some individual spectral features differed between the 2 studies. The earlier study found generally greater scattering intensity in pathology-positive measurements, including at longer wavelengths, whereas the present node-level analysis found higher I700 intensity, a higher I630/I360 ratio, a deeper blue trough, and a larger red shoulder in pathology-negative nodes. The differing wavelength-specific directions should not be interpreted as direct replication or contradiction because the studies differed materially in specimen state, acquisition context, analytical unit, preprocessing, aggregation, and modeling. The earlier specimens were formalin fixed and analyzed at individual-measurement level, whereas the present specimens were assessed fresh and spectral information was aggregated within lymph nodes. Taken together, the studies support the broader hypothesis that metastatic involvement is associated with differences in optical scattering profiles, while the wavelength-specific direction and magnitude of those differences require independent investigation under standardized acquisition conditions.

Repeated acquisition reduced dependence on a single contact site but did not remove technical variation. Within-node ICCs ranged from 0.78 for blue trough depth to 0.91 for I630 intensity, indicating that amplitude-related features were more repeatable than some local shape features. Operator-specific AUROCs were similar, but each node was assessed by only 1 operator, so a direct paired estimate of interoperator reproducibility was not possible. Future studies should use locked surface-preparation and timing procedures, record probe pressure and contact angle prospectively, and include repeated assessments of the same nodes by multiple operators.

This observation may also have a biological explanation. The ESS probe interrogates only a small superficial tissue volume, approximately 500×300×300 µm, meaning that each spectrum represents a local optical microsample rather than the entire node. Metastatic deposits may be focal, peripheral, central, or microscopic, and individual spectra may therefore capture slightly different aspects of nodal architecture. Aggregating multiple spectra from the same lymph node is consequently more than a statistical exercise; it represents repeated sampling of biological heterogeneity. The improvement observed with node-level aggregation suggests that repeated optical interrogation stabilizes classification by integrating information across multiple microenvironments within the same node. This interpretation is consistent with the probe geometry described in the original ESS nodal study, where collected photons originated from a defined superficial scattering volume rather than a whole-node measurement.

This node-level framing is particularly relevant when compared with imaging. Clinical examination, CT, MRI, PET-CT, and ultrasound remain essential in preoperative staging, yet each

XSL•FO
RenderX

can struggle with small-volume or biologically ambiguous nodal disease. Historical clinical and radiological studies have shown substantial false-negative and false-positive rates in the neck, and contemporary meta-analyses continue to show that advanced imaging is useful but imperfect [6,7,22,23]. ESS addresses a different point in the pathway. It is not a preoperative staging test. Its most realistic role is ex vivo assessment of dissected lymph nodes, helping to identify nodes that warrant closer histopathological attention, expedited review, or targeted deeper sectioning.

Patient-level sensitivity was 96% and specificity was 90% when a patient was classified as positive if at least 1 ESS-assessed node exceeded the cross-validation–derived summary threshold. This analysis provides an exploratory indication of performance at patient level, but it was based only on the ESS-assessed node set and should not be interpreted as complete pathological staging of the neck. The maximum-node approach may also be influenced by the number of nodes assessed per patient because patients contributing more nodes have more opportunities to generate a high node-level probability. Prospective evaluation in which the clinically relevant nodal yield is assessed according to a predefined sampling protocol will be required to establish patient-level clinical performance.

The potential clinical role of ESS should be framed as augmentation rather than replacement. Histopathology remains the reference standard and must continue to determine the final diagnosis. ESS may warrant prospective evaluation as an investigational triage tool for identifying high-probability nodes that could be prioritized for review or additional pathological assessment, while all nodes continue to undergo the required routine histopathological pathway. Whether this approach improves turnaround time, workload, or diagnostic safety remains to be demonstrated prospectively.

Any future clinical system would need to provide automated quality control and a simple probability or indeterminate output within a time compatible with gross specimen assessment. Evaluation should compare routine pathology with and without ESS-guided specimen prioritization and, where relevant, benchmark diagnostic performance and turnaround time against rapid sentinel-node or frozen-section pathways [24].

The observed node-level NPV of 96.6% at the cross-validation–derived summary threshold is potentially relevant to future triage applications but remains dependent on disease prevalence and should be interpreted as a secondary descriptive operating characteristic of this internally validated cohort. The prevalence of metastatic nodes will differ between elective and therapeutic neck dissections, tumor stages, anatomical sites, sampling strategies, and referral settings. Calibration was acceptable within the present cohort, but both predictive values and probability calibration may change in an independent population. External validation should therefore use a prospectively locked threshold, evaluate whether recalibration is required, and consider an indeterminate probability range rather than assuming that every node should receive a forced binary classification.

Strengths

The study has several strengths. Histopathology was used as the reference standard, repeated spectra were acquired from each node, and explicit quality-control criteria were applied before modeling. The primary validation kept all nodes and spectra from each patient together, and model fitting, hyperparameter selection, probability calibration where required, and threshold optimization were restricted to training data within the nested validation process. Performance was reported with patient-clustered CIs, calibration measures, patient-level results, case-level error review, and technical repeatability analyses. Moreover, 6 node-level index-test no-results were also reported explicitly rather than being treated as model classifications. The lower discrimination of area-normalized and shape-focused analyses suggests that amplitude information contributed materially to model performance in this cohort, although this finding reinforces the need for careful control of acquisition conditions and independent external validation.

Limitations

Several limitations remain. First, this was a single-center model-development and internal-validation study involving 45 patients. Although the analytical dataset contained 274 analyzable nodes and 760 retained spectra, observations were clustered within patients; the effective number of independent biological units was substantially smaller than the number of spectra or nodes, and spectrum-level fitting gave greater influence to patients contributing more nodes and to nodes retaining 3 rather than 2 spectra. Future work should compare patient- or node-weighted fitting with direct node-level spectral aggregation. Prospective external validation is, therefore, required. Second, the patient-level analysis represented the ESS-assessed node set rather than complete pathological staging of every node recovered from each neck dissection. The ESS-assessed nodes represented a pragmatic availability-based sample rather than the complete pathological nodal yield, so the observed node-level prevalence and diagnostic performance may not transfer directly to an unselected routine pathology population. Third, 6 of 280 ESS-assessed nodes produced no analyzable node-level results, and all 6 were pathology negative. The small number of no-results precluded reliable assessment of whether acquisition failure was associated with pathology, node characteristics, or other technical factors. Fourth, deeper levels and pancytokeratin immunohistochemistry were used selectively rather than systematically, so very small metastatic deposits could theoretically have been missed by the reference-standard assessment. Fifth, some technical variables were derived from archival records, while probe pressure and precise contact angle were not measured quantitatively. Sixth, each lymph node was assessed by only 1 operator, preventing paired assessment of interoperator reproducibility. Operator, acquisition batch, and case mix were not fully crossed within the same specimens, so operator-stratified and batch-based analyses could not completely separate technical effects from differences in patient or nodal characteristics. Seventh, amplitude contributed materially to discrimination and may be influenced by surface hydration, blood contamination, tissue handling, probe contact, system response, and elapsed time from excision. Eighth, the hybrid model family was selected because

XSL•FO
RenderX

it had the highest pooled patient-grouped out-of-fold AUROC point estimate among the candidate families. Its AUROC of 0.966 is therefore an internally validated, exploratory estimate of the selected model's performance, rather than independent validation of a prospectively fixed final model. Using the same out-of-fold predictions for model-family selection and performance reporting may introduce selection optimism; independent evaluation of a prospectively specified and locked model remains necessary. Ninth, the pooled binary operating characteristics were calculated using a summary threshold derived from the distribution of training-derived thresholds after repeated internal cross-validation and should be interpreted as descriptive rather than as validation of a prospectively locked clinical threshold. Tenth, the specimens were collected between 2016 and 2021 using a research ESS platform, so differences in contemporary devices, specimen handling, staging practice, and pathology workflows may affect transportability. Finally, 3 fixed acquisitions sampled only small superficial tissue volumes and may not consistently capture focal, peripheral, or heterogeneous metastatic deposits. Prospective studies should evaluate predefined acquisition protocols, denser or scanned sampling, automated quality control, and an independently locked model and decision threshold.

Future Work

A particularly important next step will be site-matched optical-pathological correlation. Future studies could coregister ESS acquisition points with digital histopathology and quantitative image analysis to determine whether wavelength-specific changes correlate with tumor area, nuclear density, keratinization, fibrosis, inflammatory infiltrates, vascularity, or other measurable tissue features. Such work would allow ESS findings to move beyond diagnostic discrimination towards biologically interpretable optical pathology and may clarify the cellular and subcellular origins of the wavelength patterns identified in this study.

Future evaluation should use a prospective multicenter design in which the acquisition protocol, preprocessing sequence, quality-control rules, classifier, probability-calibration procedure, and decision threshold are specified and locked before evaluation of the external validation cohort. The study should include multiple devices, operators, pathology teams, and clinically relevant patient groups. Outcomes should include discrimination, calibration, operator reproducibility, acquisition failure, indeterminate results, turnaround time, pathology workload, missed disease, and costs. The appropriate comparison is not ESS vs histopathology as competing diagnostic methods, but routine pathology with and without ESS-guided specimen prioritization.

Conclusion

In this single-center ex vivo model development and internal validation study, ESS showed promising node-level discrimination of metastatic cervical lymph nodes after repeated spectral acquisition and node-level aggregation. Patient-grouped validation produced lower performance estimates than validation grouped only at lymph-node level, emphasizing the importance of accounting for clustering of multiple nodes within patients. The findings remain exploratory and do not establish clinical utility. ESS should therefore be regarded as an investigational adjunct for pathology triage rather than a clinically ready diagnostic test. Prospective multicenter external validation using a prespecified and locked analytical pipeline and decision threshold, together with explicit assessment of no-results, calibration, paired operator reproducibility, acquisition variability, and workflow performance, is required before clinical implementation.

Abstract

Background: Technology is changing the way the world communicates and how we learn, remember, and transform information. The ascendancy of the internet has dramatically altered the landscape of health information access and seeking behaviors. This transformation is embodied by the concept of digital health literacy (DHL) and the need for interventions that improve DHL.

Objective: This study aims to explore readiness for DHL transformation and intervention preferences from the perspectives of patients with cancer, caregivers, and health care professionals.

Methods: We conducted semistructured telephone and on-site interviews with 19 patients with cancer, 6 caregivers, and 10 oncology health care professionals. Purposive sampling was used to recruit the participants. We followed the 7 stages of the Framework Method analysis: transcription, familiarization with the interview, coding, developing a working analytical framework, applying the analytical framework, charting the data into the framework matrix, and interpreting the data. This was used to investigate participants' beliefs about technology adoption, their preferences for DHL training, and the facilitating conditions for adopting such training. We used a hybrid deductive-inductive approach to data analysis, starting with a priori themes and allowing emergent themes to develop as the analysis progressed. The Unified Theory of Acceptance and Use of Technology informed our data generation and analysis.

Results: The following 6 themes emerged from the analysis: introducing technology-driven solutions, simplifying technology training materials, providing user-friendly training materials, patient-centered care, partnership, and addressing cultural and linguistic barriers. We found that patients with cancer and caregivers were self-sufficient and motivated to use new technology to improve their DHL; however, health care professionals were concerned about the reliability of online information. By mapping interview themes to the Unified Theory of Acceptance and Use of Technology, we identified specific recommendations for the creation of a DHL intervention: content should be concise, easy to understand, and web-based; content should include training on how to identify reliable cancer information; patients would like to be involved in content creation in addition to medical and government stakeholders; and content should be accessible in multiple languages.

Conclusions: Patients with cancer and their caregivers were motivated to use modern technology to improve cancer DHL, despite the quality issues raised by health care professionals. The participants' preferences regarding DHL training align with the innovative microlearning pedagogy. Microlearning could leverage technology to deliver tailored DHL training for patients with cancer. Collaboration with multiple medical and nonmedical stakeholders could facilitate the delivery of cancer DHL training. Future work should focus on designing and assessing the feasibility of implementing a microlearning-based DHL training program that involves end users and diverse stakeholders.

Introduction

Online technologies have changed societies and affect our daily lives in many ways. This is reflected in the growing use of the internet and mobile devices by consumers to access health information and services [1]. Saudi Arabia's Vision 2030 outlines an ambitious plan to transform the health care sector through digitalization [2]. This transformation includes aspects of digital health literacy and technology-driven health engagement, focusing on improving access, efficiency, and patient empowerment through digital health [3].

In Saudi Arabia, approximately two-thirds or more of individuals get their health-related information from social media or the internet [4]. Internet use can be particularly effective when there are barriers to accessing traditional health information, especially for stigmatized conditions such as cancer [5,6]. Patients with cancer widely seek digital health information, as demonstrated in a study reporting that 76.4% of survivors of cancer use the internet for health-related information [7].

Digital health is now considered a complement to cancer care to meet key unmet needs, such as "support to help cope with a diagnosis" and "cancer education and information" [8]. Indeed, one study reported "information and education" as one of the most needed digital health functions for patients with cancer, caregivers, and health care providers [9].

Digital health literacy (DHL) is the ability to use information and communication technologies to find, evaluate, create, and communicate health information, and it requires both cognitive and technical skills [10]. Information searching is often described as a problem-solving task that involves a series of complex cognitive processes, such as inferences and decision-making [10]. Complex or confusing digital health information is especially difficult for patients with cancer since their cognitive abilities decrease due to the effects of the cancer and chemotherapy treatment [11]. A 2023 systematic scoping review found that patients with cancer and caregivers struggle to identify reliable information resources and can be misled or misinterpret information online [12]. A study in Saudi Arabia demonstrated that participants with higher DHL scores were more likely to have increased breast cancer literacy [13]. Another study reported that almost one-third of participants face challenges formulating precise health-related inquiries, highlighting the critical need for specialized DHL education initiatives in Saudi Arabia [14]. Mackert et al [15] and Zarcadoolas et al [16] have advocated for user-friendly educational interventions to bridge the DHL gap.

Health education needs to adapt and develop innovative ways of relating appropriately to the way we live, work, and learn today. A recent systematic review reported many interventions to improve laypeople's DHL, including interactive workshops, community outreach programs, and educational initiatives. However, no one has used a novel educational approach or targeted patients with cancer [17]. Low DHL in cancer care contributes to adverse health outcomes, hinders self-management of patients' conditions, and is considered a barrier to engaging with digital health technologies [18].

Digital health readiness is defined as a patient's ability and comfort with using digital tools for health care engagement [19]. This concept expands on existing literature describing DHL to include factors such as health care trust, acceptance of technology, and relevance to care. Current approaches to DHL intervention design are evolving from viewing patients as merely passive consumers of care to viewing them as active coproducers in their care management [20,21]. Coproduction in health care delivery is a reciprocal, collaborative process in which patients and health care providers work together to deliver care, sharing information and setting goals to create value [20]. Digital health interventions in cancer care have been reported to reduce symptoms [22], improve health behaviors [23], and promote psychological well-being and quality of life [24].

Nutbeam [25] outlined the need to invest in research to improve our understanding of how effective health interventions should be implemented. Eccles et al [26] further argued that we need to see greater use of theoretical approaches underpinning the design and implementation of interventions. Although theories have been used to evaluate digital health interventions [27], there is a lack of theoretically informed research in the field of digital health readiness.

The Unified Theory of Acceptance and Use of Technology (UTAUT) is a comprehensive digital health readiness framework that integrates and extends various theories to explain the acceptance and use of technology [28]. It incorporates elements from 8 previous models of technology acceptance, namely the Theory of Reasoned Action, the Technology Acceptance Model, the Motivational Model, the Theory of Planned Behavior, a combined model of Technology Acceptance Model and Theory of Planned Behavior, the Model of Personal Computer utilization, the Diffusion of Innovations theory, and Social Cognitive Theory [28]. It has 4 determinants (performance expectancy, effort expectancy, social influence, and facilitating conditions) and 4 moderators (gender, age, experience, and voluntariness of use) [28]. The UTAUT model has demonstrated its broad applicability across diverse fields, including the Internet of Things [29], artificial intelligence products [30], and electronic health technology [31,32], but has not yet been applied to educational interventions targeting patients with cancer.

The aim of the paper was to explore the readiness for DHL transformation and intervention preferences from the perspectives of patients with cancer, caregivers, and health care professionals using the UTAUT model. To our knowledge, our paper is the first to use the UTAUT to explore readiness for DHL transformation and intervention preferences from the perspectives of patients with cancer, caregivers, and health care professionals. The UTAUT was chosen to help us understand the following objectives: participants' beliefs about technology adoption, preferences regarding DHL training adoption, and the conditions that facilitate DHL training adoption. Knowledge of technology adoption is crucial to ensure the delivery of quality cancer care education.

XSL•FO
RenderX

Methods

The COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist [33] was used to guide reporting of the study (Checklist 1). It also provides a structured account of the study's methodological rigor, transparency, and researcher reflexivity.

Study Design

The study design domain describes a qualitative content analysis approach [34] informed by the UTAUT. The UTAUT was relevant because it enables in-depth exploration of the unconscious behaviors that drive the uptake of health education initiatives. Semistructured on-site and telephone interviews were conducted with patients with cancer attending the oncology department for chemotherapy treatment and their caregivers, as well as oncology health care professionals at King Fahad Specialist Hospital (KFSH), Dammam, Saudi Arabia. The researchers selected the semistructured interview format because it allowed them to preformulate questions, compare data across participants, and adjust questions as necessary during the interview [35].

Sampling and Recruitment

Purposive sampling was used to provide rich, relevant, and diverse data that were not intended to be representative of a broader population [36]. We deliberately sampled a mix of ages, genders, and socioeconomic statuses from different participant types, including patients with cancer and their caregivers and oncology health care professionals, based on preidentified inclusion and exclusion criteria (Textbox 1). Patients and caregivers were recruited face to face. Paper-based posters, recruitment emails, and telephone calls were also used to facilitate the recruitment. Oncology health care professionals were recruited through gatekeepers in the oncology department. We recruited 44 participants, including 24 patients, 6 caregivers, and 14 health care professionals; 5 patients and 4 health care professionals declined to participate. In total, 35 participants agreed to participate in the study. Saturation was used as a guiding principle to assess the adequacy of the purposive sample [37].

Textbox 1. Inclusion and exclusion criteria for the different participant types, including people with cancer, their caregivers, and health care professionals involved in cancer care.

Inclusion criteria

1. Patients with a personal history of cancer who are considered in remission
2. Family/friend caregivers involved in helping care for patients with cancer for 2 or more hours per week, providing emotional or other support
3. Health care professionals involved in cancer care (assistant consultants/consultants, nurses, health educators)
4. ≥18 years old, male or female, and able to understand and answer in Arabic
5. Must have used the internet to search for cancer information

Exclusion criteria

1. Patients with no personal history of cancer; patients with a personal history of cancer but not considered in remission
2. Caregivers with no significant involvement in helping with care as defined by less than 2 hours per week of emotional or other support
3. Health care professionals not involved in cancer care
4. <18 years old, unable to understand and answer in Arabic
5. Never used the internet to search for cancer information

Interview Question Design

A panel of 5 stakeholders agreed on the interview questions. The panel included 2 clinicians and 3 academics with expertise in DHL. The semistructured interview questions were open-ended focusing on the following areas: (1) digital learnability, (2) DHL training mode of delivery, (3) DHL training information content and display, (4) DHL training interval and duration, (5) DHL training design, and (6) facilitators of the DHL training adoption. The questionnaire initially had 10 questions. An additional question was added following a small number of pilot interviews to better understand the facilitators for adopting DHL training. This question and the DHL training design question received the most interest from patients with cancer and caregivers. Health care professionals were most interested in discussing the DHL training content; however, differences emerged among patients with cancer, their caregivers, and health care professionals' preferences. We developed the interview guide in English to allow discussion with the English-speaking researchers. The interview guide was translated into Arabic, as the interviews were conducted in Arabic per the protocol and inclusion criteria. Participants were provided with an Arabic version of the topic guide before consultation. Multimedia Appendix 1 includes the English and Arabic versions of the interview guide. Sociodemographic data were collected via a brief pre-interview questionnaire that was posed by the interviewer and answered by the participants.

Data Collection

A female PhD researcher (HM) with no prior interaction with participants carried out the interviews in Arabic. No one else was present besides the participants and the researcher. The researcher disclosed that the study was part of her doctoral research on DHL. The researcher has professional-level fluency in Arabic and English and is a DHL expert, with experience in

XSL•FO
RenderX

qualitative research, the research topic, and Saudi culture. The researcher completed the Good Clinical Practice course before conducting the study. The researcher conducted 35 telephone and on-site (KFSH) interviews with patients with cancer, caregivers, and oncology health care professionals following written and verbal informed consent. The interviews were conducted in cycles between August 15, 2024, and February 15, 2025, at times and locations convenient to the participants. Interviews were audio-recorded, transcribed, and coded using a thematic analysis approach within the Framework Method described in the following paragraphs [38]. No field notes were made during and/or after the interview. No repeat interviews were carried out. At the close of each interview, the audio recordings were transcribed into Microsoft Word. The description of the coding tree was not included in the main manuscript nor its appendices but can be shared upon reasonable request. Most of the interviews lasted 30 minutes to 45 minutes. However, interviews with patients with cancer and caregivers lasted between 30 minutes and 35 minutes, while health care professionals ' interviews lasted longer (35 - 45 min). There were no differences in interview quality between patients with cancer or caregivers and health care professionals or between telephone and on-site interviews. We reached data saturation after conducting the 35 interviews, as no new themes were emerging during interviews 34 and 35. We first assessed code saturation to ensure it was sufficient to understand the issues identified. Second, we assessed meaning saturation to ensure that no further dimensions, nuances, nor insights into the issues could be found. We also evaluated whether specific characteristics of codes influenced code or meaning saturation to provide parameters for estimating saturation based on the nature of codes developed in a study [37]. These approaches provided confidence that the collected data adequately captured the breadth of relevant perspectives within the study population, thereby ensuring the depth and credibility of the findings.

Data Analysis

Audio recordings of the interviews were made with the participants' consent and transcribed verbatim in Arabic. The quotes were translated forward and backward into English by the principal investigator (HM; researcher translator). A bilingual health literacy expert consultant reviewed the translation (MM). The transcriptions were analyzed by iteratively reading transcripts. Thematic analysis was conducted using the Arabic versions of the transcripts; the results section used English translations of the quotations for readability by a wider audience. We used a hybrid deductive-inductive approach to data analysis [38], starting with a priori themes and allowing emergent themes to develop as the analysis progressed. This blend helped balance theoretical grounding with a rich, data-driven understanding of the topic. Given the potential value of theory as a heuristic for qualitative analysis processes [39], data generation and analysis were informed by the UTAUT. Emergent themes were subsequently mapped onto the 4 determinants of the UTAUT [28]. The mapping process relied on iteratively moving between the emergent themes and the UTAUT determinants to build knowledge about applying UTAUT to the project data.

The Framework Method sits within a broad family of analysis methods often termed thematic analysis or qualitative content analysis. The Framework Method can be adapted for use with qualitative analyses that are deductive, inductive, or combined [40]. It also facilitated constant comparative techniques by reviewing data across the matrix; as such, it was found to be appropriate for our paper as it involves different types of participants (patients, caregivers, and health care professionals) [40]. The following 7 stages of the Framework Method analysis were followed: transcription, familiarization with the interview, coding, developing a working analytical framework, applying the analytical framework, charting the data into the framework matrix, and interpreting the data [40].

Reflexivity measures were applied to mitigate potential bias arising from the researcher's background in DHL. Two researchers from different professional backgrounds independently conducted coding in NVivo 14 to explore the development of inductive themes and the application of deductive ones. This approach helped to ensure intercoder reliability and to heighten reflexivity [41].

Transcript analysis was carried out at primary and secondary levels. Whereas first-level coding created descriptive, low-inference codes directly from the data, second-level analysis allowed for the reorganization of primary codes into appropriate categories, subthemes, and themes [41].

Member checking is crucial in qualitative research to ensure credibility and validity, reduce researcher bias, increase trustworthiness of the findings, and ensure participants' expertise was fully used [42]. A researcher prepared a draft of the findings, including anonymous quotations, 1 month after data collection and shared it with one-half of the participants individually (an equal number of health care professionals and patients). The researcher asked questions about accuracy, interpretation, completeness, fairness and respect, and clarification. The participants provided their answers through written feedback. The feedback was used to revise interpretations, clarify ambiguities, and add missing information.

To ensure the awareness of reflexivity in that one's own beliefs can affect interpretation [41], 3 additional members of the research team, a cancer survivor, and a consultant oncology doctor, reviewed the themes, subthemes, and categories and refined them, seeking clarity on language and suggesting additional work. The research team worked in a group throughout the analysis, comparing coding, discussing how the data related to the UTAUT coding frame, and refining the coding frame. Data analysis clinics were also used to strengthen the initial inductive analysis and to map themes onto the UTAUT. A narrative description was provided for each of the themes speaking to readiness for DHL transformation and intervention preferences.

Ethical Considerations

All the procedures performed in the study involved human participants. Ethical approval was obtained before data collection from the KFSH research ethics committee (April 23, 2024/EXT0429). The method of collecting and analyzing data was carried out in a manner that was compliant with all

XSL•FO
RenderX

applicable ethical norms. Full disclosure was made regarding the investigation's objective and the legal rights of those participating. Each participant was given a pseudonym to preserve confidentiality and maintain anonymity. Every participant provided informed consent before the interview began. Participation in the study was entirely voluntary throughout the process. Participants did not receive compensation for their participation in the study. Data will be stored on the principal investigator's (HM) password-protected Outlook OneDrive account for 2 years then destroyed.

Results

Participants' Characteristics

The first 24 patients who met the study criteria were invited to participate in the study; 5 patients declined (3 men and 2 women) because they were too ill to be interviewed on the day of the appointment. In addition, 6 caregivers agreed to participate in the study. Of the 14 health care professionals recruited, 4 refused to participate (3 nurses and 1 health educator) because they were too busy during the data collection period. Only 10 health care professionals (assistant consultants and consultants) agreed to participate in the study. The total number of patients, caregivers, and health care professionals interviewed was 35. Table 1 presents the participants' characteristics including age, gender, and participant category. Questions were asked regarding demographics, including education, and socioeconomic status; however, many participants declined to disclose these, most likely as they were considered sensitive information. Given the extent of the missing data, these variables have not been reported.

Table . Participant characteristics for those who participated (n=35) in the semistructured interviews in King Fahad Specialist Hospital, Dammam, Saudi Arabia, between August 15, 2024, and February 15, 2025.

Participant category	Participants, n	Male, n	Female, n	Age (years), range
Patients with cancer	19	9	10	30 - 65
Cancer caregivers	6	1	5	30-50
Oncology health care professionals	10	7	3	40-55

Qualitative Findings

Findings on readiness for the DHL transformation and intervention preferences are presented in Textbox 2 and framed around the 4 determinants of the UTAUT. We identified 6 themes and 9 subthemes under the UTAUT determinants. For the first 2 subthemes, there were categories that were considered individually as indicated in the following sections.

XSL•FO
RenderX

Textbox 2. The 4 determinants of the Unified Theory of Acceptance and Use of Technology and their definitions, themes, subthemes, and categories describing the factors that influence digital health literacy training preferences in people with cancer in a sample size of 35 participants.

Performance expectancy (user's belief that using technology will enhance their search performance and productivity)

1. Introduction of technology-driven solutions
    a. Digital literacy learnability
        1. Self-efficacy for using the technology to search for cancer information
        2. Willingness to engage with new technology to improve cancer digital health literacy
    b. Demand for technology-driven solutions to improve cancer digital health literacy
        1. Addressing the digital divide
        2. Designing an educational digital health literacy training

Effort expectancy (the degree of ease associated with the use of technology)

1. Simplifying technology training materials
    a. Bite-sized information
    b. Desire for reliable information
2. Providing user friendly training materials
    a. Self-paced training
    b. Short-duration training

Social influence (the impact of external factors on an individual's decision to adopt technology)

1. Patient-centered care
    a. Willingness to be involved in the design of the training material

Facilitating conditions (availability of resources, support, and infrastructure necessary for technology adoption and use)

1. Partnership
    a. Collaboration with multiple stakeholders (medical and nonmedical)
2. Addressing cultural and linguistic barriers
    a. Providing bilingual training material

Performance Expectancy

There were 2 subthemes under performance expectancy: digital literacy learnability and demand for technology-driven solutions to improve cancer DHL.

Digital Literacy Learnability

Digital literacy learnability refers to the self-efficacy of patients with cancer and their willingness to engage with technology.

Patients with cancer and their caregivers spoke about their self-efficacy in navigating online cancer information. Inversely, many health care professionals expressed concerns about the quality of cancer information retrieved by patients online.

> *I feel confident when opening web browsers to search for cancer information.* [Patient 5]
>
> *I feel confident to click on a link to visit a cancer website.* [Caregiver 2]
>
> *Nowadays, patients are increasingly dependent on the internet to search for cancer information; however, most of the information they brought to me was unreliable.* [Health care professional 3]

Patients with cancer and caregivers expressed being motivated to engage with new technologies, with a view to learning and improving their cancer care. Health care professionals also noted patients' eagerness to search online, often before their doctor's visit.

> *I am interested to learn about my health through the new technology channels.* [Patient 8]
>
> *I believe learning through the new technology can affect patients' health positively.* [Caregiver 5]
>
> *Most of the patients nowadays prefer searching online even before visiting the doctor.* [Health care professional 7]

XSL•FO
RenderX

Demand for Technology-Driven Solutions to Improve Cancer DHL

Demand for technology-driven solutions to improve cancer DHL refers to addressing the digital divide to ensure that technology is accessible to all users, regardless of their geographical location or socioeconomic status and designing educational DHL training.

Patients, caregivers, and health care professionals reported a preference for web-based DHL training. They believed that online training would help address the digital divide and facilitate digital inclusion.

> *Going far away from my home to get the training is costly, and I don't have the energy like before.* [Patient 5]
>
> *I won't be able to attend training conducted even 5 minutes away from my house, as it requires a lot of dedication.* [Caregiver 4]
>
> *I would say if the educational training is provided online, it will be easily accessible for the consumers and more engaging.* [Health care professional 2]

Patients and caregivers spoke about designing a smartphone app to deliver the DHL training. On the other hand, many health care professionals demonstrated a need for an educational video to improve cancer DHL.

> *I feel more engaged with smartphone applications as I hold my phone most of the day.* [Patient 15]
>
> *If the educational materials are provided through the applications, they will be easily accessible.* [Caregiver 6]
>
> *I believe designing an educational video to be available for the general public would be of great value, as they provide easy-to-catch information.* [Health care professional 7]

Effort Expectancy

There were 4 subthemes under effort expectancy: bite-sized information, desire for reliable information, self-paced training, and short-duration training.

Bite-Sized Information

Patients with cancer and caregivers emphasized the importance of providing concise educational content to reduce cognitive effort and time. Health care providers discussed the impact of chemotherapy on the learning abilities of patients with cancer, necessitating the provision of small-bundle information.

> *I am a busy person with my family, work, and now a cancer patient; I don't have that energy like before to learn complex educational materials.* [Patient 11]
>
> *I think providing educational material in small bites may reduce the learning burden.* [Caregiver 1]
>
> *Patients with cancer face many difficulties concerning learning, especially after receiving chemotherapy; they would benefit from small pieces or guides of information.* [Health care professional 8]

Desire for Reliable Information

Patients and caregivers expressed a need for training on identifying reliable cancer information. They recommended learning tips for evaluating the reliability of online information and identifying high-quality websites, while health care providers spoke about the importance of educating laypeople about common cancer misconceptions.

> *I want to learn about excellent quality websites for lay people to search cancer information.* [Patient 13]
>
> *I want to learn how to evaluate the reliability of online health information.* [Caregiver 1]
>
> *Many patients with cancer come to my clinic with worsening symptoms and poor prognosis due to misinformation. It is essential to increase public awareness about common cancer misconceptions.* [Health care professional 3]

Self-Paced Training

Most patients and caregivers stated that they like the flexibility of online training and being able to go at their own pace.

> *Accessing the training material with no fixed schedule and the ability to set my times would help me to engage.* [Patient 12]
>
> *I want to reach the training when I want, at the time I want, and with the time I have.* [Caregiver 6]

Short-Duration Training

Patients, caregivers, and health care professionals spoke about providing short-duration training to reduce cognitive load and optimize attention span for memorizing information.

> *It could even be an educational training that does not exceed 10 minutes to be able to focus and memorize it.* [Patient 11]
>
> *They can be 10 minutes, but then they are almost too long.* [Caregiver 6]
>
> *Short training, 5 minutes maximum to reduce the learning load.* [Health care professional 8]

Social Influence

There was 1 subtheme under social influence: willingness to be involved in the design of the DHL training.

Patients with cancer expressed a strong desire to be involved in the design of the training material.

Caregivers and health care professionals believed that the patient voice should be heard to ensure relevance and acceptability of training materials.

> *Nobody knows it better than yourselves, having gone through it… You can set up all the processes on paper: This happens, this happens, this happens, but until you actually press play and go through it.* [Patient 6]
>
> *People who set the training materials have never passed through a cancer journey. They see it from the other side of the desk, but to actually involve*

XSL•FO
RenderX

> *people who have been on the receiving end.* [Caregiver 15]
>
> *Getting patients with cancer involved could help to cover a huge gap that comes between the delivery and acceptance of the training materials.* [Health care professional 6]

Facilitating Conditions

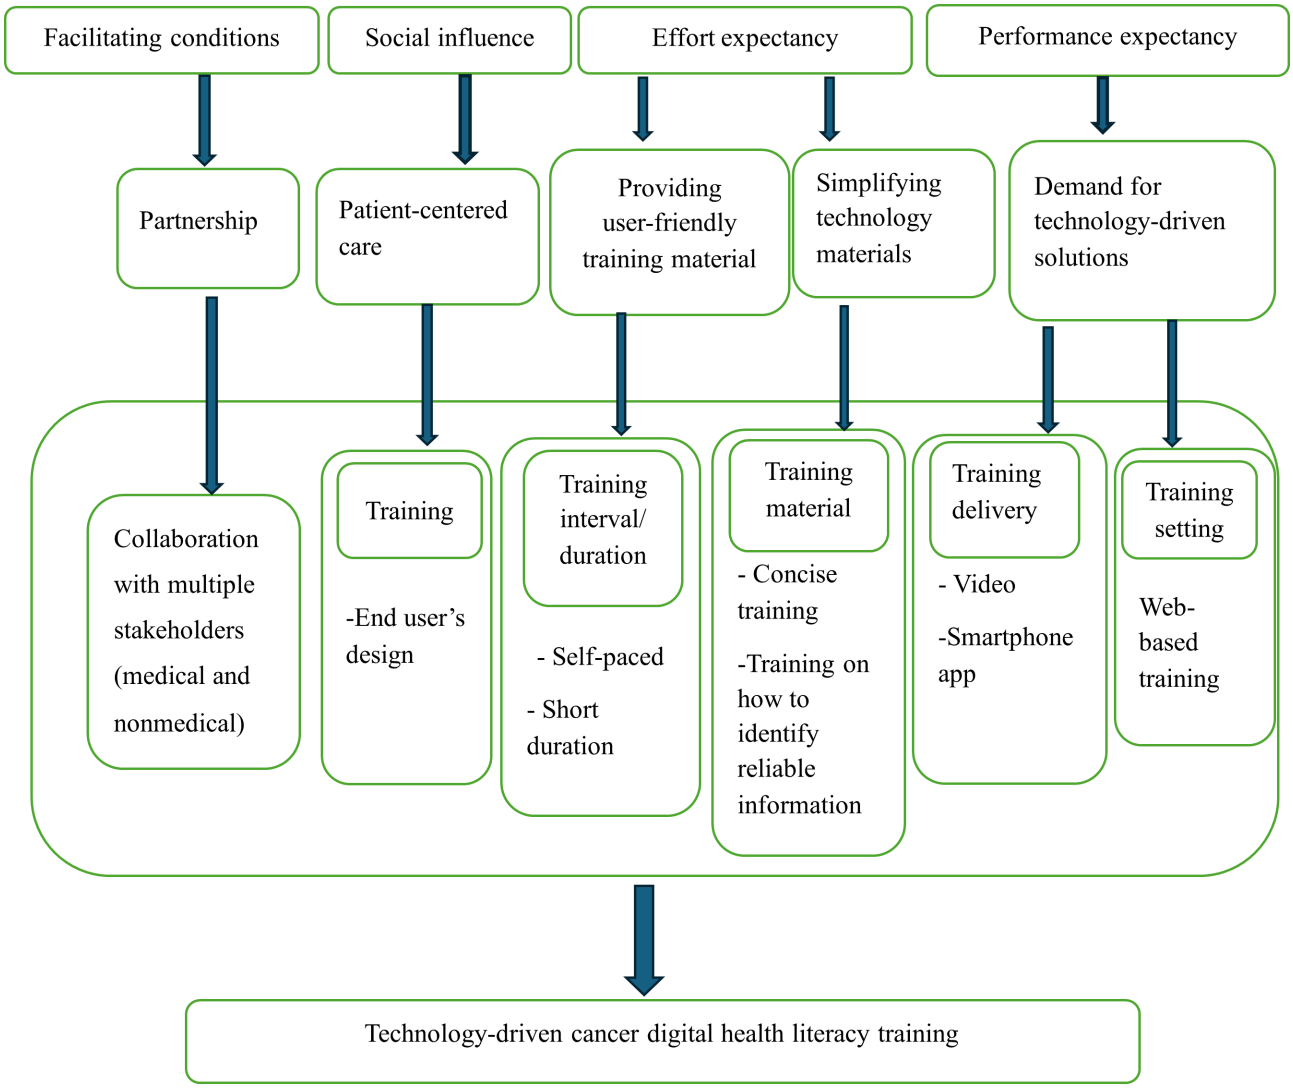
There were 2 subthemes under facilitating conditions: collaboration with multiple stakeholders (medical and nonmedical) and providing bilingual training materials.

Collaboration With Multiple Stakeholders (Medical and Nonmedical)

Patients with cancer, caregivers, and health care professionals spoke about the essential role of collaborative work in the design of the training materials. They emphasized the role of technology assistants, governmental authorities, and health care professionals in designing the educational materials.

> *I trust the oncology doctors, nurses, health educators, researchers, and governmental authorities. Why don't they put their hands together to deliver such training?* [Patient 3]
>
> *It is not an easy game that one person can play; it is the health of cancer patients… it needs different expertise in different sectors. It is worth connecting to deliver such a lifesaving game.* [Caregiver 1]
>
> *I would see it as a cooperative work; one hand will not clap. We are not in front of the computer to see how this work can be done. We want to work as one unit to see this work delivered properly.* [Health care professional 1]

Providing Bilingual Training Materials



Patients with cancer, caregivers, and health care providers expressed a need for providing bilingual DHL training to deliver culturally appropriate material.

> *I think it would be worthwhile if the training is provided in Arabic and English.* [Patient 19]
>
> *Our native language in Saudi Arabia is Arabic, while some residents from different cultures speak English also. I believe providing an educational training in both languages would be useful for both.* [Caregiver 4]
>
> *Providing bilingual training in both Arabic and English may facilitate the use of the educational training by the end consumers from different cultures.* [Health care professional 6]

We integrated the findings into the commonly identified themes to generate a conceptual framework for cancer DHL training (Figure 1). The framework explores how the pre-identified themes and subthemes were mapped onto the 4 determinants of the UTAUT to generate technology-driven cancer DHL training.

XSL•FO
RenderX

Figure 1. Cancer digital health literacy conceptual framework based on the main findings of the study in conjunction with the Unified Theory of Acceptance and Use of Technology, including the useful training components derived from the thematic analysis and theory determinants.

Discussion

Principal Findings

We found that patients with cancer and caregivers were self-sufficient and motivated to engage with new technology to improve cancer DHL; however, health care professionals were concerned about the reliability of online information. We identified specific recommendations for creating cancer DHL training: Content should be concise, easy to understand, web-based, and delivered through technology-driven solutions; content should include training on how to identify reliable cancer information; patients would like to be involved in content creation; and training should be self-paced and of a short duration. Our findings demonstrated collaboration between medical and nonmedical stakeholders to facilitate DHL training adoption.

Comparison With Prior Work

Participants' Beliefs About Technology Adoption

Our findings indicated that patients with cancer and caregivers were self-sufficient and motivated to use novel technology to improve cancer health literacy. Previous studies in Saudi Arabia reported that most participants prefer to use the internet to search for health information [43-45]. A qualitative focus group study found that most participants recognized the benefits of using technology to manage their health care, despite expressing concerns about its use [16].

Car et al [46] identified several barriers to the use of digital health information, including a lack of motivation and cognitive skills to find and use information. The expectation that online health information will be useful is one of the strongest predictors of internet use [47], and a lack of skills was debated as one possible reason for not using the internet [46]. Specifically, potential users may lack the skills to effectively locate, evaluate, and use online health information [48]. Motivation was reported as an essential step in line with education for DHL training adoption [46].

Participants' Preferences Considering DHL Training Adoption

Our findings indicated that most participants preferred web-based DHL training. This approach has been reported in previous DHL interventions [49-53]; however, those interventions were not microlearning-based. An online learning

XSL•FO
RenderX

environment has certain limitations; as such, learning materials should be as explicit and purposeful as possible, thus microdesigned. Microlearning could leverage the use of technology to deliver tailored DHL training but not a technology-dependent format of learning [54].

Our findings indicated that the participants preferred to receive DHL training through technology-driven solutions, namely smartphone apps and videos. A study in Saudi Arabia used an educational video to improve participants' ability to detect health-related misinformation in WhatsApp messages [55]. Nokes and Reyes [56] targeted patients with HIV through an educational video about identifying reliable internet sites. As a cost-effective approach, mobile health apps can also appropriately deliver interventions to patients with cancer [57] and patients with chronic conditions [58]. The "SUCCESS app" is a DHL cross-platform application developed to support Australian adults with chronic kidney failure to improve patients' critical health literacy skills [59]. The "WebChoice" application was developed to provide reliable and useful links and resources for patients with cancer [60].

Effective microdesigned videos and health apps have recently been reported in health professional education studies [61-63]. However, to our knowledge, no microdesigned DHL apps or videos targeting patients with cancer have been developed yet. More research is needed to understand participants' views on how smartphone apps and videos could be microdesigned to improve DHL for patients with cancer.

We noted that the preferred style for information display for patients with cancer was a bite-sized format. Buchem and Hamelmann [64] contended that large bundles of information on the internet are often ignored, whereas small pieces of the whole are tagged and linked in ways that create new patterns, ideas, and meaning. Microlearning, therefore, has the capacity to present information in the most common way people learn today [65]. The individual learning units had a clear, focused message that reinforced two of the aims of microlearning: reducing cognitive load on working memory [66] and adapting to the pressures of a limited attention span [67].

Our paper identified demand for training on how to identify reliable cancer information, including learning to identify high-quality cancer websites and tips for evaluating online information. Both approaches were observed in prior DHL interventions and were reported to be effective in a systematic review [17]. A DHL workshop introduced participants to cancer websites of various top-level domains and web pages accredited by the Health on the Net Foundation [68]. A DHL tutorial also introduced participants to the MedlinePlus.gov website to search for health information [69]. Previous interventions have used several tools to teach people how to evaluate online information, including the SEEK (Source, Evidence, Explanation, and Knowledge) criteria [70], the DISCERN critical appraisal tool [49], and the PILOT (purpose, information, links, originator, timeliness) criteria [71]. However, Bernstam et al [72] reported that commonly cited website quality criteria are not effective at identifying inaccurate online information about breast cancer. Future research could focus on using the quality criteria to assess their effectiveness in evaluating other cancer web pages.

Health care professionals in our study identified a need to increase public awareness of common cancer misconceptions. A cross-sectional study conducted in Saudi Arabia explored the 7 commonly identified cancer misconceptions in Saudi Arabia [45]. However, the results of the study are not available in lay language. The next essential step is translating and disseminating the research findings into lay language, which could be facilitated through technology-driven DHL interventions.

Our findings indicated that the participants preferred self-paced, short-duration DHL training. This approach was seen in prior DHL interventions [56,70]. However, none of those interventions fit within the microlearning time frame. Unlike formal learning, the time spent on microlearning ranges from a few seconds to 15 minutes [64]. With microlearning's ability to space out the learning process over time, a more extended period is often required to learn the content, thereby leveraging retrieval spacing effects to improve information retention and support perpetual, sustainable lifelong learning [65].

Our findings indicated that cancer patients were interested in being involved in the design of cancer DHL training. Mohamed et al [17] reported using this approach in a few studies and considered it a facilitator of intervention use by end consumers. Kemp et al [18] called for using participatory design principles to address DHL in cancer care. Microlearning focuses on users' social interactions to drive content creation and can transform consumers into producers (prosumers) [64]. We identified a small body of literature focusing on users' feedback in the design of microlearning interventions in cancer care [73]. Future research could focus on developing microlearning-based DHL interventions from end users' perspectives.

Several educational approaches have been trialed to improve consumers' DHL, such as didactic lessons [71,74] and collaborative learning [75]. However, driven by the patient-centered care concept and the era of rapidly advancing technologies, Lee et al [76] called for the use of student-centered pedagogical approaches to educate health consumers. One such innovative pedagogy that could meet our participants' demand for bite-size, discrete learning bundles is microlearning [77].

Facilitating Conditions for DHL Training Adoption

In our study, the participants called for a collaborative approach between medical and nonmedical staff to deliver DHL training. Previous research reported the delivery of several DHL interventions through the collaboration of multiple stakeholders [53,56,68,74]. Most of those interventions were reported to be effective in a systematic review study [17]. Partnerships have become increasingly relevant in the delivery of health care services over the last few decades [78]. For instance, a 2012 Institute of Medicine report listed calls for enhanced collaboration among the public, private, health care, and non-health care sectors to improve chronic disease prevention [79]. Other studies have echoed recommendations for cross‐sector collaboration to address social determinants of health [80,81]. Recently, the infosphere has been recognized by Morley et al [82] as a social determinant of health, defining it as the entire information environment that influences health-related behaviors and outcomes, alongside socioeconomic status, income, education, age, race, ethnicity, and gender.

Strengths and Limitations

This study has several limitations. We only explored the perspectives of patients with cancer, caregivers, and oncology health care professionals. Our paper did not consider the opinions of policymakers, technology advisers, and other health care professionals (nurses and health educators). Future research can include diverse stakeholder types. Only 6 caregivers were included in our study. Future research could include more caregivers to compare their experiences with those of patients with cancer. The study focused on participants from a single hospital, limiting generalizability to broader populations. Future research should include a diverse sample across multiple health care settings. The study participants were all deliberate internet users, selected to understand their experiences with online navigation needs. Addressing noninternet users and considering their preferences for DHL intervention were not considered in our paper. Implementing digital health in cancer care must address the variability of DHL in recipients to enhance digital inclusion and digital health equity. The Framework Method used for thematic analysis was time-consuming and resource-intensive and requires a high level of training to be used successfully within a multidisciplinary team.

The UTAUT was found to be a good fit for our study, as it captured the content discussed in the interviews and helped explore which technology-driven DHL training works well from the perspectives of end users and health care providers. To our knowledge, our study is the first to apply the UTAUT to propose a microlearning-based DHL training program. However, we did not examine the effect of the UTAUT moderators (age, gender, experiences, voluntariness of use) on participants' intention to adopt technology. Future research could use a health literacy lens to examine the interactions among those factors and participants' technology adoption.

Implications for Practice

To ensure patient-centered care, it is essential to involve the end users in designing future DHL interventions. Collaborating with multiple stakeholders across relevant fields could facilitate shared decision-making. Education, combined with targeted design, can help effectively implement digital health in cancer care.

Driven by the issue raised in our paper regarding the digital health literacy gap for patients with cancer, microlearning could help address the need to learn infrequently used or new skills, thereby improving patient safety [64]. A previous feasibility study of microlearning to deliver information on chemotherapy side effects to patients with lung cancer demonstrated improvements in participants' cancer literacy and self-management coping strategies [73]. However, to our knowledge, our paper is the first to propose microlearning as a subscription model for designing a DHL intervention. Future work should focus on creating a prototype and examining its feasibility for short-term implementation.

Despite using microlearning as an instructional educational strategy, it may eventually be superseded by emerging innovations such as nanolearning, metaverse learning, or artificial intelligence–assisted learning, which promise opportunities to improve the quality and accessibility of education and to facilitate lifelong learning.

Conclusion

Patients with cancer and caregivers were motivated to use modern technology-driven solutions to improve cancer DHL. The participants' preferences regarding DHL training aligned with the innovative microlearning pedagogy. Microlearning could leverage technology to deliver tailored digital health literacy training for patients with cancer. Collaboration with multiple medical and nonmedical stakeholders could facilitate the delivery of cancer DHL training.

Future work should focus on designing and assessing the feasibility of implementing a microlearning-based DHL training program that involves end users and diverse stakeholders.

Acknowledgments

We are grateful to the journal editors and anonymous reviewers for their helpful comments and suggestions. We thank all patients and caregivers and acknowledge all health care professionals who participated in the study. No generative artificial intelligence, including tools like ChatGPT or other language models, was used in any portion of the manuscript generation. All content was created and written by the authors.

Funding

No external financial support nor grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Data Availability

The research data are unavailable to access because the data include sensitive and confidential information.

Abstract

Background: Small cell lung cancer (SCLC) is a challenging disease to treat due to rapid progression, development of chemoresistance, and discrepancies in outcomes between real-world data and clinical trials. There is a lack of comprehensive analyses in other studies with regard to intermediate events and the treatment process, such as treatment decisions, progression of disease, and the occurrence of adverse events (AEs) over time.

Objective: The aim of this study was to apply advanced statistical methods to a longitudinal SCLC dataset in order to identify factors of importance for the risk of AEs and for survival.

Methods: Treatment pathways of 421 patients with SCLC collected from Karolinska University Hospital, located in Stockholm, Sweden, between 2016 and 2022, were analyzed with data-driven modeling. The analysis focused on the impact of dose adjustment on AEs, including neutropenia, by estimating odds ratios (ORs) using Bayesian mixed effects modeling. Covariates' effects on Eastern Cooperative Oncology Group performance status (ECOG PS) deterioration and early discontinuation of chemotherapy with cause-specific hazard ratios (csHR) were explored using competitive risk models. This approach was applied to patient cohorts receiving combinatorial first-line platinum/etoposide and second-line platinum/etoposide or platinum/irinotecan.

Results: At the end of the first-line treatment, most patients exhibited tumor regression (n=167). Patients with neutropenia had longer overall survival (hazard ratio 0.70, 95% CI 0.53-0.92). Higher etoposide dose levels were associated with subsequent occurrences of AEs (OR 5.97, 95% CI 1.41-30.5) and neutropenia (OR 3.55, 95% CI 1.03-13.3). Dose adjustment did not affect overall survival if the patient completed the 4-dose regimen treatment. With regard to second-line therapy, fewer patients completed 4 treatment cycles, and the most common reason for early discontinuation was tumor progression (n=72, 58%). Male patients (n=118) experienced fewer AEs and better first-line treatment response compared to females (csHR 0.51, 95% CI 0.25-0.90). High-risk patients (defined as ECOG PS 2 - 3 or age >75 years) with early discontinuation of therapy had survival outcomes similar to those who did not receive any therapy.

Conclusions: Our results indicate that first-line therapies may benefit from more individualized dosing strategies. It would also be beneficial to assess the risk-benefit of treating specific subgroups, including patients receiving second-line therapy. Real-world data proved beneficial for studying therapy response and risk-benefit of treating patient groups that are underrepresented in clinical trials.

Introduction

Small cell lung cancer (SCLC) is an aggressive and challenging disease to treat, mainly due to the lack of knowledge surrounding chemoresistance mechanisms [1,2]. Standard SCLC treatment consists of defined treatment lines, each comprising 4-6 cycles of platinum-based chemotherapy (cisplatin or carboplatin) with etoposide (PE) or irinotecan (IP). For patients with cancer stages I-III, this is often combined with concurrent thoracic radiotherapy. In stage IV cancer, immunotherapy with checkpoint inhibitors can be combined with chemotherapy, though with a modest median overall survival gain of 2 - 3

XSL•FO
RenderX

months in randomized controlled trials (RCTs) and with even smaller survival benefits reported in real-world studies [3,4]. However, most patients with SCLC experience relapse within 6 months after initial treatment, necessitating further therapy, though with limited survival. Real-world studies further indicate that outcomes beyond second-line therapy are poor [5], and the 5-year overall survival for patients with SCLC remains below 10% [6].

In the setting of disease relapse, the distinction between sensitive-relapse and resistance-relapse plays a crucial role in predicting survival. Patients with sensitive disease, defined by relapse occurring more than 90 days after the completion of first-line platinum-based chemotherapy, might be rechallenged with the same chemotherapy regimen administered as first-line and demonstrate significantly better survival outcomes compared to those with resistance disease, where relapse occurs within 90 days [7,8]. In this latter case, the most common approach is to change to other chemotherapy agents if the patient is still in acceptable general condition.

The rapid progression of SCLC often makes it difficult to manage [9], which results in discrepancies in observed outcomes between clinical trials and real-world patients [10]. The knowledge gap between clinical trials and the real-world underrepresented patient populations can be overcome by treatment adjustments based on clinical experience, including choice of chemotherapy agents, dose adjustments, and end-of-life care [9,11,12]. The focus of previous studies has mainly been on survival outcomes, often overlooking patients who received subsequent treatment lines after first-line chemotherapy. Further, there is a lack of studies that analyze events that occur over time in the treatment process [9,13-15].

Real-world data, here defined as health care data produced for the primary purpose of treatment in a clinical setting, offer an opportunity to retrospectively explore the impact of treatment decisions and pathways on patient outcomes, given the variability in the real-world patient population [16,17]. As such, real-world data have the potential to inform the individualization of treatments for specific subpopulations [18,19], such as patients with poor Eastern Cooperative Oncology Group performance status (ECOG PS), older patients, and patients with brain metastases who tend to be underrepresented in clinical trials [10].

However, evidence generation from real-world data is challenging because of complex clinical workflows and issues related to its secondary use, such as inherent biases in data collection and decision-making processes, and nonobservable effects [20,21]. In SCLC treatment, the nuances of dose adjustments, planned treatment pauses, assessment of response, and early discontinuation of treatment due to severe toxicity or health deterioration exemplify the intricacies involved [22,23].

The aim of this study is to describe the time dynamics of patient trajectories in a clinical patient with SCLC cohort in order to identify factors of importance for dose adjustments and survival outcomes. This approach necessitates an appropriate choice of data analysis [24]. While artificial intelligence and machine learning have shown much promise for analyzing real-world data, issues of transparency and interpretability pose a potential risk of propagating biases from the data, including not-captured information and operational confounders [10,25].

Here, the focus was on selecting transparent modeling approaches [25,26], allowing for clinical contextualization and interpretation [10,21]. Then, the analysis consisted of a combination of Bayesian [27-29] and mixed effects models [11,30,31] for studying dose adjustments and their impact on adverse events (AEs; Bayesian logistic regression [32]) and the grade of toxicity (Bayesian cumulative link ordinal regression [32]). Competitive risk Fine-Gray regression [33] was applied to compute cause-specific hazard ratios (csHR) and predict the time course of the therapy, ECOG PS deterioration, and early discontinuation of treatment, defined as discontinuation before completing 4 planned chemotherapy cycles due to AEs, or radiological and clinical signs of tumor progression.

Methods

Collection of Longitudinal Data

This study included a total of 421 patients diagnosed with SCLC at the Karolinska University Hospital in Stockholm, Sweden, between 2016 and 2022. Baseline patient characteristics such as age, sex, smoking status, TNM (tumor node metastasis) stage (*International Association for the Study of Lung Cancer, 8th Edition*), Charlson Comorbidity Index, brain metastasis (CNS), and previous cancer prior to SCLC were recorded. ECOG PS was recorded at baseline and at the start and cessation of each treatment line. Blood values, including hemoglobin, creatinine, sodium, lactate dehydrogenase (LDH), C-reactive protein (CRP), and albumin, were computed at baseline and at the start of each treatment line.

The specific drug regimen received by each patient was recorded. Body surface area (BSA) and estimated glomerular filtration rate (GFR) were recorded before the start of treatments. These two variables were used to compute the dose of chemotherapy administered for each patient (eg, GFR for carboplatin dosing using the Calvert formula [34] and BSA for etoposide and irinotecan; see Table S1 in Multimedia Appendix 1). The date and percentage of dose administered for each chemotherapy treatment were registered, including the reason for any modifications or adjustments to the administered doses, for the calculation of dose interval and intensity.

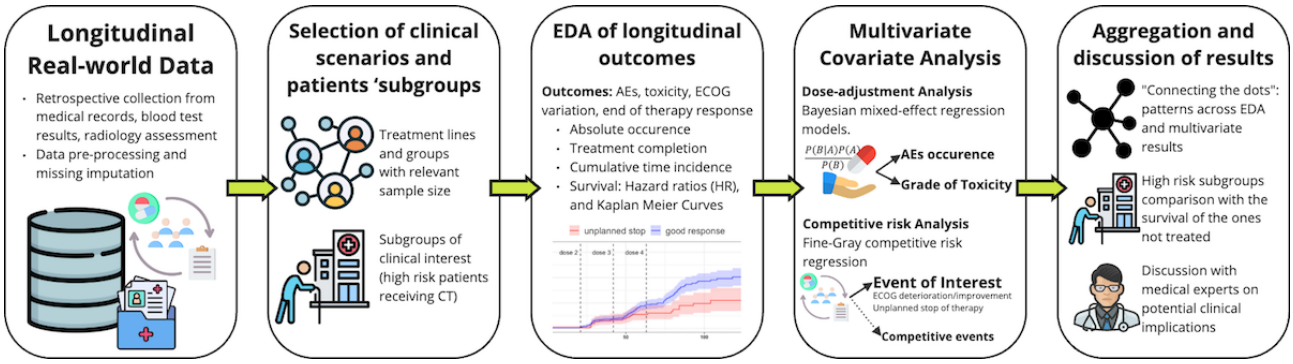
The reason for the dose reduction was recorded. AEs were classified by type and grade of severity of toxicity according to the Common Terminology Criteria for Adverse Events (CTCAE) version 5. In this work, high toxicity was defined as AEs with CTCAE G3-4 [35].

Details on radiotherapy, including the treatment indication (curative, consolidating, as a separate treatment line, or palliative) and fractionation, were reported. At the end of each treatment line, the tumoral response was assessed: complete response, partial response, stable disease, or signs of tumor progression.

The overall survival (OS) was calculated from the date of diagnosis until the patient's death or the end of the study period, whichever came first. For each treatment line, progression-free

XSL•FO
RenderX

survival (PFS) was calculated from the date of the administration of the first dose until signs of progression or death.



Analysis Description

Overview of the Real-World Data Pipeline

Several aspects of the treatment process were analyzed for each treatment line, including dose adjustments due to AEs, changes in ECOG PS from the start to the end of the treatment line, and early treatment discontinuation (stopping treatment before 4 cycles of chemotherapy due to signs of tumor progression, toxicity, deteriorating medical condition, or unwillingness of the patient to receive the treatment) versus no early discontinuation, defined as cessation of a treatment after 4 cycles of chemotherapy due to partial response or stable disease, followed by a pause.

The analytical pipeline (Figure 1) can be summarized in the following steps: selection of clinical scenarios and patient subgroups, exploratory data analysis of the longitudinal cohort, multivariate analysis of dose adjustments, multivariate analysis of competitive risks, analysis of high-risk subgroups, and aggregation and discussion of results.

Figure 1. Analytical pipeline description. AE: adverse event; ECOG: Eastern Cooperative Oncology Group; EDA: exploratory data analysis.

Selection of Clinical Scenarios and Patient Subgroups

Prior to commencing the analysis, the collected data were analyzed with a broad perspective to identify key subpopulations of interest. The cohort was explored in terms of baseline characteristics at the first-line treatment decision and the administered chemotherapy lines using summary statistics and Sankey flows for the subsequent treatment lines. Treatment lines with relevant sample size (cohort ≥20 individuals [36]) were detected for the next analysis steps. Moreover, special subgroups of patients receiving treatment but with highly fragile conditions (underrepresented in RCTs) or subjected to a high risk of poor survival outcomes were selected. The continuous covariates with high skewness were log-transformed before starting the analysis. Furthermore, in case of missing values, for each treatment line analysis, values were imputed using the machine learning algorithm MissForest [37]. MissForest was chosen because it is particularly effective for datasets with mixed-type variables and complex interactions, maintaining low imputation errors and preserving relationships among variables even with high percentages of missing information [38].

Exploratory Analysis of the Longitudinal Cohort

CTCAE G3-4, ECOG PS change at the end of treatment, and early discontinuation of therapy were assessed by exploring absolute count and relative percentages. Hazard ratios (HRs) and Kaplan-Meier curves were computed to estimate the impact on survival outcomes [39]. The cumulative incidence-time curves of dose reduction due to AEs, separating patients with good therapy response and the ones with unplanned stops, were analyzed [40]. Moreover, the survival outcomes were estimated by stratifying patients by those receiving 4 doses (full course) without dose reduction, patients who received 4 cycles but with dose reduction, and patients who received fewer than 4 cycles.

Multivariate Analysis of Dose Adjustments

For the dose adjustment analysis, the association between dose reductions caused by an AE and the grade of toxicity was explored. This was done by training 2 Bayesian mixed-effect regression models: a binary logistic regression for the AE incidence [32,41] and a cumulative link regression for the grade of toxicity modeled as an ordinal outcome [32,42]. The priors used in these Bayesian models were the empirical ones computed from the analyzed cohort. The longitudinal variables (dose level, dose interval, and their mutual interaction) were analyzed with respect to the key baseline characteristics. The Bayesian logistic regression can be summarized as follows:

$$Y_{AE}=\log[P(AE_{i+1})/(1-P(AE_{i+1}))]=b_0+b_D D_i+b_{\Delta t}\Delta t_i+b_{D\Delta t} D_i\Delta t_i+\sum_{n=1}^{x} b_n x_n+\sum_{m=1}^{} \text{random}_m$$

where $P(AE_{i+1})$ is the probability of a dose reduction due to an adverse event at dose i+1 caused by the ith dose D_i, with interval Δt_i between the doses, x baseline covariates with b its estimated regression coefficient, and random effects (unexplained individual variability term). The cumulative link ordinal Bayesian regression can be summarized as follows:

$$Y_{GT}=\log[P(GT_{i+1}\le j)/(1-P(GT_{i+1}\le j))]=b_{0j}+b_D D_i+b_{\Delta t}\Delta t_i+b_{D\Delta t} D_i\Delta t_i+\sum_{n=1}^{x} b_n x_n+\sum_{m=1}^{} \text{random}_m$$

With similar notation for the Bayesian logistic regression, where $P(GT_{i+1}\le j)$ is the probability of grade of toxicity lower than or equal to j (with j=0,..., 4), and b_{0j} is the baseline intercept for the jth level. The Bayesian models were trained by running 4 independent Markov chain Monte Carlo simulations with 2500 iterations for each chain. The convergence of the chains was assessed through trace plots, density plots, Gelman-Rubin statistics, and estimates of the Markov chain effective sample size. In case of lack of convergence, the model was retrained by increasing the iterations (see Multimedia Appendix 2). The odds ratios (exponentials of the coefficients b) with the 95% CIs were estimated for all the covariates. The random effects

XSL•FO
RenderX

were estimated for the individual patients, administered doses, and the dose interval. This allowed for individual differences and the time-dependent nature of the dose variables to be considered.

Multivariate Analysis of Competitive Risks

For the variation of ECOG PS at the end of the treatment line and the early discontinuation of the therapy, a competitive risk time-to-event model was developed. Fine-Gray competitive risk regression was used with the outcomes [32], the PFS associated with the investigated treatment line, and the event of interest to estimate the distributed HRs of the covariates. The model can be summarized as follows:

$$hj(t)=h0(t)exp(b1x1+\ldots+bmxm)$$

where h_j is the cause-specific hazard of the event of interest, h_0 is the baseline hazard, and the exponential of the mth coefficient b is the distributed hazard ratio of the mth covariate x. The csHRs were computed for ECOG PS deterioration/improvement (in competition with unchanged PS or improvement and deterioration) and the early discontinuation of the therapy in competition with the planned stop of treatment due to partial response or stable disease. Here, we indicate the OS or PFS Cox hazard ratios with HR, csHR for the cause-specific hazard ratios computed with the Fine-Gray model, and OR for the odds ratios obtained by the Bayesian mixed effects models.

High-Risk Subgroups Analysis

Multivariate analysis was performed for the subgroups of patients with detected fragile conditions receiving treatment. The OS of these patients was compared to the OS of patients with similar characteristics that did not receive chemotherapy. This allowed the comparison of survival outcomes of patients with poor responses with the ones who did not receive chemotherapy, thus comparing the benefits and risks of the received treatment.

Aggregation and Discussion of Results

The considerations obtained during the exploratory data analysis are discussed together with the results obtained from the multivariate analysis. This allows for creating a connection between covariate effects on the longitudinal outcomes that can impact the OS or treatment decision. Moreover, the high-risk subgroups of patients are compared with the ones that did not receive treatment stratified by the significant covariates or longitudinal outcome discovered during the multivariate subgroup analysis to assess the risk-benefit of receiving treatment. Finally, the overall outcomes are discussed with the clinical experts regarding the potential clinical implications.

Ethical Considerations

The study received ethical approval from the Swedish Ethical Review Authority (approval number: 2023-07389-01). Patients still alive at the time of data collection signed a written informed consent. The data was anonymized prior to use, and the approval covers secondary analysis without additional consent. Research was performed in accordance with the Declaration of Helsinki.

Results

Selection of Clinical Scenarios and Patient Subgroups

The cohorts taken into consideration were the patients receiving PE as first-line therapy and the patients receiving either rechallenge with PE or IP as second-line therapy. The analysis included stage III-IV patients and excluded patients with ECOG PS of 4 (n=29). Figure S1 in Multimedia Appendix 3 reports the inclusion/exclusion flowchart of the cohort. In terms of toxicity, only neutropenia was analyzed in detail in this study because it was the most commonly reported treatment-related AE (see Table S2 in Multimedia Appendix 1). Figures S1-S4 in Multimedia Appendix 3 show Sankey flows of the subsequent treatment lines and the dose adjustments.

The identified high-risk subgroups included the first-line patients receiving PE with ECOG PS 2‐3 (n=114), with CNS metastases (n=42), over the age of 75 years (n=99), and with stage IVB (n=135). These subgroups were selected since they are known to be either underrepresented in RCTs or are associated with relatively poor OS compared to the general population [10]. The age threshold was chosen to define a sharp subgroup of older patients from the cohort. The multivariate analysis was not performed for patients with CNS metastases due to wide confidence intervals of ORs and csHRs caused by the small sample size of the subgroup (n=42).

Laboratory covariates referred to throughout the results include hemoglobin, sodium, LDH, CRP, albumin, creatinine, BSA, and GFR. For some individuals, blood values and lab tests were missing (neutrophil counts 44.9%, LDH 22.9%, and CRP 18.3%). The percentages of missing values for neutrophil counts at the start of the treatment lines were as follows: 50.9% in the first-line PE, 34.8% in the second-line PE, and 39.3% in the second line of IP. The high percentage of missing neutrophil values was due to these not being routinely measured at baseline before the initiation of chemotherapy treatment. Therefore, these values were imputed using the MissForest algorithm as described in the Methods section.

A summary of the analyzed cohorts for the first- and the second-line is reported in Table 1.

Exploratory Survival Analysis

In the first-line setting, chemotherapy doses were reduced in 127 out of 289 (43.9%) patients, mainly due to any grade of neutropenia (n=89) and AE G3-4 (n=104) (Table 1). Similar figures were observed for the second-line setting (PE n=69, IP n=56), with neutropenia mainly associated with PE treatment (n=26). At the end of the first-line setting, 179 (out of which 167 partial responses) patients did not experience early discontinuation of treatment. Early discontinuation of therapy happened in 110 cases due to clinical (n=48) or radiological (n=23) signs of disease progression. In the second-line setting, early discontinuation (n=72) was more common than completion of treatment (n=52).

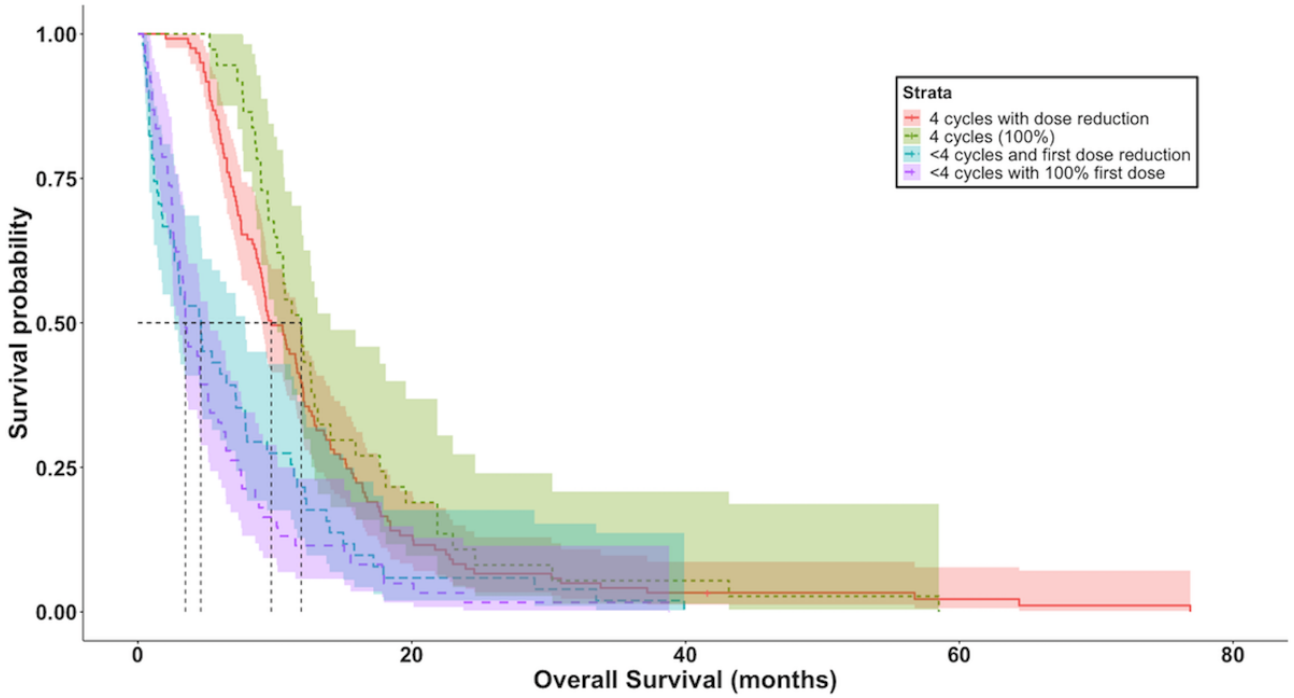

Figure 2 shows the cumulative incidences of dose adjustment due to neutropenia. The incidence was higher for patients in both lines who achieved treatment completion without premature discontinuation. In the first-line scenario, occurrences of neutropenia and other AEs were associated with more favorable OS (HR 0.70, 95% CI 0.53-0.92 and HR 0.72, 95% CI 0.57-0.95, respectively). In the second-line scenario, only neutropenia was associated with better OS (HR 0.51, 95% CI 0.33-0.80). OS of patients completing 4 cycles of first-line treatment was not affected by dose reduction due to AEs (HR 0.85, 95% CI 0.59-1.23; reference: patients completing 4 cycles without dose reduction) (Figure 3).

Figure 2. Cumulative incidences of dose reduction (%) due to neutropenia and other adverse events (AEs) for the first- and the second-line therapy. The curves are stratified by early discontinuation of chemotherapy (red curves) and therapy response (CR: complete; PR: partial; SD: stable disease) (blue curves). Dotted lines correspond to the 3-week intervals corresponding to planned administration of the second, third, and fourth doses. 1L: first-line therapy; 2L: second-line therapy.

XSL•FO
RenderX

Figure 3. Kaplan-Meier curves for overall survival of patients receiving first-line treatment stratified by administered doses. Patients receiving fewer than 4 doses experienced early discontinuation of the therapy.

Patients with early discontinuation of therapy in the first-line setting showed an expected markedly worse OS compared to patients who completed 4 cycles of chemotherapy (HR 4.27, 95% CI 3.27-5.57). Similarly, worse OS was observed for patients with early discontinuation during second-line therapy (HR 2.21, 95% CI 1.50-3.27). Moreover, ECOG PS deterioration was significantly associated with a poorer prognosis, even if this was only seen in the first-line setting (HR 2.05, 95% CI 1.54-2.72; reference: stable ECOG PS). These patients resulted in early discontinuation of therapy, of which 45 resulted in PFS less than 3 months (median 61, IQR 43-68 days).

Patients receiving PE as a second line completed the 4-dose cycle more often than the IP patients (73.36% vs 41.07%, respectively). Interestingly, the PFS of PE patients was similar compared to patients receiving IP (HR 0.84, 95% CI 0.57-1.23). However, as expected, second-line PE patients showed better OS (HR 0.51, 95% CI 0.33-0.78) compared to the ones receiving IP, when overall survival was computed from the start of the second-line treatment.

Multivariate Analysis

First-Line Therapy PE

Tables 2 and 3 detail the results of the dose adjustment and the competitive risk analysis for the first-line therapy. All the longitudinal variables presented significant variability (see Table S3 in Multimedia Appendix 1). Interindividual variability was higher than interoccasion variability. This high variability combined with the presence of patients with little longitudinal information (ie, patients receiving only one or two doses before interrupting the therapy) impacted some of the estimates resulting in large intervals.

[a]csHR: cause-specific hazard ratio.

[b]ECOG PS: Eastern Cooperative Oncology Group performance status.

[c]TNM: tumor node metastasis.

The results show a strong association between higher etoposide dose levels and the subsequent occurrence of AEs (OR 5.97, 95% CI 1.41-30.5), specifically neutropenia (OR 3.55, 95% CI 1.03-13.3). Early discontinuation of therapy was associated with higher LDH levels (csHR 1.44, 95% CI 1.14-1.82), baseline ECOG PS 2 (csHR 2.93, 95% CI 1.31-6.52), and baseline ECOG PS 3 (csHR 4.15, 95% CI 1.68-10.20).

Males showed less probability of early discontinuation of the first treatment line compared to females (csHR 0.51, 95% CI 0.29-0.90). As did subgroups of patients with M0 and those receiving consolidating radiotherapy (n=29) (Table 3). Similarly, patients with M1a status regardless of T and N stage were associated with ECOG PS improvement (Table 3).

Second-Line Therapy PE-IP

Results of the multivariate analysis for the second-line treatment are reported in Tables S4 and S5 in Multimedia Appendix 1. Due to the large confidence intervals of the ORs, the ORs are reported on a log scale.

A higher dose of platinum was associated with a higher incidence of AEs and a higher risk of neutropenia. Patients receiving IP experienced fewer AEs. Male patients were less likely to experience AEs and neutropenia. However, male patients were associated with worse PFS (HR 1.62, 95% CI 1.10-2.38) due to early discontinuation of the second line, regardless of PE or IP (n=44). Higher sodium levels were instead associated with lower risk of neutropenia and ECOG PS deterioration. Patients with TNM-M M1a had a higher probability of ECOG PS deterioration and more AEs. CNS metastasis was linked to increased risk for ECOG PS deterioration and early discontinuation of therapy.

High-Risk Subpopulation Analysis: To Treat or Not to Treat?

As defined at the beginning of the Results section, high-risk subgroups included patients with ECOG PS 2 - 3, aged ≥75 years, and TNM stage IVB disease. Multivariate analyses were performed separately within each subgroup to identify predictors of toxicity, ECOG PS variability, early discontinuation, and survival outcomes.

The results of these analyses are reported in Tables S6-S11 in Multimedia Appendix 1. Table 4 summarizes the significant covariates for each subgroup. Similar to the second-line therapy analysis, the ORs were reported in log scale due to the wide confidence intervals.

Table . Qualitative summary of statistically significant covariates identified in the multivariate analysis for high-risk subgroups[a].

High-risk subgroup	Adverse events occurrence	Neutropenia	ECOG PS[b] deterioration	ECOG PS improvement	Early discontinuation
TNM-IVB[c]	Albumin (–) Neutrophil counts (–)	Dose × interval etoposide (+) BSA[d] (–)	Neutrophil counts (+)	Neutrophil counts (–) LDH[e] (+)	LDH (+) Creatinine (+)
ECOG PS 2‐3	Etoposide 10 days regimen (+) Neutrophil counts (–) Age ≥75 years (+) Male (–)	Dose × interval platinum (+)	Neutrophil counts (+)	Neutrophil counts (–) LDH (+)	Etoposide 10-days regime (+) TNM-N0 (–) TNM-M0 (+) HB[f] (+) LDH (+) CRP[g] (+) CCI[h] (+)
Age ≥75 years	Male (–) ECOG 3 (–) CNS[i] (–)	Dose × interval etoposide (+) Weight (–) Male (–) TNM-N0 (+) TNM-M1a (+)	TNM-N2 (–)	——	ECOG 2 (+) TNM-N0 (–) LDH (+)

[a]For each outcome, covariates with statistically significant associations are shown. "+" indicates odds ratio (OR) or cause-specific hazard ratio (csHR) with a direct association with the studied outcome. "–" indicates OR or csHR with an inverse association. Detailed results are reported in Tables S6-S11 in Multimedia Appendix 1.

[b]ECOG PS: Eastern Cooperative Oncology Group performance status.

[c]TNM: tumor node metastasis.

[d]BSA: body surface area.

[e]LDH: lactate dehydrogenase.

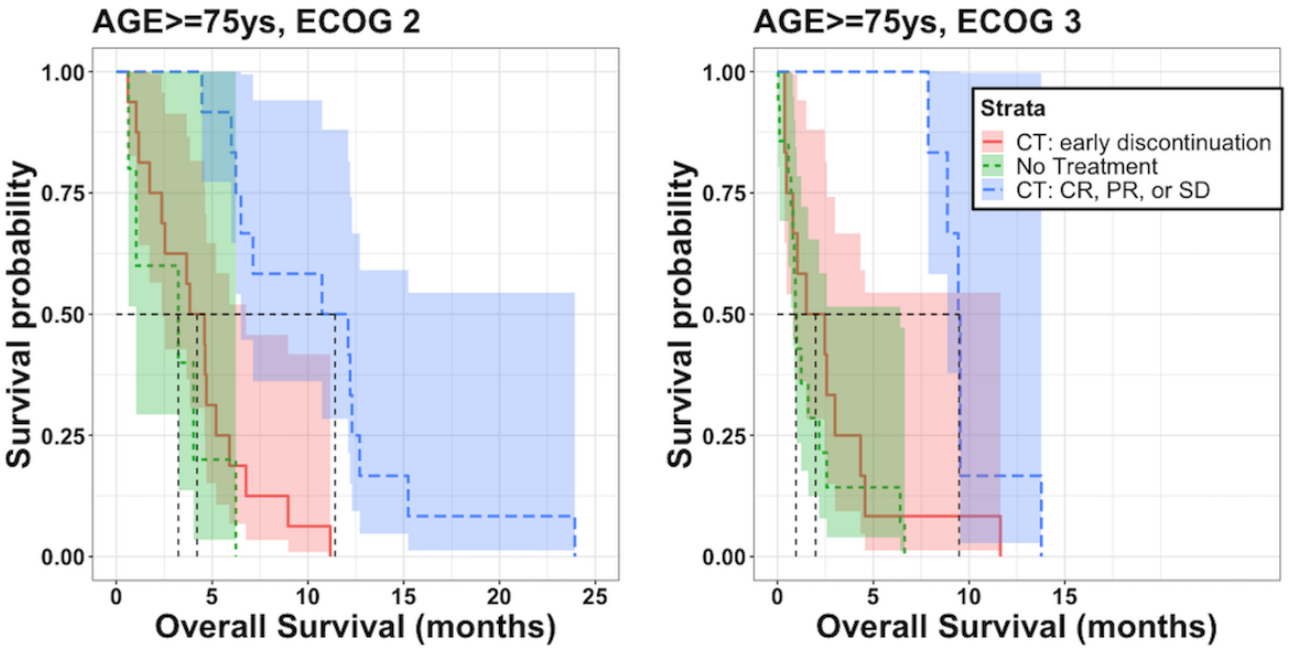
[f]HB: hemoglobin.

[g]CRP: C-reactive protein.

[h]CCI: Charles Comorbidity Index.

[i]CNS: brain metastasis.

Results observed in the subgroup analyses that aligned with the overall cohort were the consistent association of elevated LDH and ECOG PS 2‐3 with an increased risk of early discontinuation of therapy across all subgroups.



In patients with TNM stage IVB and in patients aged ≥75 years, a higher etoposide dose was associated with an increased risk of neutropenia, while older male patients (aged ≥75 years) and male patients with ECOG PS 2‐3 were associated with a lower risk for AEs. For patients with ECOG PS 2‐3, the platinum dose was associated with an increased risk of neutropenia, while the etoposide 10-day regimen was associated with an increased risk of AEs.

The comparison with patients who did not receive chemotherapy showed that, although the occurrence of AEs was associated with longer survival in the overall cohort, patients with ECOG PS 2‐3 or aged ≥75 years who experienced early discontinuation had HRs closer to those of the nontreated subgroup rather than to those patients who achieved disease control (Table S12 in Multimedia Appendix 1).

When further stratifying the high-risk subgroups using the significant variables reported in Table 4, the subgroups showed similar survival to the nontreated subgroup. For example, Figure 4 shows the Kaplan-Meier curves of the comparative analysis for patients with ECOG PS 2‐3 and age ≥75 years.

XSL•FO
RenderX

Figure 4. Kaplan-Meier curves of patients older than 75 years with ECOG performance status (PS) 2 - 3 stratified by good response to first-line chemotherapy, early discontinuation of treatment, and patients who did not receive chemotherapy. CR: complete response; CT: chemotherapy; ECOG: Eastern Cooperative Oncology Group; PR: partial response; SD: stable disease.

Discussion

In this study, we analyzed a longitudinal real-world cohort of patients with SCLC and their treatment pathways. The analysis allowed the study of the relationships between treatment decisions, phases of progression of disease, occurrence of AEs, and overall survival. To the best of our knowledge, this is one of the most detailed longitudinal datasets of SCLC real-world treatment decisions. This type of data aims to add novel insights on dosing effects over time, the emergence of toxicity, and the decision points relative to the clinical outcomes.

The improved prognosis of patients who experienced neutropenia aligns with previous findings [43,44]. The analysis allowed the investigation of treatment-related AEs in relation to the efficacy of therapy or to detect when this was instead linked to deterioration of the patient's conditions. For example, the cumulative incidence curves of AEs stratified by responding patients against early discontinuation of the therapy in Figure 2 showed the role of neutropenia when the time windows of AEs may overlap with the efficacy of treatment (Figure 3).

We identified significant ORs relating to the dose of etoposide and increased occurrence of AEs. The analysis showed a similar OS for patients receiving 4 doses during first-line therapy, regardless of whether the patient had a dose adjustment/reduction or not (Figure 3). A worse prognosis was observed when there was a deterioration in ECOG PS or early discontinuation of treatment.

We interpret our findings as indicating that the occurrence of neutropenia reflects a longer duration of treatment exposure, rather than being a causal factor for improved survival. Patients who completed all 4 treatment cycles—often at reduced doses—demonstrated better outcomes than those receiving fewer cycles at higher doses. This is supported by the higher incidence of neutropenia among patients with treatment response, suggesting that extended exposure, not intensity, is the key contributor to therapeutic benefit.

SCLC treatment effects vary widely between individuals. This could suggest the need to identify key covariates and clinically relevant subgroups that might inform a more tailored dosing, or in some cases, guide decisions against treatment altogether, in order to improve survival while avoiding AEs in patients unlikely to benefit from therapy [11,12,45]. Indeed, etoposide dose calculation is based on BSA, which has been shown to present such limitations [46]. Similar analyses could be done for the second-line therapy. In fact, only a few patients received the full expected dose without dose reduction, and the platinum dose and PE treatment were strongly associated with AEs.

ECOG PS 2 - 3 and elevated LDH serum levels are known to be prognostic factors of worse OS in SCLC [9,47]. Our results, obtained by the careful analysis of the longitudinal data line by line with the clinical experts, added a new insight by showing their role in predicting early discontinuation of treatment, which was associated with significantly poorer OS.

Another finding was the high probability of a favorable response to first-line therapy in male patients, along with their lower likelihood of experiencing AEs (Tables 3 and 4; Tables S4 and S5 in Multimedia Appendix 1). Moreover, when stratifying older patients by sex, women who developed neutropenia exhibited survival rates comparable to those in the same subgroup who did not receive chemotherapy. A possible explanation is that female patients have historically been underrepresented in clinical trials [10,48,49]. In addition, in the second-line setting, the worse PFS and high frequency of early discontinuation for male patients might suggest the need for further studies regarding different therapy responses for males and females.

The high-risk subgroup analysis allowed detection of key groups of patients such as older patients with poor ECOG PS, where

XSL•FO
RenderX

an eventual poor response to therapy is associated with similar survival as compared to patients not receiving chemotherapy. This finding is clinically relevant, as it highlights the importance of balancing the benefit and risk of treating such fragile patients and may help clinicians avoid overtreating this vulnerable population. These outcomes underline the potential role that real-world data may fill in providing evidence on treatment in groups of patients that are underrepresented in clinical trials [10].

The design of the analytic pipeline relied on the consideration that the data should be analyzed using models capable of capturing the complexity of the patient treatment pathways without sacrificing interpretability (such as black box machine learning models [25]). We believe that this is an important consideration when approaching real-world data. In fact, the discussions with the clinicians on the obtained results allowed the assessment of the validity of the results, the detection of potential inherent bias, and confounders related to operations and nonobservable effects not captured from the data. For example, it was observed that the 10-day dosing regimen of etoposide resulted in poorer survival. At the time of the present analysis, this dosing regimen had, however, already been abandoned due to toxicity caused by the limited time for patients to recover between the cycles (Tables 2 and 3).

The study had several limitations. The reason for missing values was not at random for some of the variables, thus introducing some biases in the results. Particularly for baseline neutrophil counts, where missing observations were high across all treatment lines. This bias is partially mitigated by the MissForest algorithm because it is a nonparametric model, and the algorithm does not need an explicit assumption about the missing mechanism (ie, missing at random) [38].

Further, these variables were available only at the start of the treatment line, meaning that we were not able to analyze their time profiles (ie, neutrophil counts over time between doses). Moreover, it should be stated that AEs are not always described in medical notes, thus introducing investigator bias in the collected data.

Another limitation was the sample size of the high-risk subgroups and patients receiving the second-line treatment, resulting in higher estimates of variability of the outcomes as compared to the first-line treatment cohort. In detail, the odds ratios of the mixed effects models resulted in wide confidence intervals. The reason for this high variability in outcomes could be that these small cohorts were also associated with fewer longitudinal observations per patient (the number of administered doses). Increasing the sample sizes of these subgroups in the future by collecting more data will help to provide more precise estimates of the covariate effects. Moreover, patients receiving more than two lines were not included in the multivariate analysis, as this was only observed in a few instances.

The median age of our population was 72 years, yet we chose 75 years to better isolate a more vulnerable subset of patients by moving further from the median. This aligns with existing studies that identify this age group as particularly fragile, often requiring specialized considerations in treatment planning [50]. Future studies exploring different criteria and strategies to separate older patients would be required.

This was a single-center study, and expanding the analysis by including other SCLC cohorts from other centers would be beneficial. A comparison of the dose adaptation and the follow-up processes in clinical trials would be of high importance [10]. A future aspect to explore would be to expand the collection of longitudinal real-world data, designed similarly to the study presented here, in larger initiatives such as multicenter studies or cancer registries [51-53], and recent new proposed therapies (ie, durvalumab after chemoradiotherapy [54], tarlatamab/lubri in second- and third-line settings [55], and immune-oncology therapies [9]).

This study could inform the design of future works, such as multistate models of patient survival in function of different therapies and events [56,57], or model-informed precision dosing models to explore individualized treatment and dosing to reduce the risk of AEs (eg, neutropenia) without compromising the efficacy of the treatment in terms of survival outcomes [58,59]. Furthermore, the outcomes from the approaches presented herein can inform more reliable future analyses using, for example, machine learning algorithms suitable for modeling longitudinal processes, such as physics-based neural networks [60].

A continued fruitful collaboration between clinical and technical experts when analyzing complex data and contextualizing the clinical processes, as we did in this work, would enhance the impact of real-world data in clinical practice and clinical drug development.

Abstract

Background: Delayed cancer diagnosis leads to poorer outcomes. Unintended weight loss (UWL) is a nonspecific symptom associated with cancer and other serious conditions, which can make it complex to identify the underlying cause. Clinical decision support systems (CDSSs) can provide evidence-based recommendations to facilitate timely investigation and diagnosis.

Objective: This study aimed to pilot the implementation of a CDSS for improving early cancer detection in primary care patients with UWL.

Methods: Five practices reviewed patients identified by the UWL CDSS. Staff were interviewed on the acceptability and feasibility of the CDSS. Interviews were analyzed thematically using 2 relevant frameworks: the acceptability of health care interventions and the sociotechnical model for evaluation of digital interventions framework. Clinical audits assessed the correct identification of UWL, follow-up rates, and patient characteristics.

Results: Of 60 patients identified by the CDSS as potentially having UWL, 36 (60%) had true UWL. Among the misclassified cases, most patients (16/55, 30%) were intentionally trying to lose weight; this intention was documented as free text in the clinical notes for 98% (58/60) of patients and in a structured field for only 20% of patients. Of the 36 patients, 5 (14%) were actively recalled by their practices for further follow-up; the others (31/36, 86%) were not recalled, as most were deemed already under appropriate follow-up. By 6 months, 94% (34/36) of the cohort had received follow-up care regardless of whether they had been formally recalled. One-third (12/36, 33%) of patients had no additional symptoms, while 36% (13/36) had recorded additional abdominal symptoms. Mental health conditions accounted for 19% of diagnoses linked to UWL consultation. Practice staff were generally receptive to the UWL CDSS concept. It was particularly appreciated by practices with strong quality improvement processes and prior CDSS experience. A high proportion of misclassified patients, poor workflow integration, and conflicting patients' agendas were cited as implementation barriers.

Conclusions: Our study revealed challenges and potential benefits of implementing a CDSS for identifying patients with UWL at risk of cancer in primary care. While integration issues and misclassification of patients were noted, high rates of follow-up care were observed regardless of the CDSS. These high follow-up rates prompt consideration of whether they reflect Australian

XSL•FO
RenderX

primary care and whether a CDSS with these characteristics is the most appropriate approach to support early cancer detection. Future research should focus on improving CDSS integration with existing workflows, enhancing correct identification through access to clinical notes and the use of more sophisticated digital methods (eg, AI). These findings highlight the potential of CDSS in improving patient care and the complexities involved in their successful implementation.

KEYWORDS

digital health; primary care; cancer early detection; general practice; clinical decision support

Introduction

Early detection of cancer is crucial for improving patient outcomes, offering several significant benefits. It can substantially enhance a patient's chance of survival, broaden the range of available treatment options, and contribute to an improved quality of life [1,2]. Moreover, timely diagnosis can help reduce the overall burden on health care systems by potentially decreasing the complexity and cost of treatments required for advanced-stage cancers [3]. General practice plays a pivotal role in this early detection process, often serving as the first point of contact for patients experiencing new signs or symptoms of cancer [4,5]. However, the diagnosis of cancer can be particularly challenging in many cases, given the nonspecific nature of presenting symptoms. These symptoms can often be associated with a number of other, more common and less severe conditions, making it difficult for general practitioners (GPs) to immediately identify potential malignancies [6].

Unintended weight loss (UWL) is an example of a nonspecific symptom associated with cancer. While UWL can also be associated with various benign conditions, including depression, thyroid disorders, and gastrointestinal diseases, it is also a potential indicator of several cancer types [6,7]. The diagnostic complexity is compounded by the fact that UWL can initially occur in isolation, without accompanying clear symptoms that might point toward a specific underlying cause [8]. This absence of additional clinical indicators makes it particularly challenging for health care professionals to determine the optimal route of investigation. The nonspecific nature of UWL as a symptom underscores the need for a comprehensive and systematic approach to patient evaluation, potentially incorporating advanced diagnostic tools and risk assessment models.

Given the diagnostic complexity of nonspecific symptoms' association with many cancers, clinical decision support systems (CDSSs) are being developed for use in general practice [9]. These tools are designed to assist GPs in making more informed decisions by integrating algorithms underpinned by patient data and clinical guidelines [10]. In the context of early cancer detection, CDSS can potentially streamline the diagnostic process by identifying patients who require further investigation or referral [11]. For patients presenting with nonspecific symptoms such as UWL, these tools could be particularly valuable in stratifying risk and supporting decision-making.

Studies evaluating CDSS in practice have demonstrated increased adherence to guidelines and successful diagnostic support [11]. However, the majority of developed tools fail to achieve widespread implementation, and those that are implemented often face low uptake rates [12]. While there are significant opportunities to support early cancer detection, designing tools that are useful, acceptable, and seamlessly integrated into primary care workflows is a complex, multistep process. This process necessitates continuous input and refinement from end users throughout the development cycle to ensure relevance and usability [13,14]. This study aimed to evaluate a novel CDSS designed for the early detection of cancer in patients presenting to general practice with UWL. Specifically, the study sought to assess whether the tool was acceptable to practitioners, met the diverse needs of general practice, and effectively supported the delivery of high-quality, evidence-based care.

Methods

Design

This study used mixed methods to evaluate the implementation of a complex CDSS for patients with UWL, using patient data collected in clinics through interviews with participating general practices and an electronic health record (EHR) audit.

The Future Health Today Tool

Future Health Today (FHT; The University of Melbourne) is a software platform that has been developed for use in general practice, streamlining the identification and management of chronic diseases. While the development of the tool has been described elsewhere, it underwent an extensive co-design process with GPs and consumers [15,16]. FHT is integrated with the EHR and has 2 core components: First, it is a CDSS that provides proactive, guideline-based recommendations at the point of care; the second component is a web-based portal, which supports quality improvement (QI) activities in general practice, has the ability to audit and recall patient groups within the practice population, and provides access to education and resources.

The UWL Module

The FHT tool supports a wide range of conditions, and different modules are developed for use in FHT [17,18]. This study explores the use of the FHT UWL module, which flags patient records with UWL indicated in the EHR in the past 6 months. Development of the UWL module was extensive, beginning with the development and validation of phenotyping and risk prediction algorithms to identify patients with "unintended weight loss" terms in structured EHR fields (reason for visit, diagnosis, and prescriptions) while also excluding those with indications of intentional weight loss. Additional exclusion

XSL•FO
RenderX

criteria, including recent cancer diagnoses, intentional weight loss reasons (eg, bariatric surgery or weight loss prescriptions), and/or increasing weight measurements, were further added [19]. We did not use actual weight loss as an inclusion criterion, given the low prevalence of weight measurements in Australian general practice data [20]. Algorithm criteria (age, sex, blood test results, and smoking status) determined the patient's risk profile and provided the recommendation delivered to the GP.

The phenotyping and validation process and the risk profile calculations have been described elsewhere [19]. Briefly, after applying inclusion and exclusion criteria to identify patients with UWL, the module provided 3 types of recommendations according to cancer risk:

1. For patients with low cancer risk (<2%): a recommendation to take new weight measurements and a reminder of the most common differential diagnosis according to age and sex
2. For patients with moderate to high risk (>2%) and absent or normal blood test results: recommendation to ask for symptoms and order (additional) pathology tests
3. For patients with moderate to high risk (>2%) and abnormal blood test results: recommendations to follow up with further testing (imaging, scopes, and referrals)

Figure 1 shows a simplified diagrammatic representation of the rule-based algorithm rules.

The content and wording of the recommendations and the supporting resources were developed with input from GP and consumer and were informed by evidence from a previous scoping review [21]. An example of a recommendation as it appears in the EHR is shown in Figure 2.

Figure 1. Unintended weight loss (UWL) module algorithm rules and recommendations. Black boxes represent the algorithm processes; green boxes are relevant recommendations; blue box provides further relevant extra information; red boxes represent no further recommendations. Alb: albumin; AP: alkaline phosphatase; CRP: C-reactive protein; Hb: hemoglobin; PLT: platelets; SR: sedimentation rate.

Study Participants, Recruitment, and Implementation

Recruitment of general practices occurred by approaching practices participating in the FHT program (ie, practices that already had FHT installed). Practice managers and/or practice owners were contacted and provided with study information. All recruitment documentation was created with assistance from the FHT Consumer and General Practice Advisory Group. In agreeing to participate in the study, practices were required to review a list of patients with UWL, nominate 1 person from the practice to participate in an interview, and partake in a clinical audit.

We invited, via email, practices that had at least five patients identified by the UWL algorithm. Practices recruited to participate in the pilot UWL implementation study had the FHT UWL module switched on for at least 6 months. At study initiation, the FHT team created a list of patients (also referred to as "cohort") who met the criteria for UWL, which could be accessed via the FHT web-based portal. Practices were also offered a 30-minute, Zoom (Zoom Communications, Inc)–based training session once the module was switched on. Each practice nominated an appropriate person (eg, GP, general practice nurse, and QI lead) or team of people to review the cohort of patients with UWL. The purpose of the cohort review was to determine which patients should be recalled for further follow-up or whether the recommendations should be deferred. After review of the patient list, practices were asked to fill in a log with the kind of action performed (eg, patient recalled or deferred) and the reasons for this action (eg, weight loss was intentional, patient is already being followed up, and patient requires further investigation). After the cohort review was complete, practices were invited to use FHT as they chose for the remainder of the study.

Data Collection

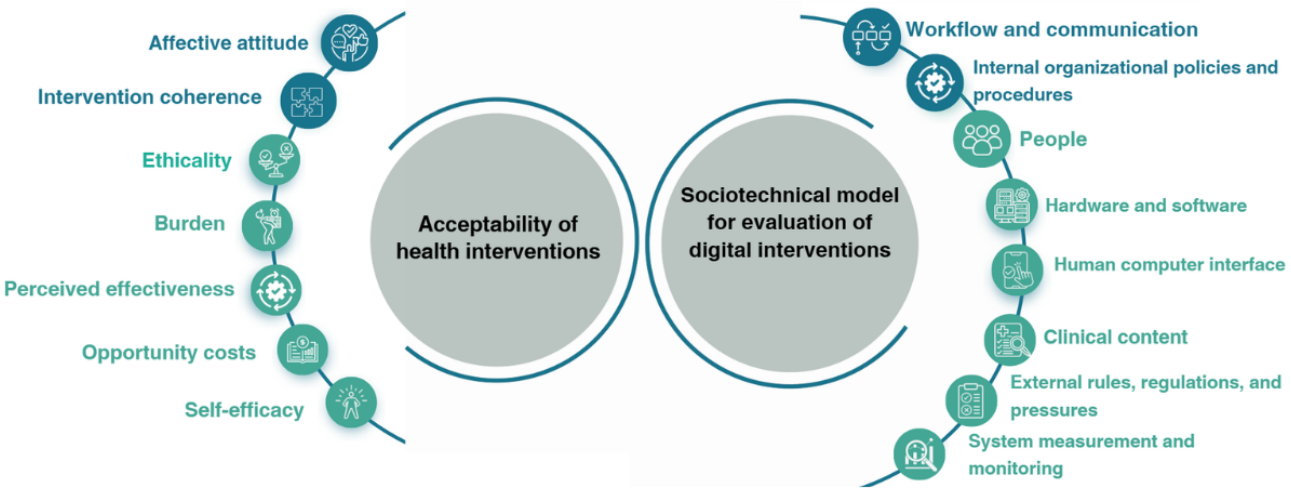
Interviews

One month after the implementation of the UWL module and completion of the cohort review, practice staff who reviewed the cohort of patients flagged with UWL were contacted to participate in an interview. At least one person from each general practice participated in a semistructured interview conducted via Zoom. Interview schedules (Multimedia Appendix 1) were informed by relevant literature and prior qualitative work conducted as part of the FHT program [22,23]. In the interview, staff were asked about the FHT technology generally, their experience using the UWL module to review and recall patients, and the UWL recommendations. The interviews explored the themes of implementation (including barriers and facilitators to use), the content and clinical appropriateness of the UWL recommendations, and usability, acceptability, and feasibility of the module in the longer term. All interviews were audio recorded for analysis and were transcribed using Otter.AI. JMG conducted the interviews. Interview duration was 30 to 45 minutes.

JMG is a female mid-career researcher and academic GP with experience in qualitative research. SC is an early-career researcher with expertise in FHT and qualitative research. JMG did not have a previous relationship with any of the interviewees. SC had previous contact with 2 practice staff from 1 practice as a research coordinator for a previous study using FHT. We did not provide information regarding personal goals or additional reasons for doing the research other than the description in the plain language statement. Participants were not asked to review interview transcripts or study findings, and no repeat interviews were conducted. Field notes were not recorded during or after the interviews. To ensure methodological rigor and transparency, the presentation of findings adhered to the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Checklist 1).

Clinical Audits

An EHR audit was conducted approximately 1 to 4 months after the creation and review of the UWL cohort. EHR data of patients who were flagged by the FHT platform as having UWL were audited by a clinical researcher using a data extraction template. The extraction template was piloted and refined by clinician researchers in the team before data collection (Multimedia Appendix 2). Data extracted from the EHR included age, sex, details on the record of UWL and all UWL-related free text, prescriptions, laboratory results, referrals, images, weight measurements, and any UWL-related follow-up and were entered into the REDCap platform [24]. The time frame of extracted data included the 6 months prior to the initial UWL presentation until the date of the clinical audit. Due to the remoteness or location of participating practices, clinical audits were conducted using TeamViewer, a secure remote access software hosted by the University of Melbourne.



Data Analysis

Interviews

Interview transcripts were uploaded into NVivo 14 (Lumivero) and thematically analyzed independently by 2 researchers (JMG and SC) [25]. We used deductive thematic analysis using 2 overarching frameworks in the analysis: acceptability of health care interventions [26] and sociotechnical model for evaluation of digital interventions framework [22] (Figure 3).

XSL•FO
RenderX

Figure 3. Frameworks used in the analysis of semistructured interviews with general practice.

We chose these 2 frameworks for their health care–specific focus and comprehensive scope, encompassing both technical and human factors in CDSS implementation. These recent frameworks offer a multidimensional approach to assess user perceptions and evaluate digital interventions, allowing us to identify a broad range of barriers and facilitators for safe CDSS testing in primary care. In addition, inductive analysis was conducted to create de novo themes developed from the data. The qualitative themes mapped onto the 2 frameworks are reported based on dominant themes arising from the interviews. Differences in interpretation were discussed and resolved by consensus. Input was sought from the wider research team, including consumer investigators, in the development and interpretation of themes.

Main themes analyzed are shown in blue, which are adapted from studies by Sekhon et al [26] and Sittig and Singh [22].

Clinical Audits and Implementation Data

Data collected in the EHR audit were uploaded to REDCap and then downloaded into a master Excel (Microsoft) spreadsheet to be reviewed, cleaned, and analyzed by 2 researchers (JMG and SC), including 1 clinician (JMG). Disagreements were discussed with the wider clinical and implementation team. Data collected via the EHR audit and clinical review log for each practice were analyzed using descriptive statistics. This included determining the binary outcomes: “Does this patient have unexpected weight loss?” (yes/no) and “Has this patient been followed up for UWL?” (yes/no). True and false positives of UWL were calculated using the information collected in the EHR audit following a predetermined set of criteria (Multimedia Appendix 3). For patients with true UWL, descriptive statistics were used to describe follow-up variables in the coded and free-text fields (diagnosis, symptoms, investigations, and referrals).

Ethical Considerations

Ethical approval was granted by the University of Melbourne Human Research Ethics Committee STEMM 1 (Ethics ID: 25308). Participants were provided with a plain language statement explaining the study. Informed consent was obtained from all participating general practices. Practices were paid Aus $1000 (approximately US $660) for participation. Participation was voluntary, and all interview participants were reimbursed for their time (Aus $100, equivalent to US $67).

Results

Practice Characteristics

We recruited 5 general practices from a pool of 40 practices that had the FHT program installed. Practices were located in Queensland and Victoria, Australia. Four practices were located in metropolitan areas, and 1 practice was located in a rural area based on the Australian Modified Monash Model [27]. The mean number of patients identified as having UWL 6 months previous to cohort creation was 13 (SD 5) patients per practice. Practice characteristics are described in Table 1.

XSL•FO
RenderX

Table . Characteristics of 5 general practices participating in pilot study (n=5).

Practice characteristics	Values
Number of active patients[a] in each practice, mean (SD)	17,619 (3368)
Number of active patients by reported gender, mean (SD)	
Male	7623 (1325)
Female	9505 (1891)
Other	491 (310)
Number of active patients aged ≥40 y, mean (SD)	8933 (1905)
Number of physicians per practice, mean (SD)	10.4 (5)
Rurality classification of practice[b], n (%)

[a]The Royal Australian College of General Practitioners defines an "active patient" as "a patient who has attended the practice 3 or more times in the past 2 years" [28].

[b]Rurality classification based on the Modified Monash Model [27].

Practice Staff Interviews

We conducted 5 interviews with 7 practice staff. Interviews were conducted via Zoom after the list of patients had been reviewed by practice staff and at least a month had passed to give patients the opportunity to come back for a follow-up appointment if they had been recalled by the practice.

Participant characteristics are presented in Table 2.

XSL•FO

[a]GP: general practitioner.

[b]PN: practice nurse.

[c]Role also involves leading the quality improvement activities in the practice.

[d]PM: practice manager.

We first describe "affective attitude" to contextualize the staff's general attitude toward the CDSS. Furthermore, 3 main deductive themes became evident from our analysis using the 2 frameworks: internal organizational policies, procedures, and culture; and workflow and communication and intervention coherence. Remaining relevant themes from the frameworks are summarized, with exemplary quotations provided in Multimedia Appendix 4.

Affective Attitude

Overall, participants liked the concept of the tool. For quality assurance purposes, the cohort tool, with the ability to create lists of patients with specific conditions and the detailed information it provided on the patient, was found to be very useful. Regarding the UWL cohort, they particularly liked that the cohorts were composed of only a few patients, as expected given the low prevalence (1.5%) of UWL reported in the literature.

Clinical and administrative staff generally favored QI initiatives and supporting software, with 1 staff member reporting frequent use of FHT in management plans and health assessments.

One clinical staff member mentioned finding both features useful:

> *I like the way that it pops up a reminder in real time when we open their record. And it's really useful to be able to develop the cohorts for auditing purposes and for purposes of developing, you know, PDSA (Plan, Do, Study, Act) cycle quality improvement activities and things like that. So, so overall, I've found FHT really, a really useful innovation.* [Clinical staff, practice 2]

> *I like when you click on the patient's name in the cohort, you know you can see the meds, there's a snapshot of their history. I like the MBS (Medicare Benefits Schedule) items that might apply, because part of my job is making sure we're sustainable and maximizing those, those chronic disease item opportunities.* [Clinical staff, practice 1]

Intervention Coherence

Despite FHT being installed for at least a year in all 5 practices, 5 (70%) participants were not well acquainted with the cohort tool in FHT. Even after co-design efforts, provision of written materials, and virtual training offers, several challenges emerged in the implementation of the UWL module. The inclusion and exclusion criteria of the algorithm were not well understood. Users were uncertain about how patients progressed through the patient management system (from "awaiting action" to

XSL•FO
RenderX

"deferred," "actioned," or "no further action needed"), indicating confusion about this component of FHT.

After reviewing the lists, clinicians identified that several patients on the list were intentionally trying to lose weight (see "Clinical Audits" section) or had only one recorded weight measurement and staff were confused by the inclusion of these patients. Technical issues further complicated matters, as the tool malfunctioned during use by the first practice. In this case, the practice staff reviewed the cohort and actioned the patients accordingly (marking them as "deferred": no action needed or "recalled"), but the system did not save these actions, causing all patients to remain in the "awaiting action" category, causing additional confusion.

Despite these challenges, there were positive aspects. The tool's visual elements and patient summaries were seen as helpful facilitators. Most users found reviewing patients in the cohort straightforward:

> *I didn't find it too hard. It was - once you went into the patient's file it was pretty self-explanatory if you just kept going through the flow of the appointments and what the doctors - because you can see where it said weight loss in the reason for visit, if you sort of read from then on, and then go back if you have to, but, it sort of flowed pretty well, so you could understand.* [Clinical staff, practice 3]

> *First of all, of the 19 patients, some of them, I'm not sure why they popped up on the list, some of them had only ever had one weight recorded. So I'm not quite sure how the tool came to conclude that they'd lost weight.* [Clinical staff, practice 2]

Internal Organizational Policies, Procedures, and Culture

Internal processes arose as the most influential factor in the use of the cohort tool.

GPs typically document most patient information in the free-text clinical notes field of the EHR. However, the CDSS algorithm is currently unable to read these notes, relying only on structured text fields such as "reason for visit" or "diagnosis," creating a substantial barrier to its effective use. This mismatch between clinician documentation and the CDSS data input requirements limited the tool's ability to provide comprehensive support.

In 2 practices, the manager asked GPs whether they would be open to a CDSS system that would issue reminder pop-ups at the point of care when a patient presented. They collectively opted not to have it installed as they were concerned about alert fatigue, showing a lack of understanding of how frequently this tool for this algorithm would appear, as UWL is a relatively uncommon presentation.

1. *Dedicated personnel:* Having a dedicated PN or allocated person, such as a pharmacist or practice manager, for QI activities facilitated the use of the cohort tool. In these cases, the integration with the practice workflow was better achieved, ensuring more consistent and effective use of the system. However, designated resources have a cost associated, and many practices do not have sufficient staff available to undertake this type of role.
2. *Existing QI systems:* Some practices already had seemingly effective systems in place for data searches and QI. Two practices, which had the same owner and manager, were very comfortable using the search tool embedded in their own EHR. Although the EHR search tool was simple and would not be able to flag patients with UWL nor identify risk of cancer, the practice manager thought it was good enough for their QI requirements, making the tool seem unnecessary for their needs. They also did not see the use of the point-of-care tool as they had determined it would result in alert fatigue. These established workflows were seen as competing with the new CDSS, depending on how well acquainted the staff were with FHT and whether this UWL algorithm integrated with existing processes.
3. *Varied models of use:* In 3 of the 5 practices, clinical staff conducting audits did not directly engage with the CDSS but instead worked from patient lists provided by practice managers or research coordinators who knew how to use FHT. In these practices, FHT was understood to be mostly a research tool, rather than a tool for everyday QI activities. This indirect use of the system led to a disconnect between the tool's capabilities and the clinical decision-making process in the clinic. The 2 remaining practices were well acquainted with the tool and were already using it for QI and clinical care activities for other conditions on their own account.
4. *Time allocation:* Time allocation for cohort review varied significantly between roles. Nurses and coordinators had allocated time for QI activities and worked within office hours, while the GP (similar to most GPs in Australia), lacking dedicated time, resorted to after-hours completion, impacting workflow integration.
5. *User familiarity and role integration:* In practices where the same person reviewed the cohort and assessed clinical relevance, there tended to be better integration of the module within the practice workflow. These individuals, often practice managers with clinical roles, were typically more familiar with the tool and could more effectively coordinate follow-up actions with GPs. This familiarity and role integration led to more streamlined use of the CDSS.

Quotes exemplifying each one of these factors or processes can be found in Table 3.

XSL•FO
RenderX

Table . Internal factors or processes affecting implementation.

Internal factor or process	Selected quotation
Organization culture and staff practices	• "No one [GP] uses this drop-down system codes [in the reason for visit field in the EHR] that takes one second" (clinical staff, practice 3). • "No, no, I haven't got [FHT] on for the GPs at all. And the reason for that is most of my doctors are anti pop ups" (practice manager, practice 5).
Dedicated personnel	• "So as part of being the nurse coordinator, I do take on a lot of the quality improvement in the practice, so I'm one of the leads on that part" (clinical staff, practice 3).
Existing quality improvement systems	• But most of our data searches in that we actually use [our EHR]. So which is, which is the software that we use. So it's much easier for us to just be working on [our EHR]" (practice manager, practice 4).
Varied models of use	• "In the program, so I went, basically made a list of all the patients and all the like possible causes. I gave it to [PM], and then kind of just assessed, like, what was going on with the patient, whether they needed to come back to see the doctor, or most of them were already, like in discussion with the doctor about that weight loss" (practice manager, practice 5).
Time allocation	• "I think they just did that out of hours, you know, an extra job to do with an evening, because I sent them, I sent everybody, at least a round of their relevant patients, and asked them to have a look" (clinical staff, practice 2).
User familiarity and role integration	• "So the portal, so yep, and like the recalling or deferring patients, so often looking up a lot of if it's the clinical side, I'll tend to look up all the clinical data and stuff like that, and refer and defer and review patient, bring it to the attention of the doctors if they're coming in for another appointment" (clinical staff, practice 3).

Workflow and Communication

Workflow and communication factors were described as crucial determinants in the use of the module. This theme, closely intertwined with internal processes mentioned earlier, stood out for both its prevalence and the depth of insights it provided.

The ease of integrating the tool into existing workflows varied among practices. Those with a special interest in data analysis and QI found it easier to embed the cohort tool into their routines. However, the lack of integration of the system with the practices' message software was a common issue, hindering direct action on strategies such as reminders and recalls.

The process of reviewing the cohort was generally consistent and considered relatively easy across practices.

1. Adaptations and workarounds: Practices developed their own methods for managing the cohort and relaying information, such as using spreadsheets or internal notes. The fact that FHT was adaptable for this was valued and highlights the need for flexible systems that can accommodate various practice styles.
2. Communication challenges: Clinical and administrative staff mentioned that communicating the need for recall to patients could prove challenging, especially when the issue (eg, UWL) was not a priority for patients or when they were unaware of the problem. This indicates that clinician judgment always sits on top of any CDSS and that the provision of a list does not automatically mean it is clinically relevant or preferred to actively recall patients.
3. Training and understanding: Three practices did not fully use all CDSS features (eg, pop-ups) due to lack of experience or training (one practice) or practice decision not to use the pop-up feature to avoid alert fatigue (2 practices). This affected their understanding of the tool's capabilities and its integration into their workflow.
4. Role-specific challenges: The workflow varied by role, with a GP reviewing pop-ups during consultations but not always acting on them due to existing audit processes. Practice nurses sometimes struggled with determining follow-up needs, highlighting the importance of role-specific training and clear guidelines.

Exemplary quotes:

> *[FHT] It doesn't talk back to [our EHR] to add any reminders or add any actions, and knowing how hard [our EHR] is to integrate with...* [Clinical staff, practice 1]

> *I think it's useful, but it's still up to the GPs to sort of use it more? Yeah, I think that's our, that's our biggest struggle is to get more of them using it.* [Clinical staff, practice 3]

XSL•FO
RenderX

> *Or if the patient has had no nurse contact, she may not have seen that patient at all. So it would have been a very awkward conversation for her to actually call the patient and go, Hey, how's it going? Are you trying to lose weight?* [Administrative staff, practice 4]

Clinical Audits

The algorithms identified 62 patients with possible UWL. We extracted data from a total of 60 patients. Two patients were excluded from analysis as records could not be accessed, given (1) no longer an active patient and (2) no weight loss recorded as a reason for the visit or in their past history. The tool correctly identified 36 of 60 (60%) patients with UWL established by clinical assessment of the information in the EHR.

Patients with UWL confirmed in the EHR were older and equally distributed by sex, while patients with intentional weight loss recorded in the EHR were younger and mostly women. Intention to lose weight was recorded as free text in the clinical notes in 98% of cases, with only 20% of patients having intention recorded in a structured field (reason for visit or diagnosis). Sixty-one percent (22/36) of patients with UWL were at moderate to high risk of cancer. Five (8%) of 60 patients were recalled for further investigation. Details of patients' characteristics and CDSS deployment can be found in Table 4.

Table . Patient characteristics and related clinical decision support system recommendations.

	All patients	Patients with UWL[a]	Patients with intended weight loss
Number of patients, n (%)	60 (100)	36 (60)	24 (40)
Age, median (IQR)	57.5 (35.5)	68.5 (130.5)	44 (21.5)
Sex, n (%)			
Males	27 (45)	18 (50)	9 (37.5)
Females	32 (53)	17 (47)	15 (62.5)
Missing	1 (2)	1 (3)	0 (0)
Recommendations[b], n (%)			
Patients at low risk of cancer	20 (33)	9 (25)	11 (46)
Patients at moderate and high risk of cancer	30 (50)	22 (61)	8 (33)
No recommendations	10 (17)	5 (14)	5 (21)
Patient recalled for further follow-up, n (%)			
Yes	5 (8)	5 (14)	0 (0)
No[c]	55 (92)	31 (86)	24 (100)
Where was intention to lose weight recorded[d], n (%)			
Reason for visit	10 (17)	5 (14)	5 (21)
Diagnosis	2 (3)	1 (3)	1 (4)
Clinical notes	59 (98)	35 (97)	24 (100)

[a]UWL: unintended weight loss.

[b]Refer to Figure 1 for definition of risk and recommendations.

[c]This includes patients for whom the practice determined did not need to be recalled for further follow-up (eg, deferred for review until a later date, already under investigation, known cause of UWL). Reasons for deferral or no action taken are reported in Table 5.

[d]Intention may have been recorded in more than one electronic health record field.

XSL•FO
RenderX

Table . Reasons for deferral in 55 patients identified in unintended weight loss (UWL) cohort (n=55).

Deferral reasons	Values, n (%)
UWL with known cause	16 (30)
Incorrectly identified according to practice	
Intentional weight loss	16 (30)
Data error	1 (1.8)
No evidence of weight loss	6 (11)
UWL with unknown cause and already under investigation	7 (12.7)
No reason for deferral given or missing	9 (14.5)

Ninety-two percent (55/60) of all patients were deferred, as practices deemed no further follow-up was needed. Reasons for deferral were divided into three main groups: (1) unintentional weight loss with known cause, (2) patient incorrectly included in cohort (eg, intentional weight loss, data error, and increased weight), and (3) unintentional weight loss with cause unknown being followed up already. Table 5 presents the frequency of reasons for referral.

A summary of clinical characteristics and follow-up of the 36 patients with UWL is described in Table 6 (more details in Multimedia Appendix 5). Following their initial UWL consultation, the vast majority of patients with UWL (34/36, 94%) received comprehensive follow-up care. This care encompassed subsequent GP appointments, specialist referrals, various investigations, and/or imaging studies as needed. On average, patients attended a median follow-up of 8 (IQR 10) visits after their initial UWL consultation until the audit date.

[a]Includes another consultation where UWL was discussed and/or any investigations, imaging, or referral after the index date.

[b]Patients may have had more than one symptom recorded at or after index date.

[c]GP: general practitioner.

[d]Patients may have had more than 1 investigation ordered.

[e]HbA_{1c}: hemoglobin A_{1c}.

[f]CRP: C-reactive protein.

[g]ESR: erythrocyte sedimentation rate.

[h]STI: sexually transmitted infection.

[i]Some patients had more than one imaging request.

[j]CT: computed tomography.

[k]Patients may have been referred to more than 1 specialty.

[l]"Related diagnosis" defined by the practice GP in the electronic health record as a possible reason for UWL recorded within 6 mo of UWL (new or preexisting).

[m]Patients may have had more than 1 diagnosis recorded.

One-third of patients (12/36, 33%) presented to the first UWL visit with UWL as their only symptom. Almost half of patients (17/36, 47%) presented with other nonspecific symptoms such as appetite loss and lethargy, and the most common accompanying specific symptoms were gastrointestinal symptoms (13/36, 36%), followed by mental health symptoms (7/36, 19%).

Eighty-six percentage (n=31) of patients had been investigated with blood tests. The most common tests ordered were full blood count tests (n=30, 83%), liver function tests (n=30, 83%), creatinine testing (n=25, 69%), iron studies (n=23, 64%), calcium testing (n=22, 61%), and thyroid function tests (n=18, 50%).

Diagnostic imaging and endoscopic procedures were frequently used in the investigation of UWL. Nearly two-thirds (22/36, 61%) of patients underwent imaging studies or endoscopic examinations. Of these, more than half (13/22, 59%) underwent CT imaging, which included abdominal, lung, and/or pelvic regions.

While direct colonoscopy referrals were relatively low (5 patients), a more common approach was to refer patients to specialists for consideration of endoscopic procedures. One-quarter (9/36, 25%) of patients were referred to either a gastroenterologist or, in rural practices, a general surgeon for consideration of upper and/or lower endoscopy.

More than half of the patients (20/36, 56%) received a diagnosis related to their UWL, as determined by their GP and documented in the EHR. The most prevalent diagnoses associated with UWL were mental health conditions, followed by cancer.

Four (11%) of 36 patients were diagnosed with cancer, including chronic lymphocytic leukemia, myeloma, breast cancer, and renal cancer. However, only the renal cancer case was diagnosed following the UWL consultation. The other 3 (8%) patients should have been excluded from the study based on the predefined algorithm, as these diagnoses were made prior to the UWL visit and within the preceding 5 years.

Discussion

Principal Findings

Our study aimed to pilot the implementation of a CDSS to identify patients with UWL at risk of cancer in primary care settings. This initiative involved extensive preliminary work, including the use of primary care databases to identify patients with UWL and calculate their cancer risk using a UK-developed risk prediction model [19]. We also co-designed recommendations and resources and tested the CDSS in simulated scenarios before implementation. The initial findings suggested that the CDSS would be both acceptable and feasible, prompting us to proceed with the implementation (unpublished data).

XSL•FO
RenderX

The implementation process involved asking clinical staff to review a list of patients flagged by the tool and make decisions to defer or recall patients based on their clinical expertise. Using 2 relevant frameworks [22,26], our analysis of staff interviews revealed that most found the concept of identifying patients with UWL at risk of cancer acceptable, and the review process was easy to understand. The most influential factors affecting specific use were the practices' internal processes, culture, workflow, and communication practices.

We observed 2 distinct opinions regarding the use and feasibility of the CDSS for implementation. Although FHT had been installed and used by all practices for over a year, staff familiar with QI activities within the FHT program found the tool useful and feasible. They reported that the process was not burdensome and could be integrated into their usual workflow. Conversely, practices unfamiliar with the tool found it less helpful, citing high misclassification of patients with intentional weight loss, lack of integration with their EHR, and inability to perform recalls through their regular workflow. This dichotomy aligns with existing literature, which identifies trust in the tool and seamless integration into workflow as major factors influencing CDSS implementation success [11]. To overcome some of these barriers, a module such as this could be made actionable within the EHR (recalls, tasking, and documentation editable directly from the cohort view) and provide configurable, role-specific triggers to reduce irrelevant pop-ups (which are a known cause of alert fatigue) [29]. Operational measures include role-tailored training, clear follow-up protocols, and decision aids for practice nurses [30]. At the organizational level, provenance and governance processes, local champions, piloted roll-outs across diverse practice types, and explicit evaluation of implementation outcomes (adoption, fidelity, and acceptability) using implementation frameworks (eg, Normalization Process Theory and Proctor's outcomes) will improve representativeness and scalability [31,32]. Together, these levers—designed and evaluated in partnership with frontline staff—should make integration more seamless, reduce cognitive burden, and increase the likelihood that the tool supports safe, equitable care across a wider range of practices.

Another significant barrier was the lack of allocated time for QI activities, particularly for GPs. This finding is consistent with broader literature on the challenges of implementing QI initiatives in primary care settings [33,34].

Clinical EHR audits showed impressively high follow-up care rates, with 94% (34/36) of patients with confirmed UWL receiving appropriate follow-up and a median of 8 follow-up visits per patient. Our study revealed an exceptionally high follow-up rate, with over 50% (20/36) of referrals made to various specialists. Australian and international literature reports delays in referral for unspecific symptoms compared with specific symptoms [35,36]. However, our findings are consistent with results from our previous randomized controlled trial that used FHT to identify patients with abnormal test results at risk of cancer. In that study, even control practices demonstrated follow-up rates exceeding 70% [17].

The high follow-up rates observed in our study may be reflective of the broader patterns of continuity of care in Australian general practice. The vast majority of Australian patients attend only 1 or 2 general practices annually, and older patients and those with chronic conditions demonstrate particularly high continuity of care [37]. Nevertheless, our findings raise important questions about the representativeness of practices participating in research studies overall. It is possible that these practices are inherently high performing compared to the broader landscape of general practice, potentially skewing our understanding of typical follow-up rates and care quality in primary care settings. Future research needs to explore this issue more thoroughly by comparing the performance metrics of research participating practices with those of a random sample of general practices, investigating the characteristics and motivations of practices that regularly engage in research, and developing strategies to involve a more diverse range of practices in primary care research. Understanding these factors is crucial for accurately assessing the generalizability of research findings and for developing interventions that can be effectively implemented across the entire spectrum of primary care practices. Regardless of the latter, the high rates of investigation and imaging in our cohort (86% had blood tests and 61% had imaging) are consistent and may reflect the accessibility of diagnostic tools in the Australian health care system. This accessibility has been credited for Australia's comparatively better cancer outcomes relative to similar high-income countries worldwide [35].

The symptom profile of patients with UWL presents an interesting diagnostic challenge. One-third (12/36, 33%) of patients identified by the UWL module had no other recorded symptoms, and nearly half (17/36, 47%) had nonspecific symptoms such as appetite loss and lethargy recorded in any field in the EHR. The high prevalence of no other symptoms or coexisting nonspecific symptoms aligns with international literature and underscores the difficulty in differentiating between benign causes and more serious underlying conditions [8,38,39]. Nicholson et al [39] highlight the complexity of interpreting weight loss in primary care, especially when it cooccurs with other nonspecific symptoms, emphasizing the need for careful clinical assessment and follow-up.

Mental health symptoms were also common in our cohort. Just more than half of the patients received a UWL-related diagnosis, primarily mental health conditions or cancer.

The most prevalent diagnoses in our cohort were mental health conditions, cancer, and chronic obstructive pulmonary disease, consistent with international literature. A study by Withrow et al [6] described the most prevalent serious conditions for people with UWL, stratified by age and sex. Given our cohort's median age of 68.5 years and equal sex distribution, our findings align with their reported common diagnoses for this age group: cancer, diabetes, and chronic obstructive pulmonary disease in men; and depression, thyroid disorders, and cancer in women.

Limitations

The algorithm identified 36 (60%) of 60 patients with UWL. Identifying UWL in EHRs is clinically and technically challenging due to inconsistent documentation practices and the predominance of free text in Australian primary care records [40,41]. In this study, "intention" of weight loss was recorded in the clinical notes for 98% of cases. Without access to

XSL•FO
RenderX

unstructured data such as the clinical notes, algorithms such as this, or even more sophisticated natural language models and AI applications have very limited potential. Furthermore, if CDSS performance depends wholly on the quality of the recorded symptoms, then if documentation is incomplete, detection will inevitably be affected. Human scribes in primary care have been shown to raise productivity, increase face-to-face time by 39% to 57%, and improve chart quality and physician satisfaction without reducing patient satisfaction [42]. Ambient AI scribes promise to scale this documentation capture, but evaluations show omissions are frequent and occasional high-severity inaccuracies occur, so clinical oversight and careful product selection are essential. Studies in Canada and the United Kingdom reported strong note-generation capabilities across multiple AI scribes but also marked variability in accuracy, usability, and technical performance [43]. Future research should focus on perfecting these technologies. A pragmatic approach would be to layer scribe-captured narratives into CDSS workflows, enabling richer free-text phenotyping (eg, unintentional weight loss with cosymptoms) while preserving clinician control and opportunities for validation, thereby balancing improved capture with safety and trust. The number of false negatives—patients with UWL not identified by the algorithm—also remains unknown, given that we did not review records not flagged by the algorithm due to cost and time constraints. We were therefore only able to identify true positives and false positives identified by the tool.

The algorithm's failure to exclude 3 patients with cancer (2 cases of lymphoma and myeloma, possibly due to information being solely in clinical notes, and 1 case of breast cancer with a coded diagnosis) highlights an unexpected algorithmic error and underscores the challenges in coding and the need to ensure coding is standardized and reviewed over time. Measured weight loss was not incorporated into the algorithm as an inclusion criterion due to a low percentage of 2 consecutive measurements in preliminary analysis; the impact of this omission on the correct identification of patients remains unclear and warrants further investigation. The study's small scale, with a limited number of patients, significantly restricts its generalizability. Although relevant and necessary to ensure patient safety and good allocation of resources, larger, more diverse patient cohorts are necessary for more robust and widely applicable findings.

These limitations highlight areas for improvement in future research, emphasizing the need for enhanced data access, refined algorithmic processes, and larger study populations to increase the reliability and applicability of methods for identifying patients with UWL.

Conclusions

Our study provides valuable insights into the implementation of a CDSS for identifying patients with UWL at risk of cancer in primary care. While we encountered challenges, particularly around tool integration and correct identification of patients with UWL, we also observed high rates of follow-up care and comprehensive investigations in our participating practices. These findings highlight both the potential of CDSS in improving patient care and the complexities involved in their successful implementation. Future research should focus on enhancing CDSS integration with existing workflows, improving access to unstructured data, to ensure clinicians' trust in these tools, specifically to enhance the usability of digital interventions, and leverage other, more sophisticated digital technologies.

Acknowledgments

We would like to thank all participating practice staff for their invaluable contribution to the study and HaBIC team at the University of Melbourne for the development of the UWL cancer module. Generative AI was not used in the study design and analysis or development of the initial draft of the manuscript. The University of Melbourne's Spark AI was used for copyediting of the revised manuscript.

Funding

JMG was funded by a Victorian State Government through a mid-career Cancer Research Fellowship (MCRF 21025). The Victorian State Government played no role in study design, data collection, analysis and interpretation of data. JDE was funded by an NHMRC Investigator grant (APP1195302). NHMRC played no role in study design, data collection, analysis and interpretation of data.

Data Availability

Unidentified transcriptions and qualitative coded data as well as unidentified audited data can be made available upon request secondary to ethics approval. Qualitative codes were developed in an iterative process by the 2 researchers. They were uploaded to NVivo version 14. They can be shared upon request.

Abstract

Background: Progression-free survival (PFS) is a critical end point in oncology, yet real-world applications of individualized, explainable machine learning (ML) predictions remain limited.

Objective: This study aimed to develop and validate explainable ML models to predict PFS using retrospective data from a national prostate cancer cohort in Brunei Darussalam.

Methods: We analyzed a retrospective cohort of 212 patients (478 longitudinal observations) treated at the Brunei Cancer Centre (January 2018 to December 2024). Clinical, laboratory, and treatment data were harmonized, with missing values imputed via extremely randomized trees. Longitudinal patterns were captured using a recurrent autoencoder to generate latent representations. We compared 4 modeling approaches: Cox proportional hazards, random survival forest (RSF), gradient boosting survival (GBS), and deep neural network survival models. Performance was evaluated using time-dependent area under the receiver operating characteristic curve (AUC), Harrell C-index, and integrated Brier score (IBS), with Shapley additive explanations (SHAP) used for interpretability.

Results: RSF demonstrated improved discriminative performance and balanced calibration, achieving a C-index of 0.906 and AUCs of 0.941 and 0.917 at 4 and 5 years (IBS=0.0698). In contrast, the traditional CPH model performed poorly (C-index 0.531 and AUC 0.706 at 4 years and 0.833 at 5 years). Deep survival (AUCs of 0.941 at 4 years and 0.917 at 5 years, C-index 0.719, and IBS=0.0887) and GBS (AUCs of 0.765 at 4 years and 0.833 at 5 years, C-index 0.844, and IBS=0.0590) models showed moderate performance. SHAP analysis identified sodium, alanine aminotransferase, mean corpuscular hemoglobin, platelet count, and specific treatment categories as key drivers of increased progression risk.

Conclusions: Tree-based ensemble approaches, particularly RSF integrated with SHAP, offer high accuracy for personalized risk stratification in prostate cancer. These findings highlight the potential of explainable ML to enhance clinical decision-making. However, external validation in a larger multi-institutional, multiomics dataset is required before routine clinical implementation.

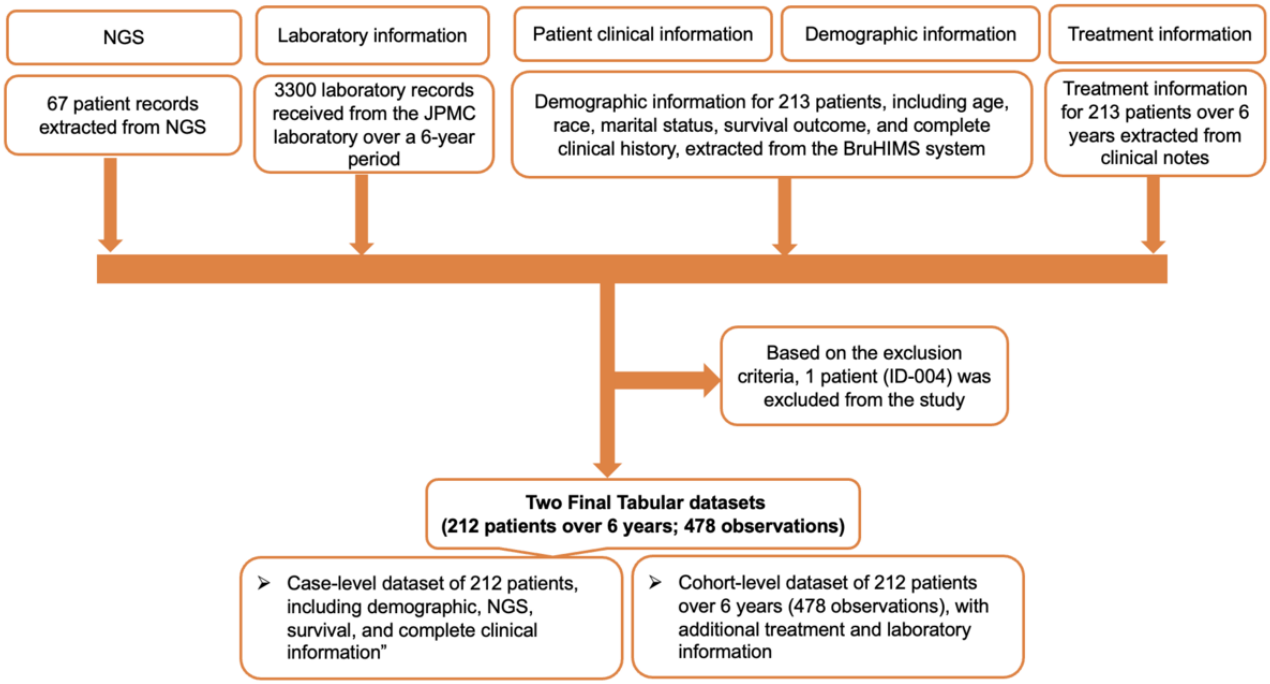
Introduction

Prostate cancer is the fourth most common cancer in men worldwide, and the incidence of prostate cancer is increasing in Africa, Asia, and Latin America and the Caribbean, raising public health concerns worldwide [1,2]. Global and regional analyses demonstrate that the highest incidence rates are reported in northern Europe, North America, and Australia, largely due to the widespread use of prostate-specific antigen (PSA)–based early detection systems, while mortality is higher in Africa, Asia, and Latin America, indicating the global disparity based on screening and diagnostic capacity [2-5]. In Brunei Darussalam specifically, the national and international cancer registry data demonstrate the increasing prostate cancer deaths in recent decades [6,7]. These epidemiological trends in prostate cancer highlight the need for locally adapted prognostic and management tools that can improve the prostate cancer care continuum in Brunei Darussalam.

Progression-free survival (PFS) and disease-free survival are widely used in prostate cancer clinical trials and observational studies to quantify the duration during which a patient remains free from radiographic or clinical disease progression after treatment [8-10]. PFS often serves as a pragmatic outcome in trials of systemic and targeted therapies, as it can be observed earlier than overall survival and may reflect the treatment effect on tumor control. According to PCWG (Prostate Cancer Working Group) criteria, PSA progression is defined as a confirmed ≥25% and ≥2 ng/mL increase from the PSA nadir (or from baseline after ≥12 weeks if no nadir is achieved), with confirmation to exclude PSA flare, while radiographic or clinical progression, if occurring earlier, takes precedence in determining PFS [11]. Additionally, the understanding of PFS extension for prostate cancer is viewed differently between patients and clinicians. Patients generally require a longer PFS benefit to consider treatment worthwhile and tend to prioritize PSA or radiological responses despite potential side effects, whereas clinicians place greater emphasis on balancing treatment-related toxicity with PFS and may recommend therapy even when the expected PFS gain is modest [12].

Over the past decade, machine learning (ML) methods, including gradient-boosted trees, random survival forests, and deep learning architectures, have been increasingly applied to survival prediction and progression modeling across many cancer types, including lung and prostate cancer [13-17]. Furthermore, multimodal data integration of clinical variables, laboratory tests, imaging and radiomics features, and molecular data to produce individualized risk estimates for progression or death often outperforms traditional statistical models in complex, high-dimensional datasets [17,18]. Despite these advances, most ML and deep learning models for prostate cancer survival prediction rely on cross-sectional or clinical trial datasets with short follow-up periods, limiting their applicability in real-world practice [19-21]. Additionally, explainability methods such as Shapley additive explanations (SHAP) play an important role in the clinical applicability of these models by providing attributions for individual predictions [18,22,23].

However, few studies have explored the sequential analysis of progression free survival with explainable methods to provide locally calibrated, interpretable predictions for progression-free outcomes. Additionally, no previous study in Brunei Darussalam has been conducted to develop interpretable ML survival models for prostate cancer progression. To fill these gaps, our study aimed to develop explainable ML models that predict PFS using retrospective clinical, laboratory, and treatment information from a national cohort in Brunei Darussalam. By developing locally tailored, AI-enabled PFS models, this study contributes to the growing body of evidence supporting the use of ML and deep learning in precision oncology, while also advancing AI-based clinical decision support systems to assist oncologists in prostate cancer management and enhance the continuum of care in Brunei Darussalam.



Methods

Study Design and Data Source

This retrospective cohort study included patients with prostate cancer treated at the Brunei Cancer Centre (TBCC), Jerudong Park Medical Centre (JPMC) between January 2018 and December 2024. The study was conducted in accordance with the TRIPOD-AI (Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis adapted for Artificial Intelligence) reporting guidelines to enhance transparency, reproducibility, and clinical applicability (Multimedia Appendix 1). Eligible participants were male patients with a histologically confirmed diagnosis of prostate cancer who received at least 1 treatment modality at TBCC. Patients with secondary metastatic prostate cancer or multiple primary malignancies were excluded following clinical review by oncologists. In total, 212 eligible patients contributed 478 time-indexed observations, capturing longitudinal treatment pathways and disease progression, as illustrated in Figure 1. Demographic, clinical, and treatment data were extracted from multiple sources, including the Brunei Darussalam Healthcare Information and Management System, the JPMC laboratory database, and both electronic and manually documented clinical records.

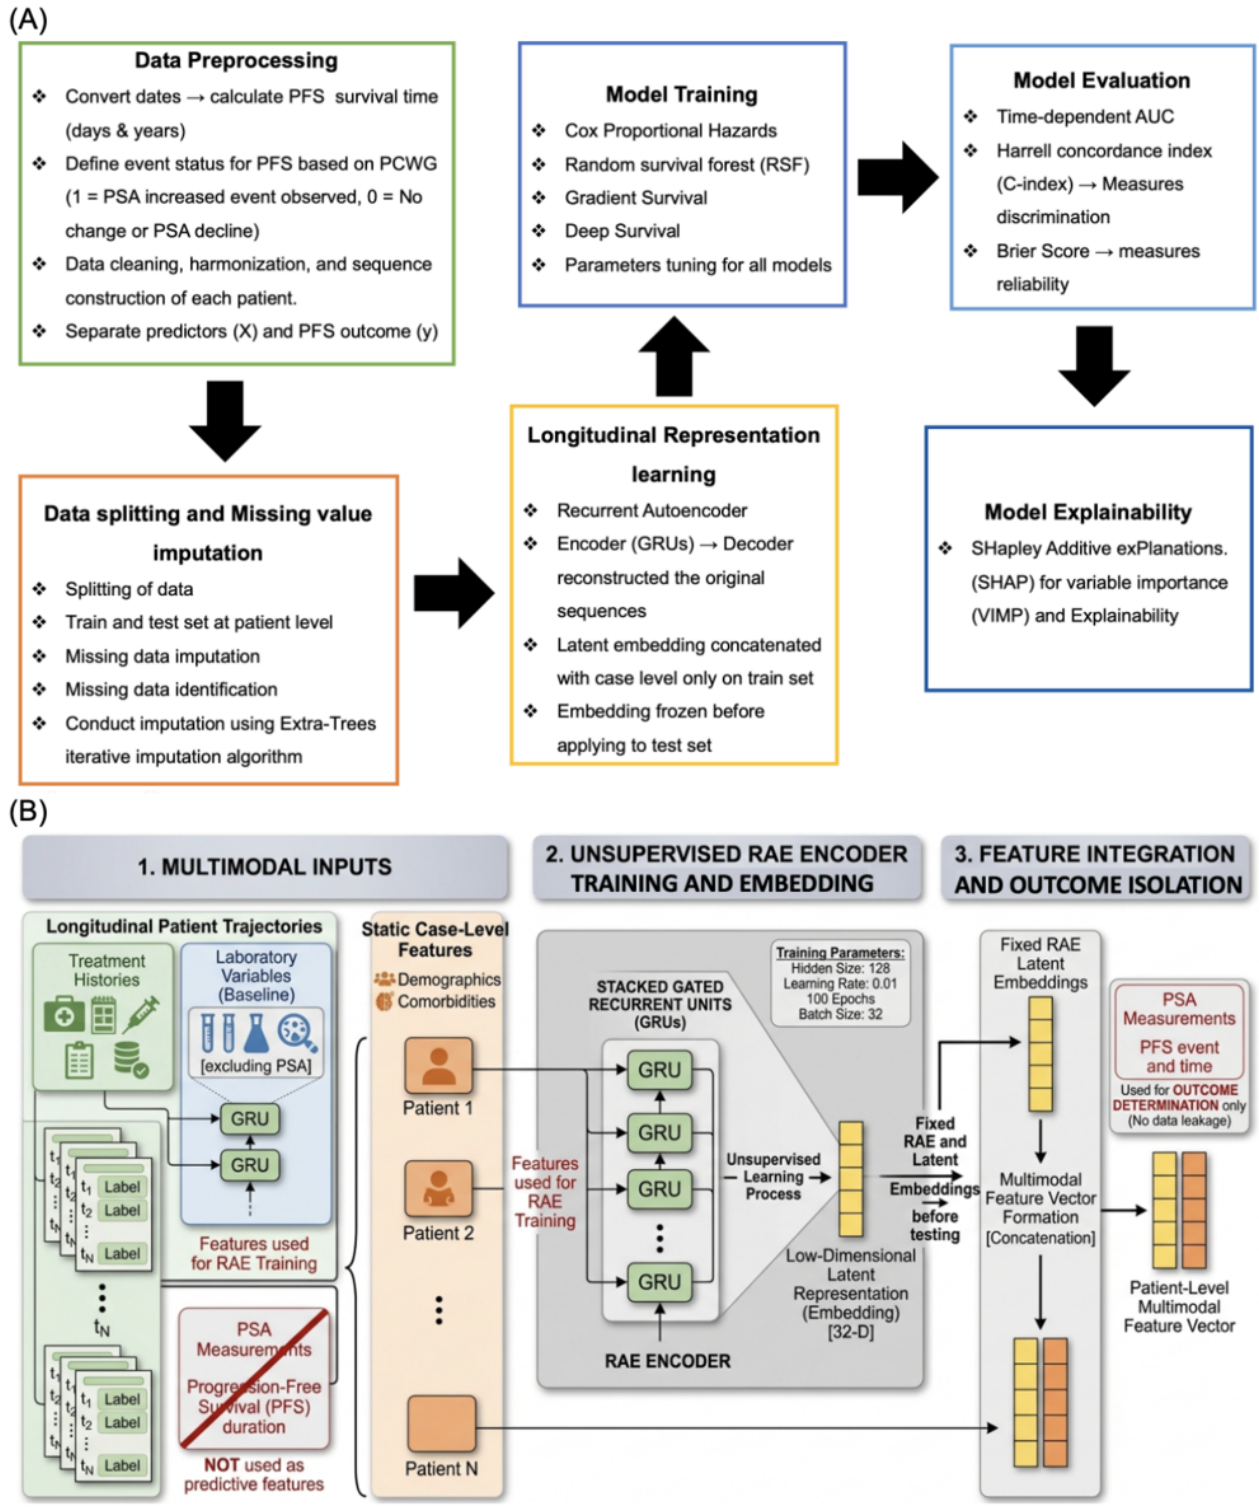
Data Structure and Outcome Definition

Data were structured across 2 hierarchical levels: the individual case level and the longitudinal cohort level. At the case level, collected variables encompassed demographic characteristics (including age, ethnicity, and marital status), medical history (eg, comorbidities and family history of malignancy), lifestyle factors (particularly smoking status), anthropometric measures (height, weight, and BMI), tumor-related features (Gleason score, tumor stage, and ECOG performance status), and survival outcomes. At the cohort level, comprehensive treatment information and 23 longitudinal laboratory measures were assembled, including baseline and 1-year posttreatment PSA values, full blood count parameters, liver and renal function indicators, erythrocyte sedimentation rate, calcium, and phosphate levels. Absolute and relative changes in PSA were derived, and tumor staging, Gleason grade groups, and National Comprehensive Cancer Network prognostic risk categories were harmonized to address inconsistencies in coding practices [24]. Except for PSA, all laboratory parameters were baseline measurements obtained before each treatment modification, enabling clinicians to assess laboratory results when determining subsequent therapeutic strategies. Data integrity was ensured through systematic cross-validation across multiple data sources and clinical verification by oncologists before analysis. The primary outcome was PFS.

PFS was calculated on a treatment-episode basis from treatment initiation to the earliest occurrence of PSA-defined progression, which was determined using PCWG-consistent criteria based on treatment-specific baseline PSA, posttreatment PSA nadir, and confirmed PSA rises (≥25% and ≥2.0 ng/mL, with timing and confirmation rules applied) or death from any cause, with patients censored at last follow-up in the absence of an event. A PFS event value of 0 indicates no biochemical progression or survival without progression at the last follow-up (censored), whereas a value of 1 indicates the occurrence of biochemical PSA progression or death from any cause. To conduct a survival analysis, PFS events, which denote the occurrence of progression or death, were used rather than PFS, which indicates the time a patient remains progression-free.

Data Preprocessing and Survival Analysis

Statistical analyses were performed using RStudio (version 4.3.3; R Foundation for Statistical Computing), Python (version 3.10; Python Software Foundation) implemented via Google Colab, and Visual Studio Code (version 1.106.0; Microsoft). Two analytic datasets were created: a case-level dataset consisting of 212 patients and a longitudinal cohort-level dataset comprising 478 time-indexed observations. Data preprocessing procedures included data cleaning, harmonization of tumor staging and Gleason grade groups, elimination of duplicate records, and construction of patient-specific longitudinal sequences. At the case level, continuous variables were compared using the Mann-Whitney *U* test, while categorical variables were assessed using the Fisher exact test, with a significance threshold set at $P<.05$. For the cohort-level analysis, mixed-effects linear and logistic regression models were used to evaluate differences between survival groups. The differences between groups, including those stratified by comorbidity status, were assessed using the log-rank test.



Data Splitting and Missing Data Handling

The overall ML model development pipeline is illustrated in Figure 2A. To minimize information leakage, data were split at the individual case level into training (80%) and testing (20%) sets using a random group-splitting strategy [25]. Missing values in both static and longitudinal variables were addressed using extremely randomized trees–based iterative imputation, a nonparametric approach derived from the random forest algorithm that accommodates mixed data types and captures

XSL•FO
RenderX

nonlinear relationships [26]. Categorical variables were transformed using one-hot encoding, and continuous variables were standardized using *z* score normalization to ensure comparable feature scales. All preprocessing steps, including imputation, scaling, and encoder fitting, were performed solely on the training dataset and subsequently applied to the testing dataset.

Longitudinal Representation Learning Using a Recurrent Autoencoder

A recurrent autoencoder (RAE) was trained on the training cohort to capture temporal patterns in laboratory and treatment histories (Figure 2B) [20]. PFS duration served as the primary temporal input, with all laboratory variables recorded as baseline measurements before each treatment decision. PSA measurements were used exclusively for PFS event determination according to biochemical progression criteria and were not incorporated as predictive features in model training. The PFS event and time were used only as indexing variables, not as features, to avoid learning in the autoencoder, thereby ensuring that the autoencoder learned purely unsupervised representations of longitudinal patient trajectories without exposure to the outcome. The RAE encoder, composed of stacked gated recurrent units (GRUs), transformed each patient's sequence into a low-dimensional latent embedding, which the decoder then reconstructed to preserve the original temporal patterns. These latent embeddings were concatenated with case-level static features (eg, race and morbidities) to form a multimodal feature vector. To prevent data leakage, the RAE was trained exclusively on the training dataset, and the learned embeddings were fixed before application to the testing set. Hyperparameters included a hidden layer size of 128, an embedding dimension of 32, a learning rate of 0.01, 100 epochs, and a batch size of 32.

Model Development

Traditional Cox Proportional Hazards Model

A Cox proportional hazards model was fitted to the training dataset as a conventional baseline for PFS analysis. The model was adjusted for clinically relevant covariates to quantify the association between predictors and the hazard of disease progression or death, defined as the instantaneous risk of a progression event at a given time, conditional on remaining progression-free up to that point [27,28]. Final covariate selection was guided by model fit, assessed using the log-likelihood ratio test. The proportional hazards assumption was examined using scaled Schoenfeld residuals and corresponding statistical tests to detect systematic departures from time-invariant covariate effects [19-32]. Predicted risk scores were generated for the testing dataset to facilitate direct comparison with ML-based PFS models.

ML Models

Three ML-based survival models were developed using an integrated feature set combining static clinical variables and latent temporal representations derived from the RAE. First, a random survival forest (RSF) model was trained as a nonparametric ensemble method to estimate cumulative hazard functions and rank predictors by importance [33]. Second, a gradient boosting survival (GBS) model (GBT-Survival) was implemented using a Cox partial likelihood loss function, enabling the modeling of nonlinear effects and complex interactions among covariates [34]. Third, a deep neural network–based Cox regression model (DeepSurv) was trained to capture nonlinear relationships between predictors and progression risk by optimizing the Cox partial likelihood [20]. Hyperparameter optimization for all models was performed using grid search cross-validation on the training dataset [35]. For the RSF, the explored parameter grid included the number of estimators (100, 200, 300), maximum depth (5, 7, 10), and minimum samples per split (10, 20, 30). For the GBS (GBT-Survival) model, the grid included learning rates (0.001, 0.01, 0.05, 0.1), the number of estimators (100, 200, 300), and maximum depth (3, 5, 7, 10). Optimal configurations, selected based on the highest concordance index, included RSF (maximum depth=7, minimum samples per split=10, 100 estimators), GBT-Survival (learning rate=0.001, maximum depth=10, 300 estimators), and DeepSurv (hidden layers=[32,35], dropout=0.1, rectified linear unit activation).

Model Evaluation and Explainability

Time-dependent area under the receiver operating characteristic curve (AUC) values could not be reliably estimated at 1, 2, or 3 years for any model because there were too few progression events and insufficient comparable patient pairs within these early periods to assess discrimination accurately. Model performance was assessed using time-dependent AUC values at the 4- and 5-year PFS horizons, together with Harrell concordance index (C-index) to evaluate discriminative ability [36]. Model robustness was examined using bootstrap resampling with 1000 iterations to derive CIs. Calibration was evaluated using the integrated Brier score (IBS) and calibration plots comparing predicted and observed progression-free survival probabilities. To enhance model interpretability, SHAP was applied to the best-performing RSF-Survival model, providing both global and patient-level insights into feature contributions to progression risk. SHAP summary, dependence, and force plots were used to visualize time-dependent predictor effects and identify key drivers of disease progression [19].

Ethical Considerations

Ethics approval for this study was granted by the Medical and Health Research and Ethics Committee, Ministry of Health, Brunei Darussalam (MHREC/MOH/2024/22(1)), on January 25, 2025. All patient data were replaced with pseudonymous research IDs since we received the data from the hospital, and no personally identifiable information was accessed or retained within the analytic or modeling environment.

Software Packages and Analytic Tools

All analyses were performed in Python using established open-source libraries, including *pandas* and *NumPy* for data manipulation; *scikit-survival* for Cox proportional hazards modeling, RSF, GBS analysis, concordance index estimation, and time-dependent AUC; *lifelines* and *pycox* for survival modeling (including DeepSurv); *PyTorch* (torch, torchvision, and torchaudio) for deep learning implementation; *fancyimpute* for iterative imputation; *scikit-learn* for data splitting and preprocessing (GroupShuffleSplit and StandardScaler); and *SHAP* for model interpretability.

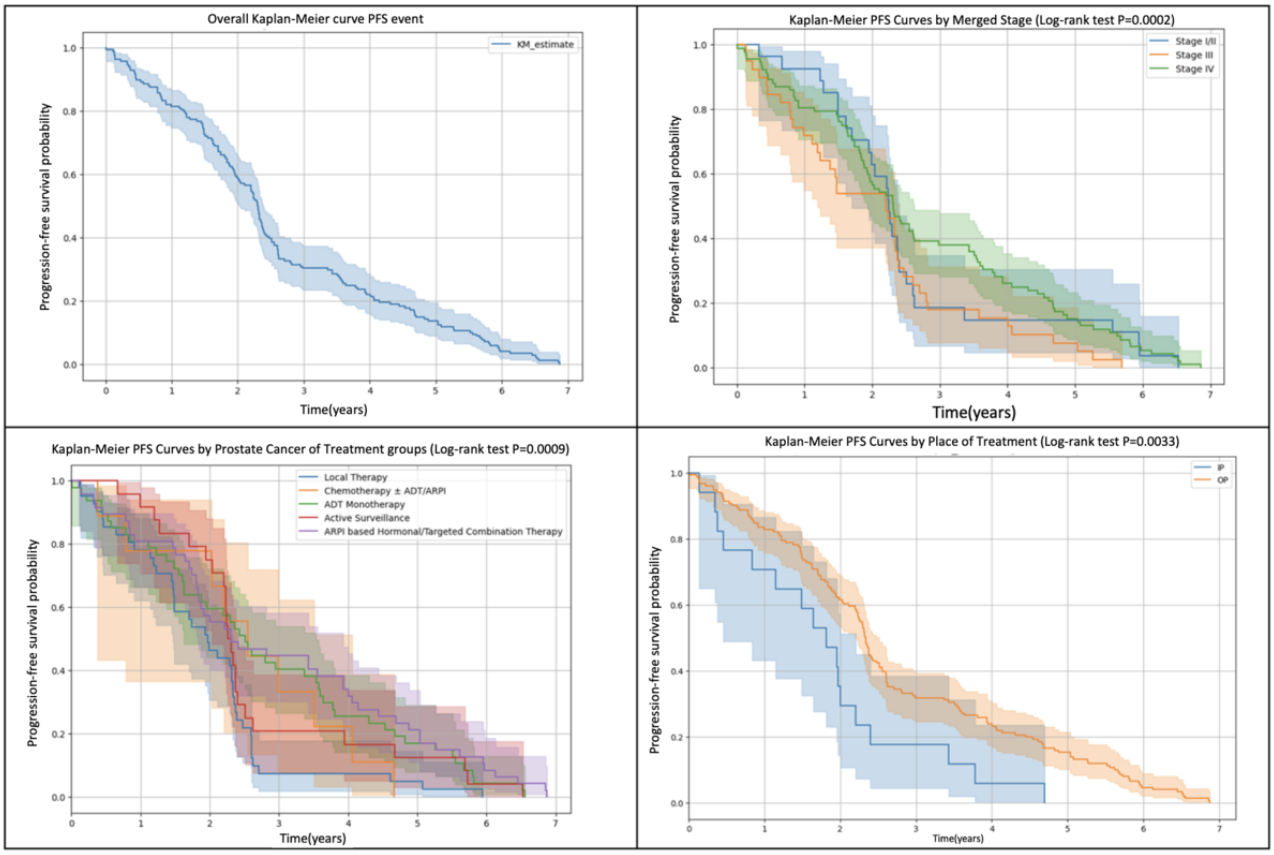
Results



Characteristics and Univariable Analysis of Study Participants

The study included 212 patients at the case level, contributing a total of 478 longitudinal observations over 6 years (detailed participant characteristics are presented in Multimedia Appendix 2). PFS events were reported in 45 observations during follow-up. At the case level (n=212), PFS outcomes differed according to tumor-related factors, including prostate cancer stage and Gleason grade group, whereas other comorbid conditions did not differ significantly between PFS outcome groups. Furthermore, at the cohort level (478 observations), significant differences between observations with and without a PFS event were observed in calcium (P<.001), chloride (P<.001), sodium (P<.001), red blood cell count (P<.01), hemoglobin (P<.01), neutrophils (P<.01), eosinophils (P<.01), baseline PSA (P<.001), and posttreatment PSA (P<.001).

Kaplan-Meier Curve for PFS

The PFS analysis with significant variables is presented using the Kaplan-Meier curves in Figure 3. The overall PFS curve demonstrates a steady decline over time, with the probability of remaining progression-free markedly decreasing after approximately 2 years of follow-up. Stratified analyses revealed significant differences across merged clinical stages (log-rank test, P=.0002), with advanced stages showing poorer PFS than earlier stages. Similarly, significant variation in PFS was observed among different prostate cancer treatment groups (log-rank test, P=.0009), indicating heterogeneity in outcomes depending on the therapeutic approach. Furthermore, PFS differed significantly according to place of treatment (log-rank test, P=.0033), with the inpatient treatment group demonstrating consistently lower survival probability over time.

Figure 3. Kaplan-Meier curves for progression-free survival among prostate cancer patients at the Brunei Cancer Centre (TBCC) from January 2018 to December 2024. ADT: androgen deprivation therapy; ARPI: androgen receptor pathway inhibitor; IP: inpatients; OP: outpatients.

Discriminative Performance of PFS Models

The discriminative performance, as measured by the time-dependent AUC at 1, 3, and 5 years (Figure 4), and the Harrell C-index (Table 1), was used to develop and compare 4 survival models. Evaluation of model performance at 4 and 5 years indicated that ML-based models outperformed the traditional Cox proportional hazards models. The Cox model demonstrated limited discriminative ability, with time-dependent AUCs of 0.706 and 0.833 at 4 and 5 years, respectively, along with a C-index of 0.531. In contrast, the tree-based models, RSF and GBT-Survival, showed markedly superior discrimination. The RSF model demonstrated strong discriminative performance at 4 and 5 years (AUCs of 0.941 and 0.917, respectively; C-index 0.906), while the deep survival model (AUCs of 0.941 at 4 years and 0.917 at 5-year; C-index 0.719) and the GBS model (AUCs of 0.765 at 4 years and 0.833 at 5-year, C-index 0.844) demonstrated moderate discriminative performance.

Figure 4. Heatmap of time-dependent area under the receiver operating characteristic curve (AUC) of progression-free survival (PFS) models, showing the relationship between predicted accuracy in fourth and fifth years. Cox: Cox proportional hazards model; DeepSurv: deep neural network–based Cox regression model; GBS: gradient boosting survival; RSF: random survival forest.

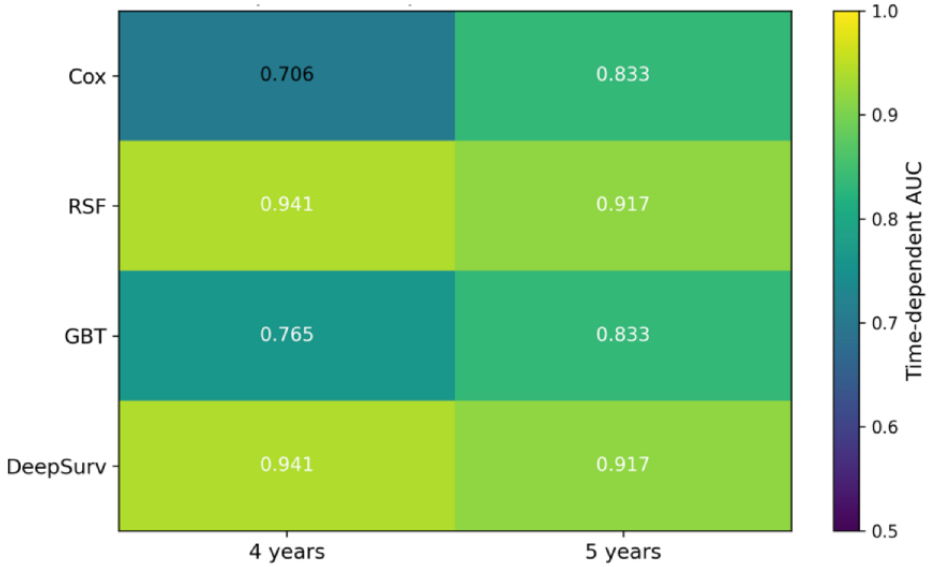

Table 1. Discriminative performance (time-dependent area under the receiver operating characteristic curve [AUC], Harrell concordance index [C-Index]) and calibration accuracy (integrated Brier score) of progression-free survival models.

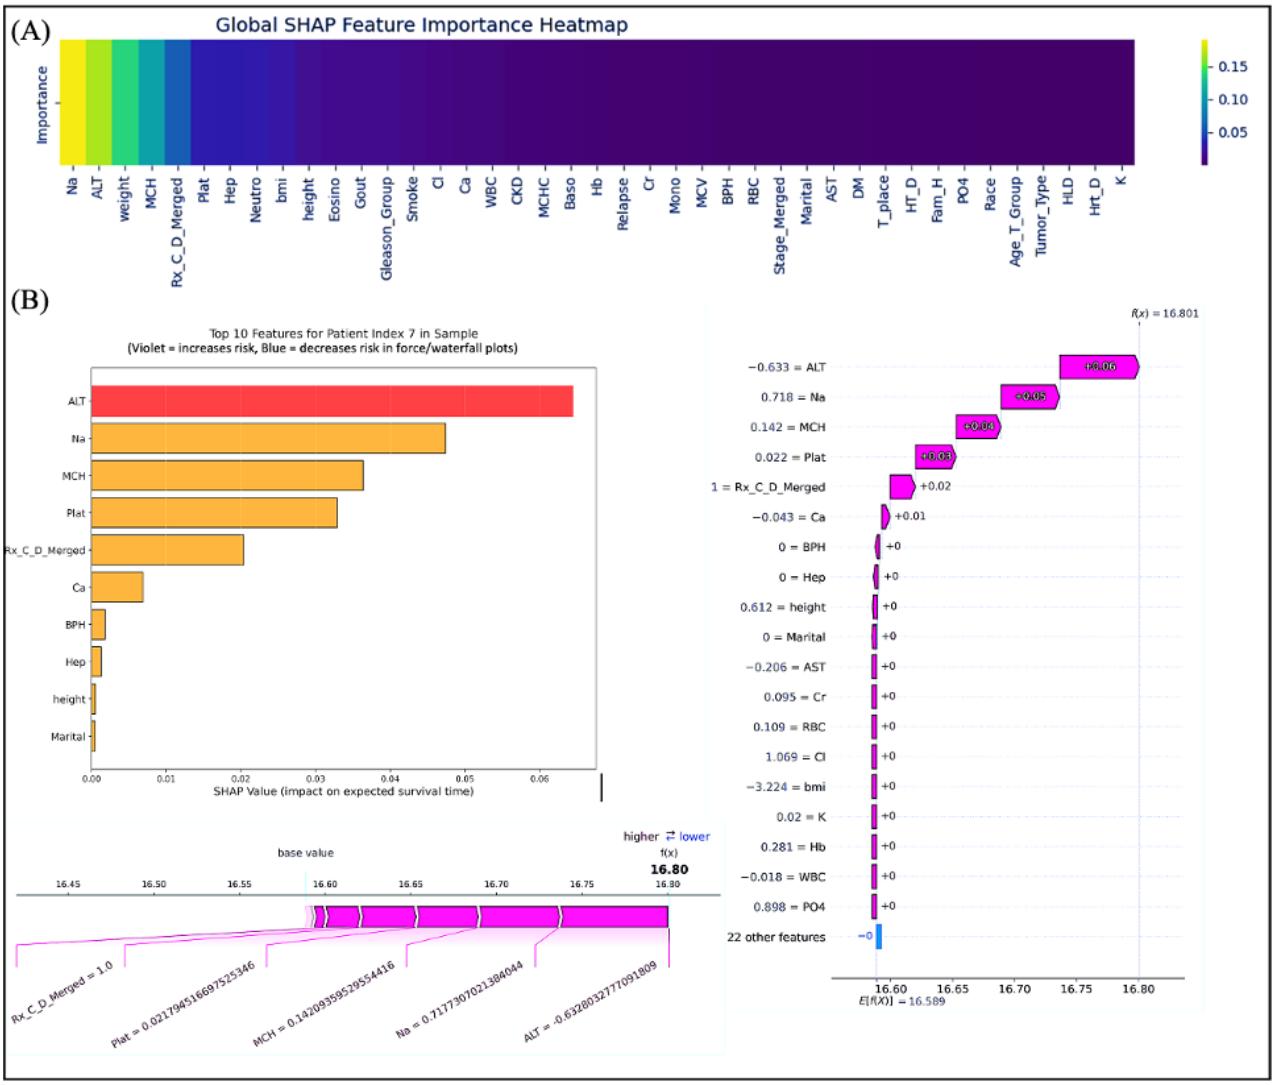
Models	Time-dependent AUC		Harrell C-index	Integrated Brier score
	4 years	5 years		
Cox proportional hazards	0.706	0.833	0.531	0.0527
Random survival forest	0.941	0.917	0.906	0.0698
Gradient boosting survival	0.765	0.833	0.844	0.0590
Deep neural network survival	0.941	0.917	0.719	0.0887

Calibration Performance Using IBS for PFS Model

Calibration performance of the PFS models was assessed using the IBS, where lower values indicate better agreement between predicted and observed outcomes (Table 1). Among the evaluated models, the Cox proportional hazards model demonstrated the best calibration accuracy with the lowest IBS of 0.0527. The GBS model demonstrated comparable calibration performance (IBS=0.0590), followed by the RSF model (IBS=0.0698). In contrast, the deep neural network survival model exhibited the highest IBS (IBS=0.0887), indicating comparatively poorer calibration despite its better discriminative performance.

Although similar time-dependent AUC values were observed between the RSF and deep neural network survival models at specific predefined time points, the limited number of events in the study may reduce the sensitivity of AUC to detect subtle performance differences between models. Therefore, we placed greater emphasis on the C-index and IBS, as these metrics provide a more comprehensive assessment of survival model performance across the entire follow-up period compared with isolated time-point AUC measurements. According to both discriminative and calibration performance, the RSF model demonstrated stable and well-calibrated risk prediction over time.

Model Explainability Using SHAP for RSF Models for PFS



Model explainability for PFS prediction using the RSF was assessed using SHAP, providing both global and individual-level interpretability (Figure 5). At the global level, the SHAP feature importance heatmap (Figure 5A) indicated that biomedical and laboratory parameters, particularly baseline sodium, alanine aminotransferase (ALT), mean corpuscular hemoglobin (MCH) level, weight, and the treatment variable (Rx_C_D_Merged), were the most influential contributors to the model's PFS predictions, while demographic variables showed comparatively lower impact. These features highlighted the dominant role of laboratory biomarkers in capturing progression risk in patients with prostate cancer. SHAP values reflect model attribution, not a causal effect.

At the individual level, with the sample patient, SHAP bar, force and waterfall plots (Figure 5B) illustrated how specific features contributed to the predicted PFS for a representative patient, demonstrating the direction and magnitude of each feature's effect on expected survival time. ALT, sodium, MCH, platelet count, and treatment category increased the predicted risk of progression, whereas other features had minimal or neutral influence. These outputs offer clinical interpretability of how individual patient characteristics contribute to PFS predictions,

XSL•FO
RenderX

thereby enhancing transparency, trust, and potential clinical utility in the prognosis of prostate cancer.

Figure 5. (A) Heatmap of global Shapley additive explanations (SHAP) feature importance for the random survival forest model. (B) Top 10 features by importance for an individual patient, bar, waterfall and force plots. ALT: alanine transaminase; BPH: benign prostatic hyperplasia; Ca: calcium; Cl: chloride; Hb: Hemoglobin; Hep: hepatitis; Na: sodium; Plat: platelet; PSA: prostate-specific antigen; Rx_C_D_Merged: treatment categories.

Discussion

Principal Findings

The study findings demonstrated that ML-based models showed improved internal discrimination compared with the traditional Cox proportional hazards model in predicting PFS among patients with prostate cancer, particularly at long-term horizons. While early PFS prediction at 1 to 3 years was not feasible due to insufficient progression events and limited comparable risk sets, robust discrimination emerged at 4 and 5 years. This reflects the delayed progression patterns and sluggish natural history of prostate cancer that are frequently seen in clinical practice [37-39]. Among the evaluated models, RSF showed the most balanced performance, achieving high time-dependent AUC values and stable calibration as measured by the IBS. These findings highlight the importance of aligning evaluation time points with disease biology and reinforce the limitations of early event prediction risk in prostate cancer cohorts [8,12,40].

Additionally, the study provided an explainability output from the RSF model using SHAP, which allows addressing the "black-box" barrier for clinical adoption of AI in oncology [19]. The SHAP-based global and individual explanations revealed that the laboratory biomarkers and treatment-related variables dominated the prediction of PFS. This aligns with emerging evidence that data-driven survival models capture complex, nonlinear associative predictors of risk that are often missed by conventional regression-based approaches [20,41]. Furthermore, the SHAP force and waterfall plots at the individual patient level enable clinicians to understand not only what the model predicts but how a particular prediction is made, which can further improve trust, auditability, and shared decision-making in clinical oncology [19,42,43].

Moreover, the application of a RAE to model the longitudinal cohort structure enabled effective compression of repeated observations into latent representations, providing a novel and efficient approach for managing complex temporal data while preserving clinically relevant information. The performance of

XSL•FO
RenderX

RSF and GBS models in this cohort was consistent with earlier reports demonstrating the superiority of tree-based methods for cancer survival prediction [19,44]. Additionally, similar to previous studies on prostate cancer, RSF models outperformed Cox models when handling high-dimensional laboratory and longitudinal data, particularly in heterogeneous real-world cohorts [36,45]. The underperformance of Cox regression in this setting supports the rationale for exploring ML survival methods, particularly RSF, which can capture complex nonlinear interactions without proportional hazards assumptions. Although earlier studies reported strong short-term predictive performance, our findings suggest that PFS prediction in prostate cancer is inherently limited at early points [39,40]. The comparatively weaker calibration of the deep neural network survival model highlighted that higher discrimination does not necessarily translate into reliable absolute risk estimation.

According to the SHAP model, sodium, ALT, and hematological parameters such as MCH and platelet count emerged as influential predictors of PFS. Dysnatremia has been associated with cancer progression and systemic inflammation, while elevated ALT may reflect hepatic stress, metabolic dysfunction, or treatment-related toxicity, all of which have been linked to poorer oncological outcomes [46-48]. Moreover, studies have indicated that the aspartate aminotransferase to ALT ratio can be used as a prognostic biomarker for prostate tumor progression [49,50]. These findings support the growing recognition that routine laboratory biomarkers capture systemic physiological states relevant to cancer progression beyond tumor-centric variables alone [51]. However, the prominence of sodium and ALT in our SHAP analysis does not indicate that these markers are biologically superior to other prognostic factors; rather, within this dataset and modeling framework, they emerged as influential predictive contributors that improved the model's ability to estimate risk.

This study has several limitations that should be acknowledged. First, the relatively small sample size, while sufficient for internal model development and evaluation, may restrict the generalizability of the results to other populations, particularly in light of regional differences in clinical practice and disease characteristics. This also limits the model's ability to capture early PFS events. Performance estimates are likely optimistic due to limited event counts. Despite these limitations, our study offers important novel contributions that address key gaps in the literature. No prior study, to our knowledge, has collected the comprehensive range of variables included here or applied a sequential approach to define PFS, whereas most existing studies use a single PFS event per patient, limiting clinical applicability. Second, the retrospective nature of the study may introduce bias due to missing data, unmeasured confounding, and evolving treatment strategies over time. Furthermore, model performance was evaluated using a held-out testing dataset; although cross-validation was applied to reduce overfitting, the absence of external validation remains a limitation.

Third, although the analysis was retrospective and conducted at a single institution, the TBCC functions as the only comprehensive oncology facility in the country and is responsible for the management of nearly all prostate cancer cases nationwide. Nevertheless, the findings highlight the potential utility of ML models incorporating SHAP-based explainability for prognostic risk assessment in prostate cancer. Finally, radiographic progression according to PCWG criteria was not incorporated into the PFS analysis because of the limitations of the imaging data available for this cohort. Future research should include independent external validation and multi-institutional, multiomics datasets with larger and more diverse cohorts to strengthen the generalizability and robustness of these findings.

Conclusions

Our study demonstrates that the ML-based survival models, particularly tree-based ensemble methods, substantially outperform the traditional Cox proportional hazards model in predicting PFS among patients with prostate cancer, especially at longer follow-up horizons. Among the evaluated approaches, the RFS model achieved the most balanced performance, combining strong long-term discrimination with stable calibration, thereby offering a robust framework for prognostic modeling in real-world prostate cancer cohorts. The integration of SHAP-based explainability addressed a key barrier to clinical adoption by providing transparent global and individual-level insights into model predictions highlighting the dominant role of laboratory biomarkers and treatment-related variables in driving PFS risk predictions in this cohort. The application of a RAE to encode longitudinal cohort data further enhanced the model's ability to capture the complex temporal patterns while reducing dimensionality. These findings support the clinical potential of explainable ML models for personalized risk stratification in prostate cancer, while also emphasizing the need for external validation, larger multi-institutional, multiomics datasets, and prospective evaluation prior to routine clinical implementation.

Acknowledgments

The authors would like to thank the Ministry of Health, Brunei Darussalam, and the Brunei Cancer Centre for granting permission to access the required data for this study. Abstract

Background: Electronic patient-reported outcome tools have the potential to enhance supportive care in oncology and support the timely and accurate identification of patients' needs.

Objective: This study aimed to develop, implement, and evaluate a user-friendly, web-based digital screening tool at a German Comprehensive Cancer Center that systematically and efficiently assesses the supportive care needs of patients with cancer and enables direct referral to appropriate supportive services through seamless integration with the hospital information system.

Methods: An interdisciplinary team collaborated with the IT department and the company CANKADO, an electronic patient-reported outcome provider, to create a 14-item digital questionnaire. The tool incorporated validated instruments, such as the Distress Thermometer, the Nutrition Risk Screening, and a short form of the Integrated Palliative Care Outcome Scale, aligned with German Cancer Society certification criteria. Patients accessed the questionnaire via QR codes. Screening results were automatically transferred to the hospital information system, where supportive care requests (SCRs) were generated automatically if indicated.

Results: Between June 2024 and May 2025, a total of 8855 QR codes were generated. Of these, 4909 questionnaires were complete and valid for analysis. This information produced 3324 SCRs. Digital screenings resulted in an SCR in 22.4% of cases for psycho-oncology, 18.7% for nutrition, and 27.6% for palliative care. The digital screening maintained or slightly improved screening rates compared to prior methods.

Conclusions: The implementation of a digital supportive care screening was feasible and effective within the Comprehensive Cancer Center setting. Future efforts should focus on overcoming barriers for patients with limited digital access or capabilities to ensure the delivery of equitable supportive care.

(JMIR Cancer 2026;12:e82392) doi:10.2196/82392

Introduction

Contemporary oncology acknowledges that supporting patients with cancer through their journey is essential. The diagnosis and treatment of cancer entail physical challenges as well as psychological and social burdens. Consequently, providing care that holistically addresses these multifaceted needs is of precedence [1,2]. Ensuring that individualized, need-based care is integrated into the treatment process requires systematic assessment of these needs [3]. Patient-reported outcome (PRO) assessments in the context of psycho-oncological and palliative care screenings are already established in Comprehensive Cancer

XSL•FO
RenderX

Centers (CCCs) across Germany and are incorporated into clinical guidelines [4-8].

The German Cancer Society recommends the implementation of an interdisciplinary screening procedure to evaluate counseling needs as an integral component of basic oncological assessment [9]. Historically, supportive needs were assessed via interviews or paper-based questionnaires. These methods, however, face limitations with regard to real-time data collection, structured documentation, and accessibility [10]. Thus, digital solutions for the collection of PROs have the potential to optimize support for patients with cancer by facilitating fast and precise identification of support needs while reducing the burden on health care professionals (HCPs) [11-13]. Furthermore, electronic patient-reported outcomes (ePROs) interventions have been shown to have a positive impact on health-related quality of life and symptom burden [13,14].

Notably, digital tools enable continuous and standardized assessment of patient needs across various treatment stages. This consistency is crucial, given that a patient's need for supportive care often evolves throughout the disease trajectory [11].

We therefore aimed to develop and implement a user-friendly, web-based digital screening tool to enable rapid and accurate collection of patient needs within a German CCC. The tool was designed to facilitate direct access to supportive services while ensuring seamless integration with the hospital information system (HIS). In parallel, challenges related to the digital implementation within routine clinical practice were examined.

Methods

Implementation Design

The implementation-oriented design of the project was guided by the EPIS (Exploration, Preparation, Implementation, Sustainment) framework, which provides a structured approach to implementing innovations in health care settings [15,16]. The project comprised 4 key phases corresponding to the EPIS framework.

Exploration

During the exploration phase (2017 - 2020), various platforms for collecting PROs were evaluated within the context of clinical studies at the CCC [17,18], as well as in the Department of Gynecology [19,20] and the Department of Hematology and Oncology [21]. Following this evaluation phase, the CANKADO platform was selected as a digital platform for web-based questionnaire delivery due to its ease of use, sustainability, and affordability [22]. An interdisciplinary working group was established, comprising experts from the fields of medicine and oncology, nutrition science, psycho-oncology, palliative care, and IT. Initial preparations for the implementation of the digital screening system began in 2020 but were delayed as a result of the COVID-19 pandemic. Compliance with information security and data protection regulations was ensured at all times (Textbox 1).

XSL•FO
RenderX

Textbox 1. Implementation steps using the Exploration, Preparation, Implementation, Sustainment (EPIS) framework.

Exploration (2017-2020)

- Formation of an interdisciplinary working group
- Development of a requirements catalog for a browser-based questionnaire platform
- Vendor screening and market research
- Pilot projects with 2 vendors
- Decision to partner with CANKADO's ePRO system
- Feasibility studies with CANKADO

Preparation (2020-2023)

- Questionnaire development
- Establishment of required IT infrastructure (automated patient registration, integration into the HIS, generation of QR codes)
- Programming and technical implementation within CANKADO and the HIS
- Data protection measures

Implementation (2023-2025)

- Pilot implementation
- Adaptation of the questionnaire based on pilot results
- Engagement and endorsement by medical and nursing leadership
- Training of HCPs in oncological departments
- Hospital-wide rollout
- Development of patient information materials

Sustainment (since 2025; ongoing)

- Refresher trainings for HCPs
- Continuous monitoring of screening uptake and effectiveness
- Implementation of support measures for patients with barriers to digital participation
- Evaluation of acceptance and use by HCPs (not part of this manuscript)
- Evaluation of patient acceptance (not part of this manuscript)

Preparation

The preparation phase involved the development of the PRO questionnaire, digital implementation, and ensuring data protection compliance.

Questionnaire Development

A tailored questionnaire, composed of existing validated short-form questionnaires, was developed in close coordination with the relevant disciplines (Department of Psycho-Oncology, Nutrition, and Palliative Care). This method ensured alignment with the certification requirements of the German Cancer Society (see Table 1). The National Comprehensive Cancer Network Distress Thermometer, the short version of the Integrated Palliative Care Outcome Scale (IPOS), and the Nutrition Risk Screening (NRS) 2002 served as the primary sources for item selection [23-26].

XSL•FO
RenderX

Table . Questionnaire.

Category and validated questionnaire		Question
Psycho-oncology (2 questions)[a]		
	NCCN[b] Distress Thermometer	1. Please circle the number (0 - 10) that best describes how much distress you have been experiencing in the past week including today.
	Request	2. Would you like psychological counseling? Yes / No / No answer
Nutrition (5 questions)[c]		
	NRS[d] and PG-SGA[e] SF	3. I currently weigh about _____ kg.
	NRS and PG-SGA SF	4. I am about _____ cm tall.
	NRS and PG-SGA SF	5. Three months ago, I weighed about _____ kg.
	NRS and PG SGA SF	6. How much did you eat last week compared to your usual amount? (Please mark a value between 0% - 150%)
	Request	7. Would you like nutritional counseling? Yes / No / No answer
Palliative care (6 questions)[f]		
	IPOS[g] (introductory text)	For each symptom, please tick the box that best describes how it has affected you over the past 3 days.
	IPOS	8. Pain: Not at all (0), Slightly (1), Moderately (2), Severely (3), Overwhelmingly (4)
	IPOS	9. Shortness of breath: Not at all (0), Slightly (1), Moderately (2), Severely (3), Overwhelmingly (4)
	IPOS	10. Poor mobility: Not at all (0), Slightly (1), Moderately (2), Severely (3), Overwhelmingly (4)
	IPOS	11. Have you been feeling anxious or worried about your illness or treatment? Not at all (0), Occasionally (1), Sometimes (2), Most of the time (3), Always (4)
	IPOS	12. Have any of your family or friends been anxious or worried about you? Not at all (0), Occasionally (1), Sometimes (2), Most of the time (3), Always (4)
	IPOS	13. Have any practical problems resulting from your illness been addressed? (such as financial or personal) Problems addressed/no problems (0), Problems mostly addressed (1), Problems partly addressed (2), Problems hardly addressed (3), Problems not addressed (4)
General (1 question)[h]		
	IPOS	14. How did you complete this questionnaire? On my own / With help from a friend or relative / With help from a member of staff

[a]A supportive care request (SCR) is automatically generated if the Distress score is >4 and psychological counseling is requested or not specified, or if psychological counseling is requested regardless of the Distress score.

[b]NCCN: National Comprehensive Cancer Network.

[c]An SCR is automatically generated if weight loss is >5% within 3 months, or BMI <20.5 kg/m², or food intake <75%, and nutritional counseling is requested or not specified, or if nutritional counseling is requested regardless of nutritional values.

[d]NRS: Nutrition Risk Screening.

XSL•FO
RenderX

[e]PG-SGA: Patient-Generated Subjective Global Assessment.

[f]An SCR is automatically generated if the IPOS-5 score is ≥8 or the IPOS-6 score is ≥10.

[g]IPOS: Integrated Palliative Care Outcome Scale.

[h]This question was taken from the IPOS but applies to the entire questionnaire.

For the identification of malnutrition and the need for nutrition interventions, the NRS was already the established screening tool in the hospital. However, the questions in the NRS were designed and validated to be completed by HCPs. For example, the first question asked whether the body mass index is less than 20.5 kg/m^2, which cannot be answered by a patient using a PRO tool. Therefore, the risk assessment points from the NRS tool were reworded analog to the wording validated in the Patient-Generated Subjective Global Assessment-Short Form, which is a validated PRO tool [23]. The cut-off points for the risk assessment remained in line with the NRS. Based on recent research results, the questions of the IPOS were adapted from IPOS-5 to IPOS-6 in April 2025 [27,28].

Key requirements for the overall questionnaire included brevity, ease of understanding for patients, and applicability across various stages of the disease. The final questionnaire, consisting of 14 items, serves as a prescreening tool. If necessary, a more detailed screening can be conducted by the relevant medical specialty. Regardless of the total score, patients also have the opportunity to actively express a desire for counseling services in the area of psycho-oncology or nutrition (items 2 and 7 of the questionnaire). This question was not included for palliative care.

A screening was considered valid if 1 or more of the following criteria were met: for the distress screening, at least 1 question had to be answered; for the nutrition screening, at least 1 question had to be answered; for the palliative screening using IPOS-5, at least 2 questions had to be answered; and for the palliative screening using IPOS-6, at least 3 questions had to be answered. Screenings that were accessed but had no items completed were not included.

Digital Implementation

The CANKADO ePRO system was initially developed for collecting PRO in clinical trials [20,29-31]. It utilizes a cloud-based electronic health record with a role-based access concept. Development and operation are carried out under ISO 27001 certification. Patients can access their ePRO questionnaires through personalized access via the web or an app. In addition, specific questionnaires can be accessed directly via a QR code. These QR codes are implemented to make access possible regardless of the device and without an additional app. Alternatively, the questionnaire can be completed via a tablet provided by the center and secured by kiosk software.

Based on this existing architecture, the CANKADO ePRO-based questionnaire was integrated into the HIS for use in routine clinical operations in oncology. The aim was to automate the entire process for HCPs and make it fully mappable within the HIS. To enable the integration of CANKADO ePRO into the hospital's existing SAP-based HIS, several components were required: (1) retrieval of a QR code linking to the digital screening questionnaire, (2) receipt of the completed digital screening as both a PDF document and structured data, (3) display of an overview of the most recent survey within a subsystem, and (4) storage of data for subsequent evaluation.

Within the existing HIS, a button was integrated to generate and retrieve the QR code. This request is routed via a Python-based HTTPS service to CANKADO. When a digital screening questionnaire is triggered in the HIS for a specific patient (based on the admission number) for the first time, this initiates the creation of a new, pseudonymized patient file in CANKADO. This file is assigned a generated identifier, which is then sent back to the HIS. At the same time, the corresponding questionnaire is assigned to the newly created patient number and coupled with a QR code, which is transmitted to the HIS. A base64-encoded image of the QR code is securely retrieved and displayed through the HTTPS service of the hospital. The generated QR code can be printed by the nursing staff and then handed to the patient, who completes the questionnaire digitally. The QR code can be regenerated for further assessments of the same patient.

After completion of the questionnaire, the data are automatically transmitted to the HIS. For security reasons, the data are received by a server located in a demilitarized zone (DMZ). The assignment to the real person takes place exclusively within the HIS. For each patient, the PDF document of the completed digital questionnaire is archived with a timestamp in the HIS. The data derived from the digital screening are additionally stored in accordance with the requirements set by the auditing bodies of the certified cancer centers in Germany. An entry in the documentation system is visible to show that a digital screening was performed. Based on the answers, a supportive care request (SCR) is automatically generated via web services (as shown in Table 1). In the final step, a physician reviews the clinical indication and grants approval.

HCPs can additionally be granted permission to access all deidentified patient records via the CANKADO web portal. There, they can view the completed questionnaires and calculated scores and export them if necessary. The structured data from the HIS are provided in JSON format and stored in a MongoDB database to facilitate efficient data evaluation and analysis. The following data can thus be analyzed in a structured manner: number of screenings performed and number of SCRs by the special departments (psycho-oncology, nutrition, palliative care).

Data Protection

The entire process was conducted in accordance with applicable data protection regulations. Approval was granted by the institutional data protection officer prior to implementation. A detailed data processing overview is shown in Table 2.

XSL•FO
RenderX

Table . Data processing overview.

Steps	Collection of personal data	Who accesses the data?	Duration of storage
Initiation			
ePRO creation by CANKADO	No personal data collected	No access	No storage
Creation of user accounts for medical staff	Data collected: 1. Email address 2. Name (optional) 3. First name (optional) 4. Place of employment 5. Address of workplace 6. Employment relationship (eg, study nurse)	Access by: • Trained CANKADO staff	Until the project ends, unless the account is no longer used or the user leaves the organization. Otherwise, until the user deletes the account.
Adding a patient	Data collected: 1. Patient ID (automatically generated by the system) 2. Year of birth (for studies) 3. Other basic data (optional)	Access by: • Trained CANKADO staff (only Patient ID) • Medical staff from the clinic/practice	Until the project ends, unless legal retention periods must be observed. Archiving and storage until the end of legal periods.
Documentation of patient data	Data collected: Project-dependent health data (eg, health status)	Access by: • Medical staff from the clinic/practice	Until the project ends, unless legal retention periods must be observed. Archiving and storage until the end of legal periods.
Project-specific evaluation of patient data	Data collected: Purpose-related analysis of anonymized patient data	Access by: • Selected staff from the clinic/practice	Until the project ends, unless legal retention periods must be observed. Archiving and storage until the end of legal periods.
End			

Implementation

The pilot phase was conducted from April to May 2023 on an outpatient oncology ward. Insights gained during this period regarding the process flow, the stakeholders involved, and the questionnaire itself were used to refine the instrument and address procedural challenges. Starting in June 2024, the interdisciplinary digital screening was rolled out across all oncology inpatient wards and several outpatient units, marking its integration into routine clinical care. To ensure consistent implementation, training sessions were organized with nursing staff and physicians in each department beginning in May 2024. These sessions were systematically conducted by designated, qualified CCC employees. The screening process is shown in Figure 1. The process, along with the designated responsibilities, was outlined in a standard operating procedure made accessible to all HCPs. Barriers and challenges were regularly addressed and evaluated during recurring meetings of the working group, where ongoing developments were also critically discussed.

XSL•FO
RenderX

Figure 1. Screening procedure. HIS: hospital information system.

XSL•FO
RenderX

The implementation of digital screening was first piloted in a single outpatient clinic. This clinic was selected due to its relatively new organizational structure, where routine, comprehensive distress screening had not yet been fully implemented at the start of the project. Distress screening rates were compared between two equivalent six-month periods: July to December 2023 (analog screening only) and July to December 2024 (a combination of analog and digital screening).

Sustainment

The sustainment phase focused on embedding the digital screening into routine clinical practice and ensuring long-term adoption. HCPs' acceptance was assessed through an evaluation in early 2025, and ongoing support structures—including patient navigators for patients facing digital barriers—were introduced to maintain equity and inclusivity. Structured data storage and integration with hospital systems allow for continuous monitoring of screening uptake and effectiveness.

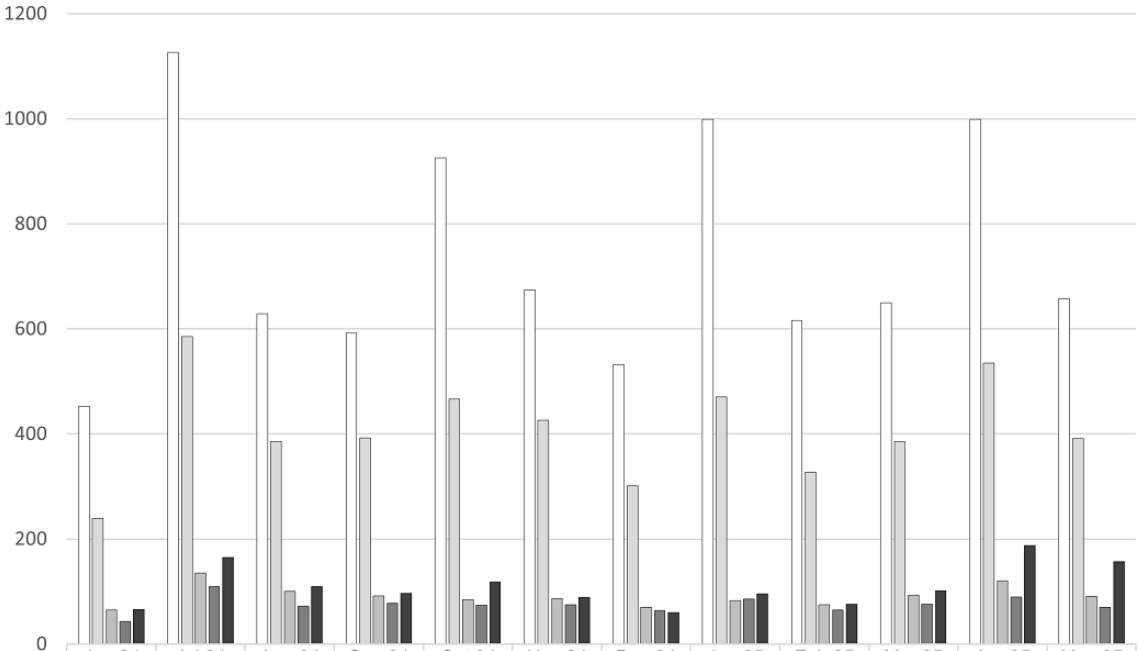
Ethical Considerations

This study used fully anonymized data analyses and involved no intervention. All data were extracted from the hospital patient information system and fully anonymized prior to analysis, precluding any direct or indirect patient reidentification. Thus, the local ethical committee provided written confirmation that no formal ethical consultation was necessary (application number 24 - 0535 KB). An informed consent was not required, and no compensation was provided to participants.

Results

HCP Training

Between May 2024 and May 2025, a total of 48 training sessions were conducted at 32 oncology wards and departments within the LMU Hospital. Thirty-two training sessions were conducted for nursing staff, and 13 were conducted for medical staff. Additionally, 3 training sessions were held for specialized departments involved in providing supplementary counseling services (psycho-oncology, nutrition, and the palliative care team). Overall, 43 of 59 (72.9%) organizational units involved in the care of patients with oncology received training on digital screening procedures. In this phase, the focus was on inpatient units and day clinics; most outpatient areas were not yet included.



12-Month Implementation Period

After the implementation of the digital screening, a total of 8855 QR codes (738 on average per month) were generated between June 2024 and May 2025. A total of 4909 (55.4%) questionnaires (409 on average per month) were completed and deemed valid. This means that, on average, 329 (44.6%) QR codes per month were either not accessed or accessed without any items being answered. In 946 (10.7%) instances, the questionnaire was accessed via the QR code, but no items were filled out. A total of 3822 (77.9%, 3822/4909) evaluable screenings were performed by the patient only once, while 1087 of 4909 (22.1%) evaluable screenings were performed at least twice.

Among the 4784 responses to the question about how the questionnaire was completed, 80.1% (n=3831) were completed independently by the patients, 15.6% (n=746) with assistance from relatives, and 4.3% (n=207) with support from staff. The screenings resulted in a total of 3324 SCRs, including 1097 (22.4%) for psycho-oncology, 903 (18.7%) for nutritional counseling, and 1324 (27.6%) for palliative care. The analysis per month is shown in Figure 2. The number of QR codes created was highest at the beginning of each quarter.

XSL•FO
RenderX

Figure 2. Development of the generated QR codes, the screenings conducted (at least 1 question answered; screenings that were accessed but had no items completed were not included), and the supportive care requests (SCRs) created in the period from June 2024 to May 2025.

	Jun 24	Jul 24	Aug 24	Sep 24	Oct 24	Nov 24	Dec 24	Jan 25	Feb 25	Mar 25	Apr 25	May 25
QR codes generated	453	1127	629	592	926	674	532	999	616	650	999	658
Digital screenings	239	585	386	393	467	426	302	471	327	386	535	392
SRC psycho-oncology	65	135	101	92	85	87	70	83	75	93	120	91
SCR nutrition	43	110	72	78	74	75	64	86	65	76	90	70
SCR palliative care	66	165	110	97	118	89	60	96	76	102	188	157

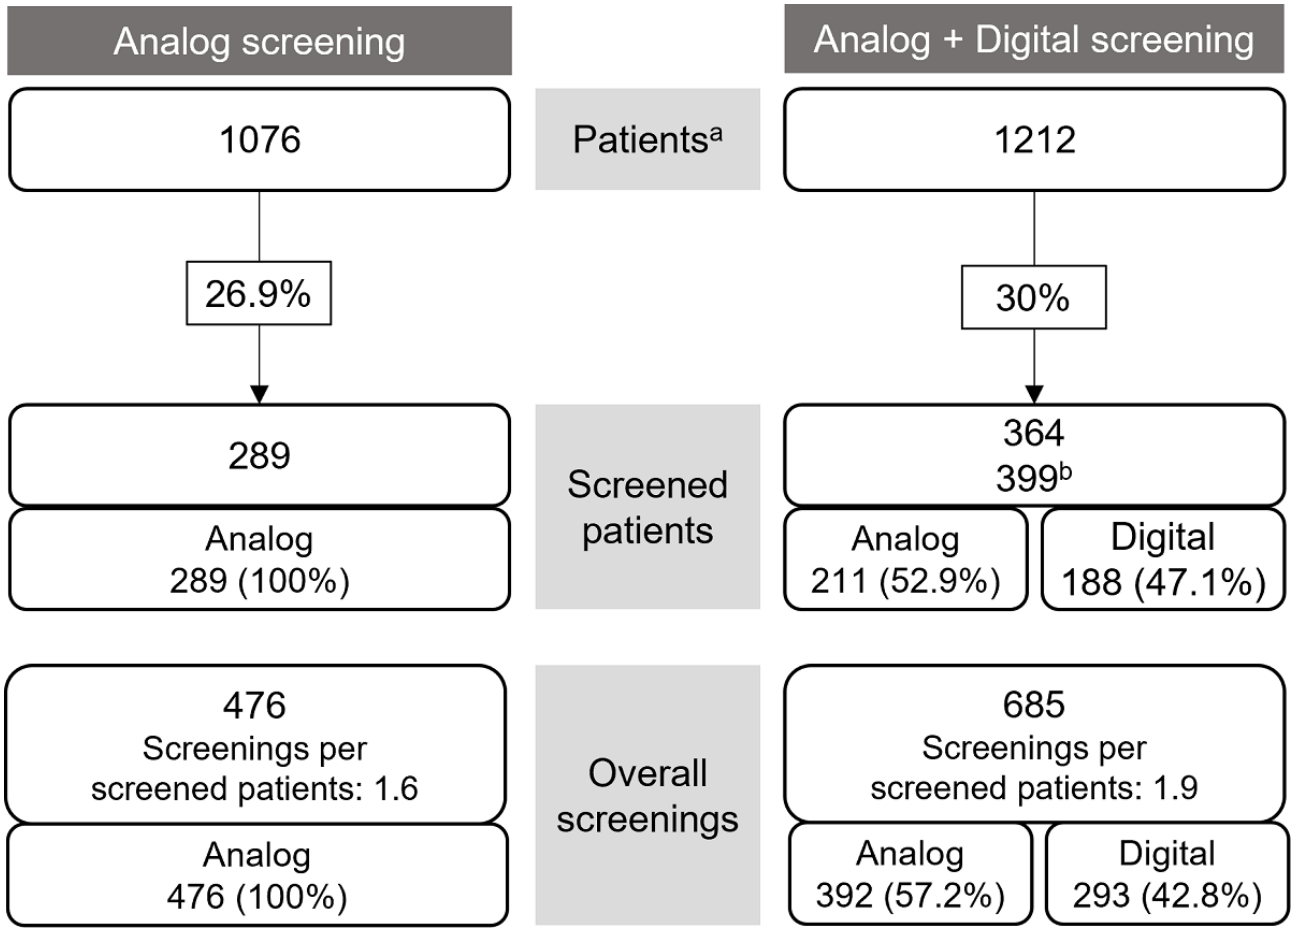
In total, 4891 patients' screenings indicated a distress value and/or the patient requested a psychosocial consultation. Of these, 56% (n=2741) had an increased distress value of more than 4 points (see Figure 3). An SCR was triggered for 32% (n=876) of these screenings, which had an increased distress score. Accordingly, no SCR was triggered for 68% (n=1865) of the people with an increased distress score, as they had rejected psycho-oncology counseling. Fifty-nine SCRs were induced due to an increased distress value, and there was no information available on whether the patient had a desire for counseling. The majority of SCRs (n=817, 74.5%) were induced by a combination of an increased distress value and a request for counseling by the patient on the digital screening. Less frequently, the SCR was triggered solely due to the request for counseling (n=221, 20.1%), as the distress value was below the threshold rate and/or not specified. The overall demand for psycho-oncological counseling was 1097 out of 4891 (22.4%).

XSL•FO
RenderX

Figure 3. Evaluation of questionnaires in the areas of psycho-oncology (distress screening), nutrition screening, and palliative care screening, as well as the initiated SCRs (supportive care requests). [a]A screening was considered valid when 1 or more of the following fields were completed: distress screening, at least 1 question answered; nutrition screening, at least 1 question answered; palliative screening (IPOS-5), at least 2 questions answered; palliative screening (IPOS-6), at least 3 questions answered. [b]Screening thresholds are detailed in Table 1. [c]The need for consultation is determined by the number of initiated SCRs in relation to the total number of screenings performed.

A total of 4828 questionnaires were completed with at least 1 item of the nutrition screening and/or the patients provided information about their need for consultation. Of these, 45.3% (n=2189) met the nutrition-specific thresholds. An SCR was triggered for 23.5% (n=515) of these screenings. Accordingly, no SCR was triggered for 76.5% (n=1674) of the screenings with corresponding nutritional values, as the patient had rejected nutrition counseling. A total of 469 of 903 (51.9%) of the SCRs for nutrition were triggered because the threshold value was exceeded and the patient requested nutrition counseling. Additionally, 388 of 903 (43%) SCRs were patient requests for nutrition counseling although the threshold value was not reached or specified. Furthermore, 46 of 903 (5.1%) SCRs were induced due to an increased nutrition threshold value, while there was no information available on whether the patient had a desire for counseling. In summary, the overall need for nutritional counseling was 903 of 4828 (18.7%).

A total of 1324 of 4793 (27.6%) of the patients who completed or partially completed the screening for palliative care (n=4793) also had an elevated IPOS score.



Overall, 1 or more counseling needs were identified and triggered in 3072 of 4909 (62.6%) of the screenings. Accordingly, 1837 of 4909 (37.4%) of the screenings revealed no unmet needs.

Comparison of Development: Analog vs Digital Derived From a Single Outpatient Clinic Within the LMU Hospital

Distress screening rates were compared in 2 comparable 6-month periods: between July and December 2023 (analog screening only) and July to December 2024 (a combination of analog and digital screening). All relevant staff of the outpatient clinic were trained in the use of digital screening in May 2024. Since the transition to digital screening was gradual, analog screenings continued to be conducted alongside the digital ones during this period. Nevertheless, after the introduction of digital screening, the percentage of screened patients increased from 26.9% to 30%. In the 6 months following the implementation, 57.2% of the distress screenings were still conducted using the analog method, while 42.8% were carried out using the digital screening (see Figure 4). The number of screenings per screened patient increased from an average of 1.6 to 1.9 after the implementation.

XSL•FO
RenderX

Figure 4. Comparison of distress screenings conducted over two 6-month periods at the oncological outpatient clinic. From July to December 2023 (6 months), distress screening was still performed using paper forms (analog screening, left side). The analysis on the right includes data collected immediately after the implementation of the digital screening, during a transitional phase in which both paper-based and digital methods were used (digital + analog screening, July-December 2024). [a]Number of patients undergoing treatment in the respective period. [b]Some patients were screened through both analog and digital methods during the specified period and therefore were counted twice.

Discussion

Principal Findings

The study demonstrates the successful implementation of a structured, standardized, and ePRO-driven digital screening process for assessing supportive care needs in oncology at LMU University Hospital. The screening tool enables the systematic collection of data in accordance with the screening requirements set by the German Cancer Society (DKG). It is fully integrated into routine clinical workflows via the HIS. A central design principle was the use of a concise questionnaire limited to 14 items, ensuring feasibility and acceptability in everyday clinical practice. Shorter questionnaires have been associated with higher participation rates, reduced respondent burden, and improved inclusivity across diverse patient populations [32-34]. A comparable implementation approach has been described by Maurer et al [35], who similarly integrated ePRO-based supportive care screening into routine clinical workflows, albeit using a more extensive questionnaire. Although the screening pathway was developed within the framework of German Cancer Society certification, the underlying concept is not restricted to the German health care setting. In fact, the concept can be adapted to other national contexts with comparable digital infrastructures and care pathways. Similar ePRO-driven screening strategies have been reported from other countries, demonstrating the feasibility of embedding digital needs assessments into routine cancer care in diverse health system contexts [36,37].

Feasibility, Adherence, and Screening Outcomes

The questionnaire incorporates short-form PRO versions of the Distress Thermometer, the NRS with wording from the Patient-Generated Subjective Global Assessment, and the IPOS. As a prescreening tool, it supports targeted follow-up assessments by the respective specialties. During the first 12 months, 8855 QR codes were generated, and 4909 (55.4%) screenings were completed. According to the literature, the proportion of patients completing standardized distress or supportive care needs screenings typically ranges from 50% to 70%, depending on the clinical setting and the methodology used [38-40]. The adherence observed in our study is therefore comparable to these published rates. However, the true adherence rate may be underestimated, as some QR codes may not have been distributed for various reasons, such as patient absence. In addition, a number of QR codes were generated for training purposes or as part of system testing during the implementation phase.

Across all completed screenings, the identification of unmet needs resulted in SCRs in 22.4% of screenings for

XSL•FO
RenderX

psycho-oncology, 18.7% for nutrition, and 27.6% for palliative care. These findings are broadly consistent with prior studies reporting substantial unmet needs among patients with oncology, although direct comparisons are limited by differences in screening scope and methodology [41,42]. Previous research reported that 23% of patients with cancer were newly referred to palliative care [43]. Our study observed a higher level of need, which can be attributed to the requirement for physician-led final approval of referrals. This finding also reflects the substantial symptom burden in a patient cohort that was not preselected based on medical status.

Equity, Digital Access, and Patient Support

Despite the advantages of digital screening, patient-related barriers may limit participation. Older age, poor health status, lack of access to digital devices, and limited digital literacy can reduce adherence and equity. To mitigate these barriers, paper-based screenings continue to be offered for selected patients. In addition, targeted measures have been introduced to improve digital inclusivity. Additional informational material has been created to explain the purpose and process of the screening, helping patients understand its importance and encouraging participation. Pilot projects are currently underway in several organizational units, where patients facing barriers to digital participation receive active support from trained patient navigators. These navigators play a central role in enabling patients—regardless of age, health status, or digital literacy—to benefit from the digital screening pathway. Institution-provided tablets are used as supportive tools to facilitate access and completion of screenings. Hybrid models combining digital tools with human support have been shown to enhance participation and effectiveness, highlighting the value of patient navigators [44].

Impact on Screening Rates in Routine Care

Screening rates were evaluated on a single outpatient ward before and after the implementation of digital screening. Following implementation, screening rates were maintained or slightly increased (26.9% vs 30%), largely through a combined use of digital and paper-based methods. Maintaining hybrid workflows ensured continuity of care and inclusivity during the transition phase.

Reported screening rates reflect all patients treated during the respective periods and are therefore lower than DKG benchmarks for newly diagnosed primary patients [45,46]. In 2024, the LMU Oncology Center achieved the required 65% threshold for distress screening, to which the digital implementation may have contributed. Distress assessments documented outside standardized reporting structures could not be captured in the analysis.

Facilitators and Barriers to Implementation

Several facilitators supported successful implementation. The DKG requirement for structured screening provided a strong regulatory framework. In addition, implementation was supported by hospital leadership, the IT department, and the technology provider. The allocation of dedicated personnel enabled systematic training, coordination, and continuous refinement of the system. Digitalization also yielded operational benefits. A unified questionnaire simplified workflow, automated data transfer, eliminated manual data entry and document archiving, and ensured the immediate availability of screening results in the HIS. The automated generation of SCRs based on predefined thresholds further reduced administrative burden and improved transparency.

Nevertheless, several barriers were encountered. Generating QR codes initially appeared more time-consuming than distributing paper questionnaires, and the downstream time savings were not always immediately apparent to staff. Comprehensive and repeated training sessions were, therefore, essential, consistent with prior implementation research [47-49]. Moreover, purely digital approaches cannot fully reach all patient groups. Approximately 20% of patients required assistance to complete the questionnaire, highlighting the need for supportive strategies.

Comparison With International Implementations

International experience with digital distress and supportive care screening reveals similar challenges. In the United States, electronic screening is often integrated into patient portals or electronic health records; however, documentation gaps and limited follow-up remain common [36]. In the United Kingdom, digital Holistic Needs Assessments are available and easy to use, but their application in everyday clinical practice is limited. The main problems include a lack of commitment, time constraints within the care team, and insufficient feedback of ePRO results into concrete care decisions, which reduce motivation to use them among both patients and professionals [50]. Australia has technically mature, digitally integrated screening workflows with high initial participation rates. Nevertheless, there are issues with acceptance in subsequent courses, particularly with repeated screenings, as well as uncertainties among staff regarding how to handle high distress values and their implications. Here, too, usage depends heavily on training, local leadership, and clear responsibilities [37,51].

In Asia, digital ePRO approaches vary considerably. In Japan, distress screening is formally established but is often only partially digitized and has limited structured follow-up [52]. In South Korea and China, there are significant barriers to acceptance: low routine use, cultural reluctance to seek psychosocial help, and low acceptance rates after a positive ePRO screening [53,54]. Singapore is an exception, as digital distress ePROs are closely linked to a multidisciplinary care model and thus achieve a high level of acceptance [55]. In Europe, the Netherlands exemplifies successful implementation when digital screening is mandatory, systematically discussed, and directly linked to care pathways [56]. Overall, international evidence suggests that technical availability alone is insufficient; sustained use depends on clear workflows, automated follow-up, leadership support, and perceived clinical relevance [57].

Generalizability and Transferability

Although conducted at a single CCC, several features support transferability. The screening content is based on internationally validated instruments and guideline-aligned supportive care domains. Technically, the CANKADO platform is HIS-agnostic. Interfaces are implemented via standardized web-based

XSL•FO
RenderX

application programming interfaces and enable integration with heterogeneous hospital IT environments beyond the SAP-based infrastructure used at LMU Hospital. Structured data exchange enables flexible mapping to local documentation and reporting requirements.

The system complies with the General Data Protection Regulation and the more stringent French Hébergeurs de Données de Santé framework, supporting international applicability. While the depth of integration achieved at LMU Hospital has not yet been replicated elsewhere, the platform is already used in multiple international settings [19,30,58,59]. Future multicenter studies are needed to evaluate scalability, resource requirements, and contextual adaptations across different health care systems.

Limitations

Despite the demonstrated feasibility and advantages of digital supportive care screening in oncology, several limitations should be acknowledged. Technical challenges, such as temporary connectivity issues, system maintenance, or software-related disruptions, may intermittently affect access to the digital platform and result in delayed or incomplete data capture. In addition, the implementation and maintenance of a secure, interoperable digital screening infrastructure require substantial technical, administrative, and human resources. Ensuring ongoing compliance with data protection regulations and IT security standards represents a continuous organizational effort.

A key limitation relates to equity and accessibility. Digital screening inherently excludes certain patient groups, particularly individuals without access to suitable digital devices or with limited digital literacy. Older patients, those with cognitive or physical impairments, and patients with advanced disease or severe symptom burdens may face additional barriers to independent participation. Although supportive measures, such as paper-based alternatives and assisted completion, were available, these barriers may have reduced the inclusivity and representativeness of the screening results.

Human resource constraints also represent a relevant limitation. High workload among HCPs, especially in nursing and medical staff, may delay the initiation of screening or the review and approval of triggered SCRs. In particular, delays in physician review of SCRs may hinder timely referral to counseling services and continuity of care. At present, systematic evaluation of approved SCRs, completed counseling sessions, or canceled referrals is not yet possible within the existing data structure; however, this functionality is currently under development and will be addressed in future analyses.

Furthermore, the digital questionnaire currently does not adequately address linguistic and cultural diversity. The lack of multilingual versions may limit accessibility for patients with limited proficiency in the primary language of care and may reduce the effectiveness of the screening in culturally diverse populations. While digital implementation allows relatively straightforward adaptation to additional languages, this feature has not yet been fully implemented at the time of evaluation.

Finally, the study was conducted at a single academic CCC with a high degree of digital maturity and IT integration. Although the technical architecture and conceptual approach are transferable, implementation depth, available resources, and organizational workflows may differ substantially across institutions. These contextual factors should be considered when interpreting the findings and underscore the need for future multicenter evaluations.

Implications for Clinical Practice

The findings of this study provide several practical implications for the implementation of digital supportive care screening in routine oncology practice. First, successful implementation requires careful preparation, clear governance structures, and the allocation of sufficient technical and human resources. Defining the scope of supportive care domains and selecting a concise questionnaire that balances clinical relevance with feasibility are essential to facilitate integration into daily workflows.

Comprehensive and role-specific training programs for HCPs are critical. Initial training should be complemented by regular refresher sessions to maintain engagement, address uncertainties, and integrate system updates. Assigning clear responsibilities to specific professional groups—for example, nursing staff for screening initiation and physicians for SCR approval—supports accountability and process reliability. Introducing the screening initially in motivated units or pilot wards may foster early adoption and generate positive momentum for broader rollout.

Maintaining flexibility in screening modalities is particularly important during implementation phases. Hybrid workflows that combine digital and paper-based screening can ensure continuity of care and inclusivity, especially for patients facing access barriers. From a technical perspective, screening data should be available both as archivable PDF documents and as structured data within the HIS to support documentation, quality assurance, and secondary analyses. Systems should also be adaptable to future modifications of questionnaire content or screening frequency.

Equally important is the proactive consideration of equity and accessibility. Implementation strategies should explicitly address patients with limited digital skills, physical impairments, or language barriers. Support structures such as patient navigators, assisted completion, and the provision of institution-owned devices can substantially enhance digital participation. Finally, digital screening will only be sustainably adopted if both patients and HCPs perceive clear clinical benefits. Automated follow-up processes, timely referrals, and visible improvements in patient care are, therefore, essential to reinforce acceptance and long-term use.

Conclusion

A digital oncological screening in the supportive care setting was successfully implemented at a German CCC. Automated integration into the HIS enabled efficient identification of supportive care needs, reduced administrative burden, and supported patient-centered care. Continuous training and standardized procedures were critical to success. Future initiatives will focus on improving digital equity and accessibility to ensure that all patient groups benefit from supportive oncology care.

Acknowledgments

We thank Gabriele Kraus-Pfeiffer and Oliver Guldner for their valuable support during the execution of the pilot phase. AI-assisted tools were utilized to support the literature search process and to assist with language editing, translation, and manuscript reformatting. Tools used included DeepL and ChatGPT. All AI-generated content was critically reviewed, revised, and approved by the authors. All authors take full responsibility for the accuracy and integrity of the final manuscript.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Data Availability

The datasets generated during and/or analyzed during the current study are available from the corresponding author upon reasonable request.

Authors' Contributions

TF and NE were primarily responsible for the study design, including conceptualization, methodology, and supervision. VH, FM, BH, RW, and ST supervised the clinical components and contributed to the overall study concept. NE, FM, and BH developed the questionnaire. TS managed the required modifications from CANKADO's side. GW implemented the necessary Information Technology programming at the hospital. UH, SM, and NT conducted the training sessions and collected the data. TF and NT performed data analysis and interpretation. TF drafted the original manuscript, which was then edited by NE. All authors reviewed and approved the final version.

Conflicts of Interest

NE has received speaker honoraria from Audi BKK, Baxter, Beiersdorf, CSL Behring, Fresenius, Freiraum, Fraunhofer Institut, Janssen-Cilag GmbH, Cognitando GmbH, and GHD. She served on the expert advisory board at Baxter and received consulting fees from Fresenius. None of these activities were related to the content of this paper. RW received honoraria for consultancy, advisory boards, and travel support from Agendia, Amgen, APOGHEVA, Aristo, Astra Zeneca, Bayer, Celgene, Clinsol, Daiichi-Sankyo, Eisai, Esteve, Exact Sciences, Gilead, Hexal/Sandoz, Lilly, MSD, Mundipharma, Mylan, Nanostring, Novartis, Onkowissen, Paxman, Palleos, Pfizer, Pierre Fabre, PINK, Riemser, Roche, Seagen, Sidekick, Stemline, Tesaro Bio, Teva, Veracyte, Viatris, Wiley, Thieme, Digimed, Eickeler, FOMF, Art Tempi, Aurikamed, Clinsol, Pomme Med, iMEDInstitut, medconcept, MCI, MediSeminar, Medicultus, H+O Communications, New Oncology Concepts, SPCC, streamed up, medupdate GmbH, and institutions: SPCC, WSG, AGO, and DKG.

Abstract

Background: Nearly 250,000 cancer cases are diagnosed annually in Canada, with breast and prostate cancer representing 25% and 22% of new cases, respectively. Artificial intelligence (AI) applications can potentially improve the accuracy, efficiency, and timeliness of cancer care, including screening, diagnostic imaging, and early treatment. However, patient acceptability of AI in cancer care remains underexplored.

Objective: This study aimed to understand the feelings and perceptions of and acceptability to patients with breast and prostate cancer regarding the inclusion of AI-powered medical robots for cancer screening, diagnosis, and early treatment and to identify barriers and facilitators to implementation.

Methods: In this qualitative study, semistructured interviews were conducted with 15 patients with breast (n=6) or prostate (n=9) cancer. Participants (mean [SD] age 67 [12] y; range 41 - 88 y) were recruited from Sunnybrook Health Sciences Centre between May and November 2022. Each participant completed 2 semistructured interviews, each approximately 1 hour in length, conducted by telephone or Zoom by a research assistant. The first interview explored initial reactions and expectations regarding AI-assisted medical technologies, allowing us to tailor questions for the second interview to better understand practical means of introducing AI into care, while further exploring salient concepts. Data were analyzed using a conventional content analysis approach. Two research assistants independently and inductively coded transcripts, iteratively generating and refining a codebook. Data saturation was assessed after 10 interviews and confirmed through analysis of all 15 participants.

Results: Three overarching categories were developed: (1) individual beliefs, understanding, and attitudes; (2) integration of AI into care; and (3) health structure, systems, and processes. Participants reported openness toward AI-assisted medical robots but emphasized the importance of reduced wait times, demonstrated safety and reliability, and patient-centered care. Patients indicated that with appropriate education and transparent communication, they would be willing to accept AI-assisted care due to its enhanced accuracy and efficiency. Key barriers included concerns about reliability, potential loss of human interaction, and inadequate mitigation strategies for technical failures. Facilitators included timely results, improved efficiency, accessible educational resources, and assurance that AI would complement rather than replace human expertise.

Conclusions: Participants demonstrated cautious willingness to accept AI-powered medical robots in cancer care if positioned as complementary to, rather than substitutes for, human-provided care. These findings underscore the need for maintaining the presence of health care providers during AI-assisted procedures, providing clear and accessible education, and ensuring transparent communication about safety and reliability. Personalizing patient education and offering multiple modes of information delivery may foster confidence and improve acceptability. While findings are exploratory and reflect the perspectives of a small,

XSL•FO
RenderX

predominantly urban sample, they provide actionable insights into patient concerns and priorities that may inform future research and guide early implementation strategies in integrating AI into cancer care pathways.

Introduction

By the end of 2025, an estimated 248,700 new cancer cases will be diagnosed in Canada. Breast and prostate cancers are expected to account for approximately 23% of all new cancer cases [1]. For patients, receiving cancer care can be a prolonged and complicated process from screening to diagnosis and treatment [2,3]. In this article, the term *screening* is used broadly, consistent with the terminology adopted in North American cancer care research, to encompass both asymptomatic individuals undergoing high-risk surveillance (eg, breast magnetic resonance imaging (MRI) or elevated prostate-specific antigen testing) and those in the early diagnostic phase following symptom presentation or initial cancer detection. This broader operational definition reflects the continuum of early detection and diagnostic processes experienced by patients with breast or prostate cancer in the Canadian health care context. Despite the high prevalence of breast and prostate cancers, patients continue to face long diagnostic and treatment intervals, limited access to specialists, and systemic delays that negatively impact outcomes and quality of life [2-7]. Weller et al [4] refer to 3 stages of cancer care: the patient interval (symptom presentation to seeking medical attention), the diagnostic interval (seeking medical attention to obtaining a diagnosis), and the treatment interval (diagnosis to treatment) [5]. The diagnostic and treatment intervals usually include medical tests and multiple appointments with health care providers across several medical offices or hospitals [5]. Typical care pathways for prostate cancer (spanning the patient, diagnostic, and treatment intervals described by Weller et al [4]) are estimated to take between 163 and 367 days [3]. For breast cancer, the continuum from the patient interval to the completion of the treatment interval can take approximately 60 days [2]. The series of multiple diagnostic and treatment procedures contributes to long wait times and fragmented care. Such delays negatively affect quality of life, increase uncertainty, and may lead to worse health outcomes [6,7].

Timely medical attention is critical for optimal patient care, but there is a shortage of health care providers in the current Canadian health care system (ie, imaging specialists, specialized oncologists, and surgeons), which adds difficulties in meeting increasing patient demand [8,9]. Advanced-stage breast and prostate cancers may require more invasive interventions, including mastectomies and prostatectomies [10,11]. Early detection and diagnosis may allow for more targeted and less invasive treatment regimens [10,12], whereas when cancer is detected too late, less invasive options may not be possible. Across oncology and other medical specialties, health care providers experience growing workload pressures due to increasing patient volumes, staffing shortages, and other systemic inefficiencies. This has contributed to nationally elevated burnout rates and compassion fatigue among health care providers [8,9]. The limited availability and overworking of health care providers contribute to accessibility issues for patients, especially in rural and remote regions, where accessibility and availability of specialized health resources are often even more sparse [13,14].

In a systematic review, Reece et al [7] identified several key issues regarding delayed or failed follow-up for breast cancer screening in primary care settings: physician-patient miscommunication, automated alert systems creating an overinflux of information, reduced coordination of patient medical health records, and inconvenient clinic hours and lack of availability of primary care. Urquhart et al [15] interviewed survivors of prostate cancer about their experiences with follow-up and posttreatment cancer care. Participants described various issues, including lack of information, resources, and psychosocial support, which left them feeling unprepared in their recovery process. These perceived issues in their care were related to lack of availability of health care providers and not being able to see the same health care provider throughout their care due to a staffing shortage within oncology [8,15].

Recent advances in technology, such as the use of artificial intelligence (AI) in cancer screening, represent a potential mechanism for increasing efficiency in wait times in cancer pathways, reducing the demand on health care providers, and improving accessibility within the health care system [16,17]. AI has been shown to be an effective tool for breast and prostate cancer diagnosis and in prostate cancer Gleason scoring [18]. Successful AI applications in diagnostic imaging have enabled the detection of early cancerous lesions with greater accuracy and efficiency, with trialed technology often outperforming experts [19,20]. A 2017 study showed that automated deep learning algorithms identified nodal metastases in histopathological analyses of breast tissue more accurately than an expert panel of pathologists [21]. AI deep learning algorithms have also assessed mammograms with proficiency equal to expert radiologists, with 5.7% and 9.4% reduction in false positive and false negative rates, respectively [22]. In prostate cancer screening, deep learning algorithms have demonstrated the potential to automate Gleason scoring of histopathologic images of adenocarcinomas, achieving 75% agreement with expert pathologists, demonstrating great model performance [18]. Similar AI-powered applications have been used with diffusion-weighted MRI to delineate cancerous and noncancerous prostate tissue [23]. As AI becomes more sophisticated, new opportunities in both diagnostic imaging and treatments are emerging with potential to transcend the accuracy

XSL•FO
RenderX

and time limitations of traditional methods. Specifically, with the advent of AI and robotics, telemedicine applications are feasible and have the potential to mobilize high-quality health care, allowing interventions to be carried out by medical robots, without a highly trained specialist onsite [18,23].

While AI-powered robotic systems have the potential to expedite procedures and improve patient care, the success of these technologies is contingent on patient acceptance. The needs and preferences of patients should influence both the development and the process of implementation of such technology into the health care system. This requires a comprehensive understanding of the patients' perceptions toward the use of such technology in their care. A greater understanding of what may be deemed acceptable is necessary before conducting large-scale research evaluating the use of AI in breast and prostate cancer screening and treatment [24,25]. The present study sought to elucidate patient perceptions, feelings, and acceptability regarding AI-powered medical robots in breast and prostate cancer care and to identify barriers and facilitators to implementation using a person-centered approach.

Methods

Study Design

This study employed a qualitative descriptive approach to answer the research question: How do patients feel about the use of AI-powered medical robots for cancer screening, diagnosis, and early treatment? Study objectives were to (1) illuminate patient understandings and feelings regarding the inclusion of AI in their care and (2) identify barriers and facilitators of implementing AI-powered robotic systems into cancer screening from patients' perspectives. This study is reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines (Checklist 1) [26]. A postpositivist stance [27] was taken, which assumes that while absolute truth cannot be fully captured, systematic qualitative methods can approximate patient perspectives and generate transferable insights. This orientation informed our design by emphasizing structured data collection (semistructured interviews), analytic rigor (systematic coding by multiple analysts), and reflexivity to minimize bias. This study was part of a larger program of work initiated by a multidisciplinary research team developing and testing AI technology for cancer care. Although not embedded within a larger trial, it was designed to inform future research protocols and ethical considerations for implementing AI-powered medical robots. The overarching program sought to explore the feasibility of systems capable of scanning, diagnosing, and treating patients within a single appointment. This qualitative study, therefore, focused on understanding patient comfort and acceptability of such technologies across the cancer care continuum, including perspectives on initiating treatment immediately following diagnosis.

Participants

Participants were recruited from breast and prostate cancer clinics at the Odette Cancer Centre at Sunnybrook Health Sciences Centre between May 2022 and November 2022. Purposive sampling was used to identify individuals at elevated risk of breast or prostate cancer, or with a recent diagnosis, to ensure that perspectives from both patient groups were represented. Potential participants were first identified by their treating physicians, who requested permission for research staff to contact them. Research staff approached participants by telephone following referral, explained the purpose of the study, and assessed their eligibility and interest. Inclusion criteria were (1) English speaking, (2) aged 18+ years, and (3) patients deemed *high risk* by their physician and in need of MRI as part of their screening process for breast cancer or diagnosed with breast cancer *or* male patients with elevated prostate-specific antigen levels and considered *high risk* for prostate cancer or diagnosed with prostate cancer.

Ethical Considerations

This study was reviewed and approved by the Research Ethics Board at Sunnybrook Health Sciences Centre (Research Ethics Board 5361). All participants provided verbal informed consent prior to participation, which was documented by the study team in accordance with institutional guidelines. To protect privacy and confidentiality, interview transcripts were deidentified during the transcription. All data were stored securely on password-protected institutional servers with access restricted to the study team. Participants were compensated with CAD $50 (US $36.03) per interview session, in recognition of their time and contribution.

Data Collection

Demographic information including sex and gender, ethnic identity, socioeconomic status, and geographic data (rural or urban) was collected prior to the first interview. While participants did report gender, they were referred based on a biological basis (ie, risk for or current diagnosis of prostate or breast cancer). Two semistructured interview sessions, each approximately 1 hour in length, were conducted over telephone or video (Zoom) by a graduate-level research assistant (TK) who had been trained in qualitative interviewing, with a background in clinical psychology, psychology, global health, and sociology. The 2 interviews were conducted approximately 2 weeks apart, allowing time for reflection and deeper meaning-making while maintaining recall continuity [28,29].

An interview guide was used, with flexibility for the interviewer to probe participants' experiences and perspectives. The interview guide included open-ended questions about participants' general perceptions of AI in health care; specific feelings about AI-powered robots in cancer screening, diagnosis, and treatment; perceived barriers and facilitators to AI adoption; and preferred communication/education strategies. The full interview guide is provided in Multimedia Appendix 1. During interviews, the interviewer clarified that the term *AI-powered medical robots* referred broadly to robotic systems enhanced with AI that could be applied to different parts of the cancer pathway, including imaging, biopsy guidance, and treatment support. This clarification was intended to provide participants with a shared reference point, while still allowing their natural perceptions and assumptions to guide their responses. Participants were not given a detailed technical briefing, as the intent was to elicit their existing awareness and spontaneous perceptions of AI technologies in health care. This approach

XSL•FO
RenderX

ensured that participant reflections represented authentic, experience-based understandings rather than those influenced by study-provided information.

All participants were informed during recruitment and reminded prior to each interview that the study focused on their cancer care experiences and their perspectives regarding AI-powered medical robots. The first interview emphasized participants' initial reactions, beliefs, and expectations about AI-powered medical robots in cancer care. The second interview revisited these themes in more depth, provided an opportunity to clarify or expand on responses, and explored additional reflections participants had after the first discussion. This consistent framing ensured that discussions remained grounded in participants' personal experiences of cancer care while allowing flexibility for individual interpretation and reflection.

Data Analysis

Interview recordings were transcribed verbatim by 2 research assistants (MH and JD). A conventional content analysis approach, which relies on inductive coding [30], was followed. Coders (1) immersed themselves in the transcripts, (2) performed line-by-line coding, (3) grouped codes into subcategories, and (4) clustered subcategories into broader categories. The codebook (Multimedia Appendix 2) was developed inductively from the data, with new codes added when concepts not captured by existing codes were identified. Iterative updates to the codebook were justified when coders encountered new or refined meanings across interviews, and changes were documented in the audit trail. To ensure rigor, MH and JD independently coded 30% of the transcripts, meeting to compare and reconcile code discrepancies. Disagreements were resolved through consultation with a third research team member (MBK), a graduate-level research coordinator with training in qualitative research methodology. Once agreement on the initial codebook was achieved, the coders each analyzed half of the remaining transcripts, routinely consulting with one another and MBK to discuss emerging ideas and refine codes as needed. The final coding tree was established by the 3 reviewers with input from a fourth member of the research team (AP) and the site principal investigator (JE). Including multiple perspectives helped limit the potential impact of biases of any given researcher.

Though formal coding began after all interviews were completed, the interviewer made informal notes on emerging themes during the interviews to assess data saturation [31] and guide iterative refinement of the interview guide. Reflexive memos were maintained to document thoughts on the saturation process. Reviewers maintained a thorough audit trail outlining the identification and adaptation of new and existing codes. Saturation was then formally assessed retrospectively, over the course of data analysis. Coders reviewed transcripts sequentially and confirmed that after the tenth interview, no new substantive codes were identified. The remaining interviews contributed additional depth and nuance but did not generate new categories, confirming that saturation had been reached. Given that participants were recruited from a single large urban tertiary cancer center and the sample was predominantly White and urban-residing, it is possible that this relative demographic homogeneity contributed to the point at which saturation was reached. This demographic profile reflects the typical patient population served within the breast and prostate cancer clinics at Sunnybrook Health Sciences Centre.

Positionality Statement

The research team represented a range of disciplinary, cultural, and experiential backgrounds. Interviews were conducted by a female master's student and research assistant with training in clinical psychology, global health, psychology, and sociology. Coding and analysis were carried out by 2 female research assistants (BAs in psychology), a female research coordinator with a master's degree in medical sciences and formal qualitative research training, and a male research coordinator with a BA in psychology and training in clinical psychology. Team members reflected diversity in gender and cultural backgrounds, which contributed to varied perspectives in the analytic process. The site principal investigator, a female psychiatrist specializing in psychosocial oncology and trauma, and the coprincipal investigator, a male professor of surgery with expertise in intelligent robotics, provided oversight for the study.

Trustworthiness

To mitigate potential bias and increase credibility of the findings generated in this study, we used reflexive practices, including regular peer debriefing between the coders and the third reviewer, to identify, acknowledge, and reconcile assumptions and interpretations. Engaging in reflexivity as we continuously rereviewed and discussed the transcripts allowed us to ensure that patient voices remained central in the findings, which supported confirmability of the findings. We also transcribed audio recordings verbatim for analysis, kept a thorough audit trail, and have thoroughly contextualized our work and described our methods as means of increasing dependability of this work. To address transferability, we have provided a thorough description of the study methods (including the interview questions) and the participant demographics.

Results

Participant Demographics

In total, 15 participants (6 female and 9 male participants) were recruited, all of whom completed both interviews. Of the 14 participants who reported demographic data (Table 1), 80% (n=12) were White. The mean age of participants was 67 (SD 12; range 41 - 88) years. 80% (n=12, 7 male and 5 female participants) of reporting participants lived in urban settings, 13% (n=2, 1 male and 1 female participant) lived in rural settings. Of the 10 participants who reported their annual household income, 7 (70%) reported an annual household income over US $60,000.

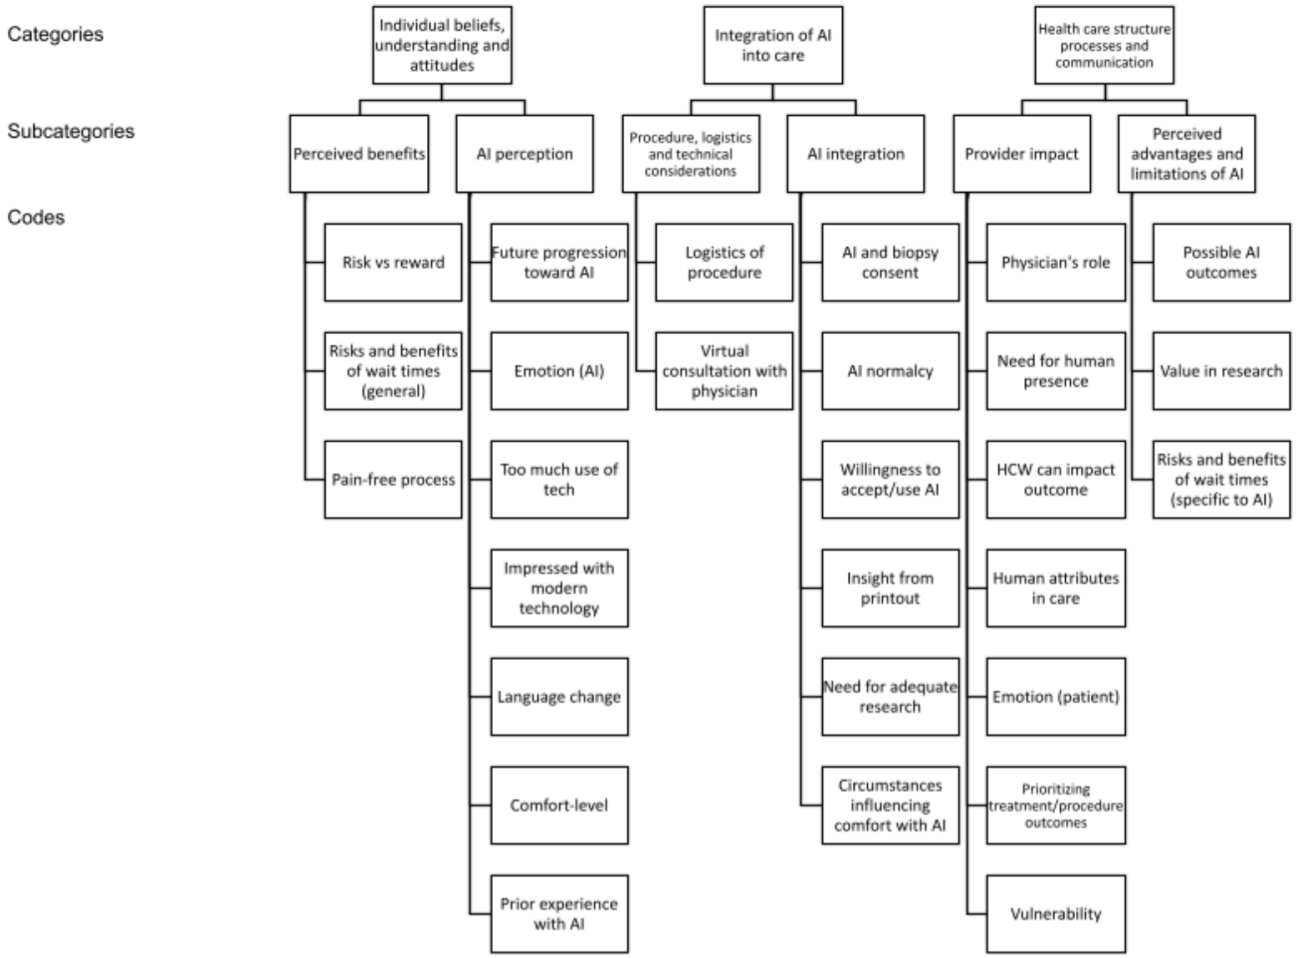
[a]One prostate cancer participant did not report any demographic information.

[b]Household income was originally collected in Canadian dollars and converted to US dollars using a currency exchange rate of CAD $1 = US $0.73



[c]Not available.

Thematic Findings

The analysis yielded 28 codes, which were then organized into 6 subcategories and further grouped into 3 overarching categories to best understand participant feelings of integrating AI-assisted medical technologies into their cancer care. The 3 overarching categories were (1) individual beliefs, (2) understanding, and (3) attitudes, integration of AI into care, and health care structure, process, and communication (Figure 1).

XSL•FO
RenderX

Figure 1. Final coding tree: organization of codes>subcategories>categories. AI: artificial intelligence; HCW: health care worker.

In the *individual beliefs, understanding, and attitudes* category, participants described a mix of openness and hesitancy toward AI-assisted technologies in their cancer care. Acceptability often depended on whether AI could meaningfully improve the experience of care, such as offering greater accuracy, reducing discomfort, or improving efficiency. Ongoing concerns centered on overreliance on technology, safety, and the need for clear backup plans in case of system failure. While some participants negatively described a general overreliance on technology, others noted that acceptance would increase as evidence accumulated:

> *[T]hey [are] as good as a human.* [ID 15, F, 53]

Concerns about dependability were especially salient in the context of unexpected events:

> *[C]ertain things can happen, who would be available, in an electrical shutdown and so on? [...] I don't know the capability of these machines, how reliable they are [...] it's reassuring to have help nearby to jump in.* [ID 50, M, 73]

Across participants, trust in AI was described as something that would grow through experience and familiarity.

The *Integration of AI into Care* category focused on the procedural, technical, and logistical considerations of integrating AI-robotic medical technology into cancer care, as well as general perceptions on AI integration into care. Participants distinguished between different stages and levels of invasiveness in the cancer pathway. Many were comfortable with AI in roles such as imaging or screening but more cautious regarding AI involvement in biopsies or surgery.

As one participant summarized:

> *I think I am okay with [the machine doing] the screening, if you could speed up the wait time. For the actual surgery I think I need more proven evidence, that it is 100% positive and reliable.* [ID 30, F, 62]

Human presence, whether in-person or virtual, was consistently described as important for reassurance, oversight, and troubleshooting during procedures:

> *[K]nowing that they were there and that there was some sort of troubleshooting capacity, would be helpful.* [ID 80, M, 65]

Participants also highlighted the need for accessible explanations of how AI works, its benefits, and its limitations. They emphasized that information should be made available proactively and through multiple accessible formats, given that patients may be unfamiliar or uncomfortable with digital resources:

> *I had to take the initiative to search through the website to get [information] and knowing so many people, they are not familiar with using technology, or some seniors, I think that was, you know, it limited*

XSL•FO
RenderX

> *the opportunity for people to get [access to] support resources.* [ID10, M, 60]

The category *health care structure, processes, and communication* described challenges within the existing health care system, particularly long wait times, fragmented communication, and limited opportunities for personalization. These issues shaped patients' broader care experiences and influenced how they envisioned AI fitting into their care. Some felt "lost in the system" [ID 45, F, 69], due to the perception that the current health care system lacks personalization.

Participants also associated long delays and fragmented care with distress and uncertainty:

> *I couldn't get any surgery done immediately. [...] It was very difficult. And I couldn't get care in a timely way.* [ID 40, M, 78]

Several participants expressed hope that AI-assisted technologies might address some of these system-level pressures by supporting more timely and/or coordinated care, while emphasizing that technological integration should not reduce human connection in the care process.

Barriers and Facilitators

Across interviews, participants described specific conditions that shaped how acceptable AI-assisted medical technologies felt to them in their care. Consistent with qualitative studies examining patient adoption of new health technologies and with implementation science frameworks (eg, studies that explore contextual factors influencing uptake) [31], these perceived conditions are referred to as *barriers* (factors that reduced comfort or confidence) and *facilitators* (factors that increased openness or ease of acceptance). Table 2 provides an overview of the barriers to integrating AI-assisted medical robots into cancer screening, diagnosis, and treatment.

Table . Factors influencing patients' decision to accept AI[a] in cancer care (barriers and facilitators).

Factor	Barrier	Facilitator
Information	Lack of information regarding the technology left patients unable to answer whether they were comfortable using it.	Providing adequate patient education and related resources would facilitate the uptake of AI-assisted technology.
Vulnerability	These patient populations are particularly in need of human care due to the vulnerable nature of the procedures.	—[b]
Reliability of technology	Fear of technical malfunctions or similar issues.	Potential for increased precision and efficiency with the use of technology; some patients noted that the most important thing is a positive outcome, regardless of whether a doctor or robotic device is completing the procedure.
Human element	Machine lacking in compassion/bedside manner in critical thinking/problem-solving skills.	No risk of human error when using AI technology.
Reduced wait times	—	The potential for reduced time between initial appointment and treatment can improve patient outcomes and eliminate distress associated with waiting periods.
Prior use of AI-assisted technology in health care	—	Patients express prior knowledge or direct experience with some form of AI technology in health care, creating a greater sense of comfort with using AI.
Pain	—	Some participants stated that they would be more inclined to consent to the procedures if they were less painful than the standard of care.
Options available	Patients might prefer standard of care when they have the option (given that the risks/rewards are similar between these options).	If there were no other options, or standard of care came with increased risk (due to waiting times, etc), patients would be more likely to consent to use of AI-assisted technology.

[a]AI: artificial intelligence.

[b]Not applicable.

Barriers most often reflected concerns about the interpersonal and safety-related dimensions of AI-assisted care. Participants frequently worried about the absence of human qualities such as compassion, empathy, and emotional support, particularly during invasive or high-stakes procedures. Many also questioned the reliability and safety of AI systems, describing uncertainty about how unexpected complications would be managed without a health care provider physically present. Some participants expressed apprehension that technological integration could reduce opportunities for communication with clinicians, thereby amplifying existing feelings of depersonalization within the health care system.

XSL•FO
RenderX

Facilitators described by patients centered on ways AI-assisted technologies could meaningfully improve their care experience. The potential to reduce wait times, streamline care, and deliver more timely results was consistently valued and often linked to reductions in distress, uncertainty, and logistical burden. Participants also described their confidence in AI's technical capabilities, such as accuracy and precision, as an important factor that could support acceptance. Several participants noted that when outcomes were perceived as likely to improve, the mode of delivery (human vs robot) became less central. Prior familiarity with AI in health care and the possibility of less painful or less invasive procedures further contributed to openness toward AI integration.

Discussion

Principal Findings

This study found that patients with breast and prostate cancer expressed cautious openness toward the use of AI-powered medical robots in their care, despite initial skepticism. Participants recognized potential benefits such as reduced wait times, improved accuracy, and less invasive procedures and also voiced concerns about safety, reliability, and the potential loss of human connection in care. Participants expressed enthusiasm for AI-assisted medical robots when given the choice, suggesting openness to innovation despite some skepticism. They often prioritized successful treatment outcomes over concerns of who or what delivered care, indicating that demonstrated efficacy could outweigh reservations. Trust in AI was described as something that would build gradually over time as experience and familiarity increased. Their accounts also underscored the critical need for systemic improvements in health care processes, particularly in reducing delays and streamlining care. These findings highlight the perceived potential of AI technologies to address longstanding system challenges, while also reflecting ambivalence regarding the risks of technological reliance. Notably, participants were generally open to the use of AI-powered medical robots in initial screening and imaging but were more hesitant when considering invasive steps such as biopsy or treatment, where human presence and oversight were prioritized.

As an exploratory qualitative study, the aim was to elucidate patients' feelings, understandings, and perceptions about the use of AI-powered medical robots in cancer screening, diagnosis, and early treatment and to identify barriers and facilitators to patient acceptance. Participant responses illustrated a mix of hesitancy and hope around embracing this technology for their own care, which is a typical response to technological advances or change [30,31]. Importantly, participants' reflections consistently emphasized that the human presence in care—particularly the compassion, reassurance, and emotional support provided by health care providers—is viewed as irreplaceable [32]. This emphasis on the importance and value of human presence in care (particularly that health care providers should remain central in a patient's care processes) underscores the importance of emotional support and other traits that are unique to humans. Without deliberate safeguards to preserve these aspects, the integration of AI technologies risks exacerbating feelings of depersonalization in care. These insights, while not generalizable due to the small purposive sample, provide valuable direction for future research and early implementation strategies.

Comparison to Prior Work

Overall, participants' reflections were broadly consistent with existing research examining patient perspectives on AI and technology-assisted care. Similar to prior work, participants expressed interest in potential benefits such as improved efficiency and reduced wait times. These factors are repeatedly identified in the literature as persistent challenges in cancer care pathways [7,16,17]. Our findings align with studies showing that patients often view AI as promising when it addresses established system-level pain points, particularly diagnostic delays and fragmented processes.

Concerns regarding the loss of human connection were also consistent with previous research demonstrating resistance to medical AI when patients perceive threats to empathy, communication, or relational aspects of care [33]. Participants emphasized the irreplaceable value of compassion and reassurance, echoing patient-centered care literature, highlighting communication, emotional support, and trust as core needs during cancer care [34-36]. Prior studies similarly note that while AI may assist with technical tasks, it cannot fully replicate relational qualities valued in clinician—patient interactions [32,33].

Consistent with earlier work, participants indicated that evidence of safety and effectiveness would be central to their acceptance of AI-assisted technologies. This is in line with studies showing that patient trust in AI increases when technologies are validated, transparent, and clearly integrated within human-led care models [30,31]. The desire for clear education about AI, expressed by many participants, is also supported by previous findings emphasizing the importance of accessible, multimodal patient education to support uptake of new technologies [35,37,38]. Altogether, the results reinforce themes seen across the broader literature: patients may be cautiously optimistic about AI in cancer care when it enhances, rather than replaces, human-delivered care; when it improves timeliness and coordination; and when adequate evidence and communication support informed decision-making. These consistencies suggest that early implementation strategies should prioritize transparency, patient education, and explicit preservation of human presence, particularly during invasive or emotionally charged stages of cancer care.

Strengths and Limitations

There are several limitations to this study. First, recruitment occurred at a single large urban hospital, which may not be representative of all patient populations. Participants were drawn from a tertiary cancer center in Toronto, potentially excluding individuals from rural or underserved regions and therefore excluding perspectives from those with limited access to tertiary care. This is related to a previously established limitation regarding the disparity in who has access to high-quality health care [39]. This may have influenced findings by overrepresenting patients with greater access to resources and

XSL•FO
RenderX

technology. Future research should intentionally recruit participants from rural and underserved regions to increase transferability.

Second, the sample was predominantly White (80%), urban-dwelling, and higher-income. Urban and higher-income populations may have more exposure to and comfort with advanced technologies compared to their rural and lower-income counterparts [40]. Additionally, the perspectives of those who live in rural settings may be impacted by experiences with resource limitations and accessibility of health care [41,42]. As a result, the findings may not reflect the views of patients from more diverse racial, ethnic, or socioeconomic groups. Within the constraints of this study setting and recruitment pathways, we were unable to broaden the sample to include more diverse participants. Although participants were provided with a shared reference point for what was meant by "AI-powered medical robots" (ie, robotic systems enhanced with AI used in imaging, biopsy guidance, and treatment support), they were not given a detailed technical briefing. As such, their responses may have reflected variability in baseline knowledge. Some participant responses also appeared general in tone (eg, referring broadly to *AI* or *technology*), but these were expressed in relation to their cancer care experiences. This likely reflects natural variability in familiarity with AI concepts among participants rather than deviation from the study focus. This could be seen as a limitation in terms of consistency, but it also provided valuable insights into organic perceptions, assumptions, and information needs regarding AI in cancer care. Third, data collection took place during the COVID-19 pandemic, which may have impacted attitudes toward access to health care, or experiences with health care delays may have been impacted by the health care climate at the time [43,44]. This context likely heightened sensitivity to wait times and system inefficiencies. While this provided timely insights, future studies should examine whether similar themes emerge in nonpandemic contexts. Finally, the sample size was relatively small, though appropriate for a qualitative descriptive study. Data saturation was achieved and confirmed during analysis; however, larger samples in future research could support broader transferability of findings and capture a greater diversity of perspectives. Despite its size, the study's use of 2 interviews per participant and a multianalyst coding process strengthened the dependability and credibility of the findings. Additionally, collecting perspectives from both breast and prostate cancer populations provided a richer understanding of how AI-assisted technologies may be perceived across different cancer care experiences.

Future Directions

Future research should ensure to include perspectives from patients who represent more diverse lenses as a means of increasing transferability of findings and understanding specific needs for integrating AI-assisted medical technology into cancer care in varying regions and cultural contexts. Future studies should also aim to include perspectives from all involved in the health care process (such as physicians and oncology assistants) to better understand how to pragmatically incorporate AI-assisted medical robots into cancer care screening, diagnosis, and treatment. More work is needed to understand which implementation models work best for both health care providers and patients, including how to provide education on the technology to both, what level of human presence is deemed acceptable and appropriate, and safe mitigation strategies in the event of technical issues. Future trials should also examine patient acceptability separately across different stages of the cancer pathway (eg, screening, diagnosis, and treatment) to determine where AI integration is most feasible and where stronger human involvement is needed.

Conclusions

In conclusion, this work explored patient perspectives on the use of AI-assisted medical robots in cancer screening, diagnosis, and early treatment, highlighting barriers and facilitators to its acceptance. The findings reveal a cautious optimism among patients, tempered by concerns about the reliability of AI and the potential for reduced human contact. Patients expressed a desire for AI to complement, rather than replace, human judgment, ensuring that final decisions remain in the hands of experienced health care providers. Alongside emphasizing the need for human presence and emotional support within the health care experience, patients described a need for education and clear communication regarding the use of new technology and suggested potential methods of making these resources more accessible (eg, through media and information sessions). As a qualitative exploratory study, these conclusions should be understood as reflecting patient perceptions within the sampled group, rather than definitive statements about broader populations. Future research is required to test these perspectives in larger and more diverse samples and to evaluate whether these patient-identified barriers and facilitators translate into measurable outcomes during actual implementation.

Acknowledgments

Abstract

Mediastinal germ cell tumors and how they differ from those associated with testicular cancer are reviewed through the experience with my son, Brendan Fahy Bequette. We reflect on others who have been diagnosed with rare tumors and discuss our need to honor Brendan's memory by "paying it forward."

(JMIR Cancer 2026;12:e93678) doi:10.2196/93678

KEYWORDS

germ cell tumor; mediastinal tumors; rare cancers; cancer treatment; acute myeloid leukemia

Background

Testicular cancer treatment is a great success story, largely due to the efforts of Dr Lawrence Einhorn at Indiana University to develop cisplatin-based chemotherapy protocols, with initial clinical trial success in 1974 [1,2]. Currently, someone diagnosed with testicular cancer has a 5-year expected survival rate of over 95%. A high-profile example is the cyclist Lance Armstrong, who was treated by Dr Einhorn in 1996. Germ cell tumors form the bulk of testicular cancers (95%). The TP53 gene is known as a tumor suppressor gene, and 50% of cancers have a TP53 gene mutation. Testicular cancers, however, have a low rate of TP53 mutations, contributing to the success of platinum-based chemotherapy treatment.

Mediastinal (in the chest between the lungs) germ cell tumors are very rare (2% of germ cell tumors) with a much lower treatment success than those that present in the testicles [3,4]. Unlike testicular cancers, mediastinal germ cell tumors tend to have a high rate of TP53 mutations. Nonseminoma mediastinal tumors treated with standard BEP (bleomycin, etoposide, cisplatin)–VIP (etoposide, ifosfamide, cisplatin) protocols have an approximately 5-year survival rate of 50%, which includes second-line treatment involving high dose chemotherapy with autologous stem cell transplant, where a patient's stem cells are separated from their blood and reinfused as part of the treatment [5]. Unfortunately, a relapse after high-dose chemotherapy results in a median survival time of 5 months. There are ongoing efforts to develop immunotherapy [6] and cell and gene (chimeric antigen receptor [CAR-T]) treatments for patients who have relapsed (often called platinum-resistant).

Personal Background

My son, Brendan Fahy Bequette, a filmmaker in New York City, was diagnosed with a mediastinal germ cell tumor in 2020 during the peak of the COVID-19 pandemic. While preparing for his initial treatment, we had a personal family contact with Dr Einhorn, who asked "how did Brendan know?" because a germ cell tumor normally progresses much further than Brendan's before detection. Brendan was a runner and had noted a pain in his chest before going to an outpatient clinic and receiving a chest X-ray 2 days before his 24th birthday. Dr Einhorn immediately contacted Dr David Shaffer at Albany Medical College (AMC), who was providing the treatment. Dr Shaffer also began correspondence with Dr Darren Feldman at Memorial Sloan Kettering Cancer Center (MSKCC) in New York. Clearly in this field of rare cancers, the specialists know each other quite well.

Brendan received his first line of treatment, BEP-VIP, at AMC; unfortunately, a brain scan indicated a metastasis, and his second line of treatment involved high-dose chemotherapy with an autologous stem cell transplant at MSKCC. While in remission, he began training for a marathon as a way of celebrating his conquering of cancer; unfortunately, the cancer returned after 2 months.

His third line of treatment was in an immunotherapy clinical trial using durvalumab and tremelimumab. Unfortunately, the cancer progressed, and he was removed from the trial after 1 month. As often happens with immunotherapy, his immune system had responded by attacking his thyroid and affecting his heart rate, causing him to need thyroid medication for the rest of his life. Overall, the clinical trial failed to meet the protocol-defined success for the 29 patients treated [7]. For the next 6 months, Brendan received several other lines of treatment, including 4 months of cisplatin plus epirubicin.

Brendan's last hope was a clinical trial for a novel CAR-T treatment for solid tumors [8]. Unfortunately, the trial was delayed by over 6 months while the sponsor automated the

XSL•FO
RenderX

process, and Brendan died on February 28, 2022, two weeks after the last enrollment.

Grief and Future Steps

My wife, Pat Fahy, and I have channeled our grief by publishing a book (The Photographs of Brendan Fahy Bequette) of black-and-white photos, many of which Brendan had taken during his cancer treatment [9,10]. The proceeds of this book support art and film awards in his name, thus "paying it forward" for young artists. When included with college scholarships in his memory, we honor approximately 8 young artists per year.

Further Reflections

The New Yorker article by Tatiana Schlossberg (John F Kennedy's granddaughter), "A Battle With My Blood," is subtitled "When I was diagnosed with leukemia, my first thought was that this couldn't be happening to me, to my family" [11].

Similarly, when we learned that our son had a tumor in his chest, Pat and I experienced the "this is not happening to us" state while simultaneously realizing that it was and that we needed to help Brendan start making a lot of important decisions about his health care. Tatiana goes on:

> *I did not—could not—believe that they were talking about me. I had swum a mile in the pool the day before, nine months pregnant. I wasn't sick. I didn't feel sick. I was actually one of the healthiest people I knew. I regularly ran five to ten miles in Central Park.*

Brendan was also fit, having been a long-distance runner since his freshman year of high school. Indeed, the reason that he went to an outpatient clinic was that he could feel a pain near his heart when sleeping the previous night—he was seriously in touch with his body. As a filmmaker in New York, he also often ran in Central Park.

When Pat and I hear that someone has been diagnosed with cancer, we immediately wonder or ask, "what type of cancer?" Tatiana was diagnosed with acute myeloid leukemia (AML) with chromosome 3 inversion, which is rare (roughly 1.5% of AML cases). Similarly, Brendan was diagnosed with a mediastinal germ cell tumor, which is approximately 2% of all germ cell tumors.

Roughly 200 or so people are diagnosed with AML with chromosome 3 inversion in the United States each year. This is almost the same as the roughly 200 or so people diagnosed with a mediastinal germ cell tumor each year in the United States. Thus, both Tatiana and Brendan had rare cancers. Notably, both were treated at MSKCC.

Role of Chemical Engineers in Therapeutics Manufacturing

Chemical engineers are largely responsible for the design and operation of the manufacturing plants that produce pharmaceuticals. Although the chemical engineering curriculum focuses on mathematical models and "algorithms," I encourage my students to think about the "human in the loop," which includes the safety of the personnel operating the plants and the consumer using the final product. I provide personal examples, such as my sister who was diagnosed with type 1 diabetes in 1977. This motivated me to collaborate on the development of an automated insulin delivery system to improve the lives of people living with type 1 diabetes. Similarly, I use the example of my son to motivate the ongoing development of immunotherapies for the treatment of cancers and other diseases [12]. In this way, I hope that my son continues to "pay it forward," as we educate the next generation of scientists and engineers.

Abstract

Background: Consumer smartwatches offer potential for continuous monitoring of physical activity during childhood cancer treatment. However, their validity for measuring step count and heart rate in this population has not been established.

Objective: This study examined the validity of a Withings smartwatch for monitoring step count and heart rate in children and adolescents undergoing cancer treatment.

Methods: Children and adolescents aged 8 to 18 years under active cancer treatment wore a Withings smartwatch for 12 weeks. For validation purposes, children and adolescents simultaneously wore an ActiGraph wGT3X-BT accelerometer for 1 week under free-living conditions to assess step count agreement and were connected to a clinical heart rate monitor under resting conditions to assess heart rate agreement. Linear mixed models with participant ID as a random effect were used to estimate mean differences and derive 95% limits of agreement for repeated measurements.

Results: A total of 14 children and adolescents participated in each of the validation analyses. The smartwatch recorded significantly fewer steps than the ActiGraph accelerometer for both steps per hour (mean difference 174 steps per hour; 95% limits of agreement=−283 to 633; $P<.001$) and steps per day (mean difference 3154 steps per day; 95% limits of agreement=−394 to 6702; $P<.001$), with increasing discrepancy at higher activity levels, suggesting proportional bias. No statistically significant difference in heart rate was observed between the smartwatch and the clinical heart rate monitor under resting conditions (mean difference −1.07 beats per minute; 95% limits of agreement=−17.55 to 15.41; $P=.24$).

Conclusions: In children and adolescents undergoing cancer treatment, the Withings smartwatch showed minimal systematic bias for resting heart rate assessment, although individual variability was considerable. In contrast, step counts demonstrated systematic underestimation and wide limits of agreement compared with a research-grade accelerometer. The use of smartwatch-derived step counts for clinical benchmarking or goal setting in this population cannot currently be recommended.

(JMIR Cancer 2026;12:e77766) doi:10.2196/77766

KEYWORDS

validity; smartwatch; steps; heart rate; pediatric oncology

Introduction

Children undergoing treatment for cancer demonstrate substantially reduced levels of physical activity compared to healthy peers [1-3]. Disease- and treatment-related symptoms such as fatigue, musculoskeletal pain, and general malaise frequently limit mobility and contribute to muscle wasting, reduced functional capacity, and decreased participation in daily life [1-3]. Persistently low physical activity may contribute to a cycle of physical deconditioning, which can further impair functional independence, social participation, and quality of life [4,5]. In addition to physical consequences, reduced activity levels have been associated with adverse psychosocial outcomes, including reduced emotional well-being and diminished cognitive and social functioning [6-10].

Therefore, promoting and monitoring physical activity during treatment may not only address physical deconditioning but also support psychosocial functioning and quality of life. Given these multidimensional consequences, insight into physical activity behavior during treatment is clinically relevant for children with cancer, their families, and health care professionals. Monitoring physical activity may support early identification of functional decline, enable timely and individualized guidance, and inform shared decision-making regarding physical activity and rehabilitation strategies.

XSL•FO
RenderX

However, such applications require accurate and feasible methods to assess physical activity under real-world conditions.

Objective measurement of physical activity in pediatric oncology relies primarily on research-grade accelerometers such as the ActiGraph, which are widely used as reference devices for quantifying physical activity, such as step count [11]. However, these devices do not provide information on physiological responses to activity, such as heart rate, and their use in routine clinical care is limited by practical considerations [12]. Data collection is usually restricted to predefined assessment periods; data are not directly accessible for children, parents, or health care professionals; and data extraction requires specialized software and expertise. Moreover, these devices may be experienced as inconvenient or uncomfortable by children. For these reasons, they are considered less suitable for continuous, long-term monitoring under free-living conditions [11].

Consumer-level wearable devices such as smartwatches offer the possibility to integrate measurement of physical activity (eg, step count) and physiological parameters such as heart rate within a single, low-burden device that can be worn continuously in daily life. This integration may provide a comprehensive picture of physical activity behavior during childhood cancer treatment while enabling real-time access to data for children, families, and health care professionals [11]. In this context, wearable devices have potential utility for monitoring activity patterns over time, supporting engagement in physical activity, and informing individualized guidance and rehabilitation strategies [13].

Several validation studies have evaluated consumer-grade wearable devices predominantly in adult populations, demonstrating promising accuracy for step count and heart rate under free-living conditions [14,15]. In pediatric populations, validation studies remain limited, and findings are heterogeneous [16]. Importantly, validation results obtained in adult or healthy pediatric populations cannot be readily generalized to children undergoing cancer treatment. In children with cancer, treatment-related symptoms, altered movement patterns, reduced gait speed, intermittent activity bouts, and physiological changes may influence sensor performance and algorithm accuracy. Therefore, device performance should be evaluated specifically within this population.

Among available consumer-grade devices, Withings smartwatches have frequently been used in research settings due to their suitability for research applications, including the availability of dedicated research infrastructure for data access and export and relatively stable software environments. Withings devices have been applied in pediatric studies to monitor physical activity behavior, primarily as tools to support physical activity interventions [17-19]. Although these devices have been validated in adult populations [17,20-25], validation has primarily focused on heart rate–related outcomes in pediatric populations, demonstrating acceptable agreement with reference methods [26]. Nonetheless, validation of Withings smartwatches in children undergoing cancer treatment in a wider context of physical activity has not yet been performed, and evidence regarding the validity of step count in any pediatric population remains limited.

Therefore, the aim of this study was to examine the validity of a Withings smartwatch for monitoring step count and heart rate in children and adolescents undergoing treatment for cancer.

Methods

Participants and Study Design

Participants were recruited within the framework of the Watch Us Move study, a prospective qualitative study examining the feasibility, barriers to, and facilitators of real-time and long-term physical activity tracking using a smartwatch in children and adolescents during treatment for cancer [18]. Eligible participants were aged 8 to 18 years; diagnosed with a malignancy; and receiving active treatment at the Princess Máxima Center for Pediatric Oncology, Utrecht, the Netherlands. Additional inclusion criteria were the ability to walk at least 50 meters without the use of a walking aid, adequate comprehension of the Dutch language, and access to a device capable of running the app. Exclusion criteria included children and adolescents who were scheduled to undergo stem cell transplantation during the study period or who had intellectual disabilities that precluded participation in long-term smartwatch use.

Eligible patients were identified during routine clinical visits between May 2023 and June 2024 and were approached by the research team in consultation with their treating pediatric oncologist or pediatric physiotherapist.

According to the design of the Watch Us Move study, children and adolescents wore a smartwatch for 12 weeks consecutively. For this substudy, children and adolescents were asked to wear the smartwatch and an ActiGraph (Ametris) accelerometer simultaneously for 1 week and keep a wear log and report nonwear periods throughout the week. Moreover, children and adolescents were asked to wear the smartwatch while connected to a heart rate monitor under resting conditions while being admitted to the day care treatment ward.

Ethical Considerations

In accordance with Dutch legislation, for children aged 8 to 11 years, written informed consent was obtained from parents or legal guardians. For children and adolescents aged 12 to 15 years, written informed consent was obtained from both the participant and their parents or legal guardians. Adolescents aged 16 to 18 years provided written informed consent themselves. The study protocol was reviewed by the Medical Research Ethics Committee NedMec (reference number 23-003).

Devices

Withings Smartwatch (Device Under Evaluation)

The Withings Steel HR and Pulse HR smartwatches were used as the device under evaluation in this study. These devices were selected for several methodological and practical reasons. First, Withings provides access to structured research data through a dedicated application programming interface, allowing for the secure retrieval of step count and heart rate data for analysis. In addition, the software environment of these devices is relatively stable, reducing the likelihood of major algorithm changes during the study period. Furthermore, Withings uses

XSL•FO
RenderX

European data storage centers, which was considered important in light of the General Data Protection Regulation. Finally, the relatively small size, moderate cost, and design resembling a conventional wristwatch may enhance acceptability and feasibility for use in children and adolescents undergoing cancer treatment.

The Steel HR (model: HWA03b-36black-Inter or HWA03b-36white-Inter; 36.3 mm) is a hybrid smartwatch, and the Pulse HR (model: WAM03-Black Mirror-All-Inter; 18 × 44 mm) is a health and fitness tracker. Both devices use identical software for monitoring step count and heart rate.

Children and adolescents were allowed to choose the wrist on which they wore the Withings smartwatch to optimize comfort and adherence. When no preference was expressed, they were instructed to wear the device on the nondominant wrist in accordance with manufacturer recommendations. Wrist side was not systematically recorded.

Both devices were worn on the wrist and were capable of measuring step count, heart rate, distance covered, and estimated energy expenditure (calories). Data were synchronized with the Health Mate mobile app. Withings smartwatch data were manually retrieved from the Withings data server via the research data interface.

A day was considered valid when heart rate was recorded at least once per hour for a minimum of 6 hours between 6 AM and midnight. Nonwear time was defined as a period of at least 60 consecutive minutes without heart rate and step measurements. This definition was applied to ensure consistency with the nonwear definition used for the reference ActiGraph device (Troiano algorithm) [27]. For step count validation, only valid wear days were taken into account. For heart rate validation, the complete period during which children and adolescents were connected to the clinical heart rate monitor was considered.

ActiGraph (Reference Device for Step Count)

The ActiGraph wGT3X-BT accelerometer was used as the reference device for step count measurement under free-living conditions. The ActiGraph is widely used in pediatric research and, although it does not represent a criterion gold standard under free-living conditions, it is frequently applied as a research-grade comparator device in physical activity validation studies [28-30]. The ActiGraph was worn on the same wrist as the Withings smartwatch whenever possible. If this caused irritation or burden, it was worn on the opposite wrist. Wrist side (dominant vs nondominant) was not systematically recorded.

ActiGraph data were obtained using the ActiLife software (Ametris). A day was considered valid when steps were measured for at least 6 hours between 6 AM and midnight, with a minimum of 4 valid wear days per participant. Nonwear time was defined using the Troiano algorithm [27], in which a period of at least 60 consecutive minutes of zero activity counts was classified as nonwear, allowing for 1 to 2 minutes of activity counts between 0 and 100 [27]. Only valid wear days were included in step count analysis.

Philips IntelliVue X3 (Reference Device for Heart Rate)

The Philips IntelliVue X3 clinical monitor was used as the reference device for heart rate measurements. This hospital-grade monitoring system provides continuous electrocardiography-based heart rate measurements and is routinely used in clinical care. Therefore, it was considered an appropriate reference under resting clinical conditions. Children and adolescents were connected to the monitor under resting conditions while admitted to the day care treatment ward. Heart rate data were retrieved from the electronic patient records.

Data Analysis

Descriptive statistics were used to summarize patient characteristics. Categorical variables were presented as numbers with percentages. Normally distributed continuous variables were reported as means with SDs, and nonnormally distributed data were presented as medians with IQRs or ranges.

Outcome measures included steps per hour (total number of steps), steps per day and heart rate per minute (beats per minute [bpm]). Measurements obtained using the smartwatch were compared with those from the reference devices (ActiGraph and heart rate monitor). Only days considered valid for both the smartwatch and ActiGraph were included in the step count analyses. All available heart rate measurements obtained during connection to the clinical monitor were included in the heart rate analysis.

Linear mixed-effects models were estimated to assess the mean difference between devices for each outcome measure. These models account for the presence of repeated measurements within participants. Participant ID was included as a random intercept. The fixed intercept of each model represents the estimated mean difference (bias) between devices.

For agreement analyses, 95% limits of agreement (LoA) were derived from the mixed-effects models. In accordance with recommendations for repeated-measure Bland-Altman analyses, the SD of the differences was calculated as the square root of the sum of the between- and within-subject variance components (ie, √[variance_participant + residual variance]) [31]. The LoA were then calculated as mean difference ± 1.96 × SD_total. Agreement was visually assessed using scatterplots and Bland-Altman plots. All analyses were performed in SPSS Statistics (version 29.0.1; IBM Corp) or R (version 4.4.1; R Foundation for Statistical Computing).

Results

Step Validation

During the study period, 14 children and adolescents wore the smartwatch simultaneously while wearing an ActiGraph in free-living conditions for 1 week (Figure 1). Of these 14 children and adolescents, 8 (57.1%) were female, and they had a median age of 13.5 (IQR 10.5-15.3) years and weight-to-height *Z* score of 0 (IQR −1.5 to 1.6; Table 1).

XSL•FO
RenderX

Figure 1. Flow diagram of the inclusion of patients.

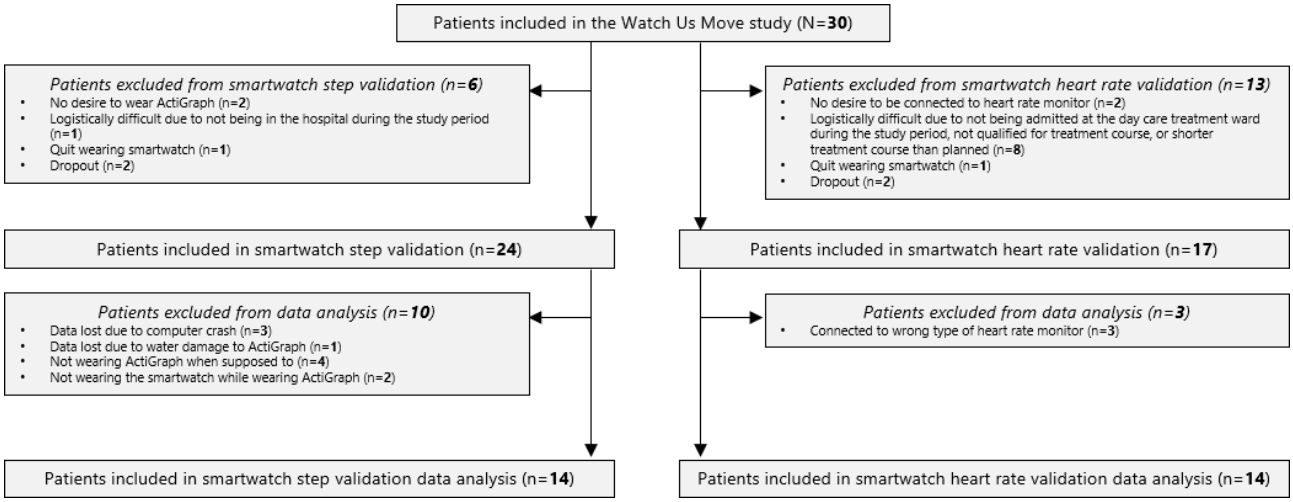

Table . Patient characteristics and free-living step count data during the step count validation study (n=14).

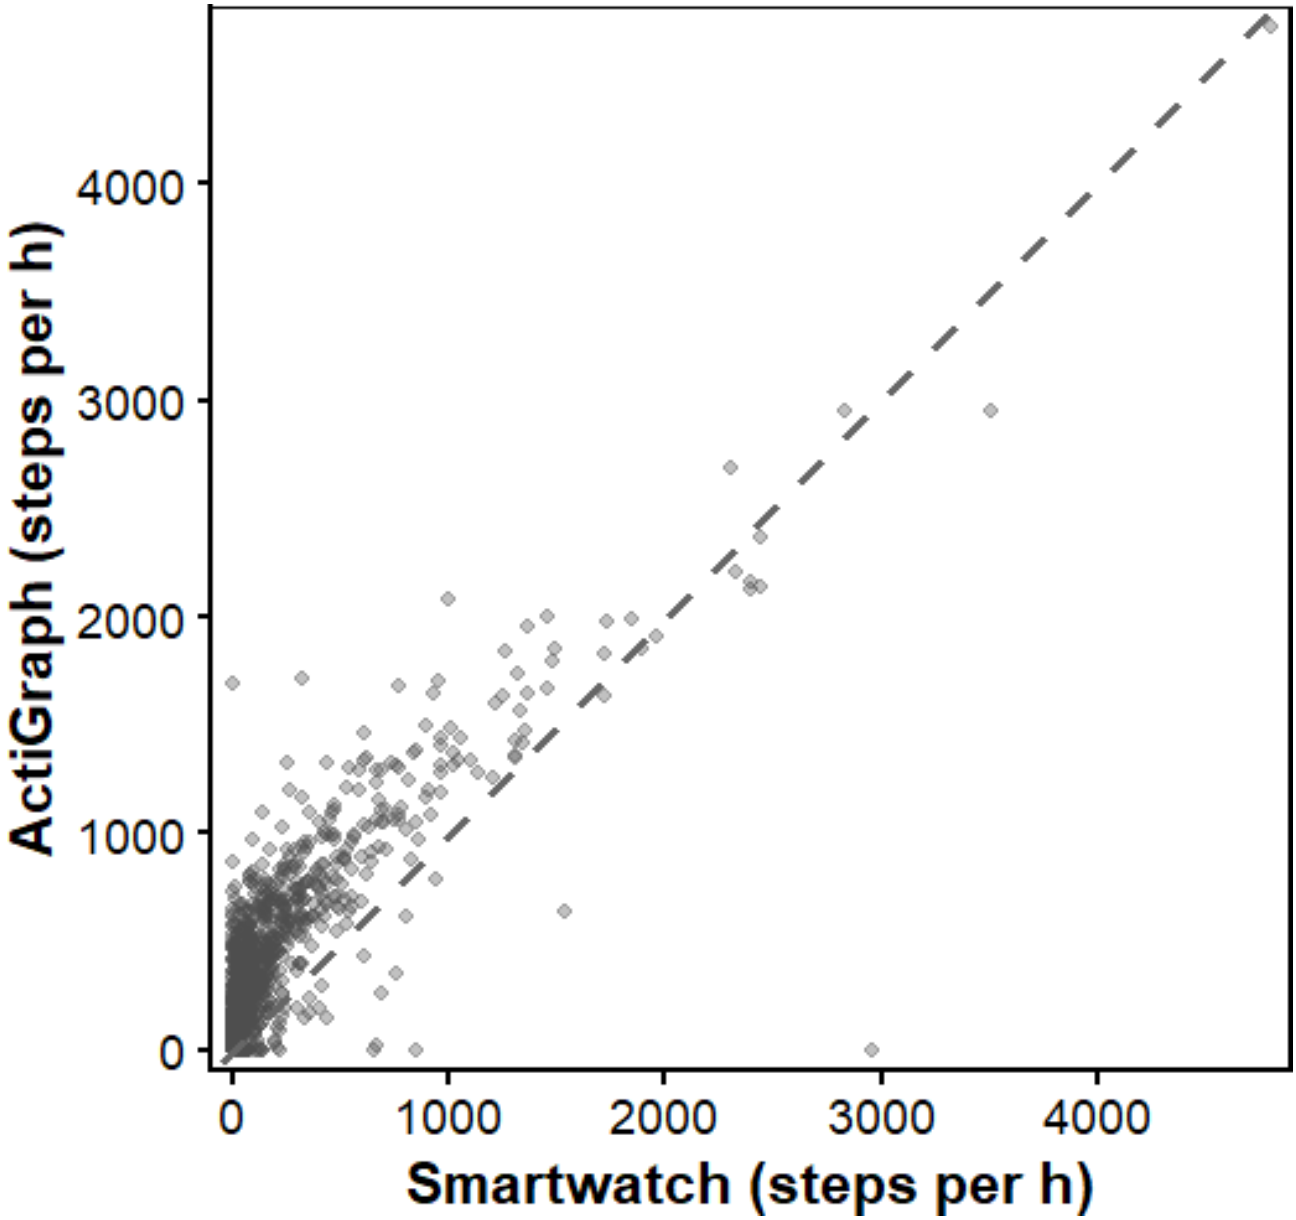

Characteristic	Values
Sex, n (%)	
Female	8 (57.1)
Male	6 (42.9)
Age (y), median (IQR)	13.5 (10.5 to 15.3)
Time since diagnosis (d), median (IQR)	108.5 (63.8 to 201.0)
Diagnosis, n (%)	
Acute lymphoblastic leukemia	6 (42.9)
Lymphoblastic lymphoma	3 (21.4)
Hodgkin lymphoma	1 (7.1)
Medulloblastoma	2 (14.3)
Osteosarcoma	1 (7.1)
Ewing sarcoma	1 (7.1)
Weight-to-height *Z* score, median (IQR)	0 (–1.5 to 1.6)
Free-living step count during the validation week, median (range)	
Steps per h measured via the ActiGraph	188 (0 to 4725)
Steps per h measured via the smartwatch	33 (0 to 4799)
Steps per d measured via the ActiGraph	5697 (1598 to 17,436)
Steps per d measured via the smartwatch	2213 (12 to 12,425)

During the 1-week study period in free-living conditions, the median number of steps per hour was 188 (range 0-4725) as measured using the ActiGraph and 33 (range 0-4799) as measured using the smartwatch. The median steps per day measured using the ActiGraph and the smartwatch were 5697 (range 1598-17,436) and 2213 (range 12-12,425), respectively.

Results from the linear mixed model revealed a significant difference in steps per hour between the ActiGraph and the smartwatch (P<.001). The mean difference (ActiGraph – smartwatch) was 174 steps per hour. The 95% LoA ranged from −283 to 633 steps per hour. Figures 2 and 3 visualize the repeated measurements and agreement for steps per hour.

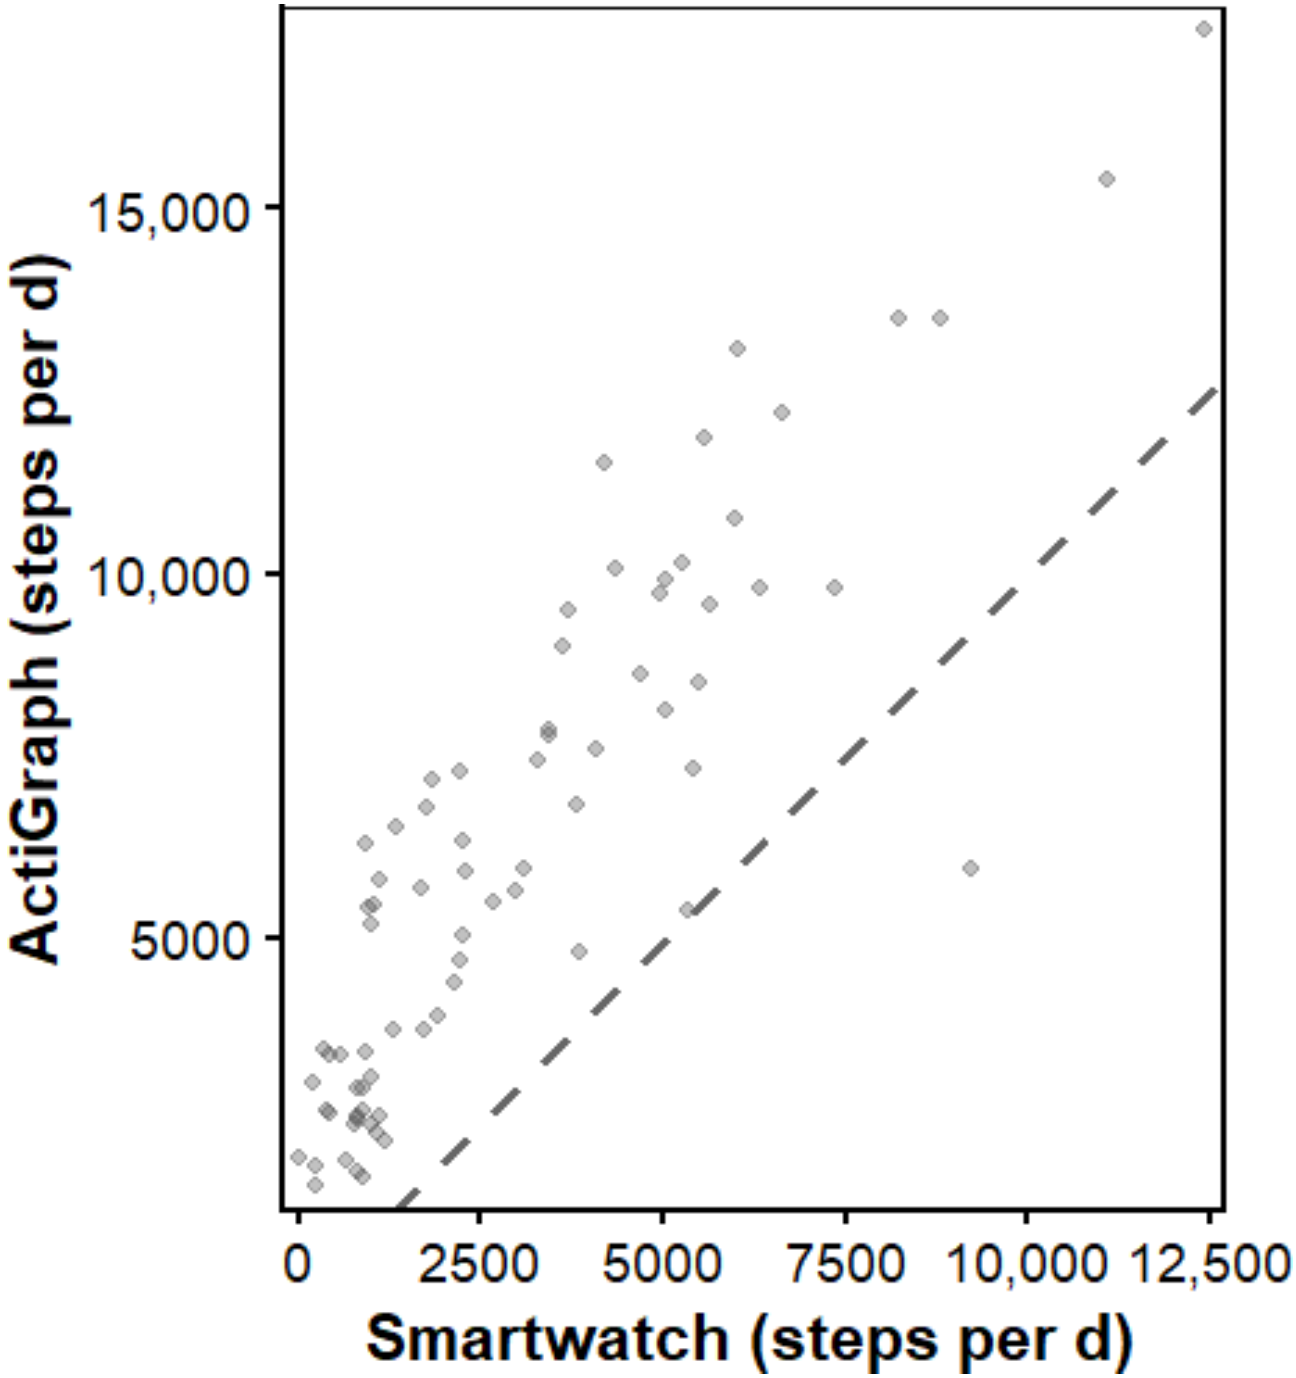

Figure 3. Bland-Altman plot for steps per hour comparing the smartwatch and ActiGraph. The solid line indicates the mean difference; the dashed lines represent the 95% limits of agreement.

Similarly, for steps per day, a significant difference between devices was observed (P<.001). The mean difference was 3154 steps per day, with 95% LoA ranging from −394 to 6702 steps per day. Figures 4 and 5 illustrate the agreement for steps per day. With increasing average hourly as well as daily step counts, the difference between devices increased, suggesting proportional bias.

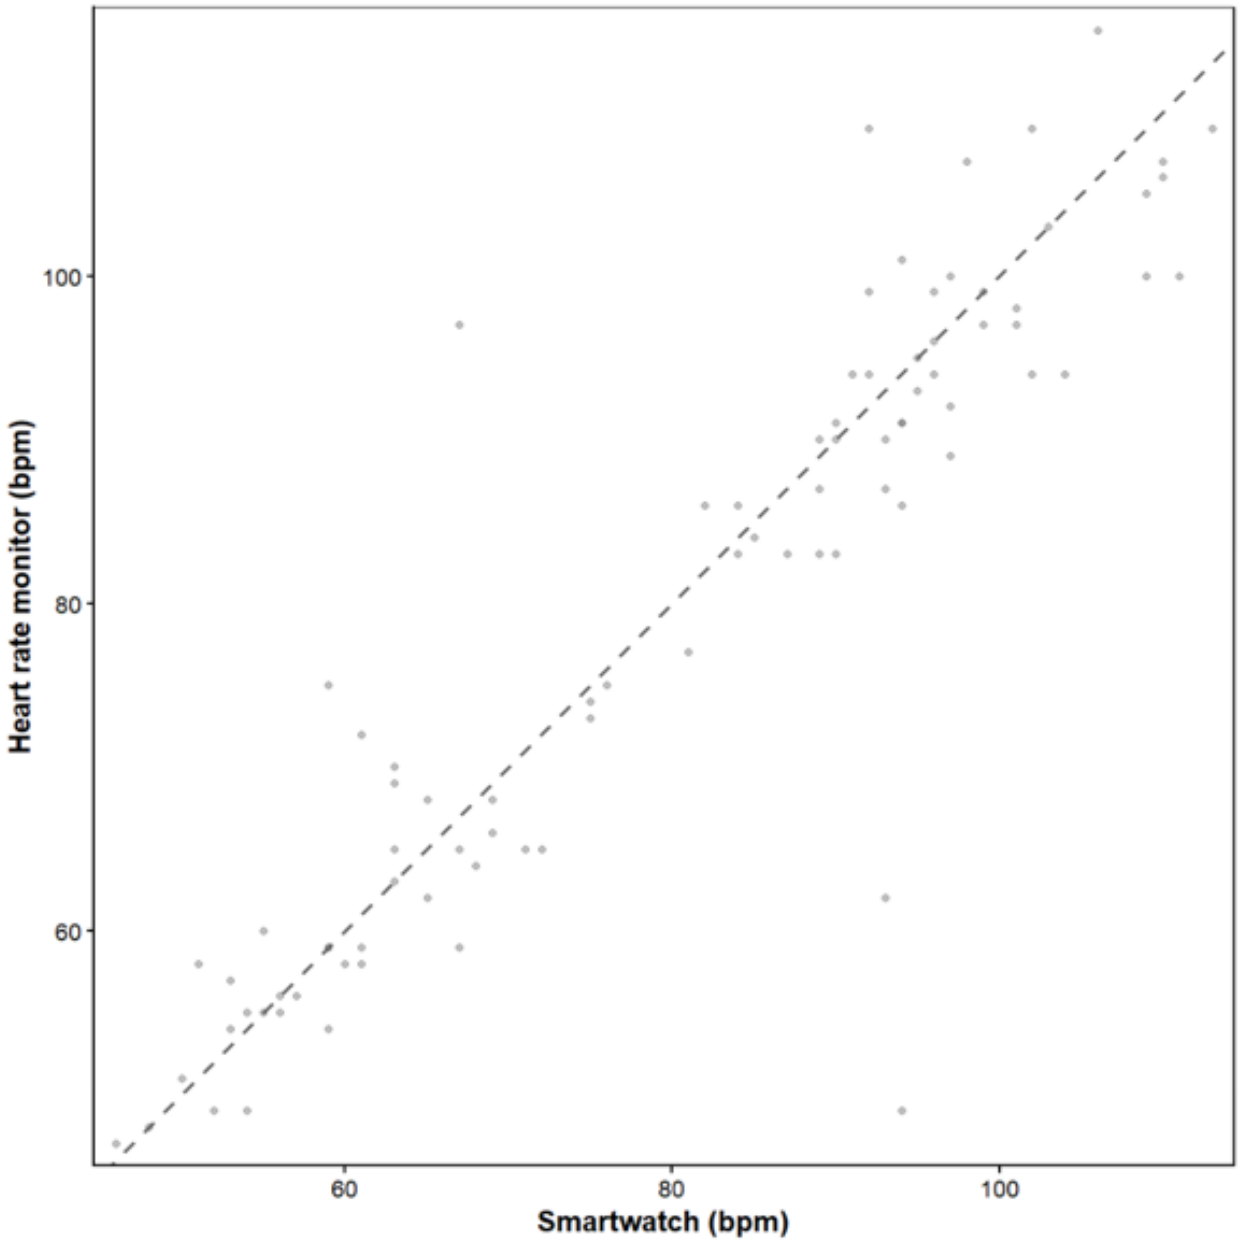
Heart Rate Validation

During the study period, 14 children and adolescents wore the smartwatch while being connected to a clinical heart rate monitor under resting conditions (Figure 1). In total, 42.9% (n=6) of them were female, with a median age of 12.5 (IQR 9.0-16.0) years and a weight-to-height *Z* score of 0.1 (IQR −1.2 to 1.1; Table 2).

Table . Patient characteristics and resting heart rate data during the heart rate validation study (n=14).

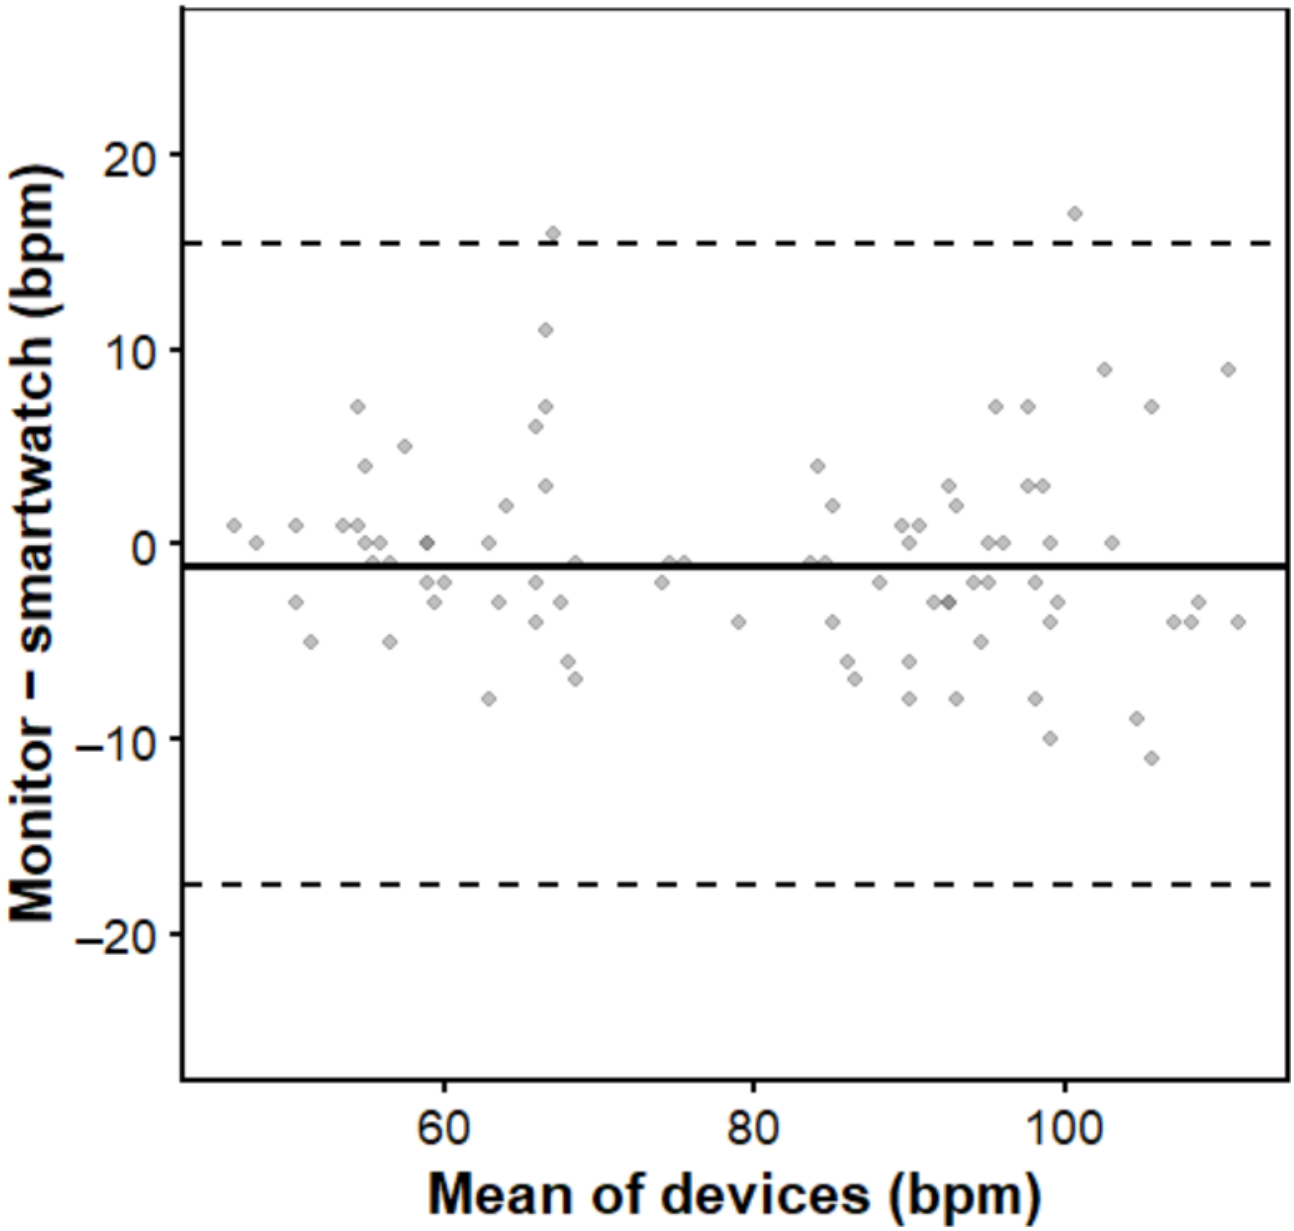
Characteristic	Values
Sex, n (%)	
Female	6 (42.9)
Male	8 (57.1)
Age (y), median (IQR)	12.5 (9.0 to 16.0)
Time since diagnosis (d), median (IQR)	95.0 (74.8 to 140.8)
Diagnosis, n (%)	
Acute lymphoblastic leukemia	9 (64.3)
Lymphoblastic lymphoma	3 (21.4)
Osteosarcoma	1 (7.1)
Ewing sarcoma	1 (7.1)
Weight-to-height *Z* score, median (IQR)	0.1 (−1.2 to 1.1)
Resting heart rate measurements	
Duration of heart rate measurement period, range	6 min to 3 h, 43 min
Heart rate measured via the heart rate monitor (bpm[a]), median (range)	83 (47 to 115)
Heart rate measured via the smartwatch (bpm), median (range)	85 (46 to 113)



[a]bpm: beats per minute.

XSL•FO
RenderX

During the resting measurement period at the day care treatment ward (range 6 minutes-3 hours 43 minutes), the median heart rate measured using the clinical monitor and the smartwatch was 83 (range 47-115) bpm and 85 (range 46-113) bpm, respectively.



The linear mixed model analysis revealed no statistically significant difference between devices (P=.24). The mean difference (monitor – smartwatch) was −1.07 bpm. The 95% LoA ranged from −17.55 to 15.41 bpm. Figures 6 and 7 illustrate the agreement between devices for heart rate per minute.

Figure 7. Bland-Altman plot for heart rate beats per minute (bpm) comparing the smartwatch and clinical heart rate monitor. The solid line indicates the mean difference; the dashed lines represent the 95% limits of agreement.

Discussion

Principal Findings

In this validation study, the Withings smartwatch systematically recorded fewer steps than the wrist-worn ActiGraph under free-living conditions in children and adolescents undergoing cancer treatment. In contrast, resting heart rate measurements showed minimal systematic bias, although individual variability remained considerable.

The smartwatch consistently recorded fewer steps than the ActiGraph, and the magnitude of this discrepancy increased with higher activity levels, indicating proportional bias. This suggests that the difference between devices was not constant across the activity spectrum but became more pronounced at higher step counts. As a result, more active children may be disproportionately affected by underestimation, and step counts derived from the smartwatch may not accurately reflect relative differences between children. In addition, the wide LoA observed in this study indicate substantial variability at the individual level. Together, these findings reinforce that smartwatch-derived step counts should not be considered interchangeable with those obtained from research-grade accelerometers, particularly when absolute step counts are used for clinical benchmarking or comparison across studies. A similar pattern has been described in older adults at risk of functional decline, where a Withings smartwatch also underestimated step count compared with a wrist-worn ActiGraph under free-living conditions [32].

Several factors may contribute to these observed differences. Wrist-worn accelerometers are sensitive to nonambulatory arm movements, which may lead to overestimation of step count when worn on the wrist. Conversely, consumer-grade smartwatches may apply proprietary filtering algorithms to minimize false-positive step detection, potentially resulting in underestimation of low-intensity or irregular movement patterns

XSL•FO
RenderX

[32,33]. In addition, differences in step detection thresholds and algorithm design between devices likely contribute to systematic discrepancies. Importantly, as no criterion gold standard for step count under free-living conditions was available, the observed discrepancy should be interpreted as a difference between device algorithms and placements rather than definitive measurement error of one device alone.

In the broader literature, consumer activity trackers have often shown good associations with research-grade accelerometers for daily step counts in pediatric populations [34-36]. However, studies have also reported systematic differences in absolute step counts, particularly at higher activity intensities [34,36,37]. For example, Fitbit devices have been found to provide comparable step estimates at low intensities but to overestimate steps during moderate to vigorous physical activity [34]. Children with cancer may exhibit altered gait patterns, intermittent low-intensity activity bouts, and treatment-related movement alterations, conditions under which wrist-based step detection algorithms may be particularly challenged. Our findings indicate that device-related discrepancies were also present in children and adolescents undergoing cancer treatment, highlighting that associations do not necessarily imply agreement in absolute step values.

In contrast to step count, heart rate measurements obtained under resting clinical conditions via the smartwatch showed minimal systematic bias compared with the reference monitor. The mean difference was small (approximately −1 bpm), indicating that group average resting heart rate values were similar between devices. However, LoA ranging from approximately −18 to 15 bpm indicate variability at the individual level, which should be considered when interpreting individual heart rate measurements. These findings are consistent with those of previous validation studies in adult populations, including patients scheduled for elective surgery and healthy adults, in which Withings smartwatches demonstrated good agreement with chest strap sensors or clinical monitors under low-intensity or resting conditions [24,38]. However, it should be noted that heart rate was assessed only under relatively stable, low-intensity conditions and within a limited heart rate range in our study. The validity of smartwatch-derived heart rate measurements during higher-intensity activities or in free-living conditions remains uncertain.

From a clinical perspective, wearable monitors may have several potential applications in pediatric oncology. Continuous monitoring can provide insights into activity quantity (eg, daily step count) as well as patterns over time (eg, diurnal variation, day-to-day fluctuations, and recovery after hospitalization), which may be difficult to capture through periodic assessments. However, the observed systematic and proportional differences in step count between devices are particularly relevant in pediatric oncology, where subtle changes in activity may reflect recovery, treatment tolerance, or emerging complications. If higher activity levels are systematically underestimated, improvements during rehabilitation or recovery phases may be less visible when relying solely on smartwatch-derived step counts. In this context, inaccurate step feedback may influence motivation and self-perception of performance. Underestimation at higher activity levels could be particularly discouraging for children who actively engage in rehabilitation or physical activity goals [18]. Therefore, interpretation of wearable-derived step data should focus primarily on intraindividual trends rather than absolute comparisons with normative thresholds or research-grade accelerometers. In this context, within-person trends over time using the same device may be more informative than absolute comparisons with predefined step thresholds or research-grade accelerometers. Such longitudinal information may support early recognition of functional decline, facilitate individualized counseling by physiotherapists, and help evaluate adherence to physical activity recommendations or rehabilitation plans. In addition, feedback from wearable devices may support motivation and engagement in an active lifestyle for some children, although this may also be confronting for others and should be used cautiously and in a supportive manner [18].

This validation study has several limitations that need to be taken into account when interpreting the results. First, no criterion gold standard for step count under free-living conditions was available. The ActiGraph was used as a widely accepted research-grade comparator. However, wrist-worn accelerometers have been shown to overestimate step count, particularly under conditions of low-intensity or irregular movement [39]. In addition, differences between devices may reflect variation in sensitivity to wrist movement, step detection thresholds, and algorithm design. Therefore, the observed discrepancy between devices may represent characteristics of both measurement systems rather than true measurement error. Second, the exact threshold values and proprietary algorithms used by both devices to define a step are not publicly available. Differences in filtering strategies may partly explain both the systematic underestimation and the proportional bias observed in the smartwatch. Third, nonwear time for the ActiGraph was determined using the Troiano algorithm [27]. In children undergoing cancer treatment, prolonged periods of very low–intensity activity are common [1-3], which makes it challenging to distinguish inactivity from nonwear using standard algorithms. This may have influenced step count comparisons, particularly at lower activity levels, where misclassification of wear time may occur. Fourth, wrist side (dominant vs nondominant) was not systematically recorded. Children and adolescents were allowed to choose the wrist to optimize comfort and adherence, which reflects real-world implementation but may have introduced additional variability in step estimates. Although dominant wrist placement has been shown to influence step counts [40], previously reported interwrist differences are generally smaller than the discrepancy observed in our study. Nevertheless, we cannot fully exclude some contribution of limb dominance. Fifth, heart rate was validated only under resting clinical conditions within a limited heart rate range and, therefore, cannot be generalized to higher-intensity activities or free-living conditions where motion artifacts and greater variability may affect smartwatch performance. In addition, disease- and treatment-related factors (eg, treatment phase, hospitalization, fatigue, neuropathy, reduced gait speed, and intermittent activity bouts) may alter movement patterns and physiological responses. Our sample size did not allow for stratified analyses by clinical characteristics. Hence, device agreement may differ across subgroups. Finally, the exploratory nature of this study and the

XSL•FO
RenderX

relatively small sample size limit the precision of the estimated LoA and reduce generalizability.

Future research should aim to further elucidate the mechanisms underlying the observed disagreement in step count between devices. Inclusion of additional criterion measures, such as direct observation or controlled laboratory-based step assessments, may help determine whether discrepancies arise primarily from overestimation by wrist-worn accelerometers, underestimation by smartwatch algorithms, or a combination of both. While waist-worn accelerometers may provide complementary insights into the influence of upper-limb movement on step detection, their feasibility for long-term monitoring in pediatric oncology is limited, and therefore, they are primarily relevant as methodological reference tools rather than implementation devices. Given the observed proportional bias, future studies should also examine whether calibration approaches or device-specific correction models could improve agreement across different activity intensities. In addition, validation of smartwatch-derived heart rate measurements under free-living conditions and across a broader physiological range is warranted. Larger studies across different treatment phases are needed to explore whether disease- and treatment-related characteristics influence device performance. Furthermore, evaluating test-retest reliability and responsiveness over time will be essential to determine whether smartwatch-derived measures are suitable for longitudinal monitoring of physical activity trajectories during and after treatment.

Conclusions

In this exploratory validation study, the Withings smartwatch showed minimal systematic bias for resting heart rate under controlled clinical conditions, although individual variability was considerable. In contrast, smartwatch-derived step counts were consistently lower than those obtained using a research-grade accelerometer and showed increasing disagreement at higher activity levels. Given the observed systematic and proportional discrepancies, use of smartwatch-derived step counts for clinical benchmarking or goal setting in children undergoing cancer treatment cannot currently be recommended.

Abstract

Background: Lung cancer remains the leading cause of cancer deaths in the United States; however, uptake of lung cancer screening (LCS) with low-dose computed tomography (LDCT) among eligible individuals remains low. Evidence suggests that limited knowledge, stigma, and false health beliefs contribute to the underuse of LDCT screening.

Objective: This pilot study aimed to examine an online educational intervention designed to improve knowledge, attitudes, health beliefs, behavioral intentions, perceived importance, and confidence related to LCS among high-risk individuals.

Methods: A single-group preintervention and postintervention design was used. High-risk individuals who smoke, defined according to the US Preventive Services Task Force criteria, completed baseline questionnaires followed by 5 self-directed online educational modules delivered through Research Electronic Data Capture (REDCap). Postintervention questionnaires assessed changes in lung cancer and screening knowledge, lung cancer stigma, health beliefs based on the health belief model and precaution adoption process model, and intentions, perceived importance, and confidence regarding LDCT screening. LCS uptake was assessed via follow-up email 3 months after the intervention. Data were analyzed using descriptive statistics and paired-samples two-tailed *t* tests.

Results: A total of 25 participants completed the intervention. Significant improvements were observed across all major study outcomes. Knowledge scores increased markedly (score=3.76-8.60; $P<.001$), while lung cancer stigma decreased (score=25.52-19.16; $P<.001$). Health belief model constructs showed significant improvements, including perceived susceptibility, perceived benefits, cues to action, and self-efficacy, alongside reductions in perceived barriers and perceived severity (all $P<.001$). Self-reported intentions, perceived importance, and confidence related to obtaining LDCT screening increased significantly. Of the 22 (88%) participants who completed the 3-month follow-up, 13 (59.1%) reported obtaining LDCT screening. Participant satisfaction with the intervention was high, with a mean score of 18.32 (SD 2.33) out of 20.

Conclusions: Findings from this pilot study support the feasibility, acceptability, and preliminary efficacy of an online educational intervention created to promote LCS among high-risk individuals. The intervention improved knowledge; reduced stigma; positively influenced health beliefs; and increased screening intentions, perceived importance, confidence, and uptake. Results provide a foundation for a larger-scale study and suggest that online educational platforms may be an effective strategy to reach geographically diverse high-risk populations and promote LDCT screening.

Introduction

Lung Cancer Incidence, Mortality, and Survival Rates

Lung cancer is the leading cause of cancer deaths and the second most commonly diagnosed cancer in both male and female individuals in the United States [1]. In 2026, it is estimated that 229,410 people will be diagnosed with lung cancer, and 124,990 people will die from lung cancer [1]. Patients with lung cancer have one of the lowest 5-year survival rates (18.6%) compared to other types of cancers in the United States, such as colorectal (64.5%), breast (89.6%), and prostate (98.2%) cancers [2]. Only 16% of lung cancers are diagnosed at a localized stage, for which the 5-year survival rate is 55%. As the length of delay

before diagnosis increases, the 5-year survival rate for patients with lung cancer significantly decreases. For example, when lung cancer is diagnosed at an advanced stage (stage IV), the survival rate drops to 4%. Additionally, more than half of people with lung cancer die within 1 year of being diagnosed [2].

Primary and Secondary Preventions for Lung Cancer

Tobacco use is the most important risk factor of lung cancer, which contributes to 80% of lung cancer deaths in the United States [3]. Other risk factors of lung cancer include exposure to radon gas, occupational or environmental exposure to secondhand smoke, asbestos, certain metals, some organic chemicals, radiation, air pollution, and diesel exhaust. The primary approach to prevent lung cancer is smoking cessation, which has been proven to effectively decrease the incidence rates of lung cancer among male and female individuals [3].
